NFPA 79, *Electrical Standard for Industrial Machinery,* 8-48, 8-137
NFPA 80, *Standard for Fire Doors and Other Opening Protectives,* 6-239, 8-37, 10-61, 10-73, 18-15, 18-16, 18-18, 19-33, 20-52
NFPA 80A, *Recommended Practice for Protection of Buildings from Exterior Fire Exposures,* 1-161, 2-71, 11-43, 18-14
NFPA 82, *Standard on Incinerators and Waste and Linen Handling Systems and Equipment,* 7-66, 11-4, 11-5, 11-8, 11-9, 11-10, 11-24, 20-152
NFPA 85, *Boiler and Combustion Systems Hazards Code,* 8-69, 9-184, 10-103
NFPA 86, *Standard for Ovens and Furnaces,* 8-6, 8-72–8-73, 8-77, 8-97, 9-19, 11-13, 11-24, 11-25, 17-34
NFPA 88A, *Standard for Parking Structures,* 8-172, 20-168, 20-169, 20-220
NFPA 90A, *Standard for the Installation of Air-Conditioning and Ventilating Systems,* 1-127, 8-3, 8-61, 10-26, 10-69, 10-71, 10-72–10-73, 10-74, 11-31, 11-41, 20-47, 20-50
NFPA 90B, *Standard for the Installation of Warm Air Heating and Air-Conditioning Systems,* 1-127, 8-153, 10-21, 10-22, 10-27, 11-41, 20-70
NFPA 91, *Standard for Exhaust Systems for Air Conveying of Vapors, Gases, Mists, and Noncombustible Particulate Solids,* 8-3, 9-62, 9-101, 17-149, 21-33
NFPA 92A, *Standard for Smoke-Control Systems Utilizing Barriers and Pressure Differences,* 8-3, 10-73, 18-43, 18-44, 18-51, 20-29, 20-81, 20-89, 20-102, 20-152, 20-164
NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria, and Large Spaces,* 3-96, 3-157, 3-192, 8-3, 10-73, 18-43, 18-44, 18-45, 18-52, 18-53, 20-29, 20-81, 20-89, 20-102, 20-220
NFPA 96, *Standard for Ventilation Control and Fire Protection of Commercial Cooking Operations,* 10-25, 10-81, 10-85, 11-32, 14-47, 20-90, 20-103, 20-120, 20-152
NFPA 99, *Standard for Health Care Facilities,* 1-139, 8-137, 8-154, 8-173, 10-4, 20-152
NFPA *101®, Life Safety Code®*, 1-32, 1-56, 1-57, 1-67, 1-101, 1-114, 1-121, 1-132, 1-139, 3-19, 3-22, 3-23–3-24, 3-176, 3-177, 3-178, 3-190, 4-3, 4-44, 4-101, 5-68, 6-35, 6-120, 8-163, 9-158, 9-181, 9-182, 10-4, 10-57, 10-65, 10-73, 13-7, 14-33, 14-47, 14-123, 15-25, 16-31, 16-106, 18-12, 18-50, 19-4, 19-62, 20-5, 21-31, 21-101, 21-147, 21-170
apartment buildings, 20-37, 20-41, 20-42, 20-43, 20-44, 20-45
assembly occupancies, 20-85, 20-87, 20-89, 20-90, 20-94
board and care facilities, 20-15–20-16, 20-17, 20-20
business occupancies, 20-110, 20-112
day-care occupancies, 20-123, 20-124, 20-125, 20-126, 20-127
design fire scenarios, 3-122–3-123, 3-124
detention/correctional occupancies, 20-129, 20-130, 20-135, 20-137
educational occupancies, 20-119, 20-120, 20-122
and egress design, 4-69, 4-71–4-81, 20-193–20-194
elevator use, 4-42
evacuations, 4-104, 4-106, 4-107, 4-108, 4-109
exit signs, 4-8
fundamental requirements, 20-11
health care occupancies, 20-139, 20-140, 20-147, 20-149, 20-150, 20-151, 20-152, 20-153, 20-154
high-rise buildings, 20-73, 20-81
hotels, 20-23, 20-25, 20-29
industrial occupancies, 20-204, 20-205, 20-208–20-209
and interior finish, 6-96, 18-24, 18-26, 18-27, 18-29, 18-35, 18-36, 18-37
library/museum collections, 20-190, 20-193, 20-194
life safety in buildings, 20-7, 20-13, Fig. 20.1.8
lodging/rooming houses, 20-49, 20-50, 20-51, 20-53
mercantile occupancies, 20-98, 20-99
motion picture/television soundstages, 20-214
occupancies in special structures, 20-217, 20-218, 20-219, 20-220, 20-222, 20-223, 20-225
occupancy load factors, 20-7, Table 20.1.3
one-/two-family dwellings, 20-55, 20-56
state adoptions, 1-65, Fig. 1.3.5
storage occupancies, 20-158, 20-162, 20-163, 20-168, 20-169, 20-170
university housing, 20-23, 20-35
vocal alarm systems, 4-43
NFPA 101A, *Guide on Alternative Approaches to Life Safety,* 20-7, 20-112, 20-153
NFPA 102, *Standard for Grandstands, Folding and Telescopic Seating, Tents, and Membrane Structures,* 3-22, 6-98, 20-171
NFPA 105, *Standard for the Installation of Smoke Door Assemblies and Other Opening Protectives,* 18-50
NFPA 110, *Standard for Emergency and Standby Power Systems,* 8-61, 8-163, 10-4, 10-7, 12-255, 14-6, 15-108, 15-115
NFPA 111, *Standard on Stored Electrical Energy Emergency and Standby Power Systems,* 8-12, 12-255
NFPA 120, *Standard for Fire Prevention and Control in Coal Mines,* 9-216, 9-218
NFPA 122, *Standard for Fire Prevention and Control in Metal/Nonmetal Mining and Metal Mineral Processing Facilities,* 9-216, 9-219, 11-57
NFPA 130, *Standard for Fixed Guideway Transit and Passenger Rail Systems,* 18-32, 21-103, 21-104, 21-115, 21-191, 21-206
NFPA 140, *Standard on Motion Picture and Television Production Studio Soundstages and Approved Production Facilities,* 20-213–20-214
NFPA 204, *Standard for Smoke and Heat Venting,* 8-3, 11-41, 18-57, 18-58
NFPA 211, *Standard for Chimneys, Fireplaces, Vents, and Solid Fuel-Burning Appliances,* 10-27, 10-35, 10-46, 10-47, 10-48, 10-53, 10-54, 11-9
NFPA 220, *Standard on Types of Building Construction,* 6-239, 9-152, 9-196, 12-130, 13-40, 19-3, 19-4, 19-13, 19-59, 20-205, 21-105
NFPA 221, *Standard for High Challenge Fire Walls, Fire Walls, and Fire Barrier Walls,* 18-14, 19-15, 19-34, 20-213
NFPA 225, *Model Manufactured Home Installation Standard,* 19-63, 20-67
NFPA 232, *Standard for the Protection of Records,* 9-109
NFPA 241, *Standard for Safeguarding Construction, Alteration, and Demolition Operations,* 11-48, 20-103
NFPA 251, *Standard Methods of Tests of Fire Resistance of Building Construction and Materials,* 2-67, 6-37, 6-39, 6-71, 6-129, 12-130, 12-131, 18-4, 19-5, 19-30, 19-34, 19-45, 19-51, 19-55, 19-72, 19-83, 19-97, 21-103
NFPA 252, *Standard Methods of Fire Tests of Door Assemblies,* 2-67, 6-39, 10-61, 18-16
NFPA 253, *Standard Method of Test for Critical Radiant Flux of Floor Covering Systems Using a Radiant Heat Energy Source,* 2-43, 4-75, 6-97, 10-63, 18-16, 18-33, 18-34, 18-35, Figs. 6.5.9–6.5.10
NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials,* 2-42, 2-44, 4-75, 6-7, 6-42, 6-43, 6-49, 6-51, 6-70, 6-96, 6-129, 6-132, 6-133, 6-225, 6-227, 6-229, 8-7, 10-27, 10-63, 18-23, 18-25, 18-27, 18-28, 18-31, 18-32, 18-35, 18-36, 18-37, 18-39, 19-5, 19-62, 19-93, 21-103, 21-173
NFPA 256, *Standard Methods of Fire Tests of Roof Coverings,* 2-70, 9-153, 19-22
NFPA 257, *Standard on Fire Test for Window and Glass Block Assemblies,* 2-67, 6-39, 18-17, 19-54
NFPA 259, *Standard Test Method for Potential Heat of Building Materials,* 6-283, 19-5

NFPA 260, *Standard Methods of Tests and Classification System for Cigarette Ignition Resistance of Components of Upholstered Furniture,* 4-77, 6-94, 6-228
NFPA 261, *Standard Method of Test for Determining Resistance of Mock-Up Upholstered Furniture Material Assemblies to Ignition by Smoldering Cigarettes,* 4-77, 6-94, 6-228
NFPA 262, *Standard Method of Test for Flame Travel and Smoke of Wires and Cables for Use in Air-Handling Spaces,* 2-44, 6-43, 6-45, 6-228, 10-75
NFPA 264A, *Standard Method of Test for Heat Release Rates for Upholstered Furniture Components or Composites and Mattresses Using an Oxygen Consumption Calorimeter* (withdrawn), 6-119
NFPA 265, *Standard Methods of Fire Tests for Evaluating Room Fire Growth Contribution of Textile Coverings on Full Height Panels and Walls,* 2-41, 6-49, 6-96, 18-28, 18-31, 18-36
NFPA 268, *Standard Test Method for Determining Ignitibility of Exterior Wall Assemblies Using a Radiant Heat Energy Source,* 2-70
NFPA 269, *Standard Test Method for Developing Toxic Potency Data for Use in Fire Hazard Modeling,* 2-45, 6-8, 6-13, 6-19, 6-20, 6-230
NFPA 270, *Standard Test Method for Measurement of Smoke Obscuration Using a Conical Radiant Source in a Single Closed Chamber,* 6-22, 6-46, 18-33
NFPA 271, *Standard Method of Test for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter,* 2-39, 6-41, 6-47, 6-228, 9-128, 18-18
NFPA 272, *Standard Method of Test for Heat and Visible Smoke Release Rates for Upholstered Furniture Components or Composites and Mattresses Using an Oxygen Consumption Calorimeter,* 6-47, 6-228
NFPA 285, *Standard Fire Test Method for Evaluation of Fire Propagation Characteristics of Exterior Non-Load-Bearing Wall Assemblies Containing Combustible Components,* 2-69, 18-32, 18-76
NFPA 286, *Standard Methods of Fire Tests for Evaluating Contribution of Wall and Ceiling Interior Finish to Room Fire Growth,* 2-41, 4-75, 6-49, 6-96, 6-227, 18-25, 18-31, 18-32
NFPA 287, *Standard Test Methods for Measurement of Flammability of Materials in Cleanrooms Using a Fire Propagation Apparatus (FPA),* 2-38, 6-46, 6-48, 6-228, 9-128, Fig. 2.3.8
NFPA 288, *Standard Methods of Fire Tests of Floor Fire Door Assemblies Installed Horizontally in Fire Resistance-Rated Floor Systems,* 6-39
NFPA 289 (in process), 6-50
NFPA 301, *Code for Safety to Life from Fire on Merchant Vessels,* 18-33, 21-181
NFPA 302, *Fire Protection Standard for Pleasure and Commercial Motor Craft,* 21-157
NFPA 306, *Standard for the Control of Gas Hazards on Vessels,* 21-171, 21-181
NFPA 307, *Standard for the Construction and Fire Protection of Marine Terminals, Piers, and Wharves,* 20-168, 20-221
NFPA 312, *Standard for Fire Protection of Vessels During Construction, Conversion, Repair, and Lay-Up,* 21-181
NFPA 318, *Standard for the Protection of Semiconductor Fabrication Facilities,* 9-124, 9-127, Fig. 9.9.5, Table 9.9.1
NFPA 325, *Fire Hazard Properties of Flammable Liquids, Gases, and Volatile Solids* (discontinued), 7-43, 7-44
NFPA 329, *Recommended Practice for Handling Releases of Flammable and Combustible Liquids and Gases,* 7-24
NFPA 385, *Standard for Tank Vehicles for Flammable and Combustible Liquids,* 7-31, 21-19
NFPA 402, *Guide for Aircraft Rescue and Fire Fighting Operations,* 21-140
NFPA 403, *Standard for Aircraft Rescue and Fire-Fighting Services at Airports,* 13-103, 13-107, 21-144
NFPA 407, *Standard for Aircraft Fuel Servicing,* 21-19, 21-137
NFPA 408, *Standard for Aircraft Hand Portable Fire Extinguishers,* 21-141
NFPA 409, *Standard on Aircraft Hangars,* 8-172, 17-62, 21-146
NFPA 410, *Standard on Aircraft Maintenance,* 21-148
NFPA 412, *Standard for Evaluating Aircraft Rescue and Fire-Fighting Foam Equipment,* 17-68
NFPA 414, *Standard for Aircraft Rescue and Fire-Fighting Vehicles,* 12-280, 13-23, 17-64, 21-19, 21-143
NFPA 415, *Standard on Airport Terminal Buildings, Fueling Ramp Drainage, and Loading Walkways,* 2-67, 21-140, 21-147
NFPA 418, *Standard for Heliports,* 20-152, 21-145
NFPA 424, *Guide for Airport/Community Emergency Planning,* 21-140
NFPA 430, *Code for the Storage of Liquid and Solid Oxidizers,* 7-45, 7-47, 11-24, 17-125
NFPA 432, *Code for the Storage of Organic Peroxide Formulations,* 7-50
NFPA 434, *Code for the Storage of Pesticides,* 6-238, 6-243, 16-88
NFPA 450, *Guide for Emergency Medical Services and Systems,* 13-153, 13-157
NFPA 471, *Recommended Practice for Responding to Hazardous Materials Incidents,* 1-145, 6-243, 12-197, 13-95
NFPA 472, *Standard for Professional Competence of Responders to Hazardous Materials Incidents,* 1-145, 6-243–6-244, 12-168, 12-197, 13-90, 13-95
NFPA 473, *Standard for Competencies for EMS Personnel Responding to Hazardous Materials Incidents,* 13-96
NFPA 484, *Standard for Combustible Metals,* 6-153, 7-66, 8-36, 11-24, 17-41, 17-149, Fig. 6.9.1
NFPA 491, *Guide to Hazardous Chemical Reactions* (discontinued), 7-43
NFPA 493, *Spontaneous Heating and Ignition of Coal and Other Mining Products* (discontinued), 3-27
NFPA 495, *Explosive Materials Code,* 2-94, 6-247, 6-251, 7-46, 8-19, 21-19
NFPA 496, *Standard for Purged and Pressurized Enclosures for Electrical Equipment,* 7-41, 8-109, 8-169, 8-171, 9-138, 17-150, 17-151
NFPA 497, *Recommended Practice for the Classification of Flammable Liquids, Gases, or Vapors and of Hazardous (Classified) Locations for Electrical Installations in Chemical Process Areas,* 3-126, 8-168, 17-151
NFPA 498, *Standard for Safe Havens and Interchange Lots for Vehicles Transporting Explosives,* 6-251, 21-19
NFPA 499, *Recommended Practice for the Classification of Combustible Dusts and of Hazardous (Classified) Locations for Electrical Installations in Chemical Process Areas,* 17-151
NFPA 501, *Standard on Manufactured Housing,* 18-32, 19-63, 20-67, 20-69–20-70
NFPA 501A, *Standard for Fire Safety Criteria for Manufactured Home Installations, Sites, and Communities,* 20-67, 20-70, 21-97
NFPA 502, *Standard for Road Tunnels, Bridges, and Other Limited Access Highways,* 16-140, 21-191, 21-193, 21-194, 21-196, 21-198, 21-199, 21-201, 21-202, 21-203, 21-210, 21-211, Table 21.11.6
NFPA 505, *Fire Safety Standard for Powered Industrial Trucks Including Type Designations, Areas of Use, Conversions, Maintenance, and Operations,* 8-31, 8-32, 20-162
NFPA 520, *Standard on Subterranean Spaces,* 20-220, 21-191
NFPA 550, *Guide to the Fire Safety Concepts Tree,* 1-159, 3-139, 20-9, 20-192
NFPA 551, *Guide for the Evaluation of Fire Risk Assessments,* 3-136, 3-139
NFPA 555, *Guide on Methods for Evaluating Potential for Room Flashover,* 6-50–6-51
NFPA 557, *Standard Fire Loads for Structural Fire Protection Design* (proposed), 6-40
NFPA 600, *Standard on Industrial Fire Brigades,* 1-139, 1-145, 7-6, 9-180, 9-199, 11-55, 12-192, 12-194, 12-195, 20-166, 20-209
NFPA 601, *Standard for Security Services in Fire Loss Prevention,* 11-48, 14-98
NFPA 650 (withdrawn), 8-3
NFPA 654, *Standard for the Prevention of Fire and Dust Explosions from the Manufacturing, Processing, and Handling of Combustible Particulate Solids,* 2-100, 8-3, 9-61, 9-101, 11-24, 17-149, 17-150

NFPA 664, *Standard for the Prevention of Fires and Explosions in Wood Processing and Woodworking Facilities,* 7-10, 9-5, 9-8, 9-9, 9-10, 9-11, 9-15, 9-18, 9-21
NFPA 701, *Standard Methods of Fire Tests for Flame Propagation of Textiles and Films,* 6-89, 6-94, 6-98, 6-99, 11-49, 11-57, 18-37, 20-93, 20-120, 20-135, 20-153
NFPA 702, *Classification of the Flammability of Wearing Apparel* (withdrawn), 6-89
NFPA 704, *Standard System for the Identification of the Hazards of Materials for Emergency Response,* 6-6, 6-239, 6-242, 7-44, 8-22, 8-24, 9-33, 9-158, 13-122
NFPA 705, *Recommended Practice for a Field Flame Test for Textiles and Films,* 2-35
NFPA 720, *Standard for the Installation of Carbon Monoxide (CO) Warning Equipment in Dwelling Units,* 14-114, 14-115
NFPA 730, *Guide for Premises Security,* 1-4, 1-98, 1-99–1-100, 1-133, 1-142, 12-205
NFPA 731, *Standard for the Installation of Electronic Premises Security Systems,* 1-99, 14-126
NFPA 750, *Standard on Water Mist Fire Protection Systems,* 2-86, 16-104, 16-136, 16-149, 16-154, 16-174, 17-36, 21-176, 21-181
NFPA 780, *Standard for the Installation of Lightning Protection Systems,* 8-142, 9-154, 11-69, 11-70, 11-73, 11-75, 11-76, 11-77, 11-78, 11-79, 17-62
NFPA 801, *Standard for Fire Protection for Facilities Handling Radioactive Materials,* 7-67, 9-162, 9-193, 9-196, 11-24
NFPA 805, *Performance-Based Standard for Fire Protection for Light Water Reactor Electric Generating Plants,* 9-193, 9-194
NFPA 806, *Performance-Based Standard for Fire Protection for Advanced Nuclear Reactor Electric Generating Plants* (proposed), 9-194
NFPA 820, *Standard for Fire Protection in Wastewater Treatment and Collection Facilities,* 9-150
NFPA 850, *Recommended Practice for Fire Protection for Electric Generating Plants and High Voltage Direct Current Converter Stations,* 7-5, 9-180, 9-181, 9-182, 9-183, 9-184, 9-185, 9-187, 11-25
NFPA 851, *Recommended Practice for Fire Protection for Hydroelectric Generating Plants,* 9-180, 9-186, 16-34
NFPA 853, *Standard for the Installation of Stationary Fuel Cell Power Systems,* 8-109, 9-180, 9-184
NFPA 901, *Standard Classifications for Incident Reporting and Fire Protection Data,* 3-61, 12-93
NFPA 909, *Code for the Protection of Cultural Resource Properties—Museums, Libraries, and Places of Worship,* 3-178, 9-108, 20-179
NFPA 914, *Code for Fire Protection of Historic Structures,* 3-178, 20-179, 20-200
NFPA 921, *Guide for Fire and Explosion Investigations,* 1-83, 1-91, 2-34, 2-35, 3-31, 3-33, 3-34, 3-68, 11-61, 19-70–19-71
NFPA 1001, *Standard for Fire Fighter Professional Qualifications,* 12-69, 12-95, 12-115
NFPA 1002, *Standard for Fire Apparatus Driver/Operator Professional Qualifications,* 12-250, 12-271
NFPA 1003, *Standard for Airport Fire Fighter Professional Qualifications,* 21-144
NFPA 1006, *Standard for Rescue Technician Professional Qualifications,* 13-14, 13-15
NFPA 1021, *Standard for Fire Officer Professional Qualifications,* 12-70
NFPA 1031, *Standard for Professional Qualifications for Fire Inspector and Plan Examiner,* 1-83
NFPA 1033, *Standard for Professional Qualifications for Fire Investigator,* 1-83, 3-33, 3-39, 12-170
NFPA 1035, *Standard for Professional Qualifications for Public Fire and Life Safety Educator,* 1-83, 5-21, 5-93, 5-136
NFPA 1037, *Standard for Professional Qualifications for Fire Marshals,* 1-83
NFPA 1041, *Standard for Fire Service Instructor Professional Qualifications,* 12-164
NFPA 1061, *Standard for Professional Qualifications for Public Safety Telecommunicator,* 12-260
NFPA 1071, *Standard for Emergency Vehicle Technician Professional Qualifications,* 12-283
NFPA 1081, *Standard for Industrial Fire Brigade Member Professional Qualifications,* 12-193
NFPA 1123, *Code for Fireworks Display,* 20-214
NFPA 1126, *Standard for the Use of Pyrotechnics Before a Proximate Audience,* 20-213–20-214

Dedication

In recognition of his extraordinary service as founder and professor of the fire protection engineering program at the University of Maryland, as chairman of the NFPA Board of Directors, as chairman of the NFPA Standards Council, as leader and mentor, this handbook is dedicated to Dr. John L. Bryan.

Contents

Preface xv

Introduction xvii

SECTION 1
Safety in the Built Environment 1-1

1.1 Challenges to Safety in the Built Environment
■ *John R. Hall, Jr., and Erin R. Twomey* 1-3

1.2 Fundamentals of Structurally Safe Building Design ■ *Bonnie E. Manley* 1-31

1.3 Codes and Standards for the Built Environment
■ *Arthur E. Cote and Casey C. Grant* 1-51

1.4 Legal Issues for the Designer and Enforcer ■ *Arthur E. Schwartz* 1-73

1.5 Fire Prevention and Code Enforcement
■ *Ronald R. Farr and Steven F. Sawyer* 1-81

1.6 Premises Security ■ *Lauris V. Freidenfelds* 1-95

1.7 Protecting Against Extreme Events ■ *Brian J. Meacham and Carl Galioto* 1-109

1.8 Emergency Management and Business Continuity ■ *Donald L. Schmidt* 1-137

1.9 Systems Approach to Fire-Safe Building Design ■ *John M. Watts, Jr.* 1-157

SECTION 2
Basics of Fire and Fire Science 2-1

2.1 Physics and Chemistry of Fire ■ *Dougal Drysdale* 2-3

2.2 Physics of Fire Configuration ■ *Ronald L. Alpert* 2-21

2.3 Flammability Hazard of Materials
■ *Daniel Madrzykowski and David W. Stroup* 2-31

2.4 Dynamics of Compartment Fire Growth ■ *Richard L. P. Custer* 2-49

2.5 Basics of Fire Containment ■ *Marc L. Janssens* 2-59

2.6 Fundamentals of Fire Detection
■ *Richard L. P. Custer and James A. Milke* 2-75

2.7 Theory of Fire Extinguishment ■ *Hong-Zeng Yu and Jeffrey S. Newman* 2-79

2.8 Explosions ■ *Robert Zalosh* 2-93

SECTION 3
Information and Analysis for Fire Protection 3-1

3.1 An Overview of the Fire Problem and Fire Protection
■ *John R. Hall, Jr., and Arthur E. Cote* 3-3

3.2 Fire Loss Investigation ■ *Richard L. P. Custer and David T. Sheppard* 3-31

3.3 Fire Data Collection and Databases ■ *Marty Ahrens and Stan Stewart* 3-43

3.4 Use of Fire Incident Data and Statistics
■ *Marty Ahrens, Patricia Frazier, and Gayle Kelch* 3-61

3.5 Introduction to Fire Modeling
■ *Craig L. Beyler, Philip J. DiNenno, Douglas J. Carpenter, and John M. Watts, Jr.* 3-93

3.6 Applying Models to Fire Protection Engineering Problems and Fire Investigations ■ *Richard L. P. Custer, David T. Sheppard, and Christopher B. Wood* 3-111

3.7 Fire Hazard Analysis Techniques
■ *Morgan J. Hurley and Richard W. Bukowski* 3-121

3.8 Fire Risk Analysis ■ *John R. Hall, Jr., and John M. Watts, Jr.* 3-135

3.9 Closed Form Enclosure Fire Calculations
■ *Edward K. Budnick, Sean P. Hunt, and Mark T. Wright* 3-145

3.10 Performance-Based Codes and Standards for Fire Safety
■ *Milosh T. Puchovsky and Morgan J. Hurley* 3-167

3.11 Overview of Performance-Based Fire Protection Design
■ *Frederick W. Mowrer and Eric R. Rosenbaum* 3-183

SECTION 4
Human Factors in Emergencies 4-1

4.1 Human Behavior and Fire ■ *John L. Bryan* 4-3

4.2 Calculation Methods for Egress Prediction ■ *Rita F. Fahy* 4-49

4.3 Concepts of Egress Design ■ *James K. Lathrop* 4-69

4.4 Techniques of Crowd Management ■ *John J. Fruin* 4-93

4.5 Strategies for Occupant Evacuation During Emergencies
■ *Daniel J. O'Connor and Bert Cohn* 4-103

SECTION 5
Fire and Life Safety Education 5-1

5.1 Principles and Techniques of Fire and Life Safety Education
■ *Edward Kirtley* 5-3

5.2 Fire and Life Safety Education Messages
■ *Ernest Grant and Rodney Eksteen* 5-21

5.3 Disaster Preparedness Education ■ *Gerri Penney* 5-29
5.4 Media's Role in Fire and Life Safety Education ■ *Robin J. Adair* 5-45
5.5 Reaching High-Risk Groups ■ *Sharon Gamache* 5-63
5.6 Juvenile Firesetting ■ *Paul Schwartzman* 5-87
5.7 Using Data for Public Education Planning and Decision Making ■ *John R. Hall, Jr.* 5-103
5.8 Evaluation Techniques for Fire and Life Safety Education ■ *John R. Hall, Jr., and Michael W. Weller* 5-119

SECTION 6
Characteristics of Materials and Products **6-1**

6.1 Fire Hazards of Materials ■ *Robert P. Benedetti* 6-3
6.2 Combustion Products and Their Effects on Life Safety ■ *Richard G. Gann and Nelson P. Bryner* 6-11
6.3 Concepts and Protocols of Fire Testing ■ *Marcelo M. Hirschler* 6-35
6.4 Wood and Wood-Based Products ■ *John M. Cholin* 6-61
6.5 Fibers and Textiles ■ *Jeffrey O. Stull and Salvatore A. Chines* 6-75
6.6 Upholstered Furniture and Mattresses ■ *Vytenis Babrauskas* 6-103
6.7 Fire-Retardant and Flame-Resistant Treatment of Cellulosic Materials ■ *James R. Shaw* 6-129
6.8 Dusts ■ *Richard F. Schwab* 6-141
6.9 Metals ■ *Tom Christman* 6-153
6.10 Gases ■ *Theodore C. Lemoff* 6-165
6.11 Medical Gases ■ *Mark Allen* 6-187
6.12 Flammable and Combustible Liquids ■ *Orville M. Slye, Jr.* 6-197
6.13 Polymeric Materials ■ *Robert P. Benedetti and Guy R. Colonna* 6-209
6.14 Pesticides in the Workplace ■ *Fred Whitford* 6-233
6.15 Explosives and Blasting Agents ■ *Lon D. Santis* 6-247
6.16 Manufacture and Storage of Aerosol Products ■ *David L. Fredrickson* 6-257
6.17 Tables and Charts ■ *Vytenis Babrauskas* 6-269

SECTION 7
Storage and Handling of Materials **7-1**

7.1 Storage and Handling of Solid Fuels ■ *Kenneth W. Dungan* 7-3
7.2 Storage of Flammable and Combustible Liquids ■ *Anthony M. Ordile* 7-15
7.3 Storage of Gases ■ *Theodore C. Lemoff and Carl H. Rivkin* 7-35
7.4 Storage and Handling of Chemicals ■ *John A. Davenport* 7-43
7.5 Hazardous Waste Control ■ *Paul R. Severson* 7-57

SECTION 8
Special Equipment 8-1

8.1 Air-Moving Equipment ■ *Jane I. Lataille* 8-3
8.2 Chemical Processing Equipment ■ *Richard F. Schwab* 8-17
8.3 Materials-Handling Equipment ■ *John K. Bouchard* 8-31
8.4 Automated Equipment ■ *L. Jeffrey Mattern* 8-43
8.5 Lasers ■ *Fred P. Seeber* 8-51
8.6 Protection of Electronic Equipment ■ *Brian P. Rawson* 8-57
8.7 Heat Transfer Systems and Fluids ■ *John A. LeBlanc* 8-65
8.8 Industrial and Commercial Heat Utilization Equipment ■ *Raymond Ostrowski* 8-71
8.9 Oil Quenching and Molten Salt Baths ■ *Raymond Ostrowski* 8-93
8.10 Stationary Combustion Engines and Fuel Cells ■ *James B. Biggins* 8-105
8.11 Fluid Power Systems ■ *Paul K. Schacht* 8-113
8.12 Refrigeration Systems ■ *Henry L. Febo, Jr.* 8-117
8.13 Electrical Systems and Appliances ■ *Robert M. Milatovich* 8-127

SECTION 9
Processes and Facilities 9-1

9.1 Woodworking Facilities and Processes ■ *John M. Cholin* 9-3
9.2 Spray Finishing and Powder Coating ■ *Don R. Scarbrough* 9-27
9.3 Dipping and Coating Processes ■ *John Katunar III* 9-39
9.4 Plastics Industry and Related Process Hazards ■ *George Ouellette* 9-53
9.5 Metalworking Processes ■ *Paul G. Dobbs* 9-67
9.6 Welding, Cutting, and Other Hot Work ■ *August F. Manz and Mark E. Blank* 9-73
9.7 Storage and Handling of Grain Mill Products ■ *James E. Maness and Lee M. Sargent* 9-85
9.8 Protection of Records ■ *James A. Beals* 9-105
9.9 Semiconductor Manufacturing ■ *Vinnie DeGiorgio and Heron Peterkin* 9-119
9.10 Oilseed Solvent Extraction Plants ■ *C. Louis Kingsbaker* 9-131
9.11 Protection of Wastewater Treatment Plants ■ *James F. Wheeler* 9-141
9.12 Fire Protection of Laboratories Using Chemicals ■ *Richard R. Anderson* 9-157
9.13 Fire Protection of Telecommunications Facilities ■ *Ralph E. Transue* 9-167
9.14 Electric Generating Plants ■ *Daniel J. Sheridan* 9-179
9.15 Nuclear Facilities ■ *Wayne D. Holmes* 9-191
9.16 Mining and Mineral Processing ■ *Larry J. Moore* 9-203
9.17 Oxygen-Enriched Atmospheres ■ *Keisa Rosales and Joel M. Stoltzfus* 9-225

SECTION 10
Building Services 10-1

10.1 Emergency and Standby Power Supplies ■ *Dan Chisholm, Sr.* 10-3
10.2 Heating Systems and Appliances ■ *Peter J. Gore Willse* 10-9
10.3 Building Transportation Systems ■ *Edward A. Donoghue* 10-57
10.4 Air-Conditioning and Ventilating Systems ■ *William A. Webb* 10-69
10.5 Ventilation of Commercial Cooking Operations ■ *David P. Demers* 10-77
10.6 Boiler Furnaces ■ *L. Jeffrey Mattern, Eugene Catania, and Shelton Ehrlich* 10-91

SECTION 11
Fire Prevention Practices 11-1

11.1 Waste Handling and Control ■ *Lawrence G. Doucet and Sharon S. Gilyeat* 11-3
11.2 Housekeeping Practices ■ *L. Jeffrey Mattern* 11-27
11.3 Building and Site Planning for Fire Safety ■ *Albert M. Comly, Jr.* 11-39
11.4 Fire Hazards of Construction, Alteration, and Demolition of Buildings ■ *Richard J. Davis* 11-47
11.5 Control of Electrostatic Ignition Sources ■ *Don R. Scarbrough* 11-59
11.6 Lightning Protection Systems ■ *John M. Caloggero* 11-69

SECTION 12
Non-Emergency Fire Department Functions 12-1

12.1 Planning for Public Fire-Rescue Protection ■ *John A. Granito* 12-3
12.2 Organizational Benchmarking and Performance Evaluation ■ *Dorinda Cline* 12-23
12.3 Needs Assessment and Hazard Analysis ■ *William F. Jenaway* 12-41
12.4 Managing Fire-Rescue Departments ■ *Rebecca F. Denlinger* 12-51
12.5 Information Management and Computer Technology ■ *Brian P. Duggan* 12-79
12.6 Liability of Fire Service Organizations for Negligent Fire Fighting ■ *Maureen Brodoff* 12-99
12.7 Safety, Medical, and Health Issues and Programs ■ *Murrey E. Loflin* 12-107
12.8 Effect of Building Construction and Fire Protection Systems on Fire Fighter Safety ■ *Glenn P. Corbett* 12-127
12.9 Fire and Emergency Services Protective Clothing and Protective Equipment ■ *Bruce W. Teele* 12-143
12.10 Training Programs for Fire and Emergency Service Personnel ■ *Jerry W. Laughlin* 12-161
12.11 Industrial Fire Loss Prevention ■ *Michael Snyder* 12-177
12.12 Disaster Planning and Response Services ■ *William Van Helden and Terry Stewart* 12-199

12.13 GIS for Fire Station Locations and Response Protocols
■ *Russ Johnson and Mike Price* 12-215
12.14 Fire Rescue Stations and Fire Service Training Centers
■ *David J. Acomb and Roger M. LeBoeuf* 12-233
12.15 Public Emergency Services Alarm, Dispatch, and Communications Systems
■ *John M. Merklinger* 12-253
12.16 Fire Department Apparatus and Equipment ■ *Robert Tutterow* 12-267
12.17 Pre-Incident Planning for Industrial and Municipal Emergency Response
■ *Michael J. Serapiglia* 12-289
12.18 Pre-Incident Planning for Emergency Response ■ *John Norman* 12-299
12.19 Community Risk Reduction ■ *Edward Kirtley* 12-309

SECTION 13
Organizing for Public Sector Emergency Response 13-1

13.1 Fireground Operations ■ *Bernard J. Klaene and Russell Sanders* 13-3
13.2 Organizing Rescue Operations ■ *Richard Wright* 13-13
13.3 Fire Streams ■ *Michael A. Wieder* 13-23
13.4 Alternate Water Supplies ■ *Laurence J. Stewart* 13-37
13.5 Wildland Fire Management ■ *James C. Smalley* 13-53
13.6 Public Fire Protection and Hazmat Management
■ *Michael S. Hildebrand and Gregory G. Noll* 13-81
13.7 Aircraft Rescue and Fire Fighting (ARFF) ■ *Jack Kreckie* 13-99
13.8 Managing the Response to Hazardous Material Incidents
■ *Charles J. Wright* 13-117
13.9 Emergency Medical Services and the Fire Department ■ *Jack J. Krakeel* 13-145

SECTION 14
Detection and Alarm 14-1

14.1 Fire Alarm Systems ■ *Wayne D. Moore* 14-3
14.2 Automatic Fire Detectors ■ *Kenneth W. Dungan* 14-15
14.3 Notification Appliances ■ *Robert P. Schifiliti* 14-29
14.4 Fire Alarm System Interconnections ■ *Fred Leber* 14-39
14.5 Inspection, Testing, and Maintenance of Fire Alarm Systems
■ *John M. Cholin* 14-53
14.6 Household Fire-Warning Equipment ■ *Daniel T. Gottuk* 14-79
14.7 Fire Protection Surveillance and Security Services ■ *Lawrence J. Wenzel* 14-89
14.8 Gas and Vapor Detection Systems and Monitors ■ *John M. Cholin* 14-99
14.9 Carbon Monoxide Detection in Residential Occupancies ■ *Art Black* 14-113
14.10 Security and Intrusion Detection Systems ■ *Shane M. Clary* 14-119

SECTION 15
Water Supplies for Fixed Fire Protection 15-1

15.1 Fixed Water Storage Supplies for Fire Protection ■ *Bruce A. Edwards* 15-3
15.2 Water Supply Requirements for Public Supply Systems ■ *Lawrence J. Wenzel* 15-23
15.3 Hydraulics for Fire Protection ■ *Kenneth W. Linder* 15-35
15.4 Water Supplies for Sprinkler Systems ■ *Wayne M. Martin* 15-63
15.5 Microbiologically Influenced Corrosion in Fire Sprinkler Systems ■ *Bruce H. Clarke and Anthony M. Aguilera* 15-75
15.6 Water Distribution ■ *John D. Jensen* 15-85
15.7 Fire Pump Controllers and Power Supply Arrangements for Motor-Driven Fire Pumps ■ *James S. Nasby and John R. Kovacik* 15-105

SECTION 16
Water-Based Fire Suppression Equipment 16-1

16.1 Principles of Automatic Sprinkler System Performance ■ *Russell P. Fleming* 16-3
16.2 Automatic Sprinklers ■ *Kenneth E. Isman* 16-15
16.3 Automatic Sprinkler Systems ■ *Roland Huggins* 16-29
16.4 Hanging and Bracing of Water-Based Systems ■ *Russell P. Fleming* 16-55
16.5 Sprinkler Systems for Storage Facilities ■ *James E. Golinveaux* 16-71
16.6 Residential Sprinkler Systems ■ *Daniel Madrzykowski and Russell P. Fleming* 16-91
16.7 Ultra-High-Speed Water Spray Systems ■ *Robert M. Gagnon* 16-109
16.8 Water Mist Fire Suppression Systems ■ *Jack R. Mawhinney* 16-135
16.9 Water Spray Protection ■ *Kerry M. Bell* 16-181
16.10 Standpipe and Hose Systems ■ *David R. Hague* 16-191
16.11 Care and Maintenance of Water-Based Extinguishing Systems ■ *David R. Hague* 16-205

SECTION 17
Fire Suppression Systems and Portable Fire Extinguishers 17-1

17.1 Carbon Dioxide and Application Systems ■ *Thomas J. Wysocki* 17-3
17.2 Chemical Extinguishing Agents and Application Systems ■ *James D. Lake* 17-17
17.3 Characteristics and Hazards of Water and Water Additives for Fire Suppression ■ *John A. Frank* 17-31
17.4 Foam Extinguishing Agents and Systems ■ *Joseph L. Scheffey* 17-45
17.5 Fire Extinguisher Use and Maintenance ■ *Mark T. Conroy* 17-71

17.6 Halon and Halon Replacement Agents and Systems
■ *Philip J. DiNenno and Gary M. Taylor* 17-93
17.7 Application of Gaseous Agents to Special Hazards Fire Protection
■ *Jeff L. Harrington* 17-123
17.8 Explosion Prevention and Protection ■ *Erdem A. Ural and Henry W. Garzia* 17-141

SECTION 18
Confining Fires **18-1**

18.1 Confinement of Fire in Buildings ■ *Hossein Davoodi* 18-3
18.2 Interior Finish ■ *Marcelo M. Hirschler* 18-23
18.3 Smoke Movement in Buildings ■ *James A. Milke and John H. Klote* 18-43
18.4 Venting Practices ■ *Gunnar Heskestad* 18-57
18.5 Penetration Sealing ■ *John E. Kampmeyer* 18-73
18.6 Deflagration (Explosion) Venting ■ *Richard F. Schwab* 18-79

SECTION 19
Structural Fire Protection **19-1**

19.1 Types of Building Construction ■ *Peter J. Gore Willse* 19-3
19.2 Structural Integrity During Fire ■ *Richard J. Davis* 19-29
19.3 Structural Fire Safety in One- and Two-Family Dwellings
■ *Kuma Sumathipala* 19-59
19.4 Analyzing Structural Fire Damage ■ *Stephen Pessiki* 19-65
19.5 Approaches to Calculating Structural Fire Resistance ■ *Barbara Lane* 19-77

SECTION 20
Protecting Occupancies **20-1**

20.1 Assessing Life Safety in Buildings ■ *John M. Watts, Jr.* 20-3
20.2 Board and Care Facilities ■ *Philip R. Jose* 20-15
20.3 Hotels and University Housing
■ *April Berkol, Byron Briese, and Ed Comeau* 20-23
20.4 Apartment Buildings ■ *Kenneth Bush* 20-37
20.5 Lodging or Rooming Houses ■ *Richard R. Anderson* 20-49
20.6 One- and Two-Family Dwellings ■ *James K. Lathrop* 20-55
20.7 Manufactured Housing ■ *Kirsten M. Paoletti* 20-63
20.8 High-Rise Buildings ■ *James R. Quiter* 20-73
20.9 Assembly Occupancies ■ *Gregory Miller and Edward Roether* 20-85
20.10 Mercantile Occupancies ■ *Ed Schultz* 20-97
20.11 Business Occupancies ■ *Brian L. Marburger* 20-105
20.12 Educational Occupancies ■ *Alex L. Szachnowicz* 20-115

20.13 Day-Care Occupancies ■ *Catherine L. Stashak* 20-123
20.14 Detention and Correctional Occupancies ■ *Thomas W. Jaeger* 20-129
20.15 Health Care Occupancies ■ *Daniel J. O'Connor* 20-139
20.16 Storage Occupancies ■ *Jeffrey Moore* 20-157
20.17 Library and Museum Collections ■ *Danny L. McDaniel* 20-179
20.18 Industrial Occupancies ■ *David P. Demers* 20-203
20.19 Motion Picture and Television Studios and Soundstages ■ *Raymond A. Grill* 20-211
20.20 Occupancies in Special Structures ■ *Wayne D. Holmes* 20-217

SECTION 21
Transportation Fire Safety **21-1**

21.1 Passenger Vehicle Fires ■ *R. T. Long, Jr., Jeff D. Colwell, Rose Ray, Helene L. Grossman, Ben Thomas, and Robert Strassburger* 21-3
21.2 Fire Safety in Commercial Vehicles ■ *Brian Routhier* 21-15
21.3 Automotive and Marine Service Station Operations ■ *Carl H. Rivkin* 21-29
21.4 Vehicle Fueling Using Gaseous Fuels ■ *Carl H. Rivkin* 21-41
21.5 Fuel Cell Vehicles ■ *Glenn W. Scheffler and William P. Collins* 21-77
21.6 Recreational Vehicles ■ *Bruce A. Hopkins* 21-91
21.7 Fixed Guideway Transit and Light Rail Systems ■ *Tom Peacock* 21-101
21.8 Rail Transportation Systems ■ *Charles J. Wright* 21-109
21.9 Aviation ■ *Brian Boucher* 21-135
21.10 Marine Vessels ■ *Randall Eberly* 21-151
21.11 Road Tunnels and Bridges ■ *Arthur G. Bendelius* 21-187

Index I-1

Preface

The *Fire Protection Handbook*®—there is no other fire protection reference quite like it. For more than a century, the *FPH*™ has been *the* compilation of fire protection data and best practices. This 20th edition honors the traditions of thoroughness and accuracy that make this handbook so central to any fire protection library. At the same time, this edition includes new and expanded information throughout. For example, there are 25 new chapters and more than 500 new figures and tables. The pool of authors grew from 247 in the 19th edition to our current 260.

FPH users face a unique challenge: navigating quickly though such a wealth of information. This edition includes several new features to make it easier for readers to find the information they need. The most obvious change is the use of a second color to highlight important information such as subheads and expanded cross references to related chapters.

Other changes include the following:

- The addition of new features such as "Key Terms" and "Chapter Contents"—tools to help make the information easier to find
- The reorganization of the sections, so that each section contains fewer chapters

Clearly, a big team participated in creating the *FPH*. The authors are at the center of that team—and I'm particularly grateful for the evening and weekend time they devoted to their chapters. The authors were unfailingly cheerful and were marvelous at fitting the *FPH* into their busy lives and careers.

The section editors recruited authors, reviewed draft material, and resolved technical differences. They were simultaneously diplomats and technical taskmasters responsible for as many as 24 chapters. Their job was far from simple. The three associate editors completed a particularly important job in reviewing new chapters.

Special places in heaven are reserved for my colleagues, Robine Andrau (who timed her retirement to accommodate the *FPH* schedule), Betsey Henkels, and Michael Gammell. They faced a huge manuscript—a stack of paper and electronic files equivalent to 12,000 pages and 2,500 illustrations—and tamed it, one page at a time.

Many other people contributed to this handbook in large and small ways. We all share a simple goal of making our world a bit safer. I tip my hat to you all.

Pam Powell
Managing Editor and Senior Product Manager

Introduction

This is the 20th edition of the *Fire Protection Handbook*®. It has changed significantly since its inception in 1896 as the *Handbook of the Underwriter's Bureau of New England.*

The original author, Everett U. Crosby, was manager of the Underwriter's Bureau and one of the stock fire insurance company executives who came together to develop a consistent set of sprinkler rules in 1895 that led to the formation of NFPA. He also became the first secretary of NFPA, serving from 1896 to 1903, and was chairman of the executive committee from 1903 to 1907. Henry A. Fiske, who later succeeded Crosby as manager of the Underwriter's Bureau, joined Crosby as co-editor of the second edition in 1901. The third edition in 1904 was called the *Handbook of Fire Protection for Improved Risks,* and the fourth edition in 1909 became known as the *Crosby-Fiske Handbook of Fire Protection,* the title used until the 10th edition in 1948. H. Walter Forster, chair of NFPA's Safety to Life Committee, joined the editorial team in 1918 and became an editor for the sixth edition in 1921.

In 1935, Crosby, Fiske, and Forster donated all rights to their handbook to NFPA, which published the eighth and all subsequent editions. By the 11th edition, in 1954, the work was entitled the *NFPA Handbook of Fire Protection.* From the 12th edition in 1962 to this 20th edition, the handbook has been known simply as the *Fire Protection Handbook.*

The explosion of fire-related technology and fire protection knowledge during the last quarter of the twentieth century and into the beginning of the twenty-first century has driven exhaustive changes in the format and content of the *FPH*™. The original 5" × 7" pocket handbook is now a two-volume 8½" × 11" set.

As the most pressing concerns of fire protection have evolved—from property protection concerns of the late 1800s, through life safety concerns for public occupancies in the beginning of the 1900s, to the computer-modeled, risk assessment–based systems approach in use today—the number of subjects covered by the *FPH* has increased greatly.

Creation of the *Fire Protection Handbook* through 20 editions and 111 years has involved literally thousands of fire protection experts from within and without NFPA. It is their expertise that has established the *Fire Protection Handbook* as *the* reference source for fire protection practitioners worldwide.

Every effort has been made to make the content consistent with the best available information on current fire protection practices. If readers discover errors or omissions, the editors would appreciate those shortcomings being called to their attention. In offering this edition of the *Fire Protection Handbook,* the editors solicit suggestions for improvements to make future editions increasingly useful.

Arthur E. Cote, P.E., FSPE
Editor-in-Chief
NFPA Executive Vice-President and Chief Engineer (retired)

SECTION 12

Non-Emergency Fire Department Functions

John A. Granito

12.1 Planning for Public Fire-Rescue Protection
12.2 Organizational Benchmarking and Performance Evaluation
12.3 Needs Assessment and Hazard Analysis
12.4 Managing Fire-Rescue Departments
12.5 Information Management and Computer Technology
12.6 Liability of Fire Service Organizations for Negligent Fire Fighting
12.7 Safety, Medical, and Health Issues and Programs
12.8 Effect of Building Construction and Fire Protection Systems on Fire Fighter Safety
12.9 Fire and Emergency Services Protective Clothing and Protective Equipment
12.10 Training Programs for Fire and Emergency Service Personnel
12.11 Industrial Fire Loss Prevention
12.12 Disaster Planning and Response Services
12.13 GIS for Fire Station Locations and Response Protocols
12.14 Fire Rescue Stations and Fire Service Training Centers
12.15 Public Emergency Services Alarm, Dispatch, and Communications Systems
12.16 Fire Department Apparatus and Equipment
12.17 Pre-Incident Planning for Industrial and Municipal Emergency Response
12.18 Pre-Incident Planning for Emergency Response
12.19 Community Risk Reduction

Section 12 of the *Fire Protection Handbook*® presents, in nineteen chapters, an overview of the policy, planning, organizational, and management issues that are basic—and often most challenging—to fire department, municipal, and corporate officials as they strive to keep their people, property, and environments safe by maintaining effective fire-rescue organizations. Chapters 2, 3, 12, and 13 are new; other chapters have been significantly revised.

The purpose of Chapter 1, "Planning for Public Fire-Rescue Protection," is to demonstrate that adequate fire protection and related public safety services are essential and that both the level and types of services provided should be carefully considered choices based on adequate information. Topics covered include integrated risk management, planning processes, evaluation as part of planning, and public protection classifications.

Chapter 2, "Organizational Benchmarking and Performance Evaluation," examines organizational benchmarking and performance evaluation from a systems perspective in order to include the key elements of success for a fire department performance management system. Steps to implement a new system are discussed.

The purpose of Chapter 3, "Needs Assessment and Hazard Analysis," is to demonstrate the interrelationship of numerous routine or special activities that can be conducted as a component of a comprehensive needs assessment and hazard analysis—that is, the identification of the challenges faced and the resources needed to manage these challenges.

Chapter 4, "Managing Fire-Rescue Departments," provides an overview of the elements involved in organizing, administering, and managing agencies that provide fire and rescue response services.

Chapter 5, "Information Management and Computer Technology," introduces information technology and networks, as well as their application to management, emergency response and operations, and internal and public communications. Systems integration is also discussed.

Chapter 6, "Liability of Fire Service Organizations for Negligent Fire Fighting," explains legal concepts such as discretionary functions immunity, governmental immunity, liability, limited damages, negligence, public duty rule, punitive damages, and tort claims act. The chapter applies these legal concepts to the fire service environment.

Chapter 7, "Safety, Medical, and Health Issues and Programs," outlines the history of safety and health legislation as it applies to fire departments and describes relevant NFPA standards and

John A. Granito, Ed.D., is a consultant in fire-rescue services and former coordinator of NFPA's Urban Fire Forum. He is a professor emeritus and former vice-president for Public Service and External Affairs, State University of New York, Binghamton, New York.

requirements within the context of that history. The chapter concludes with a description of the risk management program that is detailed in NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program.*

The next three chapters relate to fire fighter safety. As presented in Chapter 8, "Effect of Building Construction and Fire Protection Systems on Fire Fighter Safety," fire department personnel have a very strong interest in building construction. The chapter outlines simplified principles of building construction, building codes, and building construction classification, as well as specific concerns such as building collapse.

Chapter 9, "Fire and Emergency Services Protective Clothing and Protective Equipment," describes NFPA and OSHA involvement in standards for personal protective equipment, discusses third-party certification, and offers guidelines for cleaning and maintaining personal protective equipment. Chapter 10, "Training Programs for Fire and Emergency Service Personnel," is an overview of the broad challenge of providing training for fire and emergency service personnel. The chapter presents information on the need for training, organization of training delivery, ensuring quality instruction, internal and external training programs, training safety, and records.

Chapter 11, "Industrial Fire Loss Prevention," examines the need to minimize fire loss from the corporate perspective. Topics addressed in this chapter include emergency management, fire prevention, fire risk management, hazard identification, and the role of industrial fire brigades.

Chapter 12, "Disaster Planning and Response Services," outlines the phases of emergency preparedness, techniques for a hazard vulnerability analysis, and identification of critical facilities and infrastructure. Continuity of government and continuity of operations are among the other subjects presented.

Chapter 13, "GIS for Fire Station Locations and Response Protocols," explains the use of geographic information systems in fire station location planning and site selection factors. GIS response protocols are introduced.

The next three chapters address fire department resources. Chapter 14, "Fire Rescue Stations and Fire Service Training Centers," provides a general overview of the steps necessary to develop fire stations and fire training centers. Chapter 15, "Public Emergency Services Alarm, Dispatch, and Communications Systems," provides an overview of public emergency services communication systems. This chapter addresses issues related to the design, installation, operation, maintenance, and management of such systems and the facilities that house and support them.

Chapter 16, "Fire Department Apparatus and Equipment," contains information on the standards used and procurement policies that should be followed in specifying and acquiring apparatus and equipment. The chapter discusses inspection, maintenance, testing, and retirement of apparatus and equipment.

The next two chapters address pre-incident planning. Chapter 17, "Pre-Incident Planning for Industrial and Municipal Emergency Response," defines pre-incident planning, introduces the process, and identifies data needed for pre-incident planning. Chapter 18, "Pre-Incident Planning for Emergency Response," explains how pre-incident planning allows fire-fighting personnel to view conditions within a structure or site, evaluate what these conditions are likely to develop into in the event of an emergency, and then develop strategies for dealing with the potential problems.

Chapter 19, "Community Risk Reduction," presents components and fundamentals of a community risk reduction initiative, outlines risk reduction strategies, and discusses the roles of leadership and community engagement in the community risk reduction process.

Chapter 1

Planning for Public Fire-Rescue Protection

John A. Granito

Chapter Contents

Integrated Risk Management
Background Issues Concerning Fire Protection
Steps in Planning
Evaluation as Part of Planning
Public Protection Classifications
Planning Processes

Key Terms

benchmarking, deployment, emergency medical services, fire prevention, Fire Suppression Rating Schedule (FSRS), Insurance Services Office (ISO) grading schedule, master planning, needs assessment, public fire protection, risk management, rural fire protection, technical rescue, urban fire protection

The purposes of this chapter are to demonstrate that adequate fire protection and related public safety services are essential components of any community and that both the level and types of services provided should be conscious and carefully considered choices of the community, which are made with, and based on, adequate information. As adequate public protection is designed, careful planning needs to be done to ensure that fire fighter safety is not compromised. Objective planning and evaluation can ensure that a community's desire for a stipulated level of protection is being met in as cost-effective a manner as possible.

Certain NFPA publications, including a number of codes, standards, and recommended practices, contain information that is related to this chapter. Many of these publications are listed in the bibliography at the end of this chapter.

Several other chapters in Section 12 provide information useful in the self-assessment of a public fire protection system: Chapter 2, "Organizational Benchmarking and Performance Evaluation"; Chapter 3, "Needs Assessment and Hazards Analysis"; Chapter 5, "Information Management and Computer Technology"; Chapter 7, "Safety, Medical, and Health Issues and Programs"; Chapter 12, "Disaster Planning and Response Services"; Chapter 18, "Pre-Incident Planning for Municipal Emergency Response"; and Chapter 19, "Community Risk Reduction."

INTEGRATED RISK MANAGEMENT

Growing national and international awareness of the staggering costs, both in life and dollars, of fire fighter line-of-duty deaths and injuries has given rise to the development of a newer, more comprehensive planning approach. Developed first in the United Kingdom, it is termed *integrated risk management*. This refers to a planning methodology that recognizes that citizen fire safety, plus the protection of property and the environment from fire and related causes, must include provisions for the reasonable safety of emergency responders. Chief Fire Officer Paul Young summarized the 2003 UK government white paper entitled *Integrated Risk Management and Firefighter Safety in the United Kingdom* as follows:

> Mandated Integrated Risk Management in the UK Fire and Rescue Service means that suppression resources are to be allocated on the basis of risk rather than the number of buildings in an area. This means assessing the risks faced, taking preventative action, and deploying the right resources in the right place at the right time.
>
> Far too few resources were devoted to residential areas, where most fire deaths occur, and too many resources were devoted to business districts where fewer deaths occur. Fire and rescue authorities must create local plans for fire and other emergency incidents based on local risks. There is much greater flexibility in managing risk this way, rather than under the old national standardization of response.

John A. Granito, Ed.D., is a consultant in fire-rescue services and former coordinator of NFPA's Urban Fire Forum. He is professor emeritus and former vice-president for public service and external affairs, State University of New York, Binghamton, New York.

A modern and effective fire and rescue service should serve all sections of our society fairly and equitably by:

- Reducing the number of fires and other emergency incidents
- Reducing loss of life in fires and accidents
- Reducing the number and severity of injuries in fires and other emergency incidents
- Reducing the commercial, economic, and social impact of fires and other emergency incidents
- Safeguarding the environment and heritage (both built and natural)
- Providing true value for money spent

A very important by-product of reducing the number of fires and other incidents is a reduction in the exposure of fire fighters to risk, thus improving their safety. Fewer incidents mean fewer road accidents and fewer fire fighter fatalities and injuries at the scene. The integrated risk management program (IRMP) should also ensure that the optimum operational response is made to any given incident to reduce deaths and injuries among the public. However, to do that, the response needs to be operationally effective, and that means that fire fighter crewing levels need to be adequate and, therefore, safe for the tasks. Inadequate crewing levels are not only unacceptable on the grounds of fire-fighter safety, but on the grounds of public safety as well.

In addition, fire-fighter safety depends on individual competence. Investigations into fire-fighter deaths have demonstrated often that there was no objective way of demonstrating that the fire fighters were competent to carry out the role they were performing at the time. That they had been trained did not mean that they had demonstrated their competence in a way that could be validated.

Because of this, the Integrated Personal Development System is introducing into the UK Fire and Rescue Service a competence-based training and development process that seeks to ensure that all members of the workforce can demonstrate that they are competent to carry out their role. You cannot be safe if you are not competent.

The IRMP drives the planning process for not only vehicle and equipment requirements, but also crewing arrangement, training and development, and many other factors. In short, it provides that an evidence-based approach to the management and delivery of fire and rescue Services.

BACKGROUND ISSUES CONCERNING FIRE PROTECTION

Because the safety of people, property, and the environment is so vital, questions that focus on the organization and deployment of fire-fighting resources are especially important to communities. Prompted by escalating costs, issues relating to fire suppression have attracted a great deal of public attention, even though fire fighting is but one part of what constitutes community fire protection. Although fire prevention and fire protection engineering efforts are typically less costly in the long run than fire fighting, questions relating to the appropriate size, deployment, and response protocols of fire-fighting forces remain paramount.

Financial, Technical, and Responsibility Issues

Nevertheless, governmental and public concerns that focus exclusively on emergency response issues to the exclusion of adequate provisions for the prevention of fire and other emergencies are more costly and less effective. A total fire and related protection program, which includes the application of resources to comprehensive fire prevention and life safety, provides the most effective and efficient means of saving lives, property, and the environment, plus increases the operational safety of fire fighters.

The first issue is created by the relatively high cost of fire stations, fire apparatus and equipment, on-duty personnel, and line-of-duty deaths and injuries. A second set of issues is technical in nature, dealing with the number of responders necessary to be on duty and to be dispatched, with what should be the maximum allowable time for response, and with other related technical and operational questions including the necessity for safety officers and rapid intervention teams.

The third issue considers what the process should be for determining the answers to the following technical, operational, and safety questions:

- Should communities assess their own needs and resources and provide individualized answers, or should national standards be applied?
- How should national standards and recommended practices be formulated?
- Should noncompliance with a national or industry standard expose officials to penalties?
- Should fire chiefs be obligated to inform fully their local officials concerning local hazards, risk levels, and levels of service actually available?
- Should local officials keep citizens fully informed concerning available emergency service capabilities?

These and similar questions have generated much debate about the processes of planning and evaluating community fire and rescue defenses.

Unfortunately, it appears possible that even those who are genuinely concerned with evaluating and planning for local fire, rescue, and emergency medical services may blend together the issues of cost, technical correctness, safety, and responsibility for resource decisions. When this happens, communities cannot be sure that the resulting delivery system is the most appropriate obtainable for the available financial resources.

Of course, there are multiple demands for local municipal funds. Thus, emergency protection must be fitted into a larger community priority listing of needs and desires. However, proper placement in the listing requires that a true and accurate description be publicized of existing capability compared

with accurately described community hazards, response history, and call demand predictions. When the issues are erroneously blended together, citizens may believe that adequate, timely, and safe response is available when indeed it is not and may give higher budget priority to another community interest. Or citizens may be unduly anxious over erroneous observations that fire defenses are much too meager and that even more resources must be allocated. In addition, official planning and community concern may ignore the vital issues of hazard mitigation, comprehensive prevention, and life safety education.

Publicizing the Need for Prevention Programs

Citizens are often subjected to opposing budget arguments concerning protection levels and frequently lack the knowledge necessary to arrive at sound conclusions. This understandable lack of technical expertise underscores the necessity for accurate, well-balanced, and forthright information to be widely disseminated among those who will both receive and pay for service delivery. Hazard analysis and risk assessment are extremely important.

Partly because the benefits of active comprehensive prevention programs, public safety education, and fire protection engineering efforts are not well advertised, there often is little pressure exerted on their behalf. Thus, relatively few resources are allocated to these efforts in many communities when compared with allocations for suppression work. Even though it certainly is true that the least harmful fires are those that never occur, most communities fail to consider a total fire protection plan as a wise and cost-saving instrument. The benefits of residential and high-rise fire sprinklers are well documented, for example, yet conflicting pressures have often curtailed their use. The funds allocated to fight the fires that do start, however, can be quite high. Much more emphasis is needed on the total protection program if communities and their fire fighters are to be made reasonably safe at reasonable costs. The evaluation and planning of public fire protection, then, must consider total protection efforts. Benchmarking and performance evaluation play key roles in the planning process. Efforts certainly must include provisions for emergency response, but also such efforts as locally adopted codes and ordinances, built-in structural protection, inspection programs, public education for all groups, building plan reviews, and so on must be included. The same concept, of course, applies both to the preventive and emergency-type prehospital medical services fire departments often provide.

Developing a Prevention Plan

A practical approach to the development of a community's mid- to long-range plan is first to generate a view of what the community will be by the time of the planning horizon. That information comes from an analysis of past development combined with projections of demographic changes, economic development or decline, major roadway programs, annexations, significant building projects, and so on.

The second step is to assess realistically the strengths and weaknesses of the existing fire protection system, including codes, standards, and ordinances relating to safety, fire prevention efforts, public safety education programs, and emergency response capability. This is an important facet of the risk management process.

Answering the question of what the response strength should be involves an honest assessment of stations and their locations, vehicles and equipment, staffing numbers and provisions, breadth and depth of the various service delivery areas, training and other support activities, success rate in handling emergencies, mutual-aid arrangements, dispatch and communication provisions, and response times.

In 2001 the NFPA consensus standard building process produced two new standards, one for substantially career fire departments (NFPA 1710, *Standard for the Organization and Deployment of Fire Suppression Operations, Emergency Medical Operations, and Special Operations to the Public by Career Fire Departments*) and the other for substantially volunteer departments (NFPA 1720, *Standard for the Organization and Deployment of Fire Suppression Operations, Emergency Medical Operations, and Special Operations to the Public by Volunteer Fire Departments*).

Applying NFPA Standards

NFPA 1710 (2004 edition) deals with the time frame for response to fire and medical incidents for the first-due engine company, for the entire first alarm assignment, and for the first level, basic, and advanced emergency medical responders. The number of fire fighters necessary for initial suppression attack and their roles are specified in the standard, as are other aspects of organization, suppression, operations, emergency medical and other responses, special services, staffing, and so on.

NFPA 1720 (2004 edition) addresses the organization, operation, and deployment of those departments that are substantially volunteer in staffing. Recognizing the response time differences that often occur between in-station responders and volunteers who likely are not at the station, NFPA 1720 calls for minimum numbers of fire fighters depending on local population density per square mile, and differing maximum response times, which are also related to population density.

The third step is to project the needed capabilities and capacity of the fire protection system and its vitally important fire department component as the community changes. Any additional needs of the system and the fire department, so that they can meet the projected demands, represent the content components of the plan. How that plan may be financed and implemented, and the time and timing required constitute the strategic and tactical planning necessary for success.

A major challenge in this "discovery" process often lies in assessing the existing protection system and its fire department, and in determining the steps needed to bring both to the strength required by projected demands. Additionally, tests of efficiency, cost-effectiveness, economies of scale, and other sound business practices must be applied.

The following basic questions are to be raised concerning this entire process:

- What types and levels of protection does this community need both now and to meet the upcoming community profile?

- How are the details of these needs best determined?
- What process and whose expertise should be used to arrive at the answers?
- Is fire fighter safety carefully considered?
- How may the correctness of the answers be tested?
- Are the answers as cost-effective as possible?
- How can any needed improvements best be funded?
- What should be done during and after the planning process to win the support of those directly affected by changes and those who will have to pay for any improvement?
- How and when should the plan be updated?

STEPS IN PLANNING

Public fire protection, emergency medical services, and technical rescue provisions need to be carefully planned and require that certain logical steps be taken to achieve a comprehensive, acceptable, and workable plan. There are two important aspects to any good plan: (1) the plan itself, which must be feasible and directed toward clear goals; and (2) the process by which the plan is developed, which must ensure that all major goals are considered and every constituency to be affected by the plan is reasonably involved in the planning process or made well aware of its consequences prior to plan approval.

Without adequate involvement of the necessary constituencies, implementation of the plan may likely fail because of a lack of cooperation and commitment. For a satisfactory plan to evolve, the planners must decide the end results they wish to achieve (goals), determine the status of the fire protection system in relation to those goals (evaluation), and calculate how much and what kinds of progress actually can take place over a certain period of time (objectives, tactics, time frame). Each of these three steps—setting goals, evaluating, working out the details—requires the collection and analysis of relevant information. Broad goals are achieved through planned strategies and precise objectives are achieved through implemented tactics. Each must be relevant to the other. Local data collection and information management systems are vital to planning.

Careful consideration of these important factors, which will vary considerably from one community to another and which must take into account assets, liabilities, challenges, and available resources, leads to what is often referred to as a *strategic plan.*

Evaluation of Fire Protection Services

Because some degree of public fire protection is almost always in place, it is common for the entire process to begin with both a local hazards analysis and risk assessment, plus an evaluation of the fire protection that is already available. See Section 12, Chapter 3, "Needs Assessment and Hazards Analysis." The information obtained from the evaluation, when analyzed in terms of broad, generally recognized public fire protection goals, identifies needs and provides responsible community officials with the approximate parameters of the plan to be developed.

It is important to take into consideration those fire protection and other public safety services that may be provided by a fire/rescue department and that will meet specific local needs. Examples of this are hospital transportation by a fire department ambulance and responsibility for emergency management and disaster services.

Typical fire department services include fire prevention programs—such as code administration and enforcement through plans review, inspection services, and public education—as well as fire suppression, technical rescue, emergency medical, hazardous materials response, and disaster response. Various other public services, such as health screening programs, are conducted more and more often by progressive departments. This approach to broad-based community safety service takes advantage of departmental resources, such as neighborhood fire stations and on-duty personnel, experience in public service and education, and the typically high regard in which fire departments are held by citizens.

Community Involvement

As already noted, the plan cannot be developed without the involvement of a wide variety of community groups. Even if the various constituencies seem willing to allow fire protection officials to develop and write the comprehensive plan without their consultation, the fire officials should be cautious; the citizens eventually must be willing to accommodate and pay for the implementation. Because a comprehensive plan envisions a larger group or system of integrated parts, a number of organizations and agencies outside the fire department will need to play important roles in implementation of the plan. Local elected officials typically play key roles in plan approval, implementation, and funding.

Modern practices make it necessary for fire departments to work cooperatively with a variety of agencies and organizations. These range, for example, from the local building code enforcement staff to the U.S. Coast Guard for hazardous materials spills near navigable waterways. Good planning requires consultation with all operational components on a continuing basis. A good plan today is better than a perfect plan that might be developed tomorrow.

As noted, one basic aspect of a comprehensive public fire protection plan is the concept that it is infinitely better for a community to prevent fires altogether, or to mitigate them automatically through fire safety education and built-in fire protection features, than to depend solely on the fire suppression capabilities of the community's fire department. The goal of reducing the incidence and effects of fire involves all aspects of fire prevention. Historically, much more energy and many more resources have been devoted to evaluating, planning, and implementing fire suppression/fire-fighting capabilities than fire prevention capabilities. Simply stated, the United States as a whole has focused more on "fire engines and fire fighters" than on public awareness and built-in mitigation features. That focus is still necessary and exceedingly important, but effort must also be placed on measures that do not depend solely on fire suppression personnel to reduce the toll of fire. Planning groups often have difficulty, however, in evaluating the degree of effectiveness of such multifaceted fire protection programs.

Three Types of Analysis

A reasonably effective method exists for conducting the evaluation, involving three kinds of analysis.

Community Record Keeping. The first kind of analysis requires the community, typically through the fire department, to maintain consistent and carefully recorded information each year concerning the number of fires that occur and the cost of those fires in lives and dollars including wages and tax revenues lost. When those human and physical costs are added to the expense of maintaining fire prevention and suppression systems, plus the cost of fire insurance, a standardized total cost of fire to the community can be compared with that same cost in earlier years, or over an average of three or more years. Necessary adjustments for inflation, community growth or decline, and other important variables can be made by local officials, thus permitting a community to compare its present to its prior fire performance.

Benchmarking. The second kind of analysis most useful in determining cost-effectiveness involves communities identifying other communities that are similar in ways important to fire protection (such as services desired, size, construction, hazards, and geography) and comparing their own total performance to the total performance of the similar communities. This process, termed *benchmarking,* has become a popular methodology. However, the number of site-specific variables may be so high and the span of differences so great that comparisons prove confusing. Benchmarking requires cautious application. See Section 12, Chapter 2, "Organizational Benchmarking and Performance Evaluation."

Needs Assessment and Hazard Analysis. The third kind of analysis, although self-conducted, is formatted and guided by the fire department accreditation process now available in the United States. See Section 12, Chapter 3, "Needs Assessment and Hazards Analysis."

In the first analysis, the community uses an internal data source (itself) as a yardstick, and in the second analysis it uses an external yardstick (other communities). As more data are collected concerning the total cost of fires in various communities operating with different public fire protection plans, any given community will be able to benefit relatively quickly not only from its own experience but also from the experiences of others. The Commission on Fire Accreditation International, which was developed by the International Association of Fire Chiefs in conjunction with other national organizations, provides a standardized methodology for fire departments to assess and rate themselves—with the assistance of a visiting team—along a series of categories important to community protection. Performance indications serve as points of measurement and are important components of this accreditation process. More and more departments are using this process to evaluate their condition and to benefit from both the process and the accreditation status.

Important to this planning process is the ability and willingness of the community to finance and otherwise support the total level of fire protection required by the plan's goals. Examples include legislation dealing with the retrofitting of sprinkler systems, or innovative thinking that produces a core group of senior citizen volunteers who conduct fire safety programs for their peers. In some states built-in fire protection requirements are set at the state level, and local government may not increase the level of fire safety provided by building features (automatic fire sprinklers, noncombustible roofing, etc.).

Although fire protection officials must always be concerned with reducing the total cost of fire (fire loss, plus costs of insurance, prevention, and suppression), citizens living in tight economic times will ultimately reserve the right to make decisions, or trade-offs, concerning the level of protection they wish their tax dollars to purchase. However, the safety of emergency responders cannot be reduced as part of a cost-reduction program.

To assist citizens in making decisions concerning budgets, fire protection officials must accurately describe the effect on total cost if additional or fewer resources are applied to particular prevention or suppression efforts. This kind of technical knowledge and analytical ability of officials provides a crucial element to comprehensive planning and evaluation. It is one of the most important responsibilities of the public fire protection officer.

One of the most serious issues faced by public officials and residents is that of adequate fire department staffing. In communities served by volunteer fire fighters, there may be serious volunteer recruitment and retention problems or problems in providing timely response during working hours when many of the volunteers may not be in the community they protect. In communities served by career, full-time fire fighters, restricted budgets often limit the number of fire-fighting vehicles ready to respond, or the crew size for each vehicle and, thus, the total number of trained personnel responding to the incident in time to mount an effective offense against the fire, often termed "initial attack." Fire protection officers and municipal officials need to communicate objectively the level of service being provided and how changes in fire department resources will affect that level of service. That is, the type and level of risk should be expressed in terms understandable to the fire protection nonexpert and in terms neither over- nor understated. Of course, the fire department must bear the responsibility of formulating and operating a cost-effective organization, no matter what level of service is desired.

EVALUATION AS PART OF PLANNING

In addition to assessing the capabilities of the fire department and related aspects of fire protection, fire officials evaluating the capability of the existing fire protection system must take a number of factors into account. Examples include known combustibles, the life hazard that exists, fire frequency, climatic conditions, demographic and geographic factors, and a basic consideration of the specific role of a public fire department in providing fire protection to the community. Failure to consider each of these factors adequately can lead to a large-loss fire. A fire department's suppression capabilities can never be expected to compensate totally for the deficiency or lack of built-in fire protection systems.

Local Capability and Capacity for Fire Suppression

Two concepts are useful in local suppression considerations. First is the "capability" of the fire department to respond within a short time with sufficient trained personnel and equipment to rescue any trapped occupants and confine the fire to the room or building of origin on initial attack. How many crew members and vehicles of various types are necessary depends on the type of call and the conditions of the local community, which either aid or hinder fire fighting. These variables, which certainly number more than 20, range from water supply and sprinkler ordinances to weather conditions and the age of buildings. See Section 12, Chapter 18, "Pre-Incident Planning for Emergency Response."

Thus the evaluation of local fire suppression capability, although no more important than the evaluation of local prevention and public safety education efforts, is a necessary effort for two primary reasons. First, most communities have little understanding of either the level of local protection available or the level necessary for reasonable community well-being. Second, the time availability of volunteers is quite limited, and the cost of full-time career personnel typically is significant. The actual number of available crew members—although exceedingly important—may not be realized by nonfire officials and citizens. This lack of information concerning actual resources can lead to a false sense of security.

The second concept is that of "capacity," which is the ability of the fire department to respond adequately to multiple-alarm incidents ("sustained attacks") and/or simultaneous calls of any type, including emergency medical responses. If alarm patterns are examined, the volume of multiple alarms and simultaneous response demands over a period of time can be approximated. Larger municipalities typically average more demand for capacity and, thus, typically have larger departments; but, obviously, remaining capacity is diminished as suppression units are deployed, even in the largest departments. It must be recognized that although a few fireground tasks may be performed sequentially, most need to be performed simultaneously, and the latter requires more personnel.

Evaluation Factors

In evaluating both local response capability and capacity, officials need to consider the following: in many areas it is relatively easy to increase capacity (through the use of mutual aid and group or entire shift callbacks), but it is much more difficult to improve capability, which requires immediate *response* of nearby forces. A common rule of thumb is that a community using on-duty crews at fire stations should be able to have an initial attack team composed of an entire first-alarm response on the scene within approximately 10 minutes of receipt of the alarm. This equates to about 8 minutes of running time.

Another rule of thumb is that, for a totally volunteer, nonstaffed station, the average time from when a call is received to the moment a crewed vehicle leaves the station could be 6 minutes or longer. In those situations, then, the "call to on-scene time" for a 6-minute run is about 12 minutes for one or more vehicles.

Several techniques are used by progressive fire officials to help mitigate these handicaps to achieving adequate response capability and capacity. These techniques include using *automatic,* immediate mutual-aid response from nearby departments, rapid callback systems, volunteer personnel who "bunk in" at stations, part-time or full-time on-duty crew members (combination department), special shift arrangements, elaborate regional mutual-aid agreements, and other methods. "Doing more with less" is a popular concept, but there are limits that must be realized.

As part of a local response evaluation, fire officers and other community officials can determine the status of their response forces by establishing what capabilities and capacities are necessary for adequate protection of their area and then determining what is available.

Following a local hazard analysis, for example, the following types of "what should be" questions concerning what *is needed for adequate response capability* may be posed:

- Maximum time for call processing at dispatch center
- Minimum number of persons on first-out pumpers
- Minimum number of persons on first-out aerial
- Minimum number of persons on first-out heavy rescue
- Minimum number of persons on first-out emergency medical service (EMS) vehicle
- Weekday get-out time for first-due unit
- Weekday get-out time for second-due unit
- Nighttime get-out time for first-due unit
- Nighttime get-out time for second-due unit
- Maximum clear weather running time (pumper) in district
- Maximum clear weather running time (aerial) in district
- Maximum clear weather running time (EMS) in district
- Number of qualified fire fighters plus incident commander to be at scene within 8 to 10 minutes of dispatch
- Number of qualified fire fighters plus incident commander to be at scene within 15 minutes
- Number of minutes for mutual aid to arrive at scene

Figure 12.1.1 illustrates one method for listing the actual response capability of a department for a simple, single-family-dwelling fire. Figure 12.1.1 can be expanded to include first-alarm fire responses to other types of occupancies. Response times can be verified and listed for the components of the first-alarm assignment, and other questions can be posed to identify local response capacity to handle multiple and/or simultaneous alarms.

An important stipulation put into effect in 1995, and continuing, is that a minimum of four trained personnel be at the scene of a structure fire before an interior attack can be launched, except under the most extenuating circumstances. Both the U.S. Occupational Safety and Health Administration (OSHA) and the National Fire Protection Association (NFPA) have issued documents dealing with this. Also, in the United States and in certain other countries, various governmental agencies have issued regulations and advisories concerning the necessity for certain emergency operations to have trained incident commanders and standby safety/rescue crews present, as well as to have a defined incident command system operating. Local officials are well advised to have current infor-

mation concerning all applicable federal (national), state, and provincial requirements, as well as applicable NFPA codes, standards, and recommended practices, as issued from time to time.

Rural Fire Protection

One principal difference between operation of rural and urban fire departments is that rural departments must deal with water supply issues with a broader variety of solutions than most urban departments. Rural fire department operations and apparatus emphasize not only fire-fighting requirements but also the provision of water for fire fighting. Rural fire apparatus must have large water tanks to permit effective initial attack on fires while supplementary water supplies are being brought into action. Supplementary water supplies include drafting sources on or adjacent to rural properties, and mobile water tanker vehicles for transporting water from more distant sources. Also in use are portable folding canvas tanks into which tank trucks quickly discharge their water supply through special dump valves. Rural fire departments often use apparatus and hose to relay water from sources several thousand feet (1000 ft equals 304.8 m) from the emergency. Initial response of pumpers, tankers, and auxiliary apparatus should be adequate for a quick attack on the burning property. With adequate highways and well-designed apparatus, it is often possible to bring substantial fire-fighting forces to an emergency in rural areas in sufficient time for a properly planned and executed initial fire attack operation to be effective, even though many of the personnel may arrive in private automobiles. Many rural properties are now located in areas that enjoy some level of fire protection. Some properties, of course, may have to depend entirely on their own private fire protection and whatever help they may obtain from forestry agencies or distant fire departments.

Newer approaches to fire insurance rating give "protected" status to property without a municipal water supply system if a fire station is within five travel miles and a stipulated gallons per minute flow can be maintained by the local department, as mentioned later in this chapter.

Fire-Fighting Apparatus. Minimum protection for a rural area would include a pumper with a large water tank and a water tank vehicle responding on an initial alarm. Properly designed tanks should be able to transport water from a source 1 mi (1.6 km) from the scene so a minimum of 250 gpm (946.25 L/min) can be pumped at the fire scene by the pumper. Because a larger flow is often required to provide adequate fire protection services, additional tankers must be used, or drafting sources within reasonable distance of the fire scene must be identified. Programs that encourage the construction of year-round rural drafting sites are to be encouraged. Rural apparatus should carry 3½-in. (89-mm) or larger supply hose to provide adequate water supply at the fire scene. It is always advisable to lay large-diameter fire hose from the water supply source to as near the fire scene as possible in order to avoid extensive friction loss. At the emergency, large-diameter hose is sometimes connected into smaller handlines, or used more often to supply another pumper from which handlines are extended. Other pieces of equipment, such as rescue and aerial ladder vehicles, should be provided as needed to carry out the mission. Elevated master streams are not needed extensively in rural operations, and sometimes ladder truck equipment for rescue, forcible entry, ventilation, and salvage operations is carried on pumpers and equipment vehicles.

To be even minimally effective in controlling a fire, the initial responding apparatus should reach the emergency scene before very rapid fire spread. As is the case in urban fire fighting, this move is termed "initial attack" and is aimed at stopping the fire as close to the point of origin as possible. So-called "sustained attack" attempts to reduce the loss to the exposed adjoining or nearby property. Because of longer response times, rural

departments may find themselves in the sustained attack, or "defensive," mode on arrival. Unless sufficient water can be made available within a short time frame, the British thermal units (Btu) generated by the burning material cannot be absorbed so the temperature is not reduced sufficiently to extinguish the fire. Successful rural protection planning generally boils down to response times and water availability.

Hazardous Materials and Structures. Of special concern are the sometimes extensive supplies of fertilizer and pesticides located on rural properties. Response crews must be alert also to the possibility of above- and below-ground storage tanks for fuel and other products. The safe operations guidelines for hazardous materials response are applicable in rural as well as urban areas.

Another concern for rural fire protection exists because so many large and diverse types of structures are located in rural areas. These structures include warehouses, truck centers, product distribution facilities, processing plants, storage buildings, centralized schools, churches, trailer parks, and others.

In addition, the extension of existing housing developments and the construction of new residential and commercial structures immediately adjacent to wildland areas, or in the midst of such areas, have brought about a significant increase in wildland–urban interface fires, which present new challenges to both urban and rural fire departments.

However, it is possible to give such counsel if one can make certain assumptions that may be controlled by the community. These assumptions relate primarily to the presence of appropriately placed smoke detectors and other types of fire detection devices and a means to relay that alarm to the fire suppression agency, but they also include the existence of enforced building codes that provide some degree of resistance to fire spread from the room of origin, rural sprinkler systems, home escape plans, and so on.

Urban Fire Protection

In urban areas, inadequate fire department response to initial alarms can be a major factor in fire losses due to high population and structural densities. The number of simultaneous fire-fighting operations that may need to be conducted at the incident also dictates the total amount of personnel and equipment needed to provide effective fire-fighting operations. In any "working" structural fire, several operations must be carried on simultaneously and the fire attack must be made from several points. This attack cannot be accomplished by the crew of a single fire apparatus. Multiple apparatus must be positioned properly, and adequate waterflow made available to cope with the amount of fuel (fire load) involved or exposed.

Structural Fire Suppression. In simplest terms, structural fire suppression in an urban setting involves the accomplishment of at least the following tasks, many of which must occur almost simultaneously to ensure effective and safe operations (the proper sequence will vary, depending on circumstances, as will additional tasks):

- Command, control, and coordination of the incident (to ensure both effectiveness and safety of the fire fighters)
- Adequate on-scene radio communication among attack forces
- Application of water in appropriate quantities (dependent on the fire environment and other factors)
- Provision of appropriate source of water supply for above
- Ventilation of smoke and other hazardous products of combustion from the fire area to the outside
- Search for and rescue of fire victims
- Forcible entry
- Control of utilities
- Salvage and other property conservation operations
- Standby rapid intervention/fire fighter rescue
- Provisions for emergency medical services

At large-structure fires, additional fire-fighting personnel are needed to cover the various points of fire attack. In some cases various functions can be handled more efficiently by specially trained crews such as rescue companies and hazardous material teams operating from specially equipped apparatus.

Determination of Required Equipment and Personnel. The number of personnel and equipment necessary to accomplish the above will vary with a number of factors (i.e., the expectations placed on the mobile suppression group, the material burning, the construction of the building, the type of built-in protection provided, separation between buildings, availability of water supply, the number and physical and emotional condition of persons in the fire building, the type of equipment available to fire fighters, the level of proficiency of the fire suppression crew [including the commanders], etc.). Hence, it is difficult to determine a minimum number of fire fighters or equipment required without careful, objective planning, and without considering the important variables. Obviously, personnel needs will differ significantly between a small detached structure fire and a high-rise fire. Pre-incident planning is essential. Some general considerations may, however, be listed as follows:

- The more arduous the expectations placed on the mobile fire suppression crew, the greater the required resources. (For example, the community that expects its fire department to contain fires to the room of origin should expect to provide more fire suppression resources than the community that expects its fire department only to prevent the spread of fire from one building to another. Given the same level of protection demands, the community that leaves all fire protection to the mobile fire suppression force will require a more extensive suppression force than the community that requires a high level of built-in protection.
- The more extensive the concentrated fire potential, the greater the required fire suppression resources. For example, given the same expectations of its mobile fire suppression force, a community having high-rise buildings, a high population density, and extensive industrial risks will normally require greater fire suppression resources than a largely residential community.
- The broader the services provided by a fire protection agency, the greater the need for resources. For example, a fire agency providing emergency medical services will, given the same level of expectations for its mobile suppression forces, re-

quire more resources than an agency providing only fire protection services, assuming a significantly increased *total* workload demand, including a significant increase in simultaneous calls.

- The greater the geographic area protected, the greater the resource requirement of the mobile fire suppression forces. That is, given the same service level expectations, a community providing service to 20 mi^2 (52 km^2) will require more resources than a community providing protection to only 10 mi^2 (26 km^2); this is caused by the need for timely arrival at the scene of fire, medical, or environmentally threatening incidents. Computerized geographic information systems and accompanying computerized response maps have the powerful ability to demonstrate visually the response effectiveness of various station locations.

In most smaller and medium-size communities, all initial-response (first-alarm) apparatus will not arrive at the fire scene simultaneously. In many departments with on-duty personnel, apparatus have to respond from more than one station, and some apparatus have longer travel times to the fire scene. In volunteer departments, personnel must travel varying distances to get to the fire station or the fire scene, and, thus, all apparatus cannot go into operation at the same time. Those fire fighters and vehicles that cannot arrive at the fire scene within the first critical time period have limited impact on the initial attack, regardless of the department's response assignment ("running card"). Communities may have a false sense of security in this regard, until actual response times are tested and working initial-attack personnel counted.

Minimum Manning. The critical numbers for policy makers to use in planning related to staffing of shifts and apparatus crews—sometimes termed "minimum manning"—are those that describe how many trained personnel can arrive within a stipulated initial attack time frame. Ideally, all or most will arrive as composite crews and not as individuals.

The total minimum fire force recommended for any community is necessarily dependent on community hazards and the expectations of the community and the members of the mobile fire force. Objective planning and evaluation are necessary to determine the resources required for effective and safe fire suppression operations that will meet community requirements.

Some fire agencies are addressing the suppression challenge with different arrangements of fire crews within the communities than were heretofore generally accepted (e.g., use of multipurpose apparatus task force assignments and differential staffing). It is important to note that, although these different approaches may augment flexibility, they do not appear to reduce the number of suppression personnel required to carry out fire-fighting operations safely.

It does seem reasonable to say that not fewer than two fire suppression vehicles and a command officer should respond to any structure fire and that the number of personnel responding should be sufficient to carry out the tasks indicated above, and whatever else is typically necessary in local operations, in a timely fashion. Normative data are available from some cities. It is relevant to note that, in a broad spectrum of environments that are protected by numerous urban departments, as observed by evaluation teams, between 19 and 23 personnel typically constitute the first alarm assignment to a confirmed single-family-dwelling fire.

Where necessitated by fire frequency or response distances, additional pumpers, ladder trucks, and tankers may be needed. Reserve apparatus is desirable not only to permit the repair of first-line equipment without reducing available fireground forces but also to provide additional fire-fighting units during major emergencies. Specialized vehicles for hazardous materials response, heavy-duty and specialized rescue—including boats—lighting equipment, breathing apparatus bottles, emergency medical response, and so on, also must be planned for. If these cannot be made available locally, then mutual-aid arrangements are needed. Different types of vehicles may be necessary for the various levels of emergency medical response: first responder or basic life support, advanced life support, and hospital transport. Commercial, industrial, and mercantile areas generally require additional apparatus, or more, in response to the initial alarm. If properties with considerable life hazard are involved (schools, hospitals, nursing homes, etc.) additional resources should be considered for initial alarms. Especially large numbers of personnel are needed for search and rescue operations in these properties, with several fire fighters required to "sweep and search" each floor (Table 12.1.1).

The required fire-fighting units should arrive on scene close enough in time after the initial alarm to operate as an effective fire-fighting unit following planned tactical procedures.

Operating Personnel Safety Concerns

Over the past several years, prompted by continuing line-of-duty fire fighter deaths and injuries, additional safety protocols have been instituted by OSHA, NFPA, the National Fallen Fire Fighters Foundation Initiative, various state agencies, fire departments, labor organizations, and other groups. These protocols call for on-scene safety officers, incident command teams, rapid intervention teams for fire fighter rescue, personnel accountability systems, plus other provisions to increase responder safety. Other provisions focus on the safety of emergency medical responders, technical rescue specialists, hazardous materials responders, and so on. All of these imply that the necessary additional personnel will be present at incidents in addition to those needed to conduct typical operations.

Evaluating Workload. In evaluating the adequacy of fire protection in any given area, planners must give major consideration to the ability of the fire department to handle efficiently any reasonably anticipated workload. This assessment requires an evaluation of the possibility of simultaneous working fires and other emergencies; weather factors that may contribute to the spread of fire, the delay in response, or the possibility of slow operations at the scene; and other demographic or geographic conditions that might affect the frequency, severity, and spread of fire occurrence and the response time of initial fire-fighting units.

Where fire frequency is such that any fire company may expect two or three working fires per day, or where structures to be protected require a heavy initial response, closer geographic spacing of or increased personnel assigned to individual fire companies may be necessary. The number of other fire-fighting or related operations such as grass, brush, rubbish, and automobile

TABLE 12.1.1 Typical Initial Attack Response Capability Assuming Interior Attack and Operations Plus Command Capability

	Description	*Personnel and Apparatus*
High-hazard occupancies	Schools, hospitals, nursing homes, explosives plants, refineries, high-rise buildings, and other high life hazard or large fire potential occupancies	At least 4 pumpers, 2 ladder trucks (or combination apparatus with equivalent capabilities), 2 chief officers, and other specialized apparatus as may be needed to cope with the combustible involved; not fewer than 24 fire fighters and 2 chief officers. Extra staffing of units first due to high-hazard occupancies is advised. One or more safety officers and a rapid intervention team(s) are also necessary.
Medium-hazard occupancies	Apartments, offices, mercantile, and industrial occupancies not normally requiring extensive rescue or fire-fighting forces	At least 3 pumpers, 1 ladder truck (or combination apparatus with equivalent capabilities), 1 chief officer, and other specialized apparatus as may be needed or available; not fewer than 16 fire fighters and 1 chief officer, plus a safety officer and a rapid intervention team.
Low-hazard occupancies	One-, two-, or three-family dwellings and scattered small businesses and industrial occupancies	At least 2 pumpers, 1 ladder truck (or combination apparatus with equivalent capabilities), 1 chief officer, and other specialized apparatus as may be needed or available; not fewer than 14 fire fighters and 1 chief officer, plus a safety officer and a rapid intervention team.
Rural operations	Scattered dwellings, small businesses, and farm buildings	At least 1 pumper with a large water tank (500 gal [1.9 m^3] or more), one mobile water supply apparatus (1000 gal [3.78 m^3] or larger), and such other specialized apparatus as may be necessary to perform effective initial fire-fighting operations; at least 12 fire fighters and 1 chief officer, plus a safety officer and a rapid intervention team.
Additional alarms		At least the equivalent of that required for rural operations for second alarms; equipment as may be needed according to the type of emergency and capabilities of the fire department. This may involve the immediate use of mutual-aid companies until local forces can be supplemented with additional off-duty personnel. In some communities, single units are "special called" when needed, without always resorting to a multiple alarm. Additional units also may be needed to fill at least some empty fire stations.

fires and emergency rescue operations may also require greater-than-normal staffing of equipment and closer spacing of fire companies. Major structural fires may result when the normal first-alarm coverage in a district is depleted through coverage of these other emergencies, making remaining fire-fighting forces inadequate. Staffing fire apparatus at a level below minimum requirements can result in less effective and less safe fire-fighting performance. This factor also has an adverse effect on the number of required fire companies for various alarms, because additional fire companies must be dispatched to the scene of an emergency to provide adequate total staffing.

Effective Pumper Companies. The desirable practice of assigning emergency medical responsibility to the fire department must be calculated into the staffing formula. It is also difficult to obtain effective teamwork and coordination with understrength crews. Some fire departments have attempted to solve this problem by supplementing their crews with part-time or volunteer fire fighters, or by providing off-duty fire fighters with tone-activated radio receivers and paying them for overtime when they respond to a fire. The on-duty personnel make the initial fire attack and holding action whereas off-duty personnel provide the additional assistance needed for continuing fire-fighting operations. Although useful and possibly less costly in the short run, efficiency is lost, and increased fire losses can be expected with this arrangement. Such protection should not be relied on to replace adequately the required staffing and equipment needed immediately at the scene for initial attack and rescue.

Personnel requirements are not merely a matter of numerical strength, but are also based on the establishment of a well-trained and coordinated team necessary to utilize complicated and specialized equipment under the stress of emergency conditions. Attempting to operate more fire companies than can be effectively staffed, even if some response distances must be somewhat increased, most often is less desirable than fewer but appropriately staffed companies. The effectiveness of pumper companies must be measured by their ability to get required hose streams into service quickly and efficiently. NFPA 1410, *Standard on Training for Initial Emergency Scene Operations,* should be used as a guide in measuring this ability. Seriously understaffed fire companies are generally limited to the use of small hose streams until additional help arrives. This action may be totally ineffective in containing even a small fire and in conducting effective rescue operations.

Supplementing Fire Protection Coverage. Consideration must be given also to maintaining an adequate concentration of additional forces to handle multiple alarms at the same fire,

while still providing minimum fire protection coverage for the other areas under fire department protection. If available personnel prove adequate for routine fires but inadequate for major emergencies, arrangements should be made to supplement the fire protection coverage by calling back the off-shift personnel and by promptly calling nearby fire departments for mutual aid. Off-shift personnel may operate reserve apparatus or relieve or supplement personnel on the fireground. Fire companies not dispatched or utilized on the fire scene should be repositioned throughout the remaining area of the jurisdiction to ensure minimum response times to other alarms.

Reserve apparatus should be properly maintained and equipped, and when placed in service should be staffed to a degree commensurate with standard fire apparatus requirements. Because it may take up to 30 minutes or more to place reserve units in service with personnel recalled in an emergency, these reserve units should not be completely relied on to immediately provide an adequate level of fire protection services.

Concern must be shown, under legislation and local policy, for the health and safety of fire fighters and others, for environmental protection, and for the rights of those being served. Officials must demonstrate reasonable and prudent action with establishment of incident command systems, for example, and the appointment of qualified safety officers and rapid intervention team protocols.

Cooperation Among Fire Departments

In cases in which several fire departments occupy adjacent or contiguous territories, arrangements (often termed "line response") should be made for joint response along common boundaries to high-risk hazards and for assistance in covering vacant fire stations at times of major fires. In areas where the nearest fire station or mobile unit to the incident address is not a part of the fire department district to which the address belongs, the nearest station or unit—by prearrangement—may still be dispatched to save time. This methodology is termed "closest station response." Mutual aid or mutual response should not be relied on for routine emergencies, because there could be times when local commitments will preclude the anticipated assistance. Mutual-aid agreements do not reduce the responsibility of each jurisdiction to maintain adequate facilities to handle normal fire protection needs. It also must be assumed that teamwork and tactical efficiency at a fire will be somewhat less than that expected of equal units from the same department under a united command. Often, however, specialized units (such as hazardous materials response teams) are organized to protect larger areas encompassing several fire departments.

Fairly often, consideration is given in the evaluation and planning process to the concept of merging or consolidating with one or more other departments. This unification is viewed as a possible way to attain economies of scale and to increase the breadth of service delivery to the combined area. On occasion, merging has been necessary because one district has insufficient funds available to retain viability. Other times a volunteer department may not have sufficient available personnel. Although the official combining of two or more departments may be wise, careful consideration must be given to the possible gains and losses and to the understanding that the combination of two very weak departments does not typically result in a new, strong department.

Two or more departments and often a significant number of departments in a large area—such as a county or region—may benefit greatly from what is termed "functional consolidation." This concept does not have the various departments relinquishing individual autonomy but rather cooperating and, thus, achieving economies of scale and service increases. Functional consolidation ranges from joint dispatch and stations to group purchasing and training, and from regional special response teams to combined fire prevention. Intergovernmental service contracts can facilitate these cooperative ventures.

Planning for volunteer departments in which there is a scarcity of response personnel may involve the addition of full-time or part-time personnel to carry part of the workload. So-called combination departments appear more and more necessary as community demographics change and workload increases. Various methodologies are used to produce response crews. These plans include using students and others as station "bunkers," rotating volunteer-duty shifts, using on-call personnel, and making automatic mutual-aid agreements.

Basing Response Requirements on Waterflow

In the past it was a common practice to relate the number of pumping engines and their pumping capacity, and other apparatus personnel requirements, to the population to be protected. With the industrialization of many areas and the construction of commercial shopping centers, hospitals, schools, and nursing homes in residential areas, it is possible that concentrations of life hazard and property value in areas of small or large populations may require substantial fire-fighting forces. Those with the responsibility for providing public fire protection must be prepared to cope with fire potential in any location in the jurisdiction. Fire department response requirements are now based on the waterflow in gpm (L/min) that may have to be applied. A rule of thumb is to provide one company for each 250 gpm (946.25 L/min) that may be needed in an interior attack, plus personnel for rescue and other operations that need to be performed simultaneously with the advancing of hose lines.

Some may argue that it is not the public's responsibility to provide adequate fire protection to high-hazard risks that should have built-in fire protection systems. However, failure to attempt to provide fire protection for large taxable values on which the economy of a community may be based would place the community's fiscal viability at risk. Burned-out businesses may not rebuild, and then local people will lose employment. Also, fire spread to other properties is possible.

Setting Time Requirements

Time is another critical factor in the evaluation of public fire protection. It is generally considered that the first-arriving piece of apparatus should be at the emergency scene in 5 minutes of the sounding of the alarm at the fire station, because additional minutes are needed to size up the situation, deploy hose lines, initiate search and rescue, and so on. In dense urban settings the desired response time is often shorter, and 4 minutes for the

first-responding pumper is a rule-of-thumb maximum time for 90 percent of an urban area. An old adage says that the first 5 minutes of most fires is the determining factor as to whether that fire will remain a small fire or become a large fire. Although this may not always be true, delays in sounding an alarm obviously must be minimized or eliminated, as well as delays in responding and initiating rescue and attack. Time, however, cannot become the all-important factor at the expense of safety. In the interest of safety, some departments have responding vehicles run to certain calls without the use of warning devices and obeying all traffic laws ("run silent alarms").

Specialized Apparatus

There are numerous instances in which highly specialized apparatus and equipment must be available to municipalities. One category of specialization concerns apparatus designed to handle hazardous materials, including spills of petroleum products and other chemicals that require special extinguishing agents such as foams or dry powders, and special equipment to apply these agents. These dangerous substances may be present because of airports, marinas, manufacturing or storage facilities, or transportation routes in the district. Another category of specialization includes apparatus and equipment needed because of particular structures or facilities such as research laboratories, hospitals, high-rise buildings, oil and gas wells, and seaports. In some communities, fire departments are expected to conduct specialized functions such as extricating at automobile wrecks and performing water and mountain rescue, as well as providing emergency medical services. These services also require special equipment and possibly special vehicles. The necessity for many departments to deliver at least first-responder emergency medical service, and for the delivery of a wide variety of technical rescue and disaster response services, cannot be overlooked.

As with standard fire-fighting equipment and apparatus, specialized tools cannot be used effectively and safely unless personnel are highly trained in their use under a wide variety of circumstances. Whether personnel are volunteer or career, in rural or urban areas, no plan can be implemented and no reasonable level of protection afforded to the community unless well-designed and well-managed training programs are carried out.

Progressive departments of all types and sizes also concentrate on providing a broad range of community-oriented services.

Fire Prevention

The term *fire prevention* as used here generally includes inspections, education, and equipment meant to reduce the occurrence of fire and to mitigate the effects of that fire prior to the arrival of the mobile suppression force. As an example, the installation of a sprinkler system is not designed to prevent fire but to control it in its very early stages; the "Stop, Drop, and Roll" message of the NFPA's *Learn Not to Burn*® program is clearly a mitigation rather than a prevention effort. Other education efforts, such as NFPA's *Risk Watch*® program, are directed at stopping the occurrence of fire and in promoting a wide range of safe behaviors. See Section 12, Chapter 19, "Community Risk Reduction."

Evaluating Prevention Activities. As noted previously, fire prevention activities are somewhat difficult to evaluate. In a real sense, if prevention activities are effective, fires and fire-related tragedies occur with less frequency. There is a reduction or absence of fire activity, and these results are statistically evident although they do not appear in dramatic news clips and photographs. Some departments do report not only dollar amounts of fire loss but also the value of structures that were threatened by fire and thus "saved." Without careful and systematic long-term record keeping concerning the incidence of fires, fire losses, and related tragedies, the effect of prevention programs cannot be documented. Inability of fire officials to demonstrate the value of committing some additional community resources to the broad range of possible prevention activities may well result in a withdrawal of resources from prevention programs and a subsequent increase in the need for a much larger suppression budget. Rational decisions and sound recommendations concerning evaluation and planning cannot be made unless fire officials learn what changes there can be to total fire cost by reallocating resources applied to the total fire defense system.

Planning requires recognition of the component and integrated parts of a fire prevention system. Until recent years prevention was often greatly limited or nonexistent in most smaller communities. In urban areas it was limited frequently to the periodic inspection of certain types of buildings. More modern approaches to fire prevention recognize that a comprehensive program includes all organized activities, other than suppression, that reduce the incidence of fire and fire-related losses. Ideally, these activities would be carried out in communities of every size, whether rural or urban, with appropriate adjustments made for community size, type, location, and fire history. Community- and neighborhood-based focus programs, often emanating from the local station, appear to have excellent effects.

Categorizing Prevention Activities. Prevention activities may be categorized in several ways, but it is usually helpful to group them as follows:

- Activities that relate to construction, such as building codes, the approval of building and facility plans, and occupancy certification and recertification for new occupants; also included may be a sign-off for the presence of smoke detectors when new or old properties are sold
- Activities that relate to the enforcement of codes and regulations, such as inspections of certain occupancies, the licensure of certain hazardous facilities, the design of new regulations and codes, and legislation to adopt existing model codes
- Activities that relate to the reduction of arson, such as fire investigation, the collection of information, public education, and data related to setting fires; included may be arson investigation and related court proceedings, and programs such as counseling for juvenile firesetters
- Activities that relate to the collection of data helpful in improving fire protection, such as standardized fire reporting, case histories, and fire research
- Activities that relate to public education and training, including fire prevention safeguards, evacuation and per-

sonal safety steps, plant protection training for industrial and other work groups, hazardous materials and devices safeguards, and encouragement to install early warning and other built-in signaling and extinguishing devices; very popular are programs for school children, such as NFPA's *Learn Not to Burn* curriculum and self-help classes such as water safety, urban survival, and similar "Stay Alive 'Til We Arrive" projects

An analysis of the community's fire history, conducted during the evaluation phase of the fire protection plan, will usually indicate to fire experts and citizen groups which categories need strengthening. Comparing the number of fires and fire-related incidents, plus fire loss (property, life, injury) statistics over several years as more prevention activities are phased in, provides an assessment of program effectiveness. Calculating the total cost of fire to a community (fire loss plus prevention costs plus suppression costs plus fire insurance costs) will enable the fire department and the community to estimate the efficiency or cost-effectiveness of a proposed prevention program.

PUBLIC PROTECTION CLASSIFICATIONS

Fire Department Service-Level Analysis

The public, fire and other government administrators, organized labor, fire protection organizations, and the fire service in general have for many years sought to find a generally accepted method for the evaluation of services provided to a community by its fire protection agency. The approaches have been as varied as the fire service agencies being evaluated and the parties doing the evaluation. This has resulted in the application of inconsistent methodology and criteria.

For many years material developed by NFPA has been used in the analysis of services provided by fire protection organizations. However, the application of NFPA materials has been inconsistent. The fire department accreditation program is entirely voluntary, and Insurance Services Office (ISO) reviews are typically conducted whenever there is an indication that changes have occurred that would point toward a potential revision to the classification number.

Insurance Services Office (ISO) Fire Suppression Rating Schedule (FSRS)

Although not all states in the United States use the latest edition of the Insurance Services Office (ISO) grading schedule, and it is not used in other nations, it is applied to public fire departments in 48 states. (Two states—Louisiana and Washington—use an earlier edition of the grading schedule.) The purpose is to aid in the calculation of fire insurance rates and is not for property loss prevention or life safety purposes.

The service focus of ISO has broadened considerably over the past few years. The ISO prepares Public Protection Classification (PPC) reports for over 43,000 fire protection districts in the United States. In addition ISO has created a Building Code Effectiveness Grading Schedule to determine how well a municipality enforces its building code.

Furthermore, the new ISO Community Outreach Program collects information on essential fire protection features within a community. This information will lead to sound benchmarking data, permitting individual communities to better assess their own safety level and to respond accurately when completing the Commission on Fire Accreditation International's self-assessment forms.

In a January 2001 survey of 502 U.S. fire chiefs and fire department officials, 92 percent responded that their ISO Public Protection Classification number is a direct reflection of the improvements made in their community. They reported that important local uses of the ISO PPC program are as follows:

- Helping save lives and property (90%)
- Helping save money on fire insurance (67%)
- Planning for and budgeting for changes in community fire protection (61%)

The older form of the grading schedule (1974) contains more categories and more items than the schedule in current use. However, the older form is still applied in two states and is still used by some community officials as a reference tool in self-evaluations.

In Section I of the ISO grading schedule, the result and classification apply to properties with a needed fire waterflow of 3500 gpm (13,248 L/min) or less. Private and public properties with larger needed flows are individually evaluated in the grading schedule. The result and classification apply to properties with a needed fire waterflow of 3500 gpm (13,248 L/min) (134 Section II).

With improved ratings, fire insurance companies that subscribe to the ISO rating system usually lower commercial and residential fire insurance premiums to reflect the projected decrease in loss severity. At least one insurance company is using a somewhat broader approach to determine premium costs for residential properties, by reviewing total insurance costs for all hazards across zip code or other defined areas and evaluating the fire exposure separately.

The *Grading Schedule for Municipal Fire Protection,* developed originally by the National Board of Fire Underwriters (NBFU) and continued by its successor, the American Insurance Association, and then by the ISO, has provided a guideline for municipalities to classify their fire defenses and physical conditions. The gradings obtained under the schedule are used in establishing base rates for fire insurance purposes. The schedule has been subject to change with the state of the art, and sweeping changes were made in the 1980 edition with the development of a revised FSRS, and with additional changes in 1995, 1998, and 2003. Other changes will continue to be made as warranted. With the 2003 revisions (under certain circumstances), credit for a minimal water supply (4000 gallons [15,140 L]) may now be given for property within 5 road miles (8 km) of a fire station, even though a municipal water supply system is lacking.

The current ISO grading schedule reviews and correlates those features of public fire protection that have a significant effect on minimizing fire damage. Credit is given for existing fire protection, instead of debit for what is not in place.

The Fire Suppression Rating Schedule (FSRS) produces 10 different Public Protection Classifications, with Class 1,

representing an exemplary fire suppression delivery system, and Class 10, not meeting FSRS criteria. The FSRS simply defines different levels of public fire suppression capabilities that are credited in the individual property fire insurance rate relativities.

Starting in 1975, on a state-by-state basis following Insurance Department approval, ISO implemented the Commercial Fire Rating Schedule (CFRS), which was a major revision to the method used to develop individual property rate relativities. The CFRS was later replaced by the Specific Commercial Property Evaluation Schedule (SCOPES). The SCOPES reviews and correlates the construction, occupancy, exposures, and private and public fire protection (represented by the Public Protection Classification number). This correlation allows development of an equitable rate relativity applicable to the individual property. To this rate relativity, affiliated companies add their cost of doing business and profit margins to produce the applicable fire insurance rate. The FSRS represents a revision in the method used to derive the Public Protection Classification number used in the SCOPES. The Public Protection Classification number is also used as a rate relativity variable for most class-related properties, in addition to construction and occupancy variables.

The *Grading Schedule for Municipal Fire Protection,*[1] although a much-improved system from previous editions, was not developed as an integral part of the individual property rating system. The previous schedules were somewhat independent primarily due to their historical development by the National Board of Fire Underwriters (NBFU), which was not an insurance rating organization. The previous schedules were used more to quantify underwriting information but did define different levels of public fire protection that could be used for a specific rating.

The FSRS is designed to assist in an objective review of those features of available public fire protection that have a significant influence on minimizing damage once a fire has occurred. This revision ties logically to the review of contributive and causative hazards that can be identified using the SCOPES.

FSRS Class Groupings

As stated earlier, the ISO prepares Public Protection Classification (PPC) reports for over 43,000 fire protection districts in the United States. Districts include political jurisdictions identified as counties, cities, towns, villages, municipalities, and fire districts. A district may support an organized fire department or contract with an existing fire department for fire suppression services. Each PPC report is prepared using an information base established from a city grading evaluation conducted by one of ISO's regional field representatives, who are highly trained in the application of the FSRS. ISO conducts municipal surveys in 45 of the 50 states. Mississippi and Washington State have elected to use the 1974 edition of the FSRS. Hawaii, Idaho, and Louisiana administer the current edition of the FSRS through state rating organizations. The District of Columbia and New York City are not graded using the FSRS.

The scope, objectives, and methods of application for the current FSRS are significantly different from previous grading schedule documents. Technological change in the real world is reflected in all elements of the current grading schedule pertaining to the three major items of coverage, which are as follows:

- Receiving and handling fire alarms
- Fire department
- Water supply

Today, the FSRS provides an objective tool for the review of city public fire suppression facilities, equipment, and programs. Credits are assigned for specific fire protection features covered by the grading schedule. Calculating deficiencies on individual items has been dropped; the percentage of adequacy is now determined for each item. Each grading schedule survey involves an extensive review of fire department records, field surveys of the city, and the testing of fire protection equipment and municipal water-supply systems.

Information gathered during the field survey is applied to the individual items in the grading schedule using quantitative analysis. The city's fire suppression potential capability is then assigned a Public Protection Classification number according to the following class groupings:

- Classes 1 through 8 are the protected property classification. All properties assigned a Class 1 through 8 have a recognized fire department with engine company response limited to 5 travel miles (8 km) in most states and a recognized water delivery system. The minimum water supply from each credited fire hydrant is 250 gpm (946 L/min) for a 2-hour duration; therefore, a recognized water system must also deliver the same minimum flow and duration.
- Class 8B recognizes a fire protection delivery system that is superior to Class 8 except for a lack of water supply system capable of the minimum Fire Suppression Rating Schedule (FSRS) fire flow criteria of 250 gpm (946 L/min) for 2 hours.
- Class 9 is the semiprotected property classification. All properties assigned a Class 9 have a recognized fire department generally limited to 5 travel miles (8 km). However, structural property is beyond 1000 feet (305 m) of a recognized water supply. The current FSRS provides a documented method for fire departments to deliver adequate water to fire sites using mobile water tankers to permit structural property in Class 9 areas to qualify for a protected property classification (Classes 1 through 8). Water delivery demonstration projects have improved Class 9 PPC districts all the way to a Class 4.
- Class 10 is the unprotected property classification for structural property. Class 10 property is generally located beyond 5 travel miles (8 km) of a recognized fire station, regardless of available water supply. Only a selected few insurers will write insurance policies for Class 10 property. When available, the insurance rates are very high compared to other property classes.

Scope and Content of the FSRS

The grading schedule is divided into two major sections: the public fire suppression and the individual property fire suppression.

Section I: Public Fire Suppression. This section is applied to develop a Public Protection Classification (PPC) for all class-rated properties and for specifically rated properties in a city

with a needed fire flow (NFF_i) of 3500 gpm (13,249 L/min) or less. The section is, in turn, divided into three major items for evaluation, which are as follows:

1. *Section 400: receiving and handling fire alarms.* Ten percent of a city's overall grading is based on how well the alarms are received and the fire department is dispatched. ISO evaluates the alarm-dispatch center by looking at the telephone service capability, the number of telephone lines coming into the center, the listing of emergency numbers in the area telephone book, and the number of operators on duty in the center at all times. The ISO review also examines all dispatch circuits and the electronic methods used to notify fire fighters of the location of fire incidents. The ISO uses NFPA 1221, *Standard for the Installation, Maintenance, and Use of Emergency Services Communications Systems,* as a guide for grading public sector fire alarm systems.

2. *Section 500: fire department.* Fifty percent of the city's overall grading is based on the fire department evaluation. The grading schedule considers a first-alarm assignment to be a minimum of two engine companies and one ladder-service company to all structure fires. ISO evaluates the distribution of engine companies and ladder-service companies for response areas of the city in accordance with whether the built-on area of the city has a first-due engine company within 1.5 mi (2.4 km) and a ladder-service company within 2.5 mi (4 km).

ISO also checks to determine whether the permanently mounted pumps on the fire apparatus are tested regularly and inventories are taken of each engine company's complement of fire hose, nozzles, self-contained breathing apparatus (SCBA), and small equipment items. Furthermore, ISO checks on the number and type of ladders, including both ground and aerial ladders, plus service equipment that includes salvage covers, power saws, ventilation equipment, and lighting equipment. Finally, ISO reviews fire company records to determine the following:

- Extent of structural fire suppression training provided to fire company personnel
- Actual personnel who participate in training programs
- Number of fire fighters who respond to structure fires
- Level of building familiarization and documented prefire planning conducted by fire personnel

ISO references several NFPA standards in the evaluation process of fire departments.

3. *Section 600: water supply.* Forty percent of the grading is based on the city's water supply. ISO examines the following three components of each water system to assure that sufficient water capacity, flow rate in gallons (liters) per minute, and pressure at 20 psi (138 kPA) residual pressure, are available at selected sites throughout the city:

- Water-supply works
- Water-supply mains feeding fire hydrants
- Fire hydrant installation, maintenance, and inspection; the water-supply works and pipe distribution system account for 35 percent of the entire city grading. To accomplish an analysis of a given water system, the ISO field representative does the following:
  - Examines whether sufficient water is available for fire suppression beyond the city's maximum daily consumption
  - Surveys all components of the water supply system, including stationary pumps, filtration capacity to provide potable water, and potable water storage to supply water mains
  - Observes fire-flow tests at representative locations in the city to determine the rate of flow provided by water mains
  - Counts the distribution of fire hydrants up to 1000 feet (305 m) from representative categories of property throughout the city; the classes of property evaluated include but are not limited to industrial, commercial, educational, religious, health care, and residential
  - Considers the size, type, and installation of fire hydrants, along with the operating condition of all fire hydrants

Fire hydrants should receive semiannual inspection, as outlined in the American Water Works Association Manual 17, *Installation, Field Testing, and Maintenance of Fire Hydrants.*

Section II: Individual Property Fire Suppression. This section develops Public Protection Classification for specifically rated properties that have a needed fire flow greater than 3500 gpm (134,248 L/min). The following are supporting topics on Public Protection Classification:

1. *Preparing for an ISO grading evaluation.* A city can maximize earned credits through a systematic and proper preparation for an ISO grading evaluation. Doing so involves having in place current maps, inventories, equipment test records, and personnel reports for the ISO field representative to review and evaluate in accordance with each item documented in the FSRS. The chief executive officer (e.g., mayor, city manager) of a city can request from ISO (or obtain from its website http://www.isomitigation.com) a presurvey information packet that details the information requested when an ISO field representative visits a city.

2. *Impact of a city's public protection class on fire insurance premiums.* Theoretically, the better a city's classification, with Class 1 being the best class, the lower will be both insurance rates and insurance premiums when compared to a higher class number. This is generally true for a commercial property that is specifically rated by the insurance industry. Other factors, however, enter into the premium calculation, including the following:

- Fire protection equipment such as installed fire extinguishers, early warning detection and fire alarm systems, smoke control systems in some occupancies, and, most importantly, the installation of automatic sprinkler systems
- Fire loss, or loss costs, to the insurance industry in the city or county where the building risk is located

It needs to be recognized that individual insurance companies may file with state insurance commissions for "rate deviations" from "standard rates" for specific classes of property

based on that company's loss experience and insurance reserves. This practice underscores the highly competitive nature of the property insurance industry today.

PLANNING PROCESSES

Whenever a community—rural, suburban, or urban—considers its fire defenses, it must scrutinize the past and present and make predictions or forecasts for the future. Reviewing the past is called *data analysis* and depends on good record keeping. *Evaluation,* which is looking at the present, requires the ability to examine a situation objectively. The process of forecasting future conditions and preparing for them requires that a planning process be followed. This *planning* process results in a plan and its implementation, so that future challenges to the community are met. As the plan is implemented, the process must include the establishment of a *feedback loop,* providing a continuing assessment of how well the plan is contributing to successful completion of goals and objectives, and feeding revised data back into the plan so continuing redesign occurs.

Fire protection organizations, and especially fire departments, need to develop several kinds of plans related to fire prevention and fire suppression. These plans should be quite specific, directed at clearly defined goals, and operational over a relatively brief time period (usually from 1 to 5 years). Typically, such plans are internal to the department and do not involve broad-based planning groups from the outside. Examples of these types of plans, which are most often technical in nature, are apparatus replacement plans, training program plans, revised initial-response plans, plans for a special hazardous-materials attack unit, and plans for adapting fireground procedures to incorporate the use of larger-diameter hose. However, once department planning begins to consider aspects of fire protection and other related operations that will have an impact on external groups, those groups will need to be consulted and incorporated into the planning process. Fire department planning, for example, must consider land-use planning (zoning), water department planning, building code enforcement, emergency management, and possible terrorist activities.

Examples of fire department planning that require the early involvement of other groups are station relocations or closings, building inspection programs, public education programs, and changes in the scheduling of work platoons. These plans, although involving some other groups, are still fairly narrow in scope and usually can be formulated over a relatively short time.

A third type of planning, often called comprehensive, master, or strategic planning, addresses the total community fire protection problem, incorporating both prevention and suppression, and obviously involves many community agencies and organizations and, today, county, state, and federal agencies. Comprehensive planning is a necessity for communities and is aimed at integrating all community efforts at prevention, suppression, disaster response, and improving efficiency and cost-effectiveness of those activities. Improved total community protection is the goal of this planning. Its degree of success must be measured by figures relating to the total cost of fire to the community, and not just in gains for one subsystem. Comprehensive plans often consist of a number of subplans from various agencies that are developed at the same time as part of a larger, total process, and that fit together to make a comprehensive and integrated plan.

Comprehensive plans have clearly stated goals with agreed-on ways of measuring their attainment. These overall goals are reached through overall strategies acceptable to all involved agencies and to the citizens who must pay for the fire protection system. Each goal is composed of some number of subgoals or objectives, and for each objective there are tactics designed to reach that objective. All objectives lead to the accomplishment of the overall strategies. When the objectives and tactics are laid out on a time line, the overall time required to implement the comprehensive plan is then known, and the timing for attaining each objective is apparent.

Fire protection has been largely a local responsibility, and for good reasons it seems destined to remain so.*

Each community has a set of conditions unique to itself. To be adequate, the fire protection system must respond to local conditions and especially to changing conditions. Planning is the key: without local-level planning, the fire protection system is apt to be ill-suited to local needs and unadaptable to the changing needs of the community.

Excellent fire protection (for example, in the form of automatic extinguishing systems such as residential sprinklers or in the form of technically advanced and trained fire-fighting forces) is technically available and certainly can be provided with the resources of most communities. Even with considerable public support, however, this protection may require several years to attain. In the meantime, in every fire jurisdiction (whether a municipality, county, or region), fire protection goals must be set and plans made to achieve those goals. The issues below discuss some of the concepts to be defined in setting these standards.

Goal-Setting Concepts

Adequate Level of Fire Protection. The question of "adequacy" is addressed not only in day-to-day needs but also in major contingencies that can be anticipated for future needs. A definition of "optimal" protection is needed—in contrast to "minimal" protection, which fails to meet contingencies and future needs, and "maximal" protection, which is usually more expensive than a community can afford.

Comprehensive planning must include contingencies drawn from an analysis of community hazards. This process of hazard identification and analysis is crucial to fire department planning.

Reasonable Community Costs. Fire, both as threat and reality, has its costs, including deaths, injuries, property losses, hospital bills, and lost tax revenues, plus the costs of maintaining fire departments, paying fire insurance premiums, and providing built-in fire protection. Each community must decide on an ap-

*Some of the information that follows in this chapter has been extracted in whole and in part from *America Burning*[2] and *America Burning Revisited.*[3]

propriate level of investment in fire protection. Some costs that are beyond the public's willingness to bear may be transferred to the private sector (as when buildings over a certain size or height or with a certain occupancy are required to have automatic extinguishing systems).

Acceptable Risk. A certain level of fire loss must be accepted as tolerable simply because of limited resources of a community. Conditions that endanger the safety of citizens and fire fighters beyond the acceptable risk must be identified as targets for mitigation.

Consideration of these matters helps to determine what functions and emphasis should be assigned to the fire department, other municipal departments, and the private sector both now and in the future. It helps to define new policies, laws, or regulations that may be needed. Most importantly, consideration of these matters makes it clear that fire safety is a responsibility shared by the public and private sectors. Because the fire department cannot prevent all fire losses, formal obligations to have built-in fire protection fall on owners of certain kinds of buildings. For the same reason, private citizens have an obligation to exercise prudence with regard to fire in their daily lives. But prudence also requires education in fire safety, and the obligation to provide that education appropriately falls in the public sector, chiefly the fire department. The public sector (again, chiefly the fire and building code enforcement departments) also has an obligation to see that requirements for built-in protection in the private sector are being met. A fire department, then, has more than one responsibility—and the aforementioned responsibilities are not exhaustive.

Functions of Fire Protection Agencies

The following are significant functions for which fire protection agencies typically have primary or significant roles.

Fire Suppression. Fire fighters need proper training and adequate equipment to save lives, to extinguish fires quickly, and to ensure their own safety.

Specialized Emergency and Disaster Services. These situations include hazardous materials incidents, floods, earthquakes, multiple-vehicle accidents, cave-ins, collapsed buildings, volcanic eruptions, searches for lost persons, attempted suicides, a variety of specialized technical rescue services, weapons of mass destruction training, and so on.

Emergency Medical Services. Capabilities needed during fires and other emergencies include first aid, resuscitation, and possibly advanced life support (paramedical services). (The term *paramedical services* means emergency treatment beyond ordinary first aid, performed by fire service personnel under supervision—through radio communication and preapproved treatment protocols, for example—of a physician.)

Fire Prevention. This prevention includes approval of building plans and actual construction; inspection of buildings, their contents, and their fire protection equipment; and investigation of fire cause and spread to guide future fire prevention priorities and determine when the crime of arson has been committed.

Fire Safety and Dangerous-Situation Education. Fire departments have an obligation to bring fire safety and dangerous-situation education not only into schools and private homes but also into occupancies such as restaurants, hotels, hospitals, and nursing homes that have a greater-than-average fire potential or life safety hazard. These programs may include such topics as swimming pool safety, babysitter training, latchkey child safety, and so on. See Section 5, Chapter 2, "Fire and Life Safety Education Messages."

Deteriorated Building Hazards. In coordination with other municipal departments, fire departments can work to abate serious hazards to health and safety caused by deteriorated structures or abandoned buildings.

Regional Coordination. Major emergencies can exceed the capabilities of a single fire department, and neighboring fire jurisdictions should have detailed plans for coping with such emergencies. But effectiveness may also be improved through sharing of day-to-day operations—such as, for example, an area-wide communication and dispatch network or a joint training facility.

Data Development. Knowledge of fire department performance and how practices should change to improve performance depends on adequate record keeping. Computers and information management systems play a key role in fire protection and emergency management planning. See Section 12, Chapter 5, "Information Management and Computer Technology."

Community Relations. Fire departments are representative of the local community that supports them. The impression they make on citizens affects how citizens view their government. Volunteer departments dependent on private donations must, of course, also be concerned with community relations. Moreover, because fire stations are strategically located throughout the community, they can serve as referral or dispensing agencies for a wide range of municipal services.

As communities set out to improve their fire protection, they must not consider the fire department alone. The police have a role in reporting fires and in handling traffic and crowds during fires. The cooperation of the building department is needed to enforce the fire safety provisions of building codes. The work of the water department in maintaining the water system is vital to fire suppression. In fire safety education, the public schools, the department of recreation, and the public library can augment the work of the fire department. Future community development and planning will influence the location of new fire stations and how they will be equipped.

These nine functions are just the obvious examples of interdependence. Although it may seem trivial, the manner in which house numbers are assigned and posted, for example, can affect the ability of a fire department to respond quickly and effectively to emergencies, as do many other seemingly unrelated topics.

Master Planning

Fire protection is only one of many community services. Not only must it compete for dollars with other municipal needs such as the education system and the police department, but in planning for future growth the fire protection system must account for the changes in progress elsewhere in the community. For example, if a deteriorated area is to be torn down and replaced with high-rise apartment buildings, the fire protection needs of that area will change. Changes in zoning maps will also change the fire protection needs in different parts of the community.

To cope with future growth, local administrators are turning increasingly to the concept of master (comprehensive) planning of municipal functions. Such plans include an examination of existing programs, a projection of future needs of the community, and a determination of methods to fill those needs. They seek the most cost-effective allocations of resources to help ensure that the needs will be met.

A major section of a community's general plan of land use should be a master plan for fire protection, which should be written chiefly by fire department managers. This plan should, first of all, be consistent with and reinforce the goals of a city's overall general plan and its time frame. For example, managers need to plan the deployment of personnel and equipment according to the kind of growth and the specific areas of growth that the community foresees. It is critical that the comprehensive plan determine and set goals and objectives for the fire protection system and the fire department in terms that are understandable to the citizens being protected.

Having established goals, the department officers should use the plan to establish some form of management systematic and quality assurance within the fire department. Management is most effective when each person is aware of how tasks fit into the overall goals and is committed to getting specific jobs done in a specified time.

Because fire departments exist in a real world where a variety of purposes must be served with a limited amount of money, it is important that every dollar be invested for maximum return on investment. The fire protection master plan not only should seek to provide the maximum cost-benefit ratio for fire protection expenditures but also should establish a framework for measuring the effectiveness of these expenditures. Last, the plan must clarify the fire protection responsibility for other groups, both governmental and private, in the community.

Often, as the result of a comprehensive planning effort, a community will formulate a "developmental plan." This document provides a schedule for implementing those changes in the fire protection system deemed appropriate by the community.

Key questions for developmental plans include the following:

- What are the fire protection, rescue, emergency medical, disaster response, and safety education needs?
- What organizational structure and what resources are currently available to meet those needs?
- Is there a disparity between what is available and what is needed?
- What will the community profile be like in 5 to 10 years?
- What will be needed then to provide adequate protection?
- What is and what will be the financial resource base?
- What options are and will be available to enhance protection, or to keep it at an adequate level?
- How can changes be phased in to gain community goals and cost-effectiveness?

Devising a Fire Protection Plan

The following are key questions to be asked by those planning for fire protection:

- Why is planning necessary for us at this time?
- What do we need to start the process, and are the necessary groups committed to the process?
- What are the necessary steps in the planning process?
- How will the plan be financed and implemented?
- Are all aspects of the plan legally possible and enforceable?
- How will the plan be evaluated? Will it be a part of the integrated emergency management plan of the community?
- How will feedback be gathered and the plan modified and updated?

In *Introductory Summary: Fire Prevention and Control Master Planning,* the U.S. Fire Administration[4] underscored the following still very useful set of steps in its overview of the planning process.

Master planning is a participative process that should result in the establishment of a fire prevention and control system that is goal-oriented, long term, and comprehensive; provides known cost/loss performance; and adapts continually to the changing needs of your community. Master planning involves the following:

- Master planning should consider all community elements related to fire prevention and control system elements.
- Master planning involves the participation of all parties interested in the development of a defined cost/loss relationship.
- Master planning allows you to systematically analyze fire prevention and control through commonsense procedures.

Master planning has three phases: preplanning, planning, and implementation. The preplanning phase gets necessary commitments, committees, estimates and schedules, and go-ahead approvals. The planning phase gathers and analyzes data, sets goals and objectives, determines an acceptable level of fire protection service, identifies alternatives, and constructs the plan. The implementation phase never ends, because the plan is ongoing and always being revised and updated.

The following can serve as guidelines to fire department administrators for developing and presenting a master fire protection plan as part of the comprehensive master plan outlined earlier:

Phase I

1. Identify the fire protection problems of the jurisdiction.
2. Identify the best combination of public resources and built-in protection required to manage the fire problem; within acceptable limits:
   a. Specify current capabilities of and future needs for public resources.
   b. Specify current capabilities and future requirements for built-in protection.

3. Develop alternative methods that will result in trade-offs between benefits and risks.
4. Establish a system of goals, programs, and cost estimates to implement the plan:
   a. Develop department goals and programs, including maximum possible participation of fire department personnel of all ranks.
   b. Provide goals and objectives for all divisions, supportive of the overall goals of the department.
   c. Strive to develop management development programs that increase acceptance of authority and responsibility by all fire officers as they strive to accomplish established objectives and programs.

Phase II

1. Develop a definition of the roles of other government agencies in the fire protection process.
2. Present the proposed municipal fire protection system to the city administration for review.
3. Present the proposed system for adoption as the fire protection element of the jurisdiction's general plan. The standard process for development of a general plan provides the fire department administrator an opportunity to inform the community leaders of the fire protection goals and system and to obtain their support.

Phase III

In considering the fire protection element of the general plan, the governing body of the jurisdiction will have to pay special attention to the following:

1. Short- and long-range goals
2. Long-range staffing and capital improvement plans
3. Code revisions required to provide fire loss management

Phase IV

The fire loss management system must be reviewed and updated as budget allocations, capital improvement plans, and code revisions occur. Continuing review of results should concentrate on the following areas:

1. Did fires remain within estimated limits?
2. Should limits be changed?
3. Did losses prove to be acceptable?
4. Could resources be decreased, or should they be increased?

SUMMARY

Public fire protection should consist of a broad range of safeguards, programs, and activities ranging from plan review and code enforcement to provisions for fire suppression and public safety education. Careful consideration of local hazards and demographics, plus analysis of data related to protection and suppression are necessary for the design and maintenance of an effective, cost-effective system. Further, provisions must exist within the plan to promote and assure adequate health and safety levels of its fire fighters. See Section 12, Chapter 7, "Safety, Medical, and Health Issues and Programs." This results in an integrated risk management system.

Local conditions, regulatory orders, and national standards dictate the type and level of prevention and suppression/rescue provisions necessary and appropriate for a community. The time required for response and the number and types of emergency responders and vehicles should match local needs and conform to legal and industry standard requirements. Judgments about the adequacy of local prevention and emergency response provisions can be made by local authorities, Insurance Services Office (ISO) representatives, fire department accreditation teams, or other experts. Fire insurance premiums for residential and commercial property most often reflect periodic assessments of local fire protection provisions.

Municipal planning for fire protection, fire department–based emergency medical services, hazardous materials incident response, and technical rescue services requires a review of past and present data, plus knowledge-based predictions of community change and development. Agreements concerning the level of local emergency service required then lead to decisions concerning the type, size, and deployment of suppression/rescue forces.

Chapter 2

Organizational Benchmarking and Performance Evaluation

Dorinda Cline

Chapter Contents

Organizational Acceptance
Performance Management System
Reports and Reporting Cycles
Measurements and Benchmarks

Key Terms

benchmarking, emergency management, evaluating, Government Accounting Standards Board (GASB), performance-based budget, performance management system

Evaluating and benchmarking are not new concepts to fire service professionals. They are inherent in the daily operations of a fire department. From fighting fire to patient care, the actions taken while performing the tasks at hand are measured and judged using a standard of service. Those actions directly and indirectly affect the outcome of the operation.

Evaluating and benchmarking result in quantifying and qualifying organizational performance. *Evaluating* is the process of measuring and judging performance as progress toward a defined standard of service. *Benchmarking* is the process of selecting the appropriate standard of service to use. Combined, evaluating and benchmarking provide information about performance that can be communicated. In this format, performance information can be used to obtain resources necessary to provide services, acknowledge performance success, and improve performance. Effective communication about performance creates the ability to efficiently manage performance on an organizational level.

To elevate performance management from a task level to an organizational level requires a systems approach. The organization is one system with one mission to fulfill. Within that one system are multiple subsystems that interrelate to fulfill a specific role. There are many examples of this concept in everyday life. Our vehicles have brake, electrical, and air bag systems. Our bodies have digestive, respiratory, and nervous systems. These analogies are common and may be useful in referencing this type of management approach. Whichever analogy works for the organization is the one to use; the critical importance resides in the perspective.

This chapter examines organizational benchmarking and performance evaluation from a systems perspective, to include the key elements of success for a fire department performance management system. Steps to implement a new system are discussed in each section. Based on a belief that the key elements already exist in the organization, the implementation is simplified to linking existing responsibilities and processes to communicate performance. With the perspective that a fire department is one system, performance management processes are integrated as a subsystem within the organization.

The first section discusses the factors that affect organizational acceptance of performance management concepts and a formal system. These factors are based on member recognition, education, and participation. The term "member" is used to represent those individuals who have a defined reporting relationship to the organization. It is intended to be inclusive of employees and volunteers, both sworn and civilian.

The second section is focused on the performance management system, as an integrated subsystem within the organization. The overall framework and data flow is charted, with roles and responsibilities defined. The organizational, financial, planning, and operational structures of a working fire department are examined to highlight the existing elements of performance

Dorinda Cline holds an associate's degree in accounting and a bachelor's degree in municipal operations management from Arizona State University. She has served as an accountant and senior manager at the Mesa, Arizona, fire department and is a charter member of the Scottsdale, Arizona, fire department, where she served on the transition team to convert fire protection services from a private provider to a municipal department. She provides administrative, financial, and budgetary consulting services to municipal fire departments including the Phoenix, Arizona, fire department.

management. The benefit to a centralized database is discussed and consideration is given to a performance-based budget development model.

The third section contains a sample performance report template and recommended reporting cycles. Performance reporting is categorized into three "*p*'s": *p*rogram descriptors, *p*erformance information, and *p*lanning objectives.

The fourth and final section examines how measurements begin with a count (a number) and combine with benchmarks to provide meaningful performance information. Included are examples and a list of data categories to consider.

See the following chapters in Section 12 for related topics: Chapter 1, "Planning for Public Fire-Rescue Protection"; Chapter 4, "Managing Fire-Rescue Departments"; Chapter 17, "Pre-Incident Planning for Industrial and Municipal Emergency Response"; and Chapter 18, "Pre-Incident Planning for Emergency Response."

ORGANIZATIONAL ACCEPTANCE

Organizational acceptance is necessary to realize the full potential of performance management concepts. Ways to enhance acceptance are based on member recognition, education, and participation. Recognizing member contributions and connecting them to organizational success is proposed to create a positive connotation to measuring performance. With clear direction and established goals and objectives, a team approach to integrating a system can increase member participation. The use of professional resources and a common language creates an environment in which everyone has a level of understanding and enables each to make a positive contribution.

Contribution Connection

Performance management concepts and words, such as *measuring* and *judging,* often have a negative connotation for the members of an organization. That connotation can be made positive when the standards of service that exist in everyday operations are used to demonstrate a contribution towards performance success for the whole organization. A formal performance management system has the ability to provide that connection and recognition.

Successfully integrating performance measures in an organization begins with recognizing that they already exist in every organization; they are blended into the culture. They exist in the thought processes and everyday actions of those who deliver the services, those who manage the operations, and those who make policy decisions. A performance management system should be designed to provide the connection between individual contributions and the shared mission and goals. In essence, every task is connected to a strategic goal. Every strategic goal is connected to service delivery in the community. The organization becomes one system, with many moving parts, working toward achieving defined standards of service to the customers.

A performance management system provides acknowledgment for the service delivery success that has existed all along. In addition, the measurements create the ability to communicate performance through data-based analysis, which is an excellent catalyst to obtaining resources. For all members, it can create a sense of contribution and connection to the whole system, a sense of belonging to something bigger than themselves, a sense of why and how their work affects the customers. For the customers, it can create a sense of confidence in the quality of service provided.

The integration of performance measures into the management process does not have to have a negative connotation. When combined with intuition, judgment, and experience, performance measures can significantly improve decision making that directly affects the members' ability to successfully perform their work for the customers. Like any other management concept, the key to organizational acceptance is the spirit in which it is presented and used.

Inclusive Participation

Member participation is a key to organizational acceptance. Members will actively participate in management efforts when their contributions are acknowledged as a vital component to success. They are already experts in performing the work associated with delivering services. All they need is the opportunity to understand the concepts and speak the language to make a positive contribution. As they participate, a sense of ownership is created. They are vested in making it work and become champions of success. With their participation, crafting a system to monitor and report performance represents building a useful tool to deliver the best services possible. We all appreciate good tools, like the computer that does the math for us and the vehicle that gets us to our destination. A performance management system has the potential to be a very valuable tool. Just like the computer or vehicle, the amount of appreciation it receives is directly dependent upon the extent to which it supports the members in providing quality services to the customer.

Purpose and Direction

To be a valuable tool, a performance management system must have a purpose, a reason to exist. A purpose is often best illustrated and communicated through established goals and objectives. The progress toward meeting objectives will evaluate the system itself to ensure it is functioning appropriately. Success of the system is critical to ensure the organization reports and acts on credible information. Once everyone understands why a performance management system exists, each member can make that positive contribution to its success. In order for the system to be useful and fulfill its purpose, it must provide information that guides the organization in the right direction. By nature, it must provide accurate and meaningful data that achieves the following:

Direction

- *D*irectly relates to operational and strategic goals
- *I*mproves decision making
- *R*espects professional judgment and technical expertise
- *E*ducates customers
- *C*elebrates accomplishments
- *T*imely reports activities

Team Approach

A proven method of inclusive participation is through the use of cross-functional project teams. According to Dennis Compton, author of *When in Doubt, Lead!,*[1] teams "enhance a sense of ownership and help foster responsibility and accountability within the organization." In his book, there is a team profile template with helpful guidance to ensure a team's effectiveness.

The cross-functional project team approach has many benefits. All service areas of the organization are represented. The scope of work is well documented and understood. Decisions and activities are communicated throughout the organization as work progresses. Once the team develops a performance management system, its effectiveness is tested and reported prior to implementation. As the first phase of implementation, the responsibility of project team members may include the development and delivery of an educational program or it may be passed on to a training staff. By definition, once the project is completed, this team is disbanded. At the same time, a standing team may be established to periodically test and improve the ongoing functionality of the product of the team's efforts.

Cross-functional teams complement the operational structure of the organization. To develop a performance management system, each operational service area should have at least one representative on the team. In addition, at least one operational manager and one senior manager should serve on the team. These individuals act as liaisons between the team and their respective work groups. The goal is representation for all the services provided by the organization as well as three levels of organizational performance: strategic, operational, and task. Once achieved, the chain of command is inherently represented, which empowers the team to work on behalf of the entire organization. In other words, if the senior manager on the team approves the work, then approval from all the senior managers is implied. This streamlines the effectiveness of the team. At the same time, it places a great deal of responsibility on the team members to effectively communicate the team's actions to the rest of the organization. In addition, team members must ensure the project stays within the defined scope of work, on time, and within budget.

Team members become system experts. They are responsible for selecting the appropriate resources and for designing the overall framework for a system that is useful to the organization. They develop report templates and define reporting cycles to bring consistency within the organization. They become the facilitators within their own service area as measurements and benchmarks are selected. All of these performance management aspects are discussed later in the chapter. It is important to note that these responsibilities are different from the responsibilities of an operational manager. Once the system is developed, as illustrated later in this chapter, it is the operational managers who are responsible for evaluating the performance of services delivered.

One of the most important roles of a team member is to champion the "systems" perspective. The individual services provided by a fire department complement each other or share overlapping objectives toward the shared mission. Many customers receive multiple services from a fire department. One of the worst impressions to leave with a customer is that the right hand does not know what the left hand is doing. If innovative ideas and lessons learned about the performance in each service area are shared on an organizational level, all the service areas will benefit and the customer will see cohesive performance from the organization. The project team members have the opportunity to set the stage for cohesive performance by designing a system that fosters collaborative analysis and centralized oversight for all services.

The potential benefits of this team approach are directly related to the team's profile. The keys to successfully realizing benefits reside in a carefully defined scope of work and appropriate representation from within the organization.

Professional Resources

Professional resources are used for educational purposes and universal recognition. Lessons learned from mature systems are used to avoid pitfalls. National databases and surveys are used to identify service norms. A multitude of agencies provide performance management information, ranging from conceptual models to technical standards. The best professional resources to use are those that match the philosophy, culture, and mission of the organization. Fire departments already interact with many of these agencies, seeking technical guidance and best practices, as well as national perspectives on service-related issues. Commonly referenced agencies include the following:

- National Fire Protection Association (NFPA): Provides consensus-based codes and standards for fire and life safety, as well as research, training, and education.
  http://www.nfpa.org
- Insurance Services Office, Inc. (ISO): Provides a Fire Suppression Rating Schedule that measures the major elements of a community's fire suppression system.
  http://www.iso.com
- Center for Public Safety Excellence: Provides a comprehensive system of fire and emergency service evaluation that can help local governments determine their risks and fire safety needs, evaluate the performance of the organizations involved, and provide a method for continuous improvement.
  http://www.publicsafetyexcellence.org
- International City/County Management Association (IMCA), Center for Performance Measurement (CPM): Assists counties, cities, and towns of all sizes with the collection, analysis, and application of performance information.
  http://www1.icma.org
- Governmental Accounting Standards Board (GASB), Service Efforts and Accomplishments (SEA) research project: Provides research to address the needs of state and local governments trying to develop performance measures.
  http://www.seagov.org

In addition, the experiences of other fire departments serve as useful "lessons learned" in managing performance. Municipalities commonly referenced as progressive in the performance management field are Phoenix, Arizona; Austin, Texas; and Charlotte, North Carolina.

Effective Communication

A common language is essential to communicate effectively about organizational performance. The performance measured and reported may be specific to the fire service. Whether the measurement is an input, output, or outcome, it must have a universal meaning. Many professional resources provide a glossary of performance management terms. A comprehensive example is found in a Government Accounting Standards Board (GASB) special report, *Reporting Performance Information: Suggested Criteria for Effective Communication.*[2]

An advantage to using language published by a national standards agency such as GASB is that the scope of effective communication widens. In addition to the members of the fire department, more customers and partners in performance understand the language. The barriers created by service-specific acronyms are minimized. When the fire department is working with local government services, such as the water or police departments, or is presenting funding requests to elected officials in a public forum, a common language and defined terminology increases the effectiveness of communication. Adoption of a common language is a key step to integrating a new performance management system. To create a common language for this chapter, definitions of the terms used are listed in Table 12.2.1.

PERFORMANCE MANAGEMENT SYSTEM

A successful performance management system is recognized by every member of the organization. It is charted, accessible, and easy to understand. Members know its purpose and use, as well as their roles within the system. These types of system charts are not commonly published, even though key performance measurements are published in most fire department annual reports. For the members of the organization, the visual link between daily operations and published results must exist to connect their contributions to organizational performance. The link improves understanding in how their work affects the customers and becomes an excellent basis for processing improvements.

To integrate a new system, the overall framework and data flow must be charted. An efficient process involves conducting a self-analysis of how the organization currently functions. With the belief that performance evaluation already exists in the organization, it is reasonable to assume the key elements are fragmented within existing operations. In conjunction with reviewing how the organization functions, additional steps can be identified to continue with the process of integrating a new system.

The following series of conceptual charts are derived from organizational charts provided by the Mesa Fire Department,[3] a municipal career department in Arizona. Each chart highlights how the organization functions and how the functions relate to performance management. Included is a transitional model from the organization's operational chart to visually document the integrated performance management system.

The Mesa Fire Department is managed as a system, with three levels of performance. The comprehensive body of work introducing this management concept is *Improving Performance: How to Manage the White Space on the Organization Chart,*[4] by Geary A. Rummler and Alan P. Brache. This book offers charts, checklists, hands-on tools, and case studies to demonstrate implementation of the concept.

Defined Roles and Responsibilities

A successful performance management system has top-down value. Impacts to performance are considered in the decision-making processes at all levels of the organization. Each level of authority has a role and responsibility in organizational performance. A coordinated effort from each level of the organization provides the policy decisions, operational management, and service delivery tasks that contribute to success. A review of the organizational chart shown in Figure 12.2.1 defines these levels of responsibility, with each level of authority having a role and responsibility in organizational performance.

As shown in Figure 12.2.1, the fire department's organizational chart is similar to many organizations. Direct lines of authority are established through a division of labor and reporting relationships. Commonly referred to as the *chain of command,* these lines of authority are primarily used for human resource and fiscal management. Services are not actually delivered through the lines of authority. However, the organizational chart contains key elements to performance success—that is, defined leadership and accountability.

Leaders lead by example. If their actions and language demonstrates that they value performance results, so will the rest of the organization. Holding themselves and others accountable for their role in organizational performance shows top-down value. Performance results should not be punitive. If the results are not quite where they should be, they should serve as a catalyst to ensure resources have been appropriately aligned with service delivery expectations. Processes may need to be improved. New or advanced training may be in order. Equipment may need to be replaced or technology updated. When leaders react with a holistic approach to the factors that contribute to performance success, they demonstrate universal accountability for performance results.

Resources Linked to Performance

Resources used linked to services delivered represent the ins and outs of performance. Resources used represent the inputs to performance. As shown in Figure 12.2.2, a review of the fire department's financial structure reveals the process of documenting the cost of resources used. As expenditures occur, the amount of resources used (inputs) is documented and then summarized on each level of fiscal management.

Typically, a financial structure is an accounting system aligned with the organizational chart. Generally speaking, the budget is developed and financial transactions are captured in a series of revenue and expenditure accounts. In government accounting, fire department revenue and the budget (funding allocated) are not the same. The budget is usually developed by projecting expenditures. Then, actual expenditures are recorded, as they occur, over the course of the fiscal year.

Actual expenditures are the primary focus of a performance management system. As expenditures occur, the amount of resources used (inputs) is documented. These inputs include the following:

TABLE 12.2.1 Common Performance Management System Terms

Common Terms	*Definitions*
Accountability	• Responsibility of one party to another party; in government, responsibility of elected and appointed officials to those who elected or chose them or who provide resources with which services are provided • Being obliged to explain one's actions, to justify what one does; requires government to answer to the citizenry to justify the raising of public resources and explain purposes for which they are used; governmental accountability is based on the belief that the citizenry has a "right to know"
Benchmark	• In the context of outcomes and performance discussion, refers to desired program results • May include a target or standard for the program to achieve • Denotes best practices
Budget	• A quantitative plan of activities and programs expressed in terms of assets, liabilities, revenues, expenses (or expenditures), and in some cases outputs or outcomes • A performance-based budget may express the organizational goals in terms of specific financial and operating objectives
Effectiveness	• Producing a desired result • An ends-oriented concept that measures degree to which predetermined goals and objectives for a particular activity or program are achieved; both intended and unintended results of a program may be included as part of the measurement of effectiveness
Efficiency	• Relationship between efforts (or inputs) to outputs or outcomes; measured by indicators of the resources used or cost per unit of output or outcome • Resource-usage concept, also with a least-cost notion, that is concerned with maximizing outputs or outcomes at a minimal cost or using minimum resources
Explanatory factors	• Includes a variety of information about the environment and other factors that might affect an organization's performance; they can be either factors substantially outside the control of the entity, such as environmental and demographic characteristics, or factors over which the entity has some control, such as staffing patterns
Goal	• Condition or state that one is striving to achieve • Usually long term and may be beyond what might reasonably be expected to be achieved
Input	• Amount of financial and nonfinancial resources (in terms of money, material, etc.) that are applied to producing a product or providing a service (output)
Mission	• Charge, assignment, or purpose of an organization or some part of that organization
Objective	• Statement of the condition one expects to achieve; an objective should be realistic, measurable, generally within the control of the organization, and time constrained
Outcome	• Basic unit of measurement of progress toward achieving an objective; at the least, an outcome may be initial, intermediate, or long term
Output	• Measure of the quantity of a service or product provided (may include a quality component)
Performance measure	• Quantifiable indicator of progress, achievement, and efficiency that includes outcome, output, input, efficiency, and explanatory indicators
Strategy	• Based on goals and objective, a means for transforming inputs into outputs, and ultimately outcomes, through planned use of budgetary and other resources
Target	• Organization's intended results for a program or service

Source: Definitions based on those used in GASB special report, *Reporting Performance Information: Suggested Criteria for Effective Communication.*[2]

- Employee labor and related employer expenses (payroll)
- Services provided by other departments (internal service charges)
- Services provided by outside agencies (invoices/payables)
- Commodities used in service delivery (purchase orders/payables)
- Capital equipment outlay

Linking expenditures to service delivery on an ongoing basis captures meaningful data about performance.

In government accounting, expenditures are typically recorded in cost centers that group like (related) activities. Expenditures, which are initially reported on the cost center level, are compiled into summaries for each level of fiscal management in the organization. These summaries can be useful in connecting

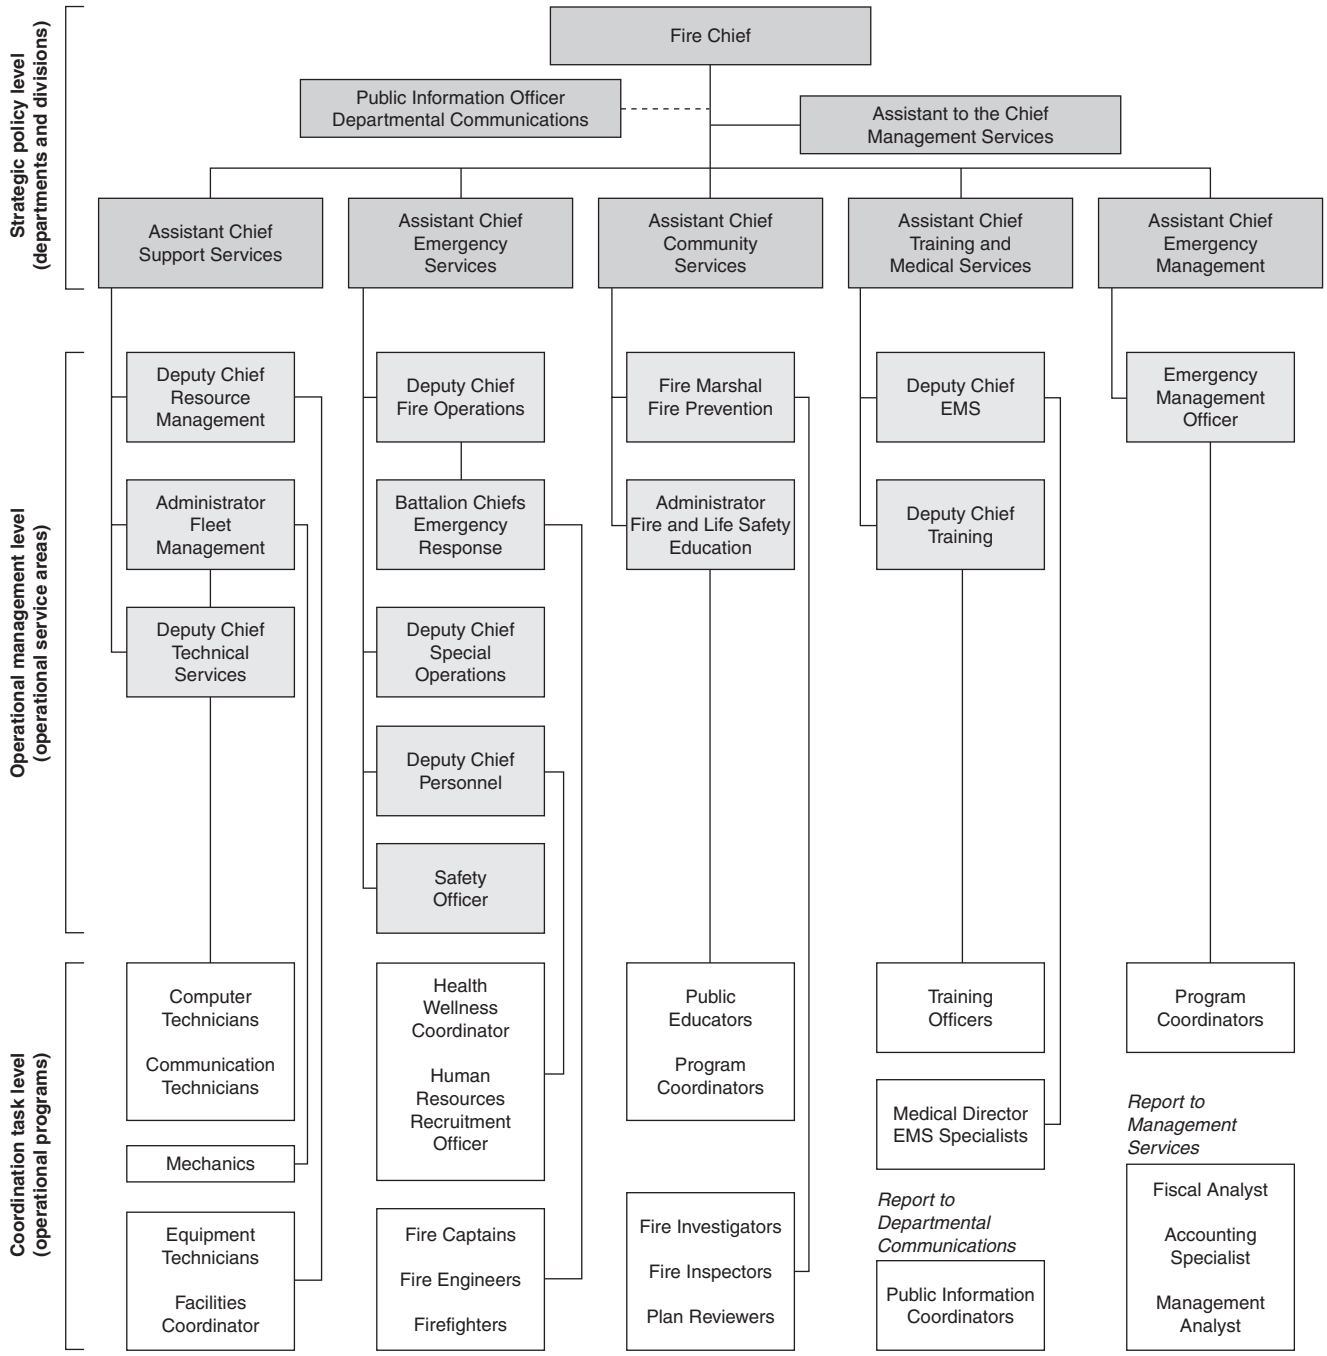

FIGURE 12.2.1 Fire Department Organizational Chart

the resources used (inputs) with the service delivered (outputs). In this type of accounting system, selecting the appropriate level cost centers will increase the usefulness of the summary reports.

One of the most common challenges in selecting the appropriate level to summarize financial data is when recording payroll (time dedicated to service delivery). Since fire department labor is the primary input to performance, this can become a significant challenge. Members may dedicate their time to multiple operational programs. Establishing a cost center for each one may, therefore, create a system that is cumbersome and difficult to use. At the same time, operational managers need detailed information about how much time is dedicated to which services. This information helps determine the efficiency of services, such as turnaround time for customers. In these cases, a cost accounting system embedded in the financial system is the most effective mechanism to use.

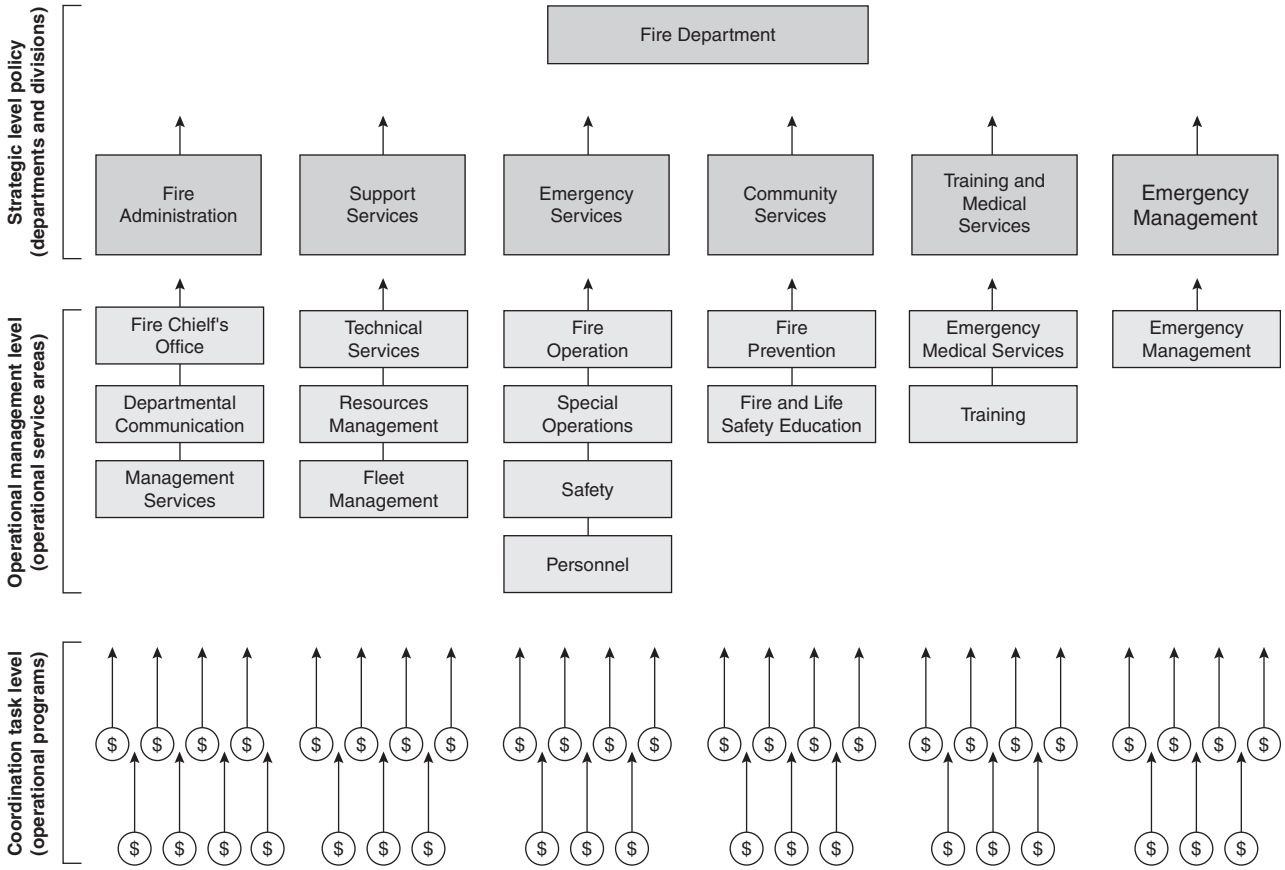

FIGURE 12.2.2 Fire Department Financial Structure

Other challenges may occur when linking an accounting system to a performance management system. A recent survey conducted by researchers at Georgia State University and the Governmental Accounting Standards Board (GASB) specifically addressed this issue with local governments. Results published in *Performance Measurement at the State and Local Levels: A Summary of Survey Results*[5] indicate that most respondents "feel there is an inadequate link between the performance measurement database and the accounting/budget database systems. . . . Nearly 80 percent of respondents from each group indicated that this is somewhat of a problem or is a significant problem."

No matter what financial structure is established or what level of automation is achieved, the key element of performance management remains the accounting of expenditures. The link between expenditures (inputs) and service delivery (outputs) must be established to calculate efficiency measures. Once calculated, they provide meaningful information that is useful to improve performance and justify budget requests.

Direct Relationship to Operational and Strategic Goals

Performance evaluation measures the success toward achieving operational and strategic goals. Planning documents contain a multitude of performance data, such as the strategic and operational goals, activity statistics, and service benchmarks. They represent valuable mediums for communicating a shared vision of performance success.

With an integrated performance management system to collect data, the process of planning is simplified and focused. Operational managers contribute the vast majority or performance data using short-range documents. With the data collected, reporting for multiple uses and to diverse audiences is quicker and easier. A review of the planning and reporting chart (Figure 12.2.3) shows the opportunities to link performance data with planning activities, which is a key step to integrating a new system.

As shown in Figure 12.2.3 the fire department's planning and reporting chart represents an inclusive tiered approach to developing and publishing the organization's mission, vision, goals, and accomplishments. Long-range, strategic-level documents include a 25 year infrastructure plan and a 10 year strategic plan. Shorter-range, management-level documents include a 5 year operating plan, 5 year reaccreditation plan with annual updates, and a 2 year financial (budget) plan. Short-range operational documents include an annual report, 6 month activity plans, program management guides, and project action plans. Operational managers contribute the vast majority of data using short-range documents, which provides the opportunity to link performance data to planning activities.

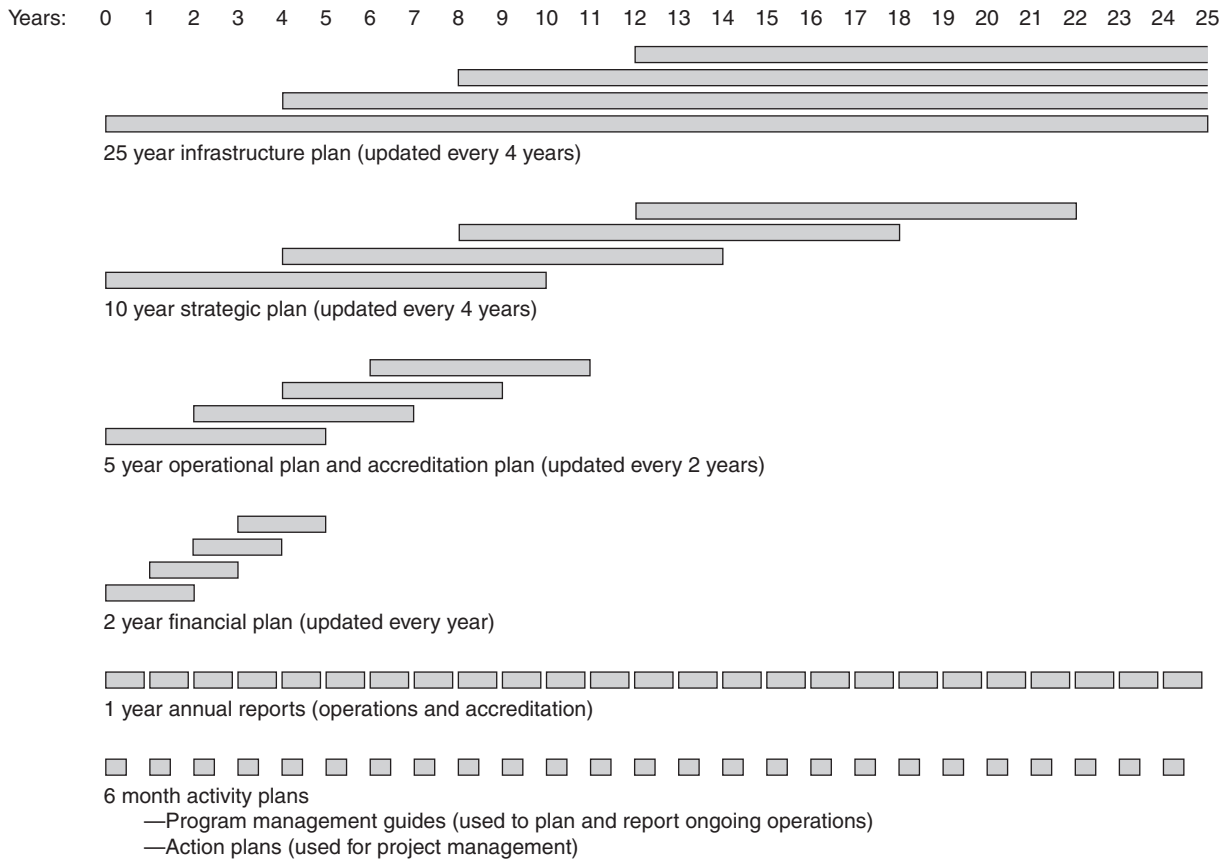

FIGURE 12.2.3 Fire Department Planning and Reporting Chart

Customer Focused Service Delivery

The performance management system quantifies how organizational efforts impact customers. When combined with professional judgment and technical expertise, it guides the organization towards performance success. The fire department's operational chart (see Figure 12.2.4) represents service delivery to the customers. In a circular model, the roles and responsibilities of each service area center around and focus on customers, both internal and external.

As shown in Figure 12.2.4, operational programs are grouped into service areas, which are grouped into divisions based on related roles in the fire department mission. All divisions have a senior manager in the leadership role. The senior managers work as a team, with the fire chief as the team leader, to develop policy and provide consistent cohesive leadership to the organization.

The operational chart is meant to capture the lateral interfaces between operational areas. This cross-functional cooperation is critical in cohesive consistent service delivery to the customers. In contrast, the traditional organizational chart as shown in Figure 12.2.1 captures interfaces vertically, aligned with the chain of command. White space exists between the divisions creating a type of silo effect. If service is delivered by following the traditional chart, a risk of critical components of service falling between the silos into the white space exists. We have all heard the expression of things falling through the cracks in an organization. Creating operational charts that manage lateral interfaces (the white space) minimizes that risk.

According to Rummler and Brache in *Improving Performance: How to Manage the White Space on the Organization Chart,*[4] "the greatest opportunities for performance improvement often lie in the functional interfaces—those points at which the baton is being passed from one department to another." With this in mind, the operational chart is the ideal framework for an integrated performance management system that maintains a focus on customers. Based on performance information, effective and efficient processes that create cross-functional responsibilities can be developed and maintained. In addition, operational managers will be able to respond quickly to customer needs identified in the performance evaluation process.

System Framework

In the transitional model shown in Figure 12.2.5, the operational chart is the starting point of a new performance management flowchart. Performance data must be captured at the point of service delivery. To integrate a performance management system, a linear flowchart was created to represent the transmission of performance data from the point of service delivery. In essence, the organizational chart was turned upside down to create a flow of information from the staff responsible for specific

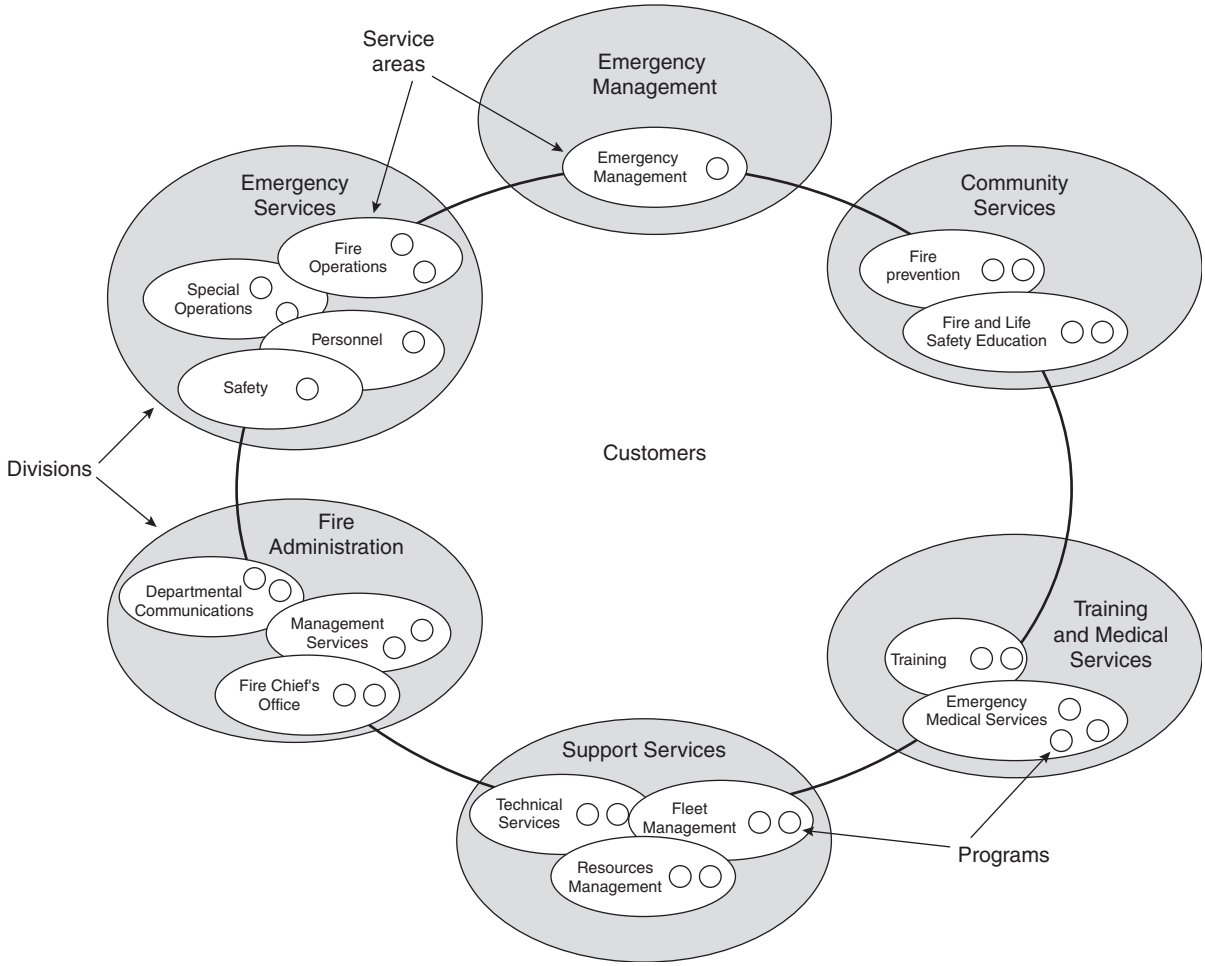

FIGURE 12.2.4 Fire Department Operational Chart

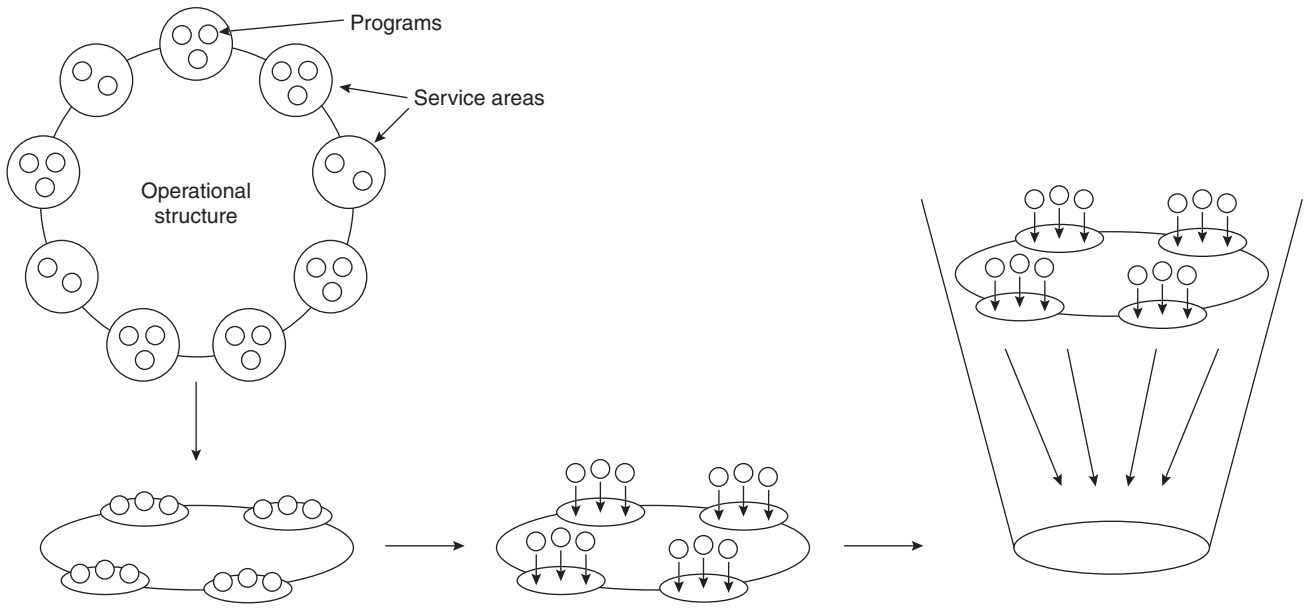

FIGURE 12.2.5 Transitional Model

services to those who manage the organization. The result is a flowchart that resembles the shape of a funnel.

In this model, a collection of individual facts can create a useful context for analysis. For example, a specific measure such as emergency response times may be placed in context with the number of calls for service or population as it flows through the system. In addition, numbers collected from various service areas may be aligned to determine relationships. For example, the number of traffic calming devices installed, media releases on pulling over for fire trucks, or the location of new housing developments may have a relationship with emergency response times. These individual facts might be captured by different service areas but they end up in the same flow of information within a system that compiles and funnels data to an operational and division/department level for analysis.

Following the flow of data through the system (funnel), operational managers are the first to analyze performance data and apply the results to operations. The process of analyzing data includes participation from the coordinators and those who accomplish the tasks related to service delivery. With a direct customer relationship, actions taken at this level will have an immediate effect on customer service.

At the operational service area level, progress toward achieving operational goals is evaluated. An advantage to this process is the ability to apply professional judgment and expertise in the first review of performance data. With the volume of data to be summarized, computer technology is essential. Computer programs will process data consistently in whatever manner they are designed to do. However, data entry is subject to human behavior, which is not quite as consistent.

Whether the technology used is a computer-aided dispatch system, incident reporting system, or spreadsheet software, it is subject to human error. An extra zero here, a dash there, or the push of a button a little differently each time, can skew performance reports. A good operational manager will be able to review data and know when something is just not quite right. Based on the goal of gaining customer confidence, it is very important for all data to be evaluated by those who manage daily operations prior to public release. At the very least, if there is unusual performance data for a given period of time, the operational manager will be prepared to respond to inquiries about the activity. Also, explanatory factors can be documented to accompany the data through the system.

The next level of data flow, moving through the system (down the funnel), is the division/department level. The leader for each area, a senior manager, is responsible to ensure that the performance data is reported appropriately. At this level, the data from individual programs is grouped into operational service areas and compiled to summarize collective progress toward achieving strategic goals. Specific program flowcharts, as shown in Figures 12.2.6 and 12.2.7, may be helpful to visualize the transmission of data through each division.

After the data is processed through the division/department level, it continues to a centralized database moving toward the small central base of the funnel. Figure 12.2.8 illustrates the flow of performance data through the department.

The most important aspect of the performance data flowchart is the evaluation process that occurs as data moves through the organization (down the funnel). By following this path and the associated processes, performance data is converted into performance *information.* Data such as individual facts about specific events, community statistics, and service delivery counts are collectively studied and benchmarked to create messages about how the organization is performing.

Centralized Database

When performance data reaches the centralized database, it has been converted from just numbers into information. Performance information is best centralized within the organization, with a designated custodian. The centralized database should be the sole source of all performance information used or published. One of the quickest ways to lose customer confidence is to publish conflicting information about service delivery. If

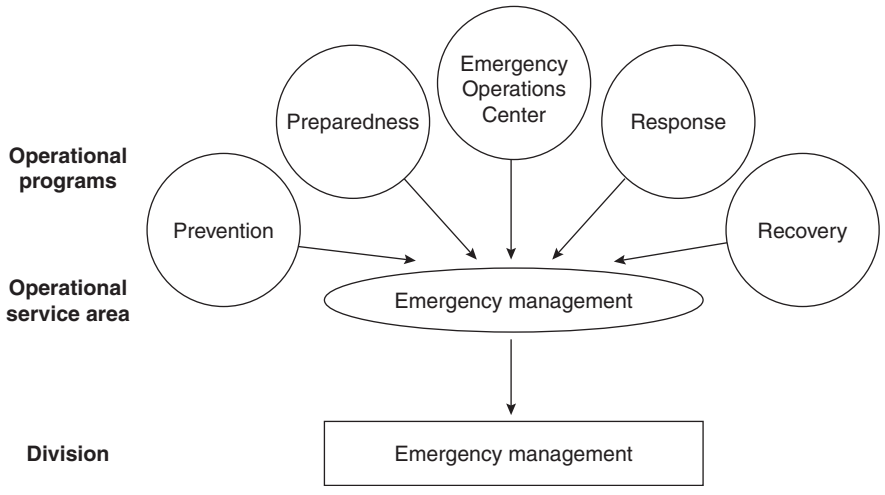

FIGURE 12.2.6 Flowchart for Emergency Management Programs

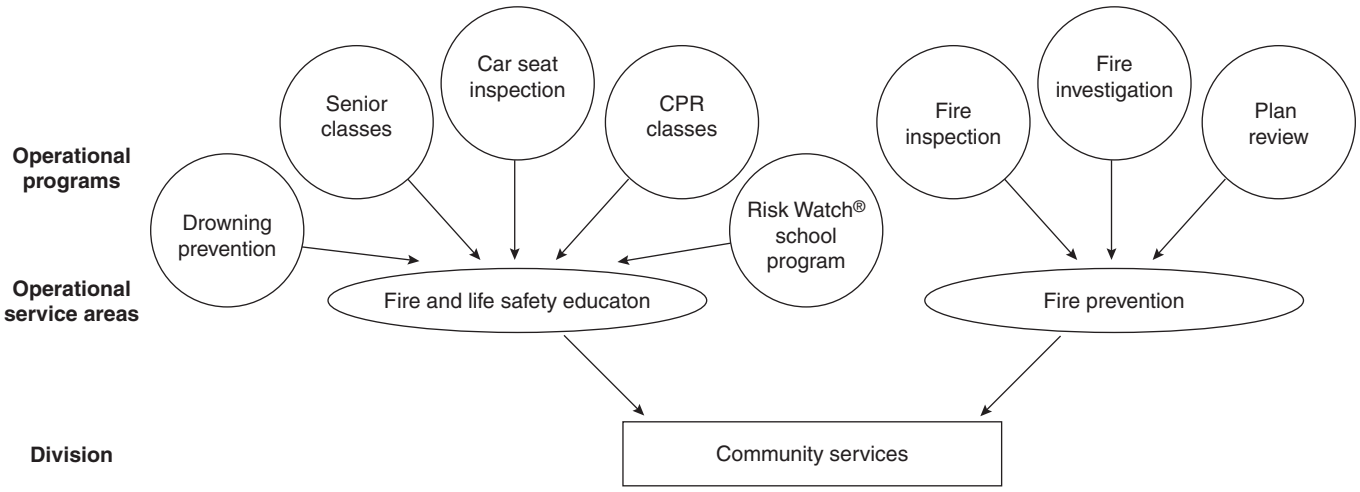

FIGURE 12.2.7 Flowchart for Community Services Programs

an existing system is not producing the information needed to manage operations, then the system should be changed. The alternative of creating multiple sources of information is not a viable option for success. A service measure as simple as the number of fire fighters on duty can vary. For example, one area may publish the people count and another area may publish the position count (to include vacancies). If an organization cannot publish consistent numbers about how many fire fighters are on duty, the credibility of more complex measures is compromised.

The ideal location for the centralized database within the organization varies. The decision depends on the staffing available and the organization's commitments to report performance. The key to successfully selecting the appropriate location is to match the custodianship with similar internal services. Planning and research, technical services, or management services

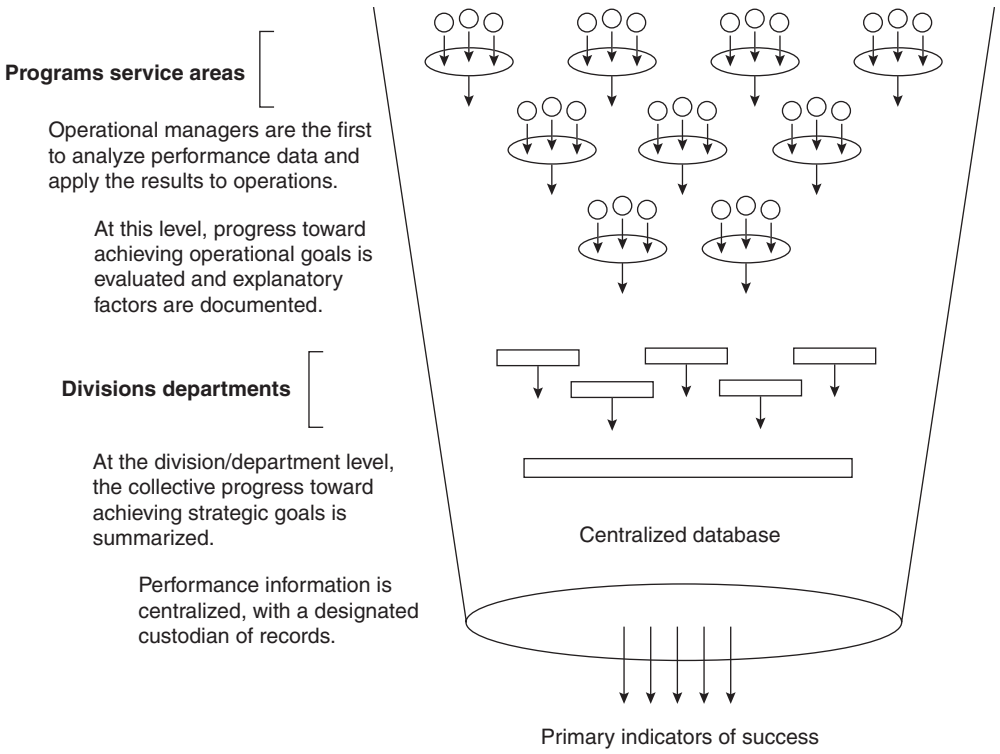

FIGURE 12.2.8 Fire Department Performance Management Flowchart

are excellent candidates. These areas may already coordinate department-wide, data-based programs, such as strategic planning, accreditation, and budget development. These internal service areas may also provide historical statistical information for process improvements and management reports. The opportunity to eliminate duplication of efforts and streamline processes resides in the selection of the centralized database location. This selection represents another step to integrating a new system.

Performance-Based Budget

Many local governments require budget documents to include performance measurements. Funding allocations are quantified to show the impact of service delivery to the community. (If operational programs are not fully funded, they will not be able to meet performance expectations). For government and community leaders, this adds value to their decision-making process. For publicly funded fire departments, accounting for resources becomes critical to maintaining funding for services. The process of budget adoption is open to the public and is participative, which provides an excellent forum for educating customers. In this environment, integrating the centralized performance database with fiscal management maximizes the opportunities to obtain resources and gain customer confidence.

Fiscal management typically resides in an administrative area, such as management services. Common fiscal management includes developing and monitoring the budget. When integrated with administrative information from multiple stakeholders and sources, such as policies, surveys, and planning documents, budget development becomes an inclusive participative process in which financial resource needs are applied to performance expectations (Figure 12.2.9). This process is commonly referred to as performance-based budgeting.

REPORTS AND REPORTING CYCLES

A standard report template streamlines the process of compiling, analyzing, and reporting data. An electronic format streamlines the transmission of data, as well as the ability to index and sort the data for multiple purposes. A fully integrated system connects service levels (outputs) with operational goals (targets), strategic goals (outcomes), and resources used (inputs). Using a report format, programs are set up by operational managers, who populate program descriptions, targets, and outcomes. The report is populated with outputs and inputs by selected criteria from other technological databases on a routine cycle.

Operational managers evaluate performance data in short-range cycles. A monthly cycle is optimal for reviewing service levels and resources used. This frequency coincides with the monthly reporting cycle of an accounting system, which allows the manager to monitor funding levels at the same time. Significant variances between the budget and expenditures are identified quickly. Remedial actions by operational managers keep

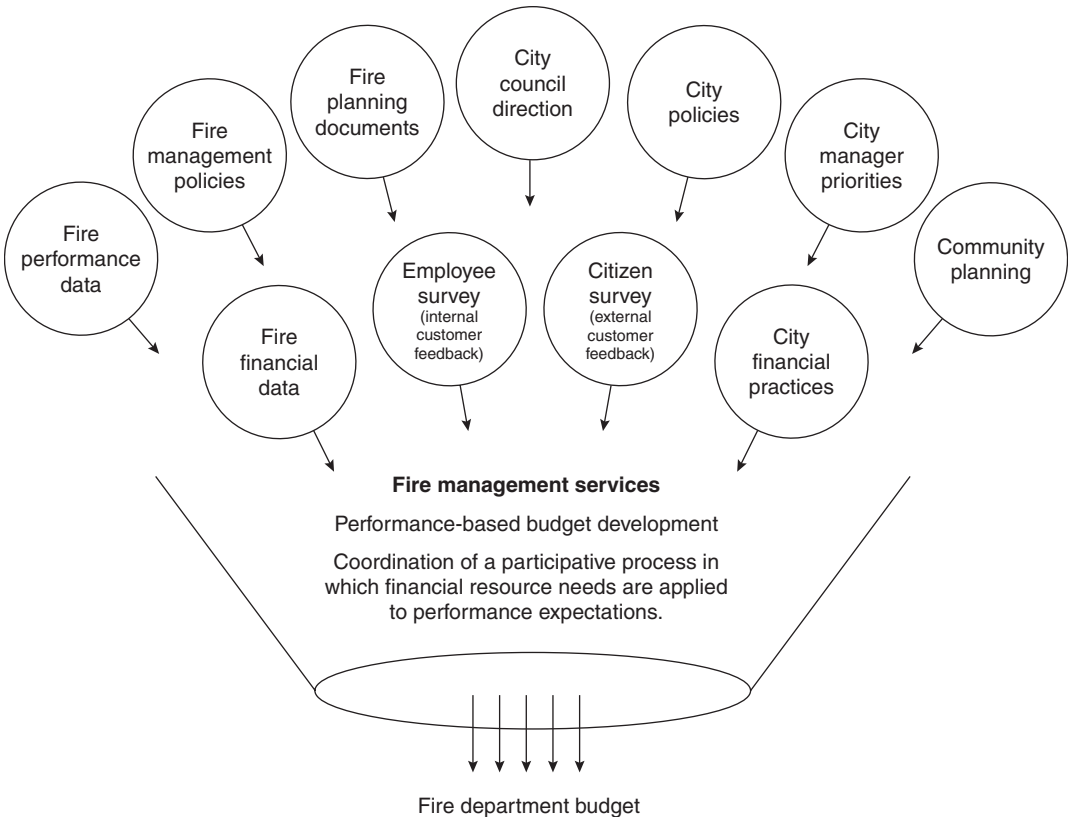

FIGURE 12.2.9 Performance-Based Budget Development

programs on track and funded, over the course of a fiscal year. A monthly cycle identifies service level trends in the early stages, as well. Operational managers are alerted to the possibility that resources may need to be realigned to meet shifts in service level demands. Early detection increases the organization's responsiveness to meet customer needs.

Senior managers evaluate performance data in longer-range cycles. A 6 month cycle is sufficient to support planning activities and budget development. For policy development, related performance data can be produced, as needed.

To integrate a new system, creating a standard report template and establishing the reporting frequencies are key steps. The sophistication of a fully integrated system may not be possible to obtain with initial implementation. In this case, the service levels (outputs), operational goals (targets), strategic goals (outcomes), and resources used (inputs) may have to be provided to operational managers on separate reports. As long as the data is linked, manually or through the use of technology, a thorough evaluation of organizational performance can be conducted.

The key elements of a performance report are summarized in Table 12.2.2 with three "*p*'s": program descriptors, performance information, and planning objectives. Included are proposed characteristics of each and a fictional program example.

MEASUREMENTS AND BENCHMARKS

Measurements and Benchmarks Defined

Measurements and benchmarks provide information. They are the mechanisms to quantify and qualify organizational performance. Using GASB definitions listed earlier in this chapter, measurements come in five major categories: inputs, outputs, outcomes, efficiency and effectiveness. The term *benchmark* has a dual meaning. In one context, it represents the standard to which we measure. In the other, it denotes the search for best practices. The common denominator of measurements and benchmarks is the provision of information about organizational performance.

Measurements linked to benchmarks create a context that increases the value of the information provided. In a numeric format, measurements quantify performance. Measurements linked to a benchmark qualify progress. The measurement is the count and the benchmark is the yardstick to which we measure the count.

The process of measuring organizational performance begins with a count (a number). The number of commercial buildings inspected is a count. The count may be stated as a percentage of a whole. The number of commercial buildings inspected as compared to the total number of commercial buildings in the community is a percentage of a whole. The number may be qualified to represent performance progress. The percent of commercial buildings inspected this year is *X* percent, compared to last year's *Y* percent. In this example, the performance benchmark is the prior year. The value of information increased when the numeric value of the measurement was linked to a benchmark to create a context.

The context of a measurement creates meaning to those who evaluate performance. As an evaluator of performance, we need more than just a number to convert data into information. As an example, a 7 digit number in itself doesn't provide information. If the 7 digit number is the odometer reading in our car, linked to a southern direction, it provides us with information about our driving progress. From our initial reading, we can calculate how far we have traveled and how much further we need to go to reach our destination. From our initial fuel level, we can calculate our miles per gallon and project the amount of fuel we will need to make it to the next gas station. Then we can benchmark our driving progress in many different ways.

Benchmarks vary and are based on the context that provides the most meaningful information to us. They may be based on technical standards, build on historical data, be comparables from like organizations, or be specific to organizational priorities. A benchmark can be the target itself.

Continuing with the example used for measurement context, we drove 600 miles today. To measure our progress, we can compare our measurement to several different benchmarks. We can compare our mileage to a technical standard. For example, our car insurance company has studied safe driving and recommends an average of 500 miles a day. We can compare it to yesterday. We drove 500 miles yesterday and set a goal of driving 500 more miles today. We can compare it to other drivers traveling the same highways. They drive an average of 700 miles per day. We can compare it to our destination. We are halfway to our destination. We can simply plan our trip based on our resources and our priorities at driving 600 miles each day.

An important note about the driving example is that the unit of measure created more opportunities to benchmark. Had we measured our progress in kilometers, it would have been difficult and time consuming to compare with external benchmarks that use miles as the norm. Due to service norms, sometimes the benchmark is selected prior to the units of measure to ensure comparability with external agencies.

Benchmarks as Best Practices

Not all things counted are measurements of performance. Many fire service professionals propose that a count such as fire fighters per capita represents a service norm as opposed to a performance measure. As discussed in *Municipal Benchmarks: Assessing Local Performance and Establishing Community Standards*[6] by David N. Ammons, "national or regional norms . . . can tell officials whether local practices and characteristics lie within or outside normal bounds, but they do not address performance."

Not all things benchmarked are measurements of performance. The term *benchmark* is also used to denote best practices. In *Managing Fire and Rescue Services,*[7] David T. Endicott examines benchmarking as a process of searching for and identifying best practices. The process involves comparing similar services provided by outside agencies in an effort to discover new and innovative practices that lead to improved performance.

Most fire departments benchmark to other fire departments. For those in major metropolitan areas, specific attention is given to neighboring communities with shared borders. This process

TABLE 12.2.2 Key Elements of a Performance Report

Key Element	*Characteristics*	*Example*
Program Descriptors		
Program title	Concise and recognizable	Emergency response
Program scope	Short description of services provided	Rapid response to emergencies dispatched through the 9-1-1 system
Program customers	Group(s) of people to whom services are provided (may be internal or external to the organization)	Residents, businesses, and visitors to the community
Program manager	Primary manager of services provided (operational level)	Deputy chief of fire operations
Strategic goal	Supports mission and directly linked to planning documents	To protect life and preserve property within the community
Operational goal	Supports strategic goal and directly linked to planning documents	Response time of 4 minutes or less, 90 percent of the time
Performance Information		
Reporting period	Date-bound reporting cycle	July 2007–December 2007
Service levels	Measurement of service provided during the reporting period, in the same units of measure as the operational goal	• Average response time: 3 minutes, 52 seconds • Response time within 4 minutes: 69 percent
Service efforts	Measurement of resources used to provide services during the reporting period, stated in format that is meaningful to the organization (may be hours, dollars, percentage of dollars, etc.)	• Regular time staffing budget: 49 percent expended, 50 percent through the fiscal year • Overtime staffing budget: 40 percent expended, 50 percent through the fiscal year
Explanatory factors	Significant factors that affected service delivery during the reporting period	Due to freeway expansion, 20 percent of major traffic corridors in the northeast section of the community have detours, causing emergency response units to use alternate routes
Major objectives	Major activity planned during the reporting period, to support operational goal; may be more than one	• Work with the transportation department to develop an electronic notification system for road construction schedules • Implement by November 30, 2007
Major accomplishments	Result of the major objective planned; may be in progress or completed; may be more than one.	New system implemented on September 18, 2007. Initial results of new system: • 100 percent of emergency response crews were notified, a minimum of 7 days prior to road construction via an e-mail distribution list. • 80 percent of crews reported the process is having a positive effect on their ability to identify the quickest route to an emergency.
Planning Objectives		
Major objectives	Major activity planned during the next reporting period to support operational goal; may be more than one	Research and recommend a digital display monitor for dispatch at multicompany stations by February 8, 2008
Projected outcome	If accomplished, how this activity will support the operational goal	The ability for emergency response crews to see the unit dispatched is projected to have a positive effect on turnout time (a component of overall response time to emergencies).

provides a wealth of useful information. At the same time, great care must be taken when selecting benchmark communities.

Prince William County, Virginia, has performed a process called Service, Efforts, and Accomplishments that selects similar municipal agencies to compare like measurements. They have run into some challenges with truly "like measures." Even though the comparison is made to other combination departments, there are organizational and cultural differences that sometimes equate to comparing apples to oranges or at best to a different type of apple.

Variables in the demographics and service dimensions of every community and region have the potential to skew measurements. An example is found in the measurement of fire fighters per capita. The variable is the scheduled workweek for fire fighters. In some regions of the United States, it is 40 hours per week. In others, it is 56 hours per week. In two communities with different workweeks, the numbers of fire fighters on duty may be the same each day but the number of fire fighters employed to fill the on-duty assignments may be significantly different. In turn, the number of fire fighters employed can skew the measurement of fire fighters per capita. Identifying these types of variables when compiling a profile of benchmark communities will increase the value of comparisons. If a true apples-to-apples comparison cannot be obtained, at least the variables that affect the measurement can be noted and considered in the evaluation process.

The decision about how to use benchmarking goes back to the practice that best matches the philosophy, culture, and mission of the organization. There is an abundance of things to measure and benchmark in a fire department. The key to providing information and not just numbers lies in the selection of what to count and which yardstick to use to create a context that has meaning.

Meaningful Measures

An example of an evaluation process to select meaningful measures is found in Figures 12.2.10 through 12.2.13. Developed by the Ontario Fire Marshal's Office as part of its "Performance Measurement and Benchmarking Project," they provide an evaluation tool to help municipalities measure all the components of community fire protection planning. (The full model is a product of work that is available by contacting the Ontario Fire Marshal's Office.)

In addition to reviewing the Ontario model, the following list of data categories may be useful in the selection of meaningful measures (many were derived from measurements used by Prince William County, Virginia, and Scottsdale, Arizona, and they appear in no particular order of importance):

Emergency Services

- Number of calls for emergency services, total and by type
  - Fire
  - Medical
  - Hazmat
  - Technical rescue
  - Aircraft rescue and fire fighting
  - Other
- Number of units dispatched, total and by type
- Response times to emergency calls, actual and average
  - Percent of responses made in under X minutes
  - Dispatch time
  - Turnout time
  - Travel time
- EMS transports (patients transported)
- EMS quality assurance review results
- AED use, deployment statistics, and usage rates
- Training hours, total and average per member, by type
- Members certified to minimum standards of services provided, by type
  - ALS (paramedic)
  - BLS (EMT)
  - Special operations
- Training participation
  - Promotional processes rates
  - Succession planning rates
  - Recruit retention rates
- Health and wellness participation
  - Exposure rates
  - Fitness rates
  - Health screening participation rates
  - SCBA fit test rates
  - Workers compensation claims, hours lost to injuries

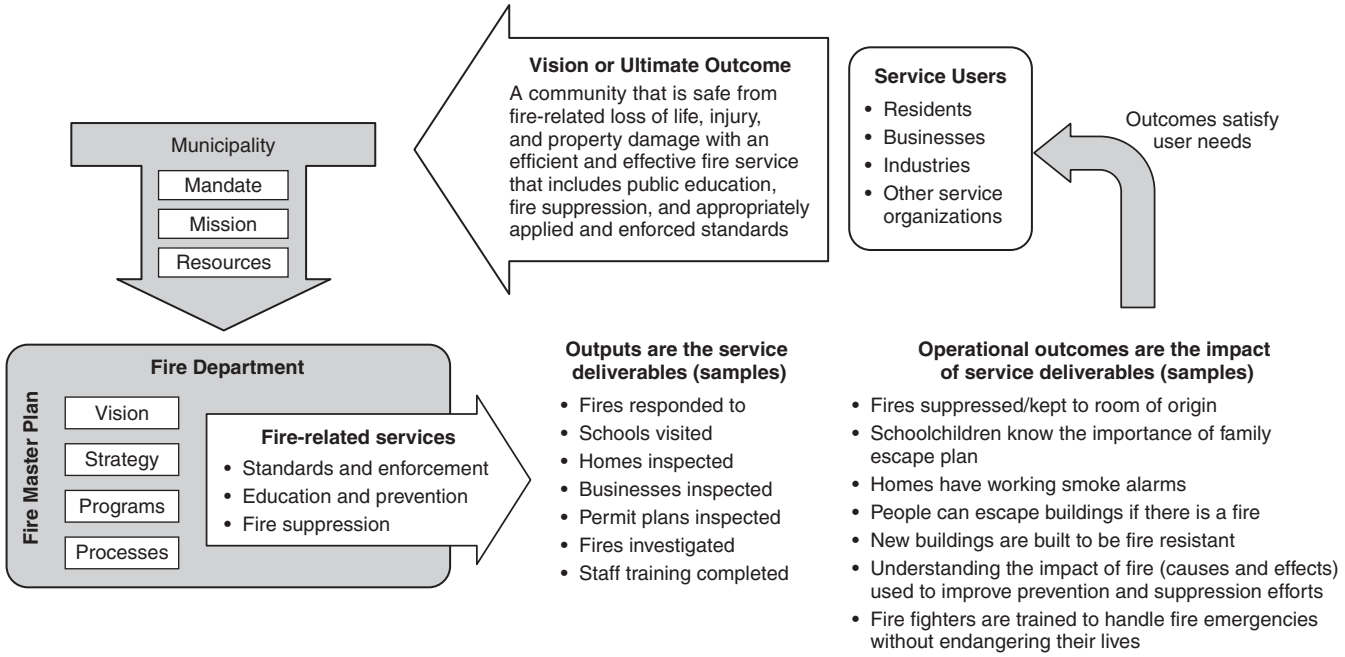

FIGURE 12.2.11 Fire Services Delivery Model (Source: "Ontario Fire Service Performance Measurement and Benchmarking Partnership Project," Office of the Fire Marshal, Province of Ontario, Canada)

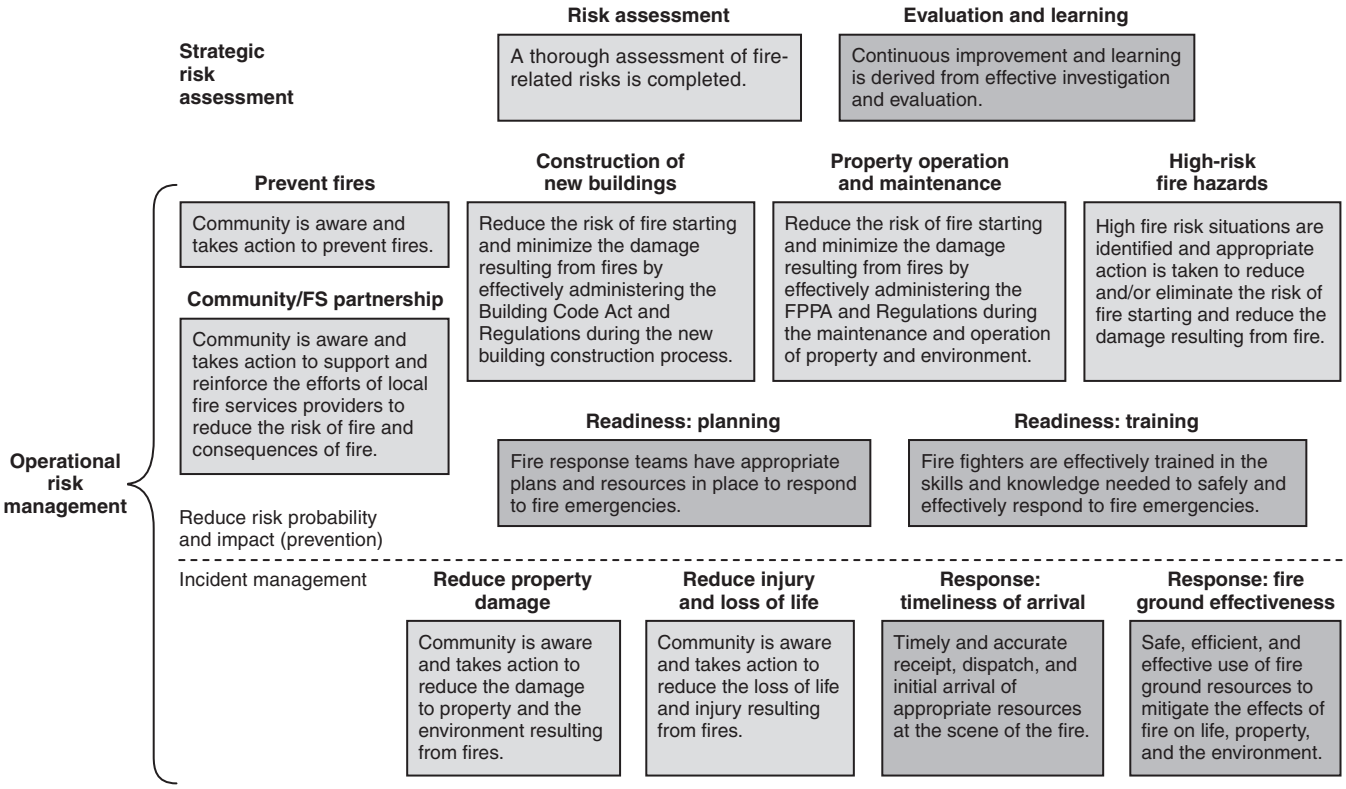

FIGURE 12.2.12 Fire Protection Outcomes (Source: "Ontario Fire Service Performance Measurement and Benchmarking Partnership Project," Office of the Fire Marshal, Province of Ontario, Canada)

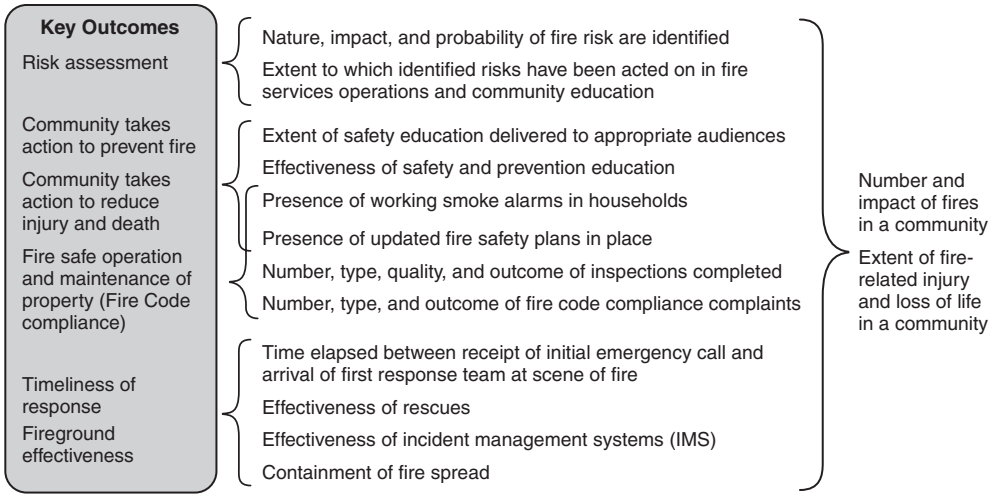

FIGURE 12.2.13 Key Performance Indicators (Source: "Ontario Fire Service Performance Measurement and Benchmarking Partnership Project," Office of the Fire Marshal, Province of Ontario, Canada)

Fire Prevention

- Inspections, numbers conducted, and turnaround time
- Number of occupancies in the community, by type
- Structure fires of the various occupancies
  - Fires contained to room of origin, unit of origin, building of origin
  - Fires contained to the level of involvement on arrival of first fire unit
- Number of false alarms
- Fire loss
- Civilian injury and death rates
- Fire investigations, number conducted
  - Cause and origin determination rates
  - Arson rates, conviction rates
- Plans reviewed, number conducted
  - Customer turnaround time
  - First review approval rates
- Complaints investigated
- Community access rates, use of technology
- Built-in protection
  - Number of residents with smoke detectors
  - Number of residents with fire sprinkler systems

Fire and Life Safety Education

- School programs, by grade level: class hours and students contacted
- Community events, participation rates, by type
  - Car seat inspections
  - Senior events
  - CPR classes
  - Drowning prevention
- Educational literature distributed, by type

Administrative and Support Services

- Citizen satisfaction survey results, by service provided
- Employee satisfaction survey results
- Employee turnover rates
- Emergency operations center (EOC) activations and drills, participation rates
- Community emergency response team (CERT) volunteers, participation rates
- Media releases provided
- Public service announcements produced
- Lawsuits filed
- Vehicle accident rates
- Number of intersections with traffic pre-emption devices
- Mapping update and distribution rates
- Incident records, processing and turnaround times
- Apparatus statistics: in service, by type; out of service, by cause
- Equipment inventory rates: out of service, by cause; lost, by type
- Personal protective equipment statistics
- Supply inventory and usage statistics

Service Dimensions

- Population
- Service area, square miles served
- Total fire department personnel, number of civilians in department, and number of sworn personnel
- Total fire department operating budget by expenditure type, dollars, and labor hours
- Total fire department capital improvement budget, by project
- Number of fire stations
- Number of on-duty personnel, per day
- Per unit staffing, minimum staffing criteria

SUMMARY

A systems approach to organizational benchmarking and performance evaluation captures the key information necessary to communicate performance expectations and success. Effective communication combined with member participation leads to organizational acceptance and accountability for performance results. An environment of universal accountability fosters process improvements and the efficient use of resources. When resources are linked to service delivery, value is added to decision-making processes and customer confidence increases.

An organization with an integrated performance management system has the ability to capture and convert data into information. Data captured on an operational level, when combined with professional judgment and expertise and centralized, provides accurate information. Performance information that is customer focused and has a direct relationship to operational and strategic goals is meaningful. Accurate and meaningful information about an organization's performance leads to excellence in service delivery for customers.

Chapter 3

Needs Assessment and Hazard Analysis

William F. Jenaway

Chapter Contents

Overview of Assessment Components and Resources
General Plans
Assessment Processes and Tools
Stakeholders and Assessment Information Resources

Key Terms

accreditation, community risk assessment, emergency planning, hazard analysis, hazard assessment, Insurance Services Office (ISO), master plan, needs assessment, risk assessment, standard of response cover, strategic plan, water supply

Fire officials, fire departments, and emergency service organizations often do not perform an adequate needs assessment and hazard analysis in their area for use in their planning processes. A needs assessment and hazard analysis is fundamental to determining necessary resources to operate a department and ensure performance of its assigned functions. Knowing what resources a department or organization will need can only be determined by understanding the hazards it faces. However, time, funding, and other priorities continually prevent fire officials from effectively analyzing needs and incorporating appropriate resources into organizational operations.

The purpose of this chapter is to demonstrate the interrelationship of numerous routine or special activities that can be conducted as components of a comprehensive needs assessment and hazard analysis—that is, the identification of the challenges faced and the resources needed to manage these challenges.

For related information see the following chapters in Section 12: Chapter 1, "Planning for Public Fire-Rescue Protection"; Chapter 2, "Organizational Benchmarking and Performance Evaluation"; Chapter 12, "Disaster Planning and Response Services"; Chapter 17, "Pre-Incident Planning for Industrial and Municipal Emergency Response"; Chapter 18, " Pre-Incident Planning for Emergency Response"; and Chapter 19, "Community Risk Reduction."

OVERVIEW OF ASSESSMENT COMPONENTS AND RESOURCES

Components of the Assessment Process

Any process to assess needs and analyze hazards must utilize a fundamental decision-making process. There are several such models; however, regardless of the one chosen, the basic components of the process remain the same and include the following:

- Developing the analytical data
- Evaluating the data developed
- Deciding on the data to use or course of action to take
- Implementing the chosen data
- Monitoring and modifying the information implemented

This decision-making process will assist decision makers in understanding what hazards exist, what actions are needed to manage those hazards, and how to fulfill the identified needs. The decision-making activity becomes a path to matching hazards and needs. For reference in this decision-making process, see related chapters in Section 12 for additional information.

William F. Jenaway, Ph.D., CFP, CFPS, SFPE, MIFE, was named Volunteer Fire Chief of the Year by *Fire Chief* magazine and IAFC in 2001. He is employed by VFIS, a division of the Glatfelter Insurance Group, and has spent over 25 years as an insurance field engineer, investigator, and vice-president in fire protection and safety.

Needs Assessment Study

A cooperative study, authorized by U.S. Public Law 106-398, required that the director of the Federal Emergency Management Agency (FEMA) conduct a national study in conjunction with the National Fire Protection Association (NFPA) to accomplish the following:

- Define the current role and activities associated with the fire service
- Determine the adequacy of the current levels of funding
- Provide a needs assessment to identify shortfalls[1]

Evaluation Areas of Study. This initiative focused on six areas. The details of the findings of the report appear throughout this chapter; however, it is important to understand what the study evaluated and its related limitations in overall needs assessment and hazard analysis. The study evaluation areas included the following:

- Services provided
- Personnel and their capabilities
- Fire prevention and code enforcement
- Facilities, apparatus, and equipment
- Communications and communication equipment
- Ability to handle unusually challenging incidents
- New and emerging technology

Although these are all valid considerations, before needs can be defined, the expectations of the public, an understanding of the risks posed within the community, and the expectations of everyone receiving and providing the service must be identified.

Resource Categories. To properly determine how the fire department will do its job, a needs assessment and a hazard analysis are integral to the process. For example, the needs assessment study completed as a result of U.S. Public Law 106-398 identifies several categories of resources, including the following:

- Fire-fighting personnel
- Training for fire-fighting personnel
- Rapid intervention teams
- Certification for fire inspectors
- Wellness and fitness programs for fire-fighting personnel
- Emergency medical service programs provided by fire departments
- Fire-fighting vehicles
- Fire-fighting equipment, including communications and monitoring
- Personal protective equipment for fire-fighting personnel
- Modifications to stations and facilities for reasons of fire fighter health and safety
- Enforcement of fire codes
- Fire prevention programs
- Education of the public about arson prevention and detection
- Recruitment and retention initiatives for volunteer fire fighters in fire departments.[1]

Although these resources were quantified to better understand the magnitude and nature of fire department needs, it must be recognized that specific needs will be driven locally and based significantly on the local hazards faced, without going below the minimum requirements defined in the standards. The study provides insight into key areas of concern at issue nationwide, but its applicability in a specific community is determined by what that community has completed in terms of coordinating hazard analysis with needs assessment.

Study Findings. The FEMA/NFPA study provided findings in the areas of revenues and budget; personnel; fire prevention and code enforcement; facilities, apparatus, and equipment; communications and communications equipment; ability to handle unusually challenging incidents; and new and emerging technology. In the updated needs assessment study of the U.S. fire service created by the U.S. Department of Homeland Security/U.S. Fire Administration and the National Fire Protection Association four years later,[2] the following were noted:

- Taxes provide at least three-fifths of the revenue for all-volunteer or mostly volunteer fire departments in the United States. Taxes plus other government payments, including per-call reimbursements, raise the total percent of revenue coming from government to at least three-fourths (77%). Fund raising provides at most 19 percent, which is the fund-raising share for rural communities of less than 2500 population.
- Converted vehicles account for 14 percent of apparatus used in communities under 2500 population and 10 percent of apparatus in communities of 2500 to 4999 population.
- Many fire departments fail to deliver a first-arriving complement of at least 4 fire fighters to a structure fire, the minimum complement needed to safely initiate an interior attack.
- An estimated 53 percent of departments are involved in structural fire fighting but have not formally trained all involved fire fighters in those duties. The corresponding percentage is 36 percent for emergency medical services, 36 percent for hazardous material response, 63 percent for wildland fire fighting, and 50 percent for technical rescue. Except for technical rescue, the percentages of departments needing more training are always higher for rural communities (less than 2500 population), in which nearly all departments are all-volunteer.
- One-quarter of the population are protected by fire departments that do not provide plan review and nearly half are protected by fire departments that do not provide permit approval or routine testing of fire protection systems. An estimated 7 percent of the population live in communities where no one conducts fire code inspections, and two-fifths of this unprotected population live in rural communities.
- Similarly, one-third of the population live in communities where there is no fire department program for free distribution of home smoke alarms, and two-fifths of the population are protected by fire departments with no juvenile firesetter program.
- An estimated 36 percent of fire stations are at least 40 years old, 54 percent do not have backup power systems, and 72 percent are not equipped for exhaust emission control.
- Half (49%) of all fire apparatus are at least 15 years old.
- An estimated 65 percent of fire departments do not have enough portable radios to equip all emergency responders on a shift. An estimated 60 percent do not have enough self-contained breathing apparatus (SCBA) and an estimated 48 percent do not

have enough personal alert safety system (PASS) devices to equip all emergency responders on a shift. An estimated 8 percent do not have enough personal protective clothing to equip all fire fighters, most of them being departments in rural communities.

- About three-fourths of departments say they cannot communicate with all their federal, state, and local partners at incident scenes, and one-fourth to one-third say they cannot communicate with any of their partners. Roughly half of all departments have no map coordinate system, and almost none use the U.S. National Grid System, which has been adopted by the Federal Geographic Committee as the system best suited for eventual national standardization.
- Written agreements to direct use of nonlocal resources are lacking for 74 percent of departments with regard to technical rescue and EMS at a defined structural collapse and 70 percent of departments with regard to hazmat and EMS at a defined chemical/biological agent incident. Written agreements are also lacking for major floods and wildland/urban interface fires. On the positive side, the percentage of departments with written agreements increased between the 2001 and 2005 needs assessments.
- Finally, the majority of departments (55%) now have thermal imaging cameras, up from only 24 percent in the 2001 survey.

Each of these situations identified by the needs assessment study pinpoints a fire department need that poses a challenge to be resolved before the hazards identified can be managed.

Terms Defined

In this text the terms *hazard, risk, needs assessment,* and *hazard analysis* are defined as follows:

Hazard: Level of harm associated with exposure to a fire or its effluent.
Risk: Expected loss from a fire of a given severity.
Needs Assessment: An analysis to determine the shortfall between expected performance and current performance.
Hazard Analysis: An analysis to determine the potential impact of a fire scenario when the hazard is involved in fire.

GENERAL PLANS

Over the years a variety of planning processes have been developed and introduced to the fire community. Each process establishes and accomplishes different objectives. The following section defines the processes involved with strategic plans, master plans, community risk assessments, pre-emergency planning, and disaster plans, and discusses what to expect from each of these processes when they are completed.

Strategic Plan

The strategic planning process serves as a single point of collection to coordinate various data points, administrative processes, and planning considerations. This integration of benchmark performance, budgetary commitments, mission statements, emergency service organization activities assessment, and so on serves the management team with a summary report of the efficiency and effectiveness of the organization.

Purpose of Strategic Focus. *Strategic planning* or *strategic focus* has been described as a set of concepts, procedures, and tools designed to assist leaders and managers in exercising control, coping with change, and developing a basis for decision making.[3] The strategic focus process can help answer such questions as these:

- What are the fire department's objectives for the next five years?
- Where will the organization be in seven years?
- What are the fire department's capital purchasing plans for the next ten years?
- What is the fire department's standard of response cover?

In recent years there have been several approaches to performance enhancement in both profit and nonprofit organizations. The terminology may vary; however, as long as managers are driving the organization to future decision and action to ensure organizational success, they are strategically focused and participating in strategic planning.

Strategic Focus Model. Creating and implementing a strategic focus helps the organization understand its resources, capabilities, and needs. In order to develop such a plan successfully, an appropriate planning model is necessary. To enable resources to meet expectations, the strategic focus model (Figure 12.3.1) employs three essential concepts:

- Organization resource assessment
- Defined service expectation
- Priority planning

With these concepts incorporated into the strategic plan, a basic decision and action process is created that helps structure the emergency service organization and spells out what it does and why it does it. In essence the process defines the future of the emergency service organization.

Basic Activities. The following are five basic activities identified in the strategic focus model:

1. Identifying, developing, creating, and analyzing key issues:
   - Mission and vision
   - Standard of response cover
   - Roles and responsibilities
   - Goals and objectives
   - SWOT (strengths, weaknesses opportunities, and threats)
   - Strategic alliances
2. Obtaining direction from key sources of input:
   - Organizational members
   - Community leaders
   - The citizenry
   - The business community
   - Mutual aid agencies

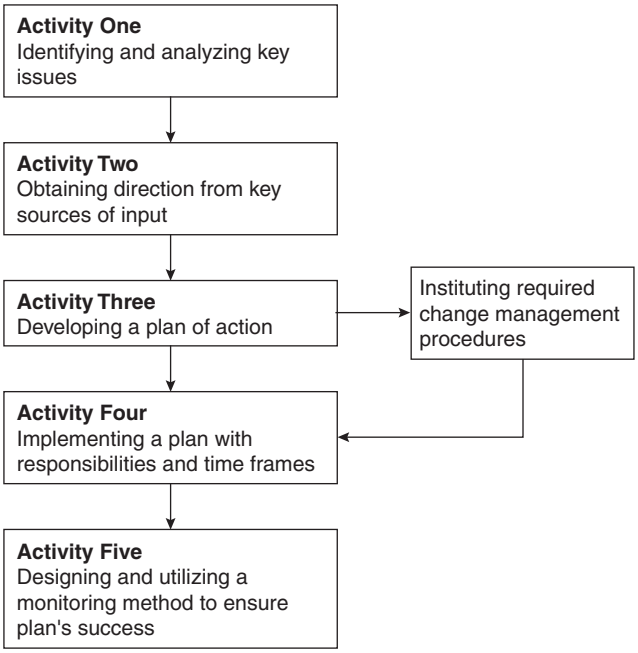

FIGURE 12.3.1 Strategic Focus Model

3. Developing a plan for implementation over a defined time period:
   - Immediate action steps to achieve goals and objectives
   - Long-term plan for implementation
4. Implementing a plan with responsibilities and time frames involving:
   - Finance
   - Personnel
   - Apparatus
   - Equipment
   - Facilities
   - Processes and procedures
5. Designing and utilizing a monitoring method to ensure plan success

Change Management Practices. Identifying and acting on the issues previously described can increase the efficiency of the emergency service organization and can help to plan for future contingencies. The result of any strategic focus initiative is change. Therefore, any such process must be undertaken by an organization that is ready for change. If the organization is not ready for change, then conflict can and will exist. As a result, change management practices must be identified and catalogued for reference as the planning process moves forward.

Identifying and prioritizing the initiatives critical to an organization's performance ensures long-term health and growth of the emergency service organization. The output from this process establishes coordinated goals, objectives, and, in some cases, action steps dealing with the following aspects of the organization:

- Finances
- Personnel
- Facilities
- Apparatus
- Equipment
- Procedures/processes

These are consolidated into planning documents, including identified costs, time frames for completion, and responsibilities for completion. The process then identifies different sets of objectives for organizational action.

In conclusion, although we may want it to be "the same old fire service as the glory years of the 60s," it isn't. Today, emergency service organizations are complex and dynamic and they must identify what they are doing, why they are doing it, and incorporate mechanisms for change if current initiatives are ineffective or problematic. The strategic focus process helps an organization develop the vision of where it wants/needs to be and how to get there.

A strategic plan establishes a "vision" and deals with more than just fire protection. To give an analogy, a strategic plan is a road map, whereas a master plan provides details on the streets, buildings, and related details encountered along the way.

Master Plan

Over the years, the term "master plan" has had several definitions and applications. In fact, some may say it is the same as a need assessment and hazard analysis. A master plan may be best characterized as a plan that helps to zero in on priorities and levels of service provided in specific operational areas. The master plan can assist in addressing adequacy and performance and align specific divisional needs with organizational expectations and the strategic plan.[4] Therefore, its development can serve as a component of comprehensive needs assessment and hazard analysis.

As noted above, a master plan differs from a strategic plan in that a master plan typically determines how much risk a community is willing to assume specifically relating to fire protection.

Community Risk Assessment

Community risk assessment, a fundamental assessment and planning process to assist in defining goals, is used to identify the community's fire protection and other emergency service needs in order to determine potential goals and objectives. Emergency service organizations must expand their use of this planning process to ensure they can meet future demands. All agencies should have a basic source of data and information in order to logically and rationally define the organization's mission. The end result of the process is to establish a long-range general strategy for the operation of the system. Emergency service organizations can achieve this goal by taking the following steps:

1. Documenting area characteristics by collecting historical data and instituting a process by which hazards are de-

fined and potential organizational goals and objectives are established.
2. Assessing the nature and magnitude of the hazards within its jurisdiction by categorizing and listing significant events to allow for future analysis and study in determining standards of coverage and related services.
3. Assessing the nature and magnitude of other hazards and risks within its jurisdiction and identifying appropriate strategies, methods of operation, and resource allocation required to mitigate potential emergencies.
4. Creating a "strategic" or other form of long-term (typically three to five years into the future) planning process that, along with a budget, guides the activities of the organization.
5. Submitting the plan to the appropriate authority having jurisdiction for review and implementation.

The coordination of these actions results in a plan to manage a community's emergency response. This plan, based on facts, will help the community better understand the emergency service organization's goals and help the organization to work toward these goals.

Pre-Emergency Planning

As personnel within the department gain particular information about a risk, they should categorize and develop this information into a database for use when needed and for training—both of which serve the function of hazard analysis and need assessment.

Figure 12.3.2 illustrates how the pre-emergency planning process works, but if data is not documented, communicated (in training and in routine communication), used to access appropriate resources, and formatted to be accessible when needed, the value in its relationship to hazard analysis and needs assessment is lost.

Disaster Plan

One need only look at emergency response information to realize that the emergency service organization responds to more than fires and thus must be prepared for each risk. In fact, in many communities today, the reality is that fires demand fewer responses but larger response capabilities. This can only be defined by a comprehensive threat/risk review and a determination

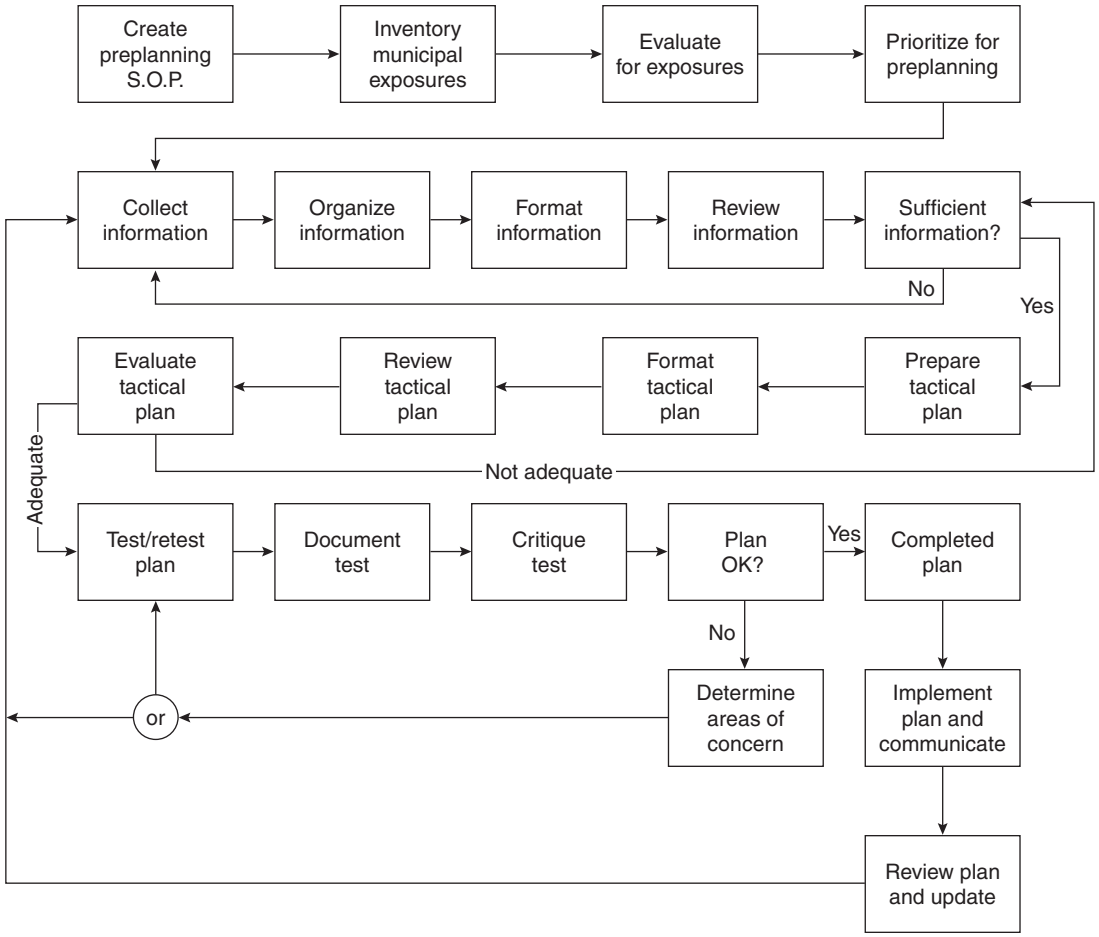

FIGURE 12.3.2 Pre-Emergency Planning Process (Source: W. F. Jenaway, *Pre-Emergency Planning,* ISFSI, Pleasant View, TN, 1996)

of how these risks must be managed. See Section 12, Chapter 12, "Disaster Planning and Response Services," for information on planning for more than fire risk.

ASSESSMENT PROCESSES AND TOOLS

Several assessment processes and tools are available to help in the analysis of hazards and determination of needs. Figure 12.3.3 illustrates related activities that fit into the assessment process, including plans (discussed in the preceding section), processes and tools, and the various stakeholders and assessment information sources.

Accreditation

One such assessment tool is accreditation. The accreditation program managed by the Commission on Fire Accreditation International provides an analytical self-assessment process to evaluate ten categories. Integrated within the ten categories is an expectation for the community to analyze itself by planning zones and for each planning zone to identify the hazards posed, ranking them by potential severity, and, as discussed in a later section, to ensure that the appropriate resources are available to manage the hazards. The accreditation self-assessment process is extremely helpful in determining needs and analyzing risks, even if the emergency service organization does not seek formal accreditation. Once the hazard is evaluated, the resources to manage the hazard can be defined, and an expected service delivery capability—that is, the standard of response cover—can be established.

Standard of Response Cover

The Commission on Fire Accreditation International defines *standard of response cover* as being "those adopted, written policies and procedures that determine the distribution, concentration, and reliability of fixed and mobile response forces for fire fighting, emergency medical service, hazardous materials and other forces of technical response."[5]

The standard of response cover can be considered a tool to accomplish several objectives, including the following:

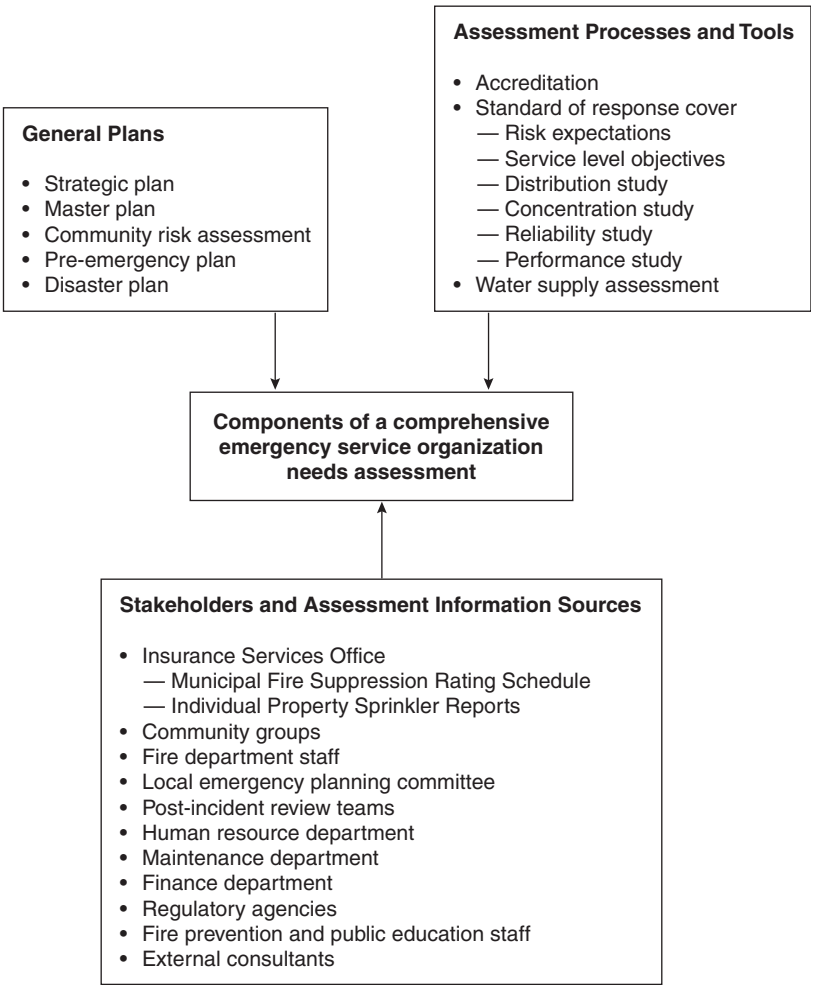

FIGURE 12.3.3 Components of a Comprehensive Emergency Services Organization Needs Assessment

- Evaluating and defining an agency's baseline of operations
- Identifying benchmarks for achieving an agency's goals and objectives
- Determining levels of service for all portions of a community
- Measuring an agency's performance over different budget operational years

Developing a standard of response cover is not quick or easy, but it is valuable to the progressive emergency service organization and should already be in place. The standard of response cover process includes an evaluation of the following eight components, all of which are integrated into a final methodology for standard of response cover (SORC) development:

1. Existing deployment
2. Risk assessment
3. Risk expectations
4. Service level objectives
5. Distribution study
6. Concentration study
7. Reliability study
8. Performance study

Existing Deployment. An evaluation of this component requires the fire department to map, measure, and understand its existing deployment, regardless of how it originated (e.g., insurance services office requirements, community growth, etc.). This will help clarify the department's total reflex and coverage capability.

Risk Assessment. Risk assessment requires the fire department to understand fire flow demand and capability, the probability of an emergency, the consequences to life safety and economic impact, and the estimation and evaluation of risk.

Risk Expectations. Evaluating risk expectations requires the fire department to identify what the community and the emergency service organization want in the form of service, what the outcomes should be, and whether the desired outcomes can be justified. These will assist in establishing critical tasking measures, shown in the following examples:

> *Structure Fire Performance Objective:*
> To stop the development of a moderate fire risk when encountered, conducting search and rescue as required, confining damage to as close to the room of origin as possible, limiting the expansion of heat and smoke damage.
>
> *EMS Risk Objectives:*
> To effectively provide a basic level of medical care at the basic life support level.
> To be on-scene in a timely fashion to:
>
> - Assess and prioritize patient situations
> - Minimize death and disability
> - Stabilize patients to the level of training of responders
> - Intervene successfully in life-threatening situations

Service Level Objectives. Service level objectives require the fire department to assemble and evaluate fire growth and flashover, EMS response needs, special service response needs, reflex and response times of on-scene operations, problem-solving critical tasks, and determining an effective response force. Examples of service level objectives as defined by the Commission on Fire Accreditation International are the following:

> *Service Level Objective:*
> For 90% of all incidents, the first arriving unit shall arrive within five minutes total reflex time (or travel time).
>
> *Service Level Objective:*
> The first arriving unit shall be capable of advancing the first line for fire control or starting rescue or providing basic life support for medical incidents.

Or the service level objective can be even more specific.

Distribution Study. The distribution study component requires the fire department to geographically analyze first-due resources for initial incident intervention to ensure quick deployment in order to minimize and terminate the hazards of average, routine emergencies. The distribution measures are up to the department, but might include percentage of square miles, percentage of equally sized analysis areas, percentage of total road miles in jurisdiction, or some similar measure.

Concentration Study. The concentration study component requires the fire department to look at the arrangement of multiple resource spacing (close enough together) so that an initial "effective response force" can be assembled at the scene within the adopted public policy time frames. The initial effective response force is one that should be able to stop the escalation of the emergency for the risk posed. Concentration measures can be similar to distribution measures.

Reliability Study. The reliability study component requires the fire department to determine the ability to meet performance expectations even if resources are committed on an existing call. This necessitates a historical measure of performance, resource exhaustion, relocation practice, and expectations.

Performance Study. The performance study component requires the fire department to evaluate information and data available, such as the following:

- Existing standards of cover documents
- Risk assessments
- Historical performance
- Cost-benefit evaluations

The information gleaned from evaluating these eight components is then used to develop the standard of response cover.

Water Supply Assessment

The water supply of the community must be known for two basic reasons. For locations subject to fire, knowledge of water supplies is necessary to determine surplus or need. The Insurance

Services Office (ISO) Municipal Fire Suppression Rating Schedule will also provide guidance on the location of hydrants tested during its analysis of water supply needed versus water supply available, indicating if a surplus or need exists for specific locations in the event of fire. (This water supply need can also be determined by the fire department during pre-emergency planning.) If water is needed, the hazard analysis component can be used to then determine where it can be obtained—whether from a static source, from a flowing stream, brought to the scene by a water tender or other means, or obtained from another water supply system—or whether a do-not-fight-the-fire scenario is the reality.

Second, it is important to know the water supply available for individuals providing sprinkler plans for review. It is important to ensure that the available water supply can meet the demand of the sprinkler system being installed, and, if not, how much water is needed and how it will be obtained. The Insurance Services Office (ISO) reports on sprinklered structures, in which the ISO has evaluated individual properties to determine the risk posed and the availability of an adequate water supply, can help provide this information.

In both of the preceding situations, understanding the hazard posed, the amount of water needed, and the amount of water available assists the fire department in hazard analysis and needs assessment.

STAKEHOLDERS AND ASSESSMENT INFORMATION RESOURCES

Insurance Services Office

The Insurance Services Office (ISO) serves the insurance marketplace with statistical, actuarial, underwriting, and claims data; policy language; information about specific locations; fraud-identification tools; consulting services; and information for marketing, loss control, and premium audit. Through its Public Protection Classification (PPC) Program, ISO evaluates municipal fire protection efforts in communities throughout the United States.[6]

ISO provides two primary support roles to the fire department in the area of hazard analysis and needs assessment: the Municipal Fire Suppression Rating Schedule and individual property sprinkler reports (as discussed earlier).

Municipal Fire Suppression Rating Schedule. The municipal fire suppression rating schedule evaluates the following three major areas:

1. The fire department
2. The water supply
3. Receiving and handling of fire alarms

When completed, the process provides an assessment of each area, complete with ratings that are translated into an insurance rate for the community. The process also facilitates the development of "improvement statements," indicating deficiencies and needed improvement in the area of staffing, water supply, equipment, apparatus, pumping capacity, aerial capacity, and so on.

Individual Property Sprinkler Reports. Similarly, ISO will conduct evaluations of structures that contain automatic sprinkler systems (as discussed earlier). These evaluations will determine whether the system is adequate for the hazard it is designed to protect and whether there is sufficient water supply to support the system if it activates. ISO's assessment identifies needs.

Community Groups

One of the most significant sources of input is the community. Not only will individuals in the community communicate their satisfaction, concerns, and expectations, they will be brutally honest. Even if the fire department is providing the best service it believes possible, the "customer" may agree or disagree. For the department to not capitalize on regular communication with the public and build its plan accordingly would be to do without the input of its most important customer. Civic groups, homeowner associations, neighborhood groups, church groups, fraternal organizations, the Rotary Club, the Chamber of Commerce, the Jaycees, and so on can be valuable resources for communication with the community.

Fire Department Staff

Similarly, to not periodically request information on planning from the fire department staff would be a mistake. These individuals know the level of service they are delivering and the hazards they are facing. Seeing the "streets" daily, they have the perspective of knowing what is out there and what is needed to deal with it.

Local Emergency Planning Committee (LEPC)

In many communities, the true hazards are found in the industrial operations of the town. Industrial facilities, often loaded with hazardous materials, pose a significant hazard to the community at large if the hazardous materials are not managed in routine operations, let alone a fire. The local emergency planning committee (LEPC) is charged with obtaining and appropriately distributing information regarding hazardous materials stored and used at various sites. The information the LEPC distributes—be it the chemical name of the hazardous material or the material safety data sheet (MSDS)—provides the critical information needed, including the product name, its hazards, and the control methods during both routine and emergency situations. As it pertains to assessing needs, it may be determined, based on this information, that large quantities of foam concentrate are needed; that extensive spill control or diking equipment should be maintained; or that specialized personal protective equipment is needed. Whatever the need is, it is identified based on the hazard analysis.

Postincident Review Teams

Each incident responded to provides a postincident analysis opportunity to learn about hazards and what is needed to manage incidents involving specific hazards. As each incident recap occurs, the team involved in the response can identify whether it had enough staff to handle the problem, the equipment was

adequate, specialized resources were available to meet the need, and so on. In each instance, based on the hazard posed by the incident responded to, the team can determine whether adequate or inadequate resources were at hand to handle the problem.

Human Resource Department

When looking to determine adequate staffing, adequate deployment, and the probability of hazardous situations resulting in accidents or injuries, the fire department needs to look no further than the human resource department. The human resource department can provide input on whether there is sufficient staffing and whether shortfalls exist because department members are unable to respond due to illness, injury, vacation, or some other factor. Because the human resource department probably has some responsibility for the safety function of the fire department, it can provide valuable information regarding the types of injuries incurred by members and the causes of those injuries. The hazard information can be used to redefine job tasks, procure personal protective equipment, or prohibit doing certain tasks to meet organizational needs.

Maintenance Department

Maintenance personnel for the department, whether building maintenance staff or apparatus maintenance personnel, provide valuable input into the condition of apparatus and facilities and thus any hazards posed by working in the stations and with the apparatus. The input of maintenance personnel is critical in determining when repairs, upgrades, rebuilds, or new acquisitions must be made, based on their educated assessment of the hazards at hand in the stations and on the vehicles.

Finance Department

Similar to the human resource department's input, the finance department provides valuable input on the rate at which funds are being spent and the manner in which spending must be managed to meet needs. If budgeted amounts are being encroached on, overtime may need to be better managed and staff may need to be reduced or redeployed, thereby requiring mutual-aid arrangements to meet the need for adequate staffing at an emergency. The same scenario exists for equipment purchasing and helps determine the input for replacement apparatus purchasing.

Regulatory Agencies

A number of regulatory agencies assist the fire department in the identification and analysis processes so needs can be determined. The Occupational Health and Safety Administration (OSHA) has assisted the fire service through the determination of workplace hazards and the actions necessary to manage them. Similarly, the Environmental Protection Agency (EPA) has established guidelines and provided staff to evaluate hazards and determine needs to be addressed. The Resource Conservation and Recovery Act (RCRA) has provided a similar capability, and many others can be found in the workplace today. In each case, the regulations provide a benchmark of safe operation based on the hazard posed, from which the personnel, equipment, materials, and the like to manage the situation at hand can be determined. The procurement or accessing of those items can then be made.

Fire Prevention and Public Education Staff

Staff performing fire prevention and public education functions provide yet another form of input similar to staff performing fire investigations, inspections, code enforcement activities, and so on. Their ability to evaluate risk in the community and create fire prevention and public education programs solves immediate needs in the community. Whether these individuals are addressing the evacuation capability of a high-rise building and educating residents on how to escape, targeting smoking as a fire hazard based on smoking materials causing fires, focusing attention on the lack of smoke detectors in residences, or addressing some other scenario, they are analyzing hazards, solving problems, and meeting the needs of the customer.

External Consultants

The external consultant plays a prominent role in today's fire protection system. Rarely used until the 1990s, consultants now are involved in several aspects of hazard analysis and needs assessment. Not only have consultants designed a number of the risk analysis systems currently in use in the fire service today, they are responsible for the implementation of these same systems in many communities.

External consultants are often called in because local communities are unable to come to a resolution on a situation. These consultants become the solution to determine where a fire station will be placed, to analyze what types of hazards exist in a community, to provide pre-emergency plans, to evaluate workload, to determine what types of apparatus will be purchased and where it will be placed, and so on. The consultants answer the tough questions that local communities cannot answer, most of which involve some type of analysis of hazards and determination of needs. However, caution must be exercised with the use of consultants. A specific "scope of work" must be developed to ensure that the consultant performs work to meet the objectives of the organization and project, with defined timelines, deliverables, and related costs. In addition, consultants should have expertise in performing the tasks defined in the scope of work and utilize staff experienced in the issue and type of community being analyzed.

SUMMARY

The FEMA/NFPA needs assessment study provides a backdrop of identified nationwide needs and serves as an excellent educational and planning tool. However, a fire department's local needs should be driven by the findings from a comprehensive local hazard analysis in which the department's needs are compared with the results of the assessment study to see if there are gaps or unidentified areas, followed by the development of an action plan. Knowing what resources the department will need can only be determined by understanding the hazards it faces.

Once the hazard type is identified, the number of personnel needed to provide the mitigation services can be determined. The number of personnel responding is also defined by the number and types of vehicles carrying these individuals to the incident, with the final variable being the response time established to achieve the response/performance objective to manage the hazard identified. The emergency services community knows that if needed resources (personnel and equipment) do not arrive in time, the nature of the emergency will grow beyond the ability of the resources to manage the problem. The objective of the hazard analysis and needs assessment is, therefore, to develop the knowledge of the hazards being faced, the nature and amount of resources needed to manage the hazard, and the assurance that the resources can be deployed efficiently and effectively. This chapter provided a look at the components of a comprehensive emergency service organization needs analysis, including various planning processes, assessment and planning tools, and the stakeholders and assessment information sources.

Governmental Relations

Key Terms

call fire fighter, career fire department, city fire department, code enforcement, combination fire department, county fire department, emergency medical services, fire bureau, fire district, fire investigation, fire prevention, fire protection district, fire service, fire suppression, mutual aid, professional qualifications, public fire and life safety education, public fire department, volunteer fire company, volunteer fire department

This chapter provides an overview of the elements involved in organizing, administering, and managing agencies that provide fire and rescue response services.

Today's fire protection agencies have their roots in centuries of community efforts that attempted to prevent hostile fire and limit the damage it caused. From the start of night watches and bucket brigades through the first organized fire-fighting forces, those efforts have evolved into the amalgam of fire departments and other fire-fighting agencies that serve the United States and Canada today.

Fire protection in the United States is provided by more than 26,000 fire departments that are organized in different ways to meet their communities' specific needs.[1] Most often, public fire protection is a function of local government, although state, provincial, and federal authorities have also organized fire agencies, primarily to provide wildland fire protection on public lands or structural fire protection for government property. Similarly, large industries often organize or contract with private fire departments at their industrial complexes. The organization and objectives of fire departments vary according to available resources, ranging from simple to complex.

Most fire departments were administered by clearly defined organizational structures and systems before such techniques were widely applied to industry and business with the advent of the industrial age. Fire departments developed systems that broke down responsibilities at a fire into tasks that were assigned to engine and ladder crews. Each person on an apparatus was responsible for performing certain functions in a designated sequence so that each team operated as a coordinated unit, effort was not duplicated, and the common goal—usually to rescue trapped occupants and extinguish the fire—was achieved.

Most public fire departments are structured around the traditional mission of fire suppression. Many now also emphasize fire prevention and public education as more effective ways to protect life and property. Most have taken on other roles in their communities as well, particularly emergency medical and technical rescue services. They may also provide hazardous materials response, building and facility plans review, fire cause determination, and fire code inspection and enforcement.

Fire departments must be organized according to a comprehensive and coordinated plan if they are to operate efficiently and effectively. The organizational plan should clearly outline the roles and responsibilities of all line and staff personnel, their interactions with each other, and their relationship to the total organization.

Emergency response services are usually provided through a decentralized system of fire stations that are strategically located throughout the community and house a range of engine, ladder, rescue, and other companies as local needs demand and resources permit. Fire departments may be staffed by career, part-time, or volunteer personnel, or any combination of these, according to the manner in which the department has developed.

Rebecca F. Denlinger, CFO, is fire chief of the Cobb County (Georgia) Fire and Emergency Services, Marietta, Georgia. She is a member of the International Association of Fire Chiefs; the Board of Directors of the National Fire Protection Association; the Georgia Homeland Security Task Force; Women in the Fire Service, International; Women Chief Fire Officers Association; and Georgia Association of Fire Chiefs. In 2004, President Bush appointed her to serve on the National Infrastructure Advisory Council.

Neighboring fire departments traditionally help each other when major emergencies or simultaneous events overwhelm one department's response capacity. To be effective, mutual-aid agreements should be carefully drafted and agreed on by all parties involved, and should take into consideration all factors that affect the agencies' ability to function in a joint effort. Mutual aid may extend beyond emergency response into the realms of training facilities, apparatus purchase, and long-range planning.

No fire department can operate well without an effective communications system that receives alarms from the public, dispatches units to the scene and coordinates their activities, and also provides for nonemergency communications for the department. The size and configuration of this system, the personnel staffing it, and the technology used, will vary considerably depending on the size of the agency and the number of emergency responses it makes.

Fire departments may depend on career, call, or volunteer personnel, or any combination of these. The type of personnel a department uses depends on financial resources, the availability of call or volunteer fire fighters, the number of emergency calls received, the range of services the department provides, and any preferences expressed by the community as to the type of fire department it wishes to have. Staffing levels and scheduling must be arranged to comply with budgetary constraints and provide 24-hour coverage with maximum efficiency.

Effective fire department management requires decisions that are suited to meet the needs of the particular community through the efficient practice of organizing, planning, directing, controlling, and analyzing.[2] One key responsibility of management is preparing, submitting, and adhering to the budget for the fire department. Fire department managers must fully understand the budgeting process used by their jurisdiction and be able to develop a budget that is fiscally manageable for the jurisdiction while at the same time allowing the fire department to perform the roles expected of it. The responsibility for personnel management and for achieving cooperation among government agencies and political bodies requires a collaborative management style and a diplomatic temperament.

Fire department equipment and supplies, procured through the jurisdiction's purchasing department, may either be requisitioned from the purchasing agency or, for specialized items, purchased through a bid process. Fire department managers must be knowledgeable about preparing purchasing specifications and interpreting the bids received.

A fire department will be most effective if it develops and maintains good working relationships with other local, state, and federal agencies whose mission overlaps or supports its own. This interaction includes local police and other law enforcement agencies, the building and water departments, and many other agencies of local government. State and federal agencies concerned with transportation, domestic preparedness, and emergency management are also key partners and allies for fire departments of all sizes and types.

EARLY FIRE SUPPRESSION AND FIRE REGULATIONS

Today's public fire departments evolved from groups of citizens who banded together to warn of and limit the spread of a threatening fire. To provide a visual context for this section, Figure 12.4.1 sketches a time line for the history of modern fire protection in the United Kingdom and the United States. The earliest efforts involved the organization of night watches. Next to develop were fire prevention regulations and the appointment of individuals charged with enforcing those regulations. In cities and towns, groups organized to salvage belongings during or after a fire. These groups were followed by volunteer fire-fighting companies, who banded together to operate pumps to extinguish fires. Eventually, fire fighters and officers were appointed and paid to operate full-time fire departments.

One of the earliest accounts of an organized effort to provide fire protection is from 24 B.C., when a "vigil," or watch service, was created in Rome during the reign of Augustus. Regulations for monitoring and preventing fires were issued, giving the vigils duties similar to today's fire marshal's office or fire prevention bureau. The vigils were also provided with fire-fighting tools and equipment, such as buckets and axes.

Another early fire protection regulation dates to A.D. 872, in Oxford, England, when a curfew was adopted requiring hearth fires to be extinguished at a specified time. After 1066, William the Conqueror established a general curfew law for England that was apparently aimed not only at fire prevention but also at preventing revolt.

Fire Brigades in the United Kingdom

Prior to 1830, night watches and other services that used fire apparatus operated without any legal authority. *The History of the British Fire Service*[3] mentions an early exception: in 1643, during the English Civil War, a company of 50 women was organized to patrol the town of Nottingham at night and raise the alarm in case of fire.

Following the devastation caused by the Great Fire of London in 1666, several insurance companies created fire insurance brigades. Each brigade fought fires only in properties insured by its company and had no lifesaving responsibilities. The brigades operated without statutory authority or obligation, and it was the insurance offices, not government agencies, who decided where the brigades would be located. In London, the insurance company fire brigades in 1833 were consolidated into the London Fire Engine Establishment, which was taken over by the Metropolitan Fire Brigade in 1865.

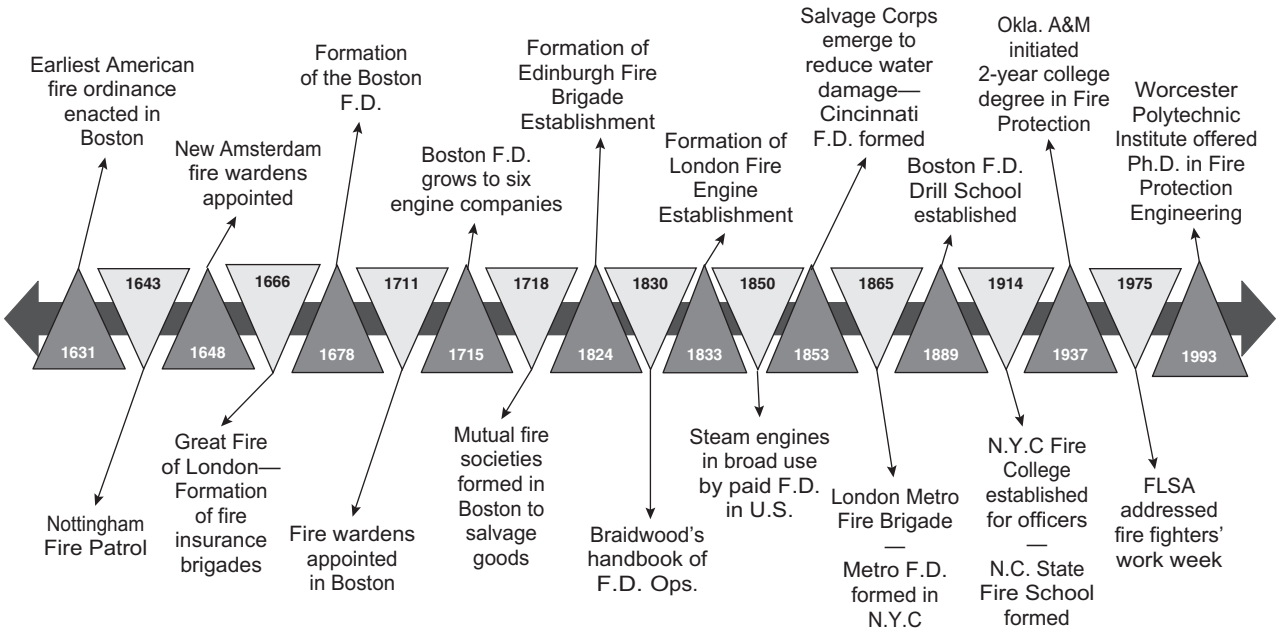

FIGURE 12.4.1 Time Line of the History of Modern Fire Protection in the United Kingdom and the United States (Courtesy of Stuart Shannonhouse, Resource Officer, Cobb County [Georgia] Fire and Emergency Services)

Edinburgh's Fire Brigade Establishment was the first public fire service to develop modern standards of operation. A surveyor named James Braidwood was appointed chief of the brigade. He chose 80 part-time aides between the ages of 17 and 25 and required them to participate in regular drills, including night training. In 1830, he wrote the first comprehensive handbook on fire department operations, which included 396 standards and set forth for the first time the kind of service a good fire department should deliver.

Fire Protection in Early America

The first fire ordinance in the New World was adopted in Boston, Massachusetts, following a disastrous fire in 1631. The ordinance prohibited thatched roofs and wooden chimneys, and was enforced by the colonial city's board of selectmen. In 1648, New Amsterdam (now New York City) appointed five municipal fire wardens with fire prevention responsibilities. This is often considered to be the origin of the first public fire department in North America.

After another conflagration in Boston, which occurred in 1679, destroyed 155 major buildings and a number of ships, laws were adopted requiring stone or brick walls for buildings and slate or tile roofs for houses. That fire also led to the establishment of the first paid municipal fire department in North America, if not the world, in 1678. The town imported a "fire engine" from England—essentially a small wooden box with carrying handles, a pump, and a small hose—and employed 12 fire fighters and a fire chief, Thomas Atkins.[4] From the start, jurisdictions in Massachusetts used paid fire fighters on an on-call basis, as contrasted with the unpaid volunteer fire companies that later were organized in other colonies.

Colonial communities required each household to keep two fire buckets at hand, and when the church bells rang an alarm, to report to the fire to form lines for passing water from wells, springs, or other water sources. As late as 1810, Boston citizens were subject to a $10 fine for failure to respond to alarms with their buckets. When hand-pumped fire engines were first obtained in the 1830s, teams of citizens were organized to operate them, and the bucket brigade supplied the pump's tank. The laws in a number of states and provinces still impose penalties on citizens who refuse to assist in fire-fighting operations upon orders from fire officers. For example, in Toronto, Ontario, the Municipal Fire Code, § 79-15 Refusal to Assist reads:

> If required to do so by the fire department, no person present at a fire shall refuse to assist in:
>
> A. Extinguishing fires;
> B. Pulling down or demolishing buildings or structures to prevent the spread of fires;
> C. Crowd and traffic control; or
> D. Other reasonable ways.
>
> [Amended 2000-10-05 by By-law No. 869-2000]

Fire wardens, who responded with their staff members to fires and supervised bucket brigades, were appointed in Boston in 1711. By 1715, Boston had six fire companies with British-made engines.

Mutual Fire Societies. According to many accounts, these companies were the forerunners of salvage corps. The first mutual fire societies were formed in Boston in 1718 when a group of affluent Bostonians organized to assist each other in salvaging goods from their homes and businesses affected by

fire. Each person's equipment included a bag in which to collect valuables, a screwdriver, and a bed key to disassemble and remove beds from burning buildings. (At the time, beds were prized and valuable possessions, not commonly owned.) These societies were active for about a century, until fire insurance became generally affordable.

Salvage Corps. By about 1850, the major cities of the United States had organized paid fire departments equipped with steam engines. Insurance interests in nineteen of these cities formed salvage corps whose job was to reduce water damage at fires. Over time, the increasing cost of operating these corps, combined with improved fire-fighting procedures, made them obsolete, and they were disbanded. Today, public fire departments carry out the function of salvage operations at fires.

Growth of Paid Fire Departments. A lack of discipline within volunteer fire brigades, coupled with their resistance to using fire pumps and steam engines, led to the organization of paid fire departments. Following disorder and occasional violent confrontations between members of competing volunteer fire companies at fire scenes, a paid fire department with horse-drawn steam engines was placed in service in Cincinnati, Ohio, on April 1, 1853. In 1855, two steam pumpers were delivered to New York City, but the volunteer fire fighters refused to use them. Ten years later, the Metropolitan Fire Department, using steamers, replaced New York City's volunteers.

Duty Systems. Until World War I, paid fire fighters worked a continuous-duty system with limited off-duty time. By World War II, most paid fire departments had adopted a two-platoon system, which allowed additional days off and reduced the fire fighter's average number of hours worked per week. Hours worked per week have continued to decline for U.S. fire fighters, although in most jurisdictions they continue to work more hours per week than other public or private workers. Many fire fighters remain on a 24-hour-duty work shift. The 1975 Fair Labor Standards Act reduced to 53 the maximum hours of work per week for a fire fighter: hours worked in excess of the maximum must be paid at a higher wage rate. Additional discussion of many of the numerous duty systems used by fire departments appears later in this chapter.

Training. In 1889, the Boston Fire Department established the first fire fighter drill school, delivering basic training to its members. Uniform company drills were also performed, promoting the task allocation system that remains in use in well-organized fire departments. Most fire departments now provide some form of basic training to their members, and many have sophisticated training divisions that develop individual and company skills in fire suppression, emergency medical services, and technically specialized areas such as hazardous materials response; trench, high angle rope, confined space, and structural collapse. The incident command system, a staple of fire service training for decades, has been adapted to meet the command and control demands of all emergency events and is incorporated into the National Incident Management System (NIMS). NIMS is taught across the United States as part of local, state, and national fire training curricula.

The first fire officer training institution was established in New York City in 1914, when the FDNY Fire College began providing advanced training to its fire officer corps. Today, officer training is a high priority in many career and volunteer fire departments. Quality officer training is available through commercially available computer-based products, consulting companies that deliver training on site, Internet programs provided by the U.S. Fire Administration, and at private, local, state, and federal training institutions around the country.

Also in 1914, the first state fire school was organized in North Carolina. The first state fire schools for volunteer fire fighters were started in Illinois and Iowa in 1925. Today, every state reports offering some level of training service to its fire fighters.[5] Funding for training programs related to weapons of mass destruction and other large-scale events has grown since the first courses that were funded by the Nunn-Lugar-Domenici Act in the 1990s. Such funding is commonly allocated to state or regional initiatives in order to prepare local responders, including fire fighters, to respond to disasters.

College degree programs related to the fire service first appeared in the United States in 1937, when Oklahoma A&M (now Oklahoma State University) initiated its two-year (later four-year) fire protection degree. More than 200 institutions in the United States now offer two-year degrees in fire protection through a variety of methods, including online and other distance learning options as well as resident programs. Several colleges offer four-year programs of study leading to degrees in fire technology or fire service management, and the Worcester Polytechnic Institute and the University of Maryland at College Park offer masters degrees in fire protection engineering. Worcester Polytechnic Institute has also offered a doctoral degree in fire protection engineering since 1993.

TYPES OF FIRE DEPARTMENTS

Career Versus Volunteer Fire-Fighting Personnel

As of 2006, an estimated 313,300 career fire-fighting personnel and frontline supervisors and 823,650 on-call or volunteer fire-fighting personnel served in the United States.[6] The principal distinction between the two is that career personnel are assigned regular periods of duty and are compensated on a regular basis, whereas on-call or volunteer personnel are not normally required to be available except for meetings, training sessions, and emergency responses. They may or may not receive compensation for their services.

Most towns of 25,000 or more employ career personnel and many use auxiliary personnel or volunteers to supplement their regular forces. Other cities and towns use combinations of career, on-call, and volunteer personnel. Some communities have a career fire chief, officers, and/or apparatus operators but rely on on-call or volunteer personnel for the rest of their staffing. Other communities use career personnel only during the daytime and rely on on-call or volunteer personnel at night.

Many fire departments—career, combination, and volunteer—provide an acceptable level of service to their respective communities. The success of their operation does not depend on

whether the personnel are paid or unpaid but on their individual and collective ability to perform and to accomplish department objectives. There are no simple guidelines that mandate the type of personnel a fire department should use. The decision must be made at the local level after carefully analyzing all pertinent factors.

Factors Influencing a Fire Department's Personnel

When a community decides to start providing fire protection, several factors influence the type of personnel the new fire department will use. These factors are (1) the financial resources of the community, (2) the availability of on-call or volunteer personnel, (3) the frequency of fire incidents, (4) the range of services expected from the department, and (5) the type of department preferred by the community.

The Community's Financial Resources. The financial resources of smaller communities will often dictate that the department be composed entirely of volunteer personnel. Salaries normally consume a large percentage of a fire department's budget, and the community may have only enough money available to purchase and maintain apparatus and equipment.

On-Call or Volunteer Personnel Availability. Some communities may find they do not have enough people willing and able to serve as volunteer fire fighters, and that the fire department must be staffed fully or partially by career personnel. This situation happens most often in rapidly growing suburbs near major cities. Originally these outlying areas were composed of small communities that provided a climate suitable for volunteer departments. As times changed, however, more and more residents became employed outside the community and were thus unavailable for emergency response in the daytime, or even to participate in the fire department at all. At the same time, rapid suburban growth increased the demand for fire protection and rescue services. As a result, many of these once-volunteer fire departments have added the services of career personnel.

Effect of Incident Frequency. Call volume, or the frequency of emergency response, will often determine the type of personnel chosen to staff a fire department. Densely populated, congested areas, especially those with extensive commercial or industrial development, will usually need fire and rescue services more often than more sparsely settled, largely residential areas. A high level of incident frequency will tend to overwhelm a volunteer operation unless the department has a large membership and the workload can be apportioned to reduce the commitment required of each individual.

In order to track the effects of call volume and the efficiency of volunteer response, the fire department should keep accurate statistics that include the number of volunteers responding per call and the length of time it takes them to respond. Weekends and weekdays should be tracked separately. Monitoring this data will help a community decide when it needs to hire career personnel in order to maintain the level of service desired.

Range of Department Services. The variety and frequency of incidents that occur in the community will determine the range of services the fire department provides. Most departments offer some level of rescue service, as extrication and emergency medical response are universal needs. The extent and type of development in a locality, and the existence of any natural hazards, also influence the scope of services offered by a fire department. In addition, the presence of a target hazard or particular critical infrastructure may also affect the range of services expected of a department.

Type of Department Personnel Preferred by the Community. Communities often have preferences for the type of personnel who staff their fire departments. In some instances, the volunteer fire department serves as a focal point of community activity, and the community is satisfied with the level of service provided by volunteer staff. In others, the career department is a well integrated part of the community. In every case, fire department personnel should be selected, trained, and equipped to provide the best possible service for the community.

ORGANIZING FIRE SERVICE AGENCIES

Most public fire service organizations in North America are established by local governments or by independent local entities created to provide public fire protection. Local government is responsible for organizing fire protection for the vast majority of people in North America. These fire protection services vary widely in character, from volunteer departments with little revenue to full-service agencies that employ career fire fighters and civilian staff. They also differ widely in their source of jurisdictional authority.

One of the most common types of fire protection agencies is the *city fire department,* a department of municipal government. The head of the department is responsible to the chief administrative officer of the municipality, typically the city manager or the mayor, or in some cases to a fire commission. Most large municipalities, as well as many small communities, operate this type of organization.

Less common is a *fire bureau,* which is usually a division of a department of public safety. In this type of organization, the public safety department head manages the administration of several important operations, including fire, police, and 9-1-1 communications center services. Since September 11, 2001, the public safety agency concept is growing in acceptance and use, as communities recognize the value of leveraging expertise of the various public safety disciplines to better effect.

The *county fire department* is gaining acceptance in many areas. In this type of organization, suburban municipalities join together to enjoy the benefits of a large, professionally administered public fire department with staff and service facilities that they could not afford individually. The transition to a county fire department often begins when a county fire prevention office and fire communications system are put in place; fire departments (often staffed by volunteers) initially remain autonomous for fire suppression purposes. Gradually, more functions are assumed by the county organization as the cost effectiveness and organizational expedience win attention and favor.

Another type of public fire protection is the *fire district,* which is organized under provisions of state or provincial law. It is, in effect, a separate, independent unit of government with its own governing body composed of commissioner, trustees, or other officials, and is commonly supported by a tax levied throughout the district. A fire district is usually organized following a vote of residents in the proposed district. The fire district may include portions of one or more political subdivisions, such as townships.

A fifth common type of fire protection authority is the *fire protection district,* which in some states is a legally established, tax-supported unit that contracts for fire protection from a nearby career (or in some instances volunteer) fire department. This arrangement provides timely fire protection for rural or suburban areas that might otherwise find it difficult to maintain effective and experienced fire-fighting forces. Contracts with a fire protection district can be a valuable source of financial support to the small municipal fire departments that participate, as well as providing fire apparatus for use in rural areas.

Another type of public fire service organization is the *volunteer fire company* or *association* that raises a portion of its funds through public activities and sometimes, subscriptions. Tax dollars comprise the majority of the funding available to volunteer fire agencies, and most of the tax dollars come from local tax sources.[1] Donations of equipment may also be received from interested units of government. Many volunteer fire associations maintain excellent equipment and facilities and also provide a location for various community activities. Certain volunteer fire companies prefer to retain independence from government, especially when purchasing equipment. It is common, however, to find independent fire organizations that are coordinated through special governmental advisory boards.

ORGANIZING FIRE-RESCUE DEPARTMENTS

In recent years, the role of the fire service in many communities has expanded far beyond its original mission of fire suppression. The term *fire department* does not begin to cover the many services progressive organizations now provide to their communities: a far broader public safety role has become the "business" of the modern fire department. Twenty-first-century fire services increasingly emphasize such proactive elements as fire prevention, code enforcement, public education, pre-incident planning, and interagency training and coordination. Citizens depend on the fire department to protect them from any emergency: fire, entrapment, explosion, building collapse, and natural disasters and other incidents that can result in mass casualties, such as biological, chemical, and radiological events. Fire departments respond to these demands with a growing range of capabilities, such as hazardous materials, technical rescue, and emergency medical services. In addition, fire-rescue departments typically are now involved in planning and training for response to disasters that exceed the capabilities of public safety agencies in the areas in which they occur.

Each community establishes the array and level of services it expects of its fire-rescue department, and these expectations will change over time. In this dynamic environment, a successful department is one that can effectively and efficiently satisfy these changing community needs. The leadership challenge for the fire service is to determine how the department should deliver needed services and to develop an organization that can manage and administer its operations. Fire chiefs must be prepared to implement changes in their department's service delivery mission that are dictated by governing boards. Fire fighters must be ready to train for and deliver those services.

Some communities have choices in selecting from companies and departments that can deliver the desired services. In such situations, the competitive edge goes to the agency best organized to deliver a range of effective services most efficiently.

Fire Prevention and Code Enforcement

Fire prevention and code enforcement are major areas of responsibility for the fire service. As fire departments have professionalized, they have tended to develop their fire suppression capacities to a much greater extent than their fire prevention abilities. Because emergencies cannot be eliminated or predicted, community protection depends on a reliable and effective response force. As a result, most of a fire department's resources are dedicated to responding to emergencies after the fact; typically, only a small percentage of resources are dedicated to preventing those emergencies. As technologies to improve the prevention, early detection, and automatic suppression of fires develop, more emphasis on proactive prevention, enforcement, and education programs within fire departments will better position communities for a safer future.

Adoption of Building Codes. The local fire department should lead the way in urging the community to adopt a complete nationally recognized fire and building code. Most fire departments have adopted one of the model codes developed by regional and national standard development organizations. These model codes can be amended to adjust for local concerns and needs. Working closely with community building and development officials, fire service leaders can tailor codes and permitting processes to support requirements for delivery of fire and emergency services. Particularly in areas that experience "build out" and consequent in-fill and redevelopment, codes should address the specific issues of street width, turnaround space for apparatus, distance to hydrants, and factors that affect service delivery.

Ideally, fire departments should assign full-time personnel to review plans and inspect buildings and fire protection systems. The widespread adoption of performance-based codes requires professionals, preferably fire protection specialists or engineers, who are trained to evaluate systems plans for adequate performance during the permitting process.

In the past, most fire prevention activities were carried out by a small nucleus of full-time specialists. The size of the fire department and the community determine the need for, and feasibility of, full-time prevention personnel. The prevention responsibilities of the fire department, however, go far beyond what a small cadre of specialists can perform. Many departments now involve fire fighters in inspections and code enforcement. All fire department personnel must recognize that fire safety

education and fire prevention are major parts of a fire fighter's responsibilities.

Pre-Incident Planning. Pre-incident planning is a necessary adjunct to tactical operations and should aid in efficiency, reduce fire loss, and help provide an optimum level of emergency service. Pre-incident plans are desirable for all target hazards, for special risks, and for large complexes. (Standard operating procedures are usually sufficient for single-family dwellings and smaller occupancies, as well as routine multidiscipline events.) The planning process must involve all fire suppression personnel on a continuing basis. Pre-incident plans should complement standard operating procedures by familiarizing personnel with unusual buildings and facilities, and with processes and products that pose unusual hazards.

Pre-incident plan information should be presented in a standard format and made available to help the incident commander manage fires or other emergencies at the site. (For an example, see the *Fire Protection Handbook,* Section 12, Chapter 17, "Pre-Incident Planning for Industrial and Municipal Emergency Response" and NFPA 1620, *Recommended Practice for Pre-Incident Planning.*) Plans should be sufficiently flexible to allow for varying conditions and should use the framework of the department's standard operating procedures as a basis. Plans that are too rigid or complex may handicap an operation more than they help it.

Fire chiefs and department staff should encourage and support multidisciplinary planning. Local response partners such as law enforcement, EMS, and public health, should be involved in the process of developing plans for large-scale emergencies. This cooperation will enhance both the quality of the plans and the preparedness of the public safety community. In situations that require unified or area command, incident management will be more effective if the incident commander is familiar with the roles and responsibilities of allied agencies. During the planning process, all relevant response agencies, including utility providers and environmental agencies, should be involved in identifying and targeting critical infrastructure in the community. Planning for response to incidents involving weapons of mass destruction should be done by a group that includes planners from all response agencies. Personnel from all such agencies should become familiar with, and have access to, the resulting plans.

The following steps are part of the pre-incident planning process:

1. *Information gathering.* Pertinent information, such as building construction features, avenues of egress, occupancy, exposures, utility disconnects, fire hydrant locations, and water main sizes, which might significantly affect fire fighting or allied agency operations, must be collected at the selected site.

2. *Information analysis.* The information gathered must be analyzed for what is pertinent and vital to fire suppression operations, so that a plan can be documented in a format that can be used during the incident. A pre-incident plan usually includes a site plan or map; floor plans and diagrams identifying pertinent features, including vertical avenues of fire travel in multistory buildings; hazards and fire control equipment; area maps indicating various staging and rally points; and additional text outlining special problems, specific tactics, hazardous contents, and information on parties responsible for specific areas.

3. *Information dissemination.* Pre-incident plans should be assembled and distributed in a standard format for easy use on the emergency scene. Plans may be maintained on paper and carried in fire apparatus, microfilmed and used with viewers in command vehicles, or stored in computer systems accessed by mobile data terminals or fax machines. Plans should be clearly dated and revised periodically, with revised plans disseminated on a systematic basis.

4. *Class review and drill.* Any fire company that might respond to an incident at a site that has a pre-incident plan should review the plan on a regular schedule. If possible, periodic drills and familiarization tours with all the companies involved should be scheduled on the property. All concerned agencies should periodically review pre-incident plans.

Fire Investigation

Competent fire investigations, performed to determine fire cause as well as to detect criminal activity, can identify factors that can lessen the number and severity of fires in the future. Information gained through investigations is a valuable tool in improving fire prevention by pointing out needed code revisions, updating public education program content, and planning for future fire protection and response needs. In addition, a thorough investigation of all incendiary or suspicious fires is a powerful arson deterrent. Adequately trained and equipped personnel should be available to investigate all fires of unknown or suspicious cause.

Community-Based Safety Education

Fire departments inevitably respond to tragedies. The challenge is to prevent these tragedies from happening in the future, and the most effective place to do this is at the community level. Fire stations have always had a community profile, yet they often have a great deal of unrealized potential. The neighborhood fire station can be a key delivery point for fire and emergency prevention efforts, and fire fighters in the stations can effectively deliver community fire prevention programs. By effectively using demographic and fire experience data, a department can customize prevention education to the needs of individual response territories. The central public education staff can then focus on delivering programs in schools, senior centers, and other facilities where at-risk populations congregate. This staff can also coordinate the prevention initiatives of the fire stations.

Although community fire education has been a part of the fire service for many years, it has only recently emerged as a major component in fire protection. National conferences that champion the public education effort have been introduced in Oklahoma and Texas. The National Fire Protection Association's (NFPA) *Learn Not to Burn*® program is one component that has been successful in reaching and educating schoolchildren on fire safety issues. "Fire safety houses," portable model homes transported on trailers, have proven to be valuable teaching tools in many communities.

To complement the fire service's expansion into emergency medical services, many fire safety education programs are now successfully incorporating NFPA's *Risk Watch*® program. This curriculum goes beyond traditional fire prevention to include accident and injury prevention. In Canada and some areas of the United States, the *community safety village* concept has been developed as a tool for delivering a full menu of public safety education programs to the community. Fire safety programs are integrated into the curriculum of these learning and education centers.

Public Relations and Community Partnerships

Fire departments supported by public funds need public support and interaction to be effective. Only with the public's interest and cooperation can fire protection and prevention programs be fully effective and the fire department operate successfully within its particular political environment. Without community support, it can be difficult for the department to obtain the needed funds to operate at the required level. Accordingly, public information and community service programs, or public relations, are an important fire department management activity.

Good public relations programs keep the public informed of departmental activities. Relations with the news media should be cordial, and the fire department needs to cooperate with representatives of the media, who can be of invaluable assistance in pushing out messages to the public. This is not always easy, because suburban fire departments are often located in communities that depend largely on a metropolitan press, and items that might be of interest to local citizens may not be newsworthy for the entire region. It may be effective to explore options, such as local weekly papers or local-area editions of metropolitan papers that do have local correspondents.

The amount of publicity fire departments get seems to vary greatly among geographic areas. In some areas, citizens are traditionally interested and involved in local governments and their fire departments, whereas in other areas, fire departments are not considered newsworthy. The latter situation obviously requires a greater effort in order to get fire-related information to the public. In general, communities whose citizens regularly participate in town affairs seem to give fire departments better support. Communities with substantial numbers of low-income residents subject to fire dangers are often most concerned with the adequacy of fire department services.

Public education information can be passed through local government publications and regional periodicals, as well as through inserts in utility bills and department newsletters. Fire departments should develop safety and awareness campaigns to target specific communities. Resourceful and energetic public relations officers will find numerous avenues for spreading public information.

News personnel should be given accurate information promptly at incident scenes. Most fire departments specify that only the incident commander or a designated public information officer (PIO) should give out information. This practice should prevent the release of conflicting, inaccurate, or ill-advised statements that might be misleading or could compromise fire investigations. The PIO position is a designated function in an effective incident command system.

Some large fire departments have a designated PIO who also functions as a public relations officer, giving the press all possible cooperation and information regarding the department's activities. In smaller fire departments, the fire chief may perform this function. Staff public relations officers often report directly to the fire chief because of the need for regular communication between the two. The public relations officer may act as a communications or media adviser to the chief, and the chief should keep the public relations officer apprised of all potentially newsworthy department decisions and activities.

Emergency Medical Services Delivery

Emergency medical service (EMS) has become an important function of many fire departments. Although fire departments have operated ambulance services for decades, the major growth in this area has occurred since 1970, stimulated by higher standards for patient care, training, and associated equipment. Increased public, medical community, and local government interest in delivery of emergency medical service has prompted many fire departments to increase their participation in EMS; consequently, the quality of EMS delivery has improved greatly.

In most fire service organizations that provide first-responder or transport EMS services, EMS runs account for 60 to 75 percent of their emergency call volume. This growing service demand has changed the business definition of fire departments throughout the country. Many fire department managers and organized labor groups link the competitiveness of their organizations with emergency medical service delivery.

The addition of the EMS mission to a fire department is a natural extension of responsibilities and can be managed so as to increase organizational productivity without a negative impact on fire protection. Fire service personnel are already oriented toward delivering emergency service and assisting citizens. Fire personnel and apparatus are housed in fire stations that are decentralized to provide rapid response to all areas, served by communications systems that receive emergency requests from the public and dispatch assistance without delay. These two elements provide the foundation of effective EMS delivery.

Increasingly, the emergency medical services delivery system may be solely the responsibility of the fire department, from first responder providing basic life support to advanced life support with paramedic-level care, including transport (Figure 12.4.2).

Nationwide, fire department emergency medical service calls outnumber fire alarms by more than six to one. Even though responding to EMS calls places an increased workload on fire companies, the combination of the two missions has proven very efficient in many jurisdictions. Providing basic EMS equipment on engine and ladder companies with emergency medical technician (EMT)–certified fire fighters enables these units to handle most life-threatening situations. In most communities, the fire department is also the lone provider of extrication and rescue services, provided via the same apparatus and personnel. Paramedics responding on ambulances or rescue

FIGURE 12.4.2 Emergency Personnel Loading a Patient into an Emergency Care Helicopter

vehicles generally back up first responders and EMTs. In some fire departments, all personnel are trained and certified at the EMT or EMT-Intermediate level, and dual-role paramedics are assigned to engine and ladder companies.

Hazardous Materials

Storing, using, transporting, and disposing of hazardous materials and hazardous waste create significant safety risks. Changing federal regulations, along with increased sensitivity to environmental protection, have created a new service demand in many communities. In many cases, the fire department is the lead agency in responding to hazardous materials incidents.

Many fire departments find they have neither the trained personnel nor the funds to support a full hazardous materials emergency response team. Regional hazardous materials response teams have been organized within counties and parishes, and in some cases across greater areas, in order to combine available resources and personnel to best effect.

Fire departments should either lead or participate in the process of gathering and organizing information, identifying risks, and planning for hazardous materials emergencies, as well as in regulating the storage, use, transportation, and disposal of hazardous materials and hazardous wastes. Federal law commonly known as the "Community Right-to-Know" provisions (the Emergency Planning and Community Reporting Act: Title III of the 1986 Superfund Amendments and Reauthorization Act) requires that facilities that hold chemicals above certain quantities report what they have on the premises to the local fire department. Fire departments should receive these reports and use them to inform effective pre-incident plans and to budget for appropriate equipment.

Rescue Services

The level and sophistication of rescue services offered by fire-rescue departments has expanded significantly in recent years. In many communities the local fire-rescue department is the lone provider of extrication services. Heavy rescue and structural collapse services are also increasingly available via the local department. More technically complex forms, such as trench (Figure 12.4.3), confined space, and high angle rope rescue, are also more common. The amount and type of equipment that has been procured through federal Homeland Security funds has made these various rescue services more prevalent than ever before. Fire departments should evaluate the potential for the need for rescue services and pursue the equipment, the training, and, if necessary, the staff to make possible the provision of the appropriate programs to the community.

Management Improvement Systems

A number of systems have been developed to improve management decision making through teamwork and enhanced working relationships. Such systems include organizational development, quality circles, and quality assurance and service improvement programs. Although these have been developed primarily for the private sector, they can also improve how public sector organizations are managed.

Progressive organizations have augmented the traditional, authoritative, fireground chain-of-command management style with private industry processes that focus on quality management. Quality management stresses a total organizational approach that makes the quality of service, as perceived by the customer, the driving force for the organization. The purpose is to improve the quality of service, productivity, and (increase) cost effectiveness through clearly stated, well-developed goals and measurable objectives. These goals and objectives are identified and accomplished by increasing the participation of both managers and workers in the organization's planning and decision making.

Every fire department should have a *mission statement* regarding the scope of services it provides. The mission of fire departments—the menu of services provided to the community—may be very similar from one part of the country to another. Many progressive organizations develop their mission statements by first creating a *vision* that states where they are headed and where they believe the future lies for their

FIGURE 12.4.3 Rescue Effort at Legacy Park, Lawrenceville, Georgia (Source: Courtesy of Cobb County Fire and Emergency Services)

organization. Many fire departments also develop a set of *values*. Values say something very individual about an organization and may reveal what is most important to the department and to the community. In addition, *goals* should be established for the department, along with measurable objectives for each level of the organization.

Information Management Systems

The information generated by a fire department—particularly in the areas of fire protection, EMS delivery, personnel, and fiscal management—should be systematically collected in an information or records management system (RMS). An effective RMS can then be used to analyze the data collected in ways that are useful to department managers. Data analysis is a powerful tool for monitoring the effectiveness of programs and services and for guiding planning. The information can be displayed in a variety of ways, including charts, graphs, maps, and reports.

Information management systems for use by fire departments are available commercially in off-the-shelf and custom formats, or can be developed locally. Sophisticated systems can interface with other computer applications, such as computer-aided dispatch and geographical information systems. Making use of the data captured in such systems requires trained personnel who have sufficient time to analyze, collate, and prepare data for management to interpret.

Some systems collect data regionally and nationally; for example, NFPA analyzes and prepares statistical reports from a national system of data collection. Many standard reports (such as *U.S. Fire Fighter Deaths*) and "customized analysis" are available from the NFPA Fire Analysis and Research Division. This information is available for use by individual departments.

Occupational Safety and Health

Fire fighting has been recognized for many years as one of the most dangerous professions. In each year between 1996 and 2005, an average of 135 fire fighters per year lost their lives[7] and roughly 58,000 were injured.[8] To address this unenviable record, NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program,* was established to guide fire departments in developing fire service health and safety programs. The standard is dedicated to making the fire service less dangerous by reducing the risk of accident, injury, and death during line-of-duty activities and to make fire fighters healthier and more physically fit.

NFPA 1500 addresses the elements of a fire department occupational safety and health program. It was developed by the fire service, for the fire service, and supports the requirements of the federal Occupational Safety and Health Administration (OSHA) fire brigade standard developed for private sector and public fire suppression organizations.

NFPA 1500 addresses health and safety as an overall program to reduce the risks to members of the fire department. The standard applies to all members of the department and specifically identifies management as a provider of the safest possible work environment, given the hazardous nature of the work. Fire service management thus must take the lead in establishing rules and procedures that support an effective health and safety program.

Entering into a comprehensive health and safety program can be difficult, as it involves a number of complex issues as well as inevitable budgetary impact. It may be easiest to implement the program on a phased basis, tailored to the specific needs of the fire department. (See NFPA 1500, Section 1.5, "Adoption Requirements.") Developing a comprehensive implementation plan will require the fire department to assess its strengths and weaknesses, determine what would be required to meet the standard, and then prioritize the steps that will be taken to reach this goal. The implementation plan should address vehicles and equipment, training and education requirements, protective clothing and protective equipment, incident command procedures and safety officer programs, facility safety, health and fitness standards, risk management procedures, and employee assistance programs.

Nearly 80 percent of active fire fighters in the United States are estimated to serve in departments with no fitness and health program.[1] A number of information sources are available on the Internet for departments interested in monitoring fire fighter health and safety issues, including the website sponsored by partnering agencies interested in preventing fire fighter deaths and injuries, http://www.firefighternearmiss.com. The International Association of Fire Chiefs' Safety, Health, and Survival Section and the International Association of Firefighters provide numerous resources for departmental health and safety programs.

DEPARTMENT STRUCTURE

Fire departments, like other organizations, are composed of people working together in a coordinated effort to achieve a common set of objectives. This coordination is achieved through organizational principles that determine how work is divided and coordinated, and through organizational plans that show the relationship of each operating division to the total organization.

Principles of Organization

One basic organizational principle is that work should be divided among individuals and operating units according to a plan. The plan should be based on the functions that must be performed, such as fire prevention, training, and communications.

A second important principle is that, as a department increases in size and complexity, the need for coordination also increases. Small departments allow frequent personal contact among individuals, reducing the need for planned, formal coordination. As departments increase in size and complexity, however, operating units must be coordinated more systematically in order to achieve their objectives. The logical grouping of similar functions and tasks will help to promote interaction that is necessary to successful management.

The most successful organizations operate as a team. Department leaders are organized as a system, in which all divisions and sections are equally important in achieving the desired objective: service to the community. Most fire departments retain a linear organizational structure, but many are recognizing the utility of creating work groups to address many management tasks. For example, the Department Information Systems manager may be responsible for specifying and recommending

a new records management system, and may seek the support of a focus group of interested employees in the process. Once the process is completed, the IS manager takes responsibility for the recommendation and moves it up the organization for further action. This team approach to accomplishing organizational goals helps limit the distancing effect that can occur in departments large enough to fund specialized staff positions.

The span of control for each manager and supervisor in an organization should also be considered. Generally, five to seven subordinates per supervisor are considered to be the ideal number for a manageable span of control. However, the complexity, importance, and sheer volume of work involved in the tasks being managed, as well as the manager's level of responsibility, should be taken into account.

Coordinating the systems within a department is an overarching function of the fire chief. This means the chief is responsible for organizing, planning, directing, controlling, and analyzing the work of the department. Activities that monitor, track, review, and revise systems as necessary will help establish and maintain an effective and efficient department that continually meets the needs of the community.

Line Functions

Line functions in fire departments normally refer to activities directly involved with delivering service to the department's customers. Fire suppression officers are considered to be line officers. This does not mean, however, that they do not have other functions. As these officers are promoted within the department they often acquire staff responsibilities as well. At the highest officer levels within the department, line responsibilities diminish and staff responsibilities increase. Line functions may include the following:

Emergency response. Fire suppression, emergency medical services, rescue operations, hazardous materials response, and other emergency services

Fire prevention. Inspection of construction and of existing properties for compliance with codes and ordinances; reviewing plans for new construction, major renovation, or installation of fire protection systems; operation of a public education program; and investigation of fires to determine the reasons fires start and spread

Staff Functions

Staff functions are activities that involve administering to or managing the needs of the department's service units and divisions, rather than dealing with day-to-day emergency incidents. Staff functions may include the following activities:

Training. Training of all personnel in their job skills; administering continuing education programs in special subject areas; administering the fire department safety program; and organizing and administering pre-incident planning

Maintenance. Maintaining apparatus, equipment, and physical facilities; recommending replacement programs for apparatus and equipment; and developing specifications for the purchase of apparatus and equipment

Communications. Providing and maintaining adequate facilities for the receipt of alarms from the public and communication with fire companies both in quarters and by radio in the field; also includes functions of developing and maintaining dispatch policy and response requirements

Research and planning. Creating the new knowledge the fire department needs to provide better service; forecasting long-range department goals; and performing the types of analyses necessary for other department functions to assess program effectiveness

Public information and relations. Maintaining contact with the public and the news media to tell the fire department's story; in larger departments, this function may also be responsible for internal communications

Financial management. Preparing a budget; monitoring expenses against the budget planning for capital expenditures; and supervising the purchase and inventory of needed materials

Personnel management. Supervising the recruitment, selection, and promotion of personnel; administering the retirement system and the benefits program; and supervising the administration of discipline within the department

Fire protection engineering. Developing proposals for code changes; and assisting in the technical aspects of plan review, code enforcement and fire investigations; also used in the research and planning functions

In large fire departments, a staff officer normally supervises each of these functions; these officers are not normally involved in line functions. The number of personnel assigned to a staff officer will vary with the size of the department and the importance of the function. In small departments, line officers may also be assigned staff functions, or a single officer may supervise more than one staff function. In the smallest of departments, the fire chief or assistant chief may directly assume many of the functions.

Organizational Plans

A department that functions effectively will have an organizational plan that shows the relationship between the operating divisions and the total organization, and allows the department to be managed effectively. (Organizational charts with typical structures of small, medium, and large fire departments are shown in Figures 12.4.4, 12.4.5, and 12.4.6, respectively.) A good organizational plan that reflects the current status of the department is essentially a blueprint of the organization.

A list of responsibilities or a job description for each position should accompany the organizational plan. In small departments, a single individual may be responsible for more than one function. For example, a single officer may be responsible for both training and maintenance. This should be detailed in the job description. The organizational chart must show how functions that may demand time and support from other personnel or groups will be coordinated within the department. The organizational plan and chart should reflect, to both fire department personnel and the public, a clear, coordinated effort to provide service to the community.

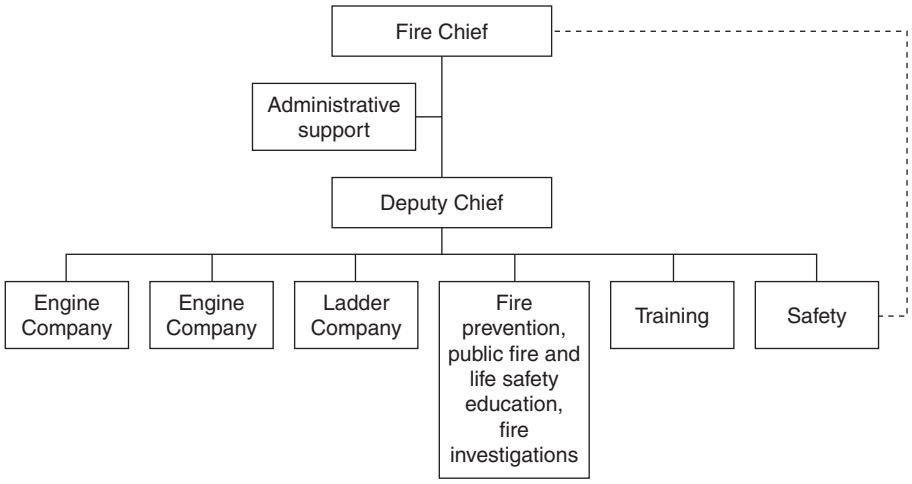

FIGURE 12.4.4 Organizational Chart for a Small Fire Department

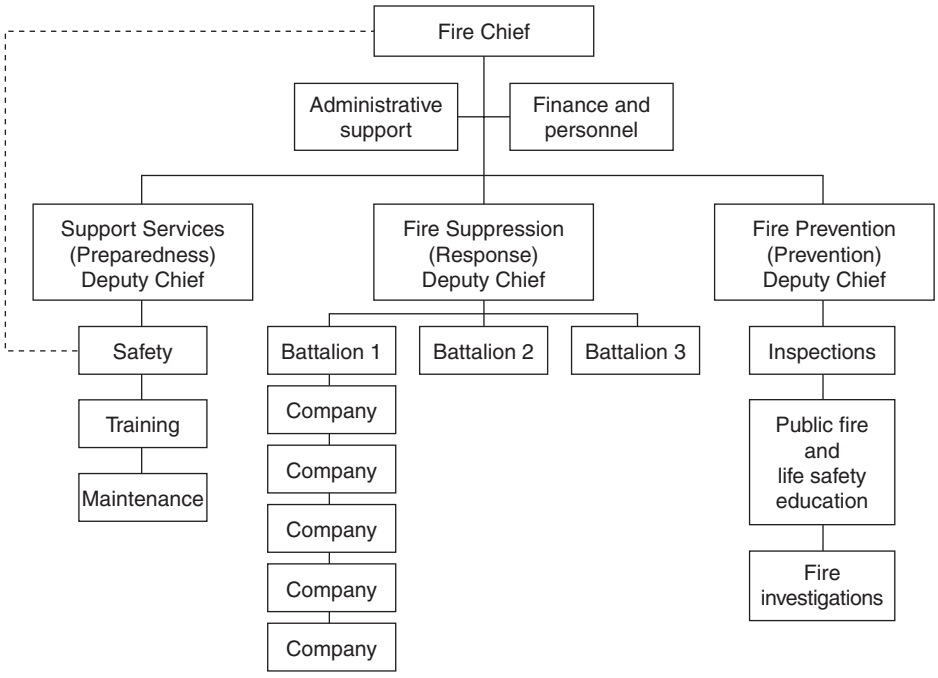

FIGURE 12.4.5 Organizational Chart for a Medium-Sized Fire Department

Rules, Regulations, Procedures, and Guidelines

As with any organization, fire departments need directives to govern operations, set performance standards, and outline expectations of behavior. Every fire department should have a set of rules and regulations, including a code of conduct, and standard operating procedures and guidelines. Operating procedures and guidelines are especially important in the fire service because the hazardous activities that are undertaken require a clear understanding of expected performance to ensure safety.

Chief officers may also issue orders when special circumstances and events require immediate or short-lived directives. Management should also create directives that specify disciplinary procedures for poor performance or for failure to follow regulations.

All directives should be written and distributed in such a manner as to ensure that they are known and accessible to all department members.

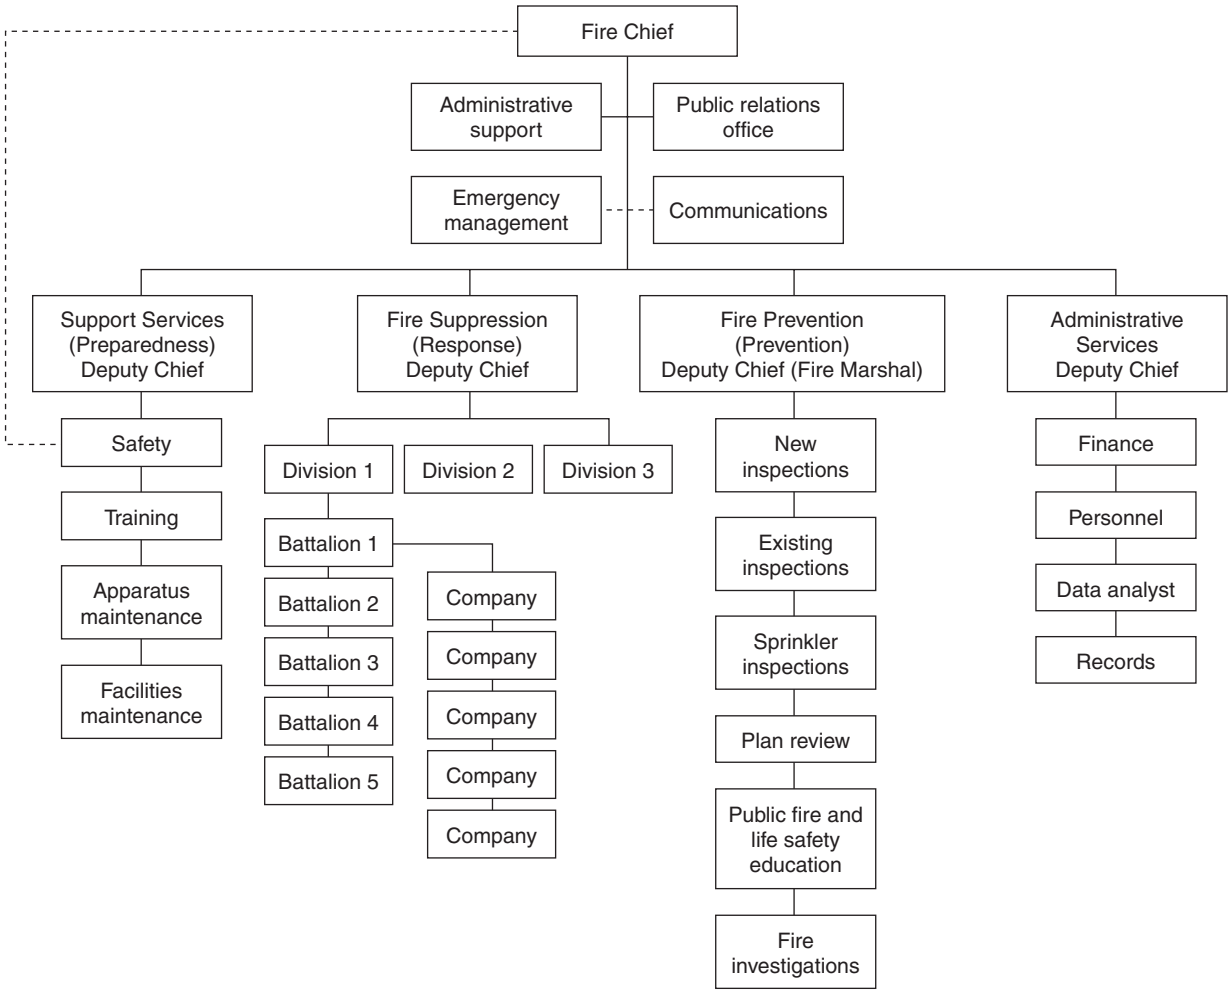

FIGURE 12.4.6 Organizational Chart for a Large Fire Department

ORGANIZING FOR EMERGENCY RESPONSE

Fire Suppression

Fire department structure is usually organized around providing fire suppression. The complexity of the response services section of the department is directly related to the size of the department. In many small fire departments, the fire chief supervises field operations. In larger departments, companies are organized into battalions or districts supervised by intermediate-level command officers (Figure 12.4.7).

The basic tactical unit of the fire department is the company, a group of personnel operating one or more pieces of apparatus under the supervision of a company officer. Several companies may operate from a single fire station. Engine and ladder companies are the most common; others are often provided to perform combined or specialized functions. These companies include rescue squads and companies that operate special tactical or support-function apparatus. In some fire departments, several companies operating from the same station are organized as task forces.

Engine Company. The most common type of company in a fire department is the engine company. The basic unit of apparatus is the engine or pumper, which carries hose, nozzles, a water tank, a pump, ground ladders, and assorted equipment, appliances, and tools. The engine company's basic tactical role in fireground operations is to deliver water through hose lines to control fires. Most engine companies also carry equipment to provide emergency medical services. In most cases, at least one engine company is based at each fire station in order to respond quickly and begin operations at a fire scene.

Ladder Company. The basic ladder company (or "truck company") apparatus is an aerial ladder or elevating platform that provides access above ground level or to rooftops, and can be used to direct elevated master streams onto fires.

Ladder trucks carry a complement of ground ladders and a selection of hand and power tools. On the fireground, ladder

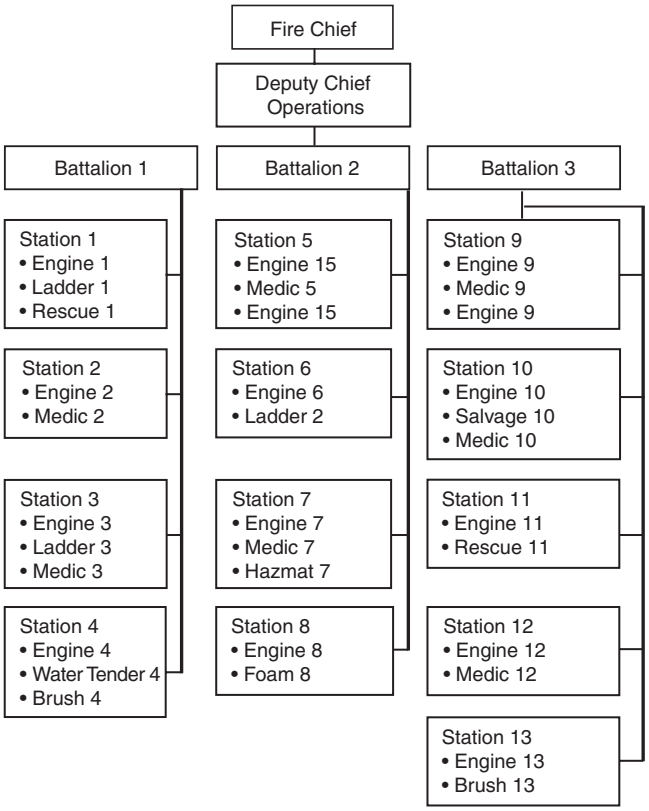

FIGURE 12.4.7 Organizational Chart for Operations Division of a Large-Sized Fire Department

companies perform search and rescue, forcible entry, ventilation, salvage, and overhaul. They also use ladders to gain access to fires and rescue persons trapped above ground level. Many departments operate ladder companies whose apparatus, called a "quint," are also equipped with hose, a water tank, and a pump. This type of ladder company can also apply water to fires through its hose lines.

The need for ladder companies, the design of ladder trucks, and the way ladder trucks are equipped, all depend on the community's needs. In a densely developed city, one ladder company may be provided for every two or three engine companies. In suburban jurisdictions that cover large response areas, the quint concept is particularly prevalent, because engine companies may have farther to travel and a choice of tactical options is desired. In rural and sparsely populated suburban areas, the functions normally performed by ladder companies are often assigned to engine companies carrying additional equipment.

Rescue Company. Many fire departments use separate rescue companies for both fire fighting and non-fire-related incidents. Rescue companies specialize in technical rescue, such as extricating victims from vehicles involved in accidents, removing injured persons from perilous locations, and assisting victims of industrial accidents (Figure 12.4.8).

On the fireground, rescue companies are usually assigned primarily to search and rescue, and to deliver medical treatment

FIGURE 12.4.8 Rescue Personnel Training for High-Angle Rescues

to civilians and responders. They may also take on some ladder company functions, particularly forcible entry, ventilation, and the use of power tools. Rescue companies may also be assigned as rapid intervention teams, with a focus on reducing injury and death to fire fighters operating at fires.

Special Apparatus. Fire departments often use specialized vehicles, such as off-road vehicles for brush fires, water tenders, hose wagons, foam pumpers, hazardous materials units, lighting trucks, breathing-air-supply trucks, and command vehicles. These may be organized as separate companies, or the role may be assigned as a second function to regular companies, with one company of fire fighters responding to an incident on either of two apparatus, depending on the nature of the incident. Some fire departments operate special companies with vehicles designed to carry little equipment other than the protective clothing and breathing apparatus used by the crew. These "flying squads" are intended to provide additional staff in a hurry to task-intensive incidents.

Fire apparatus may be purchased with a variety of options and configurations to suit the needs of the community or fire department. These options include aerial devices, water towers, and foam systems on engine-company apparatus; high-volume pumps and remotely controlled nozzles on ladder trucks; and large electrical generators and air-supply systems. The current trend is to purchase apparatus with multiple capabilities and to equip companies to perform multiple functions.

In many jurisdictions, the fire service has expanded its scope to embrace certain domestic preparedness functions. These departments have acquired specialized apparatus and vehicles for uses such as mobile decontamination trailers, incident communications centers, command and control vehicles, medical operations units, mobile radiological detection and monitoring stations, and multidiscipline response units.

The National Fire Protection Association publishes a series of standards for the design and construction of fire apparatus. Refer to Section 12, Chapter 16, "Fire Department Apparatus and Equipment," for a detailed discussion of fire apparatus.

MUTUAL AID AND MAJOR EMERGENCIES

Fire department managers should always be aware that a fire, natural disaster, disease outbreak, or terrorist attack could overwhelm the local emergency services. For this reason, most fire departments traditionally have rendered assistance to each other in times of need. Mutual-aid plans establish procedures for requesting and dispatching help between fire departments so that each party will know what is expected.

Mutual-aid plans may include immediate joint response of several fire departments to high-risk properties; joint response to alarms near the boundaries between fire department areas; coverage by outside departments when the resources of the local department are engaged; provision of additional units to assist at major fires that are too large for the local department to handle; and provision of specialized types of fire-fighting equipment not available locally in adequate quantity for the particular incident.

Mutual-aid plans also should specify that the National Incident Management System (NIMS) and ICS will be used during all incidents, and include provisions for standard operating procedures, interdepartmental communications, maps, adaptors, and other considerations that directly affect the ability of departments to operate together effectively. Command responsibility, jurisdictional questions, insurance coverage, and legal constraints should be covered in written agreements and supported by enabling legislation to establish effective mutual-aid systems.

Some communities have adopted automatic reciprocal aid agreements under which two or more fire departments are dispatched through one 9-1-1 communications center as though they were a single department. This "total boundary drop" that considers all concerned jurisdictions as one, optimizes emergency response for the citizens in the affected area. It usually results in a savings for the taxpayers as well, because it eliminates the need for multiple communications centers.

Some jurisdictions have extended the automatic-aid concept to the extent that fire department resources are pooled or merged into an integrated system with standardized training procedures. These networks may include shared facilities, joint purchases of specialized apparatus and equipment, and a coordinated approach to long-range planning.

True mutual aid is a relationship in which each member is prepared to assist the other parties to the agreement. In most areas of the country, larger fire departments are willing to assist smaller jurisdictions when requested at major incidents that exceed local capabilities. In many places, communities or individual properties known to be deficient in fire-fighting resources contract in advance to pay another jurisdiction for certain fire-fighting assistance. These programs are known as outside aid programs. In some instances, the contract covers basic first-alarm response; in other cases, additional assistance is provided for fighting major fires.

In all cases of mutual aid and outside aid, carefully worded agreements should be made in advance according to the legal requirements governing fire department operations outside normal jurisdictional areas. Local departments may have different operating methods and types of equipment, and this could hamper effective coordination of resources if a well-constructed agreement is not in place. The parties to the plan may choose to render assistance only to the extent that they feel they can do so without seriously reducing local protection; thus the plan should identify and address any coverage weaknesses.

The ideal plan is an extensive, region-wide agreement that maintains and optimizes coverage for all jurisdictions involved. As experience with natural disasters and other large-scale incidents has shown, effective plans and organizational procedures are crucial in systematically mobilizing fire forces. Most states and provinces have established large-area disaster plans involving all emergency services, coordinated under the NIMS. Such plans must integrate with the normal organizational and command procedures used by fire departments. These large-scale mutual-aid networks form a natural basis for smaller scale, more routine mutual assistance plans.

The amount of work involved in establishing and maintaining the mutual-aid agreements necessary for each jurisdiction can be a significant administrative burden. State legislation that provides mutual-aid agreement between all jurisdictions and emergency service agencies within the state can help to alleviate this burden. Such legislation can be written to allow individual communities or agencies to opt out of the agreement. This approach promotes regional planning and cooperation among all emergency responders and services, which is the cornerstone to successful response to and recovery from disaster. Similarly, interstate mutual aid agreements should be considered. Widespread effects of certain disasters can require the response of resources from states near and far. Interstate mutual-aid agreements should be examined to ensure that they provide for the release of resources for emergency response within hours of requests for assistance.

COMMUNICATIONS

An effective communications system is a key factor in fire department operations. The communications system is responsible for receiving notification of emergencies from the public; alerting and dispatching personnel and equipment; coordinating the activities of the units engaged in emergency incidents; and providing nonemergency communications to coordinate units.

Receiving Alarms

The first fire alarm telegraph system was created in Boston, transmitting the first fire alarm in 1852.[4] Although in many urban areas, municipal alarm systems remain in widespread use, today most alarms are received over landline or cellular telephone systems. Small departments with low activity levels may receive alarms through a variety of systems that provide 24 hour coverage.

In most areas, combined emergency service answering centers called public safety answering points receive calls for police, fire, and emergency medical services through a 9-1-1 emergency number; fire departments in other jurisdictions receive calls at a separate communications office. Enhanced 9-1-1 systems can identify the telephone number and location from which a call made from a landline phone originates. Other sophisticated tracing equipment enables public safety answering

points to determine the location of the cell tower closest to the origination of a call made from a cell phone.

As a result of high false alarm rates, many cities have removed municipal alarm systems or converted from telegraph to systems providing voice contact between the dispatcher and the caller. For more information, see NFPA 1221, *Standard for the Installation, Maintenance, and Use of Emergency Services Communication Systems.* Additional information is provided in Section 12, Chapter 15, "Public Emergency Services Alarm, Dispatch, and Communications Systems."

The communications center should provide recording equipment for all telephone lines and radio channels to provide immediate playback capability to verify information and to provide a complete record of all activity. In addition to telephones and municipal alarm systems, many fire departments receive automatic fire alarms from systems installed in buildings in their jurisdiction; these systems are connected directly to the fire department or relayed through a private alarm company.

Dispatching Procedures

Once an alarm has been received, personnel must be alerted and equipment must be dispatched. The complexity of this process varies with the size and population of the area served and the number of units under the alarm center's control.

The dispatcher must identify the units that are to respond to an incident based on the geographic location and type of situation, as well as the current availability of the units. The selection criteria for response units is determined in advance based on distance from, or response time to, the reported location. The type and number of units due to respond to each type of incident, often called the response array, should also be determined in advance based on risk criteria and unit capabilities.

The dispatcher must know the status of each unit in the system and be able to contact immediately all units that are available to respond to an incident. Global positioning systems (GPS) may be installed on response vehicles that enable the dispatcher to consider a unit that is closer than the recommended unit. If regularly assigned units are engaged at another incident or are otherwise unavailable, the system should identify the next units to substitute. This information is also needed if the dispatched units request additional assistance. Many communications centers and public safety answering points have computer-aided dispatch systems (CADS) that automate these functions. Printouts of automated dispatch systems are kept on hand as a backup system. Smaller systems often rely on printed "running cards" or policies to provide the dispatcher with response information for each zone.

The units assigned to respond to an incident may be alerted by radio, microwave, telephone, telegraph, other wired systems, or a combination of these. In some areas, individual pagers, outside sirens, or horns are used to alert volunteer or call personnel. Most departments use a voice message from the dispatcher to the responding unit, carried over the radio or wired circuits to the fire station. The alarm center should have at least two separate means of communication with each fire station, in case of equipment failure. In addition to voice messages, some fire departments use printers or telegraph systems as a backup. Units out of quarters are normally alerted by radio.

Radio Communications

Every fire department vehicle should be equipped with a two-way radio. Units responding to or engaged at incidents should be in radio contact with other units and with the alarm center. For larger departments, this may require several radio channels to provide sufficient communications capacity. The alarm center must be able to contact responding units en route, in order to provide additional information or directions, and units at the scene must be able to request or return additional resources. Mobile data terminals on the responding units provide the responders a view of the best information available to the dispatcher. This equipment saves time that would otherwise be spent gathering this information over the air.

The incident commander should be able to contact the alarm center at all times, providing progress reports, advising on the need for assistance, or releasing units from the scene. A dedicated fireground channel should provide communications between the incident commander and the units operating at the scene. Complex incidents may require multiple for communications within various sectors of the incident management system.

At a minimum, each company officer and sector officer should have a portable two-way radio on a fireground channel. As an essential element of safety, every member operating in a hazardous environment should have a portable radio. Units released from an incident by the incident commander should advise the alarm center when they are available to respond to other incidents.

As fire departments have become more mobile and active, with units spending less time in quarters, radio communications have become more important. The radio system must reach all units and be able to handle the volume of communications a major emergency generates. Regional communications plans are essential to coordinate activities involving units from multiple jurisdictions. Such plans may specify dedicated frequencies, specialized equipment that enables different systems to communicate, or other predetermined methods for providing a communications platform.

Communications Center Staffing

Fire communications centers require trained operators who are familiar with fire department operations and equipment. In very small communities, the fire department telephone number may be arranged to ring in a number of locations where appropriate action can be taken to dispatch fire apparatus. Dispatching may also be handled by the police department, a town office, or other locations that provide 24 hour coverage. Increasingly, small fire departments are being served by regional fire communication centers that are properly equipped and staffed.

Larger communities and regional communication centers require adequate numbers of trained, capable personnel to be on duty at all times. Enough operators must be on duty to handle the volume of communications during busy activity periods and working incidents. Procedures should be in place

to call in off-duty personnel or additional trained dispatchers, or otherwise increase capacity when major emergencies and high-activity situations exceed the effective capabilities of on-duty staff.

System maintenance and repair personnel should be on duty or on call at all times. All equipment must be maintained properly and tested for maximum reliability, and backup equipment or systems should be provided in case any key component fails. Every fire department should have a backup facility to which basic communication capability can be transferred if the primary center becomes unusable. In addition, 9-1-1 communications centers should have an agreement with a comparable center to allow for the redirection of 9-1-1 calls and dispatch of units in the event of a local phone system failure.

Information Retrieval and Storage

The communications center should have immediate access to essential information that may be needed in dispatching units to fires and emergencies. The data files must include a complete geofile index of all streets, intersections, and related numbering systems in the area. The geofile should also include all target hazards such as schools, hospitals, critical infrastructure, and large buildings. The system must allow the dispatcher to determine the appropriate response zone and map location for any reported emergency so that the proper units can be dispatched. Maintaining and updating these files is an important ongoing function, whether the information is kept in hard-copy form on cards or index systems or in a computer system. The same approach is necessary to keep pre-incident plan information and maps up to date in the communications center, as well as on fire apparatus.

Communications center data files should also include telephone numbers for responsible parties for target hazards, utility companies, and other agencies to contact during emergencies, as well as other individuals who may have to be notified of, or asked to respond to, certain incidents.

Electronic data processing equipment enhances information storage and speeds its retrieval. Information available on a particular location within a CAD system may include data on building arrangements, construction, hazards, code-inspection access, water supplies, and even prior fire experience. The system may provide for direct transmission of this information to terminals in responding vehicles or for storage in portable computers or microfiche systems carried in command vehicles.

Station/Personnel Alerting Systems

Some fire departments maintain a 24 hour watch at a console or control room in each fire station. The person on watch is responsible for receiving dispatch messages and controlling alerting devices within the station. Instead of maintaining a watch, other departments rely on the communications center to operate audible alerting devices in the stations.

Controls for lights, electrically operated doors, traffic-control devices, and similar equipment are usually located at the watch desk. Other fire departments control some or all of these devices from the communications center via radio signals or hardwired circuits.

In those stations that are staffed entirely by volunteer or on-call personnel, the communications center may alert personnel by activating sirens or horns or by tone activation of radio pagers carried by personnel or kept in their homes.

Communications center managers should carefully evaluate and anticipate the need for additional channels and frequencies and include strategies for funding the addition of these and other needed equipment in their planning. Radio systems, computer equipment, global positioning systems, software interfaces to coordinate these systems, and other communications tools are complex, expensive, and often little understood by the authorities who must agree to fund them.

Communications center managers should plan and train for the coordination of operations among public safety agencies during a disaster. Fire-rescue departments that operate a separate communications center, in particular, should prepare the communications staff for effective interagency operations.

MANAGEMENT AND BUDGETING

The operation of a fire department is normally a function of local government—in the case of a fire district, possibly the only function—that supports the service and is responsible for the level of service rendered. As with any governmental or business operation, this function involves three major areas of responsibility: (1) fiscal management, (2) personnel management, and (3) productivity. Other areas of responsibility include planning, research, and record keeping.

Fiscal Management and Budgeting

In general, fiscal management practices follow those used by the government agency supporting the department. These practices involve budgeting, cost accounting, personnel costs including payroll, and purchasing or procurement costs. The degree to which these factors are a direct responsibility of fire department management varies, depending on the practices of local government.

Fire department budgets are generally prepared and submitted by the fire chief, directly or through management structure, to the elected body that administers the community or district operations. A typical budget consists of operating, personal services, capital replacement, and capital improvement segments. Personnel costs are generally the most significant segment of a fire department's budget, accounting for approximately 85 to 90 percent of the total expenditures of a fully paid fire department.

Fire department managers must thoroughly understand their jurisdiction's budgeting system. Inadequately prepared budgets can lead to serious monetary shortfalls at the end of the fiscal year. Costs must be estimated realistically and expenditures must be monitored on an ongoing basis.

Long-range plans should be created that will project capital replacement costs for items such as staff vehicles, fire apparatus, fire stations, and other major pieces of equipment. Fire apparatus costs normally run from 2 to 3 percent of payroll costs. (Some fire departments include an apparatus replacement allowance in their operating budgets, but this item is regularly reduced or

eliminated, with the result that apparatus replacement may be included in a capital expenditures budget. Although this reduces the fire department's annual budget, it may ultimately result in higher taxes due to interest costs. However, such decisions are generally made above the level of the fire department administration.) New fire stations and new service programs are usually included in a capital improvement budget separate from the fire department budget.

Large fire departments may have separate budget accounts for staff divisions, such as fire prevention, maintenance, and training. Expenditures are charged against specific items in the line budget, and the remaining balance is shown after each expense deduction. Usually, the department head or staff division supervisors have the authority to make emergency transfers of funds between line categories, whereas transfers between major categories must be authorized by the municipal manager, finance officer, or other governing body. Purchases and procurement procedures must be executed within the policies of the governing authority.

Budget Submission

Fire department administrators are required to submit their budget estimates by a specified date for the coming fiscal year (or years, in jurisdictions that employ a biennial budget). Budgets are usually submitted to a finance officer or committee, and department heads are then asked to justify specific items. Salary totals may be governed by contract with the employees, but estimates must cover all ranks, overtime costs, and anticipated hiring and retirements. Because salary increases are not always determined before the budget is submitted, it may be necessary to incorporate a projection based on reasonable assumptions.

After a departmental budget has been approved by the governing administration, it must be approved by the city council or other governing body. In some communities, this requires a public hearing. With some municipal charters, the council can reduce but not increase the budget in order to guard against political pressure on the administration. Once approved, the budget takes effect at the beginning of the fiscal year. If not approved in time, it is customary to permit ongoing expenditures at the same rate as the previous year.

The governing authority should clearly define who is responsible for managing each area of the budget. Responsibility for keeping the department within its authorized budget most often rests with the chief of the department.

Personnel Management

A fire department is only as good as the people who work for it. Choosing new fire fighters, and promoting them to officer or other ranks, is to a great extent the job of the fire chief or other upper department management, although human relations departments take over much of this role in many jurisdictions. Hiring and promotional processes are also subject to legal constraints as well as, often, to civil service rules and local government policies. Fire department management is also responsible for assigning employees to positions within the organization (subject in some cases to the work contract agreement) and for supervising them and evaluating their performance.

Recruiting. Fire departments are often very involved in recruiting efforts to fill vacancies in their ranks. A common arrangement is to conduct recruiting efforts jointly with the local government human resources or personnel agency. (Because of their makeup, most fire districts and volunteer departments recruit their own members.) Many large fire departments have recruitment sections. Some departments coordinate recruitment efforts with other allied agencies, such as other fire-rescue departments in the region.

Fire department management has three recruitment responsibilities. The first is to develop and employ appropriate hiring standards. The second is to provide the basic training new recruits need in order to perform their assigned duties properly. The third is to certify that the newly trained fire fighters are ready for appointment as permanent fire fighters or, when individuals prove unable to perform satisfactorily, to recommend that their services be terminated.

Personnel selection must comply with local, state, and federal laws. U.S. courts have ruled that there can be no discrimination in hiring practices based on race, gender, national origin, religion, age, or marital status. State or local law may further define employment practices, expanding the list of nondiscriminatory practices or setting criminal history disqualifiers, for instance. Many communities have identified diversity in the public sector as a value and have established a goal that personnel reflect the diversity of the community they serve. Many departments thus administer comprehensive recruitment, pretraining, and mentoring programs designed to increase the representation of women and people of color within their organizations.

Periodic review of the selection, hiring, and retention practices of the department is a wise practice. Selection practices are a sensitive issue, and knowledgeable counsel should be sought when developing hiring standards in order to ensure a sound legal foundation. For example, some rulings prohibit residence requirements for recruits, although fire department rules of employment may stipulate that, because of the emergency nature of the work, employees must reside within a reasonable distance of the community. One court decision has prohibited entrance examinations that require prior knowledge of fire department practices and equipment.

In most jurisdictions, applications for employment as a fire fighter are obtained from local government personnel offices or the civil service agency. In at least two states, recruitment is handled by a state civil service commission. Age requirements for entry-level appointments vary and have been affected by recent federal regulations.

Qualifications. All fire service personnel must be fully qualified and capable of efficiently performing the wide range of functions necessary to protect life and property. Many states have established commissions on fire fighter standards that require that all personnel employed by fire departments satisfactorily complete basic training before they are given permanent employment. Many states have also adopted, or are in the process of adopting minimum fire fighter qualifications standards.

In 1971, the Joint Council of National Fire Service Organizations (JCNFSO) created the National Professional Qualifications Board for the Fire Service (NPQB) to facilitate the development

of nationally applicable performance standards for various levels of responsibility within the uniformed fire service. On December 14, 1972, the board established four technical committees to develop those standards using the NFPA standards-making system. The initial committees addressed the fire fighter, fire officer, fire service instructor, and fire inspector and investigator.

The original concept of the professional qualification standards, as directed by the JCNFSO and NPQB, was to develop an interrelated set of performance standards specifically for the fire service. The various levels of achievement in the standards were to build on each other. In the late 1980s, the standards were changed to recognize that the documents should stand on their own merits in terms of job performance requirements for a given field. Accordingly, the strict career ladder concept was abandoned, except for the progression from fire fighter to fire officer. The later revisions facilitated the use of the documents by other than the uniformed fire services.

In 1990, the NFPA assumed the total responsibility for the appointment of professional qualifications committees and the development of the professional qualifications standards. The NFPA Standards Council appointed the Correlating Committee for Professional Qualifications Standards in 1990, which assumed the responsibility for coordinating the requirements of all of the professional qualifications documents. The chair of each technical committee sits on this committee.

Currently, technical committees are working on the following projects:

- NFPA 1000, *Standard for Fire Service Professional Qualifications Accreditation and Certification Systems*
- NFPA 1001, *Standard for Fire Fighter Professional Qualifications*
- NFPA 1002, *Standard for Fire Apparatus Driver/Operator Professional Qualifications*
- NFPA 1003, *Standard for Airport Fire Fighter Professional Qualifications*
- NFPA 1005, *Standard on Professional Qualifications for Marine Fire Fighting for Land-Based Fire Fighters*
- NFPA 1006, *Standard for Rescue Technician Professional Qualifications*
- NFPA 1021, *Standard for Fire Officer Professional Qualifications*
- NFPA 1031, *Standard for Professional Qualifications for Fire Inspector and Plan Examiner*
- NFPA 1033, *Standard for Professional Qualifications for Fire Investigator*
- NFPA 1035, *Standard for Professional Qualifications for Public Fire and Life Safety Educator*
- NFPA 1037, *Standard for Professional Qualifications for Fire Marshals*
- NFPA 1041, *Standard for Fire Service Instructor Professional Qualifications*
- NFPA 1051, *Standard for Wildland Fire Fighter Professional Qualifications*
- NFPA 1061, *Standard for Professional Qualifications for Public Safety Telecommunicator*

Each of these standards defines the levels of progression within the specified job. The job performance requirements defined for each level of progression are considered the minimum requirements for individuals at that level. The intent of the committees is to develop clear and concise job performance requirements that can be used to determine whether individuals possess the skills and knowledge necessary to perform the related duties and tasks of the job. These job performance requirements can be used by any fire department in any city, town, or private fire service organization.

Under the new leadership of the National Board on Fire Service Professional Qualifications, the NPQB has assumed the role of third-party accreditor of fire service certification programs and developer of a national registry of those certified.

Certification in the fire service is based primarily on the NFPA professional qualifications standards. The Fire Service Accreditation Congress at Oklahoma State University has also been established as an accreditation agency for the fire service. The Center for Public Safety Excellence offers accreditation to qualified fire service agencies and chief fire officers.

The establishment of standards and testing procedures does not in itself ensure that all personnel will achieve the required level of competency; NFPA 1001, *Standard for Fire Fighter Professional Qualifications,* is a professional qualifications standard, not a training standard. Training programs are necessary to prepare members of the fire service to acquire the skills and knowledge necessary to meet the job performance requirements set forth for each grade. However, training should not be random. It must be organized to prepare trainees to meet the specified levels of performance demonstrated by the performance testing described in NFPA 1001.

Courts have ruled that height and other arbitrary requirements are discriminatory and may not be part of hiring criteria. Discrimination against individuals with a disability is also a violation of federal law, but candidates may be required to demonstrate their ability to perform the bona fide duties of a job. Fire departments must evaluate their hiring processes, defining and validating the "essential functions" for fire department positions.

Testing. Fire fighting requires physical endurance and strength, and fire fighters depend on each other in fire suppression and rescue operations. In some jurisdictions, the fire department's training division or other personnel may be used to test candidates for fire fighter positions. Regardless of who provides entry-level testing, recognized standards and all applicable laws and guidelines must be followed carefully. The goal of the testing process should be to select those candidates who, with training, will be capable of carrying out the functions of the job proficiently, without making the results subject to charges of discrimination.

Promotional Practices. In the vast majority of fire departments, officer ranks are filled from the pool of personnel serving in the next lower rank or ranks, although fire departments are increasingly recognizing the potential benefits of allowing qualified personnel from other areas and departments to compete for positions above the entry level. Promotional procedures are designed to take into account technical qualifications for the particular rank, as well as fire department or other relevant

experience. Examination procedures in the civil service must be competitive and nondiscriminatory.

Promotional procedures are generally administered by personnel departments or by state or local civil service authorities with the assistance of experienced persons who are knowledgeable about the particular job classification. Such subject matter experts include fire chiefs, fire fighter organizations, department personnel, and technical consultants. Their assistance may include guidance as to the relative weight to be given to experience and to the result of written examinations covering the technical qualifications of the position.

In many systems, however, the testing process is rigidly defined by civil service law or contract. In some systems, performance ratings may be included. Some supervisors tend to be much more demanding than others when rating performance; and their subordinates often have less favorable performance grades than other employees, who may actually be less qualified. Because of the question of their uniform application, subjective performance ratings are now used less frequently in the promotional process.

Some promotional processes include an oral review. Although oral reviews provide an opportunity to evaluate important attributes that are difficult to quantify and test, they can also be very subjective. Few oral interviews are scientifically designed or professionally administered, and they may reflect the interviewer's bias or be subject to a challenge of bias. As a result, more emphasis is given to written examinations that test technical knowledge exclusively.

Where permitted by law, more fire departments are now commonly relying on assessment centers as a means of selecting candidates for promotion. Assessment centers, which have long been used by private industry, require a candidate to demonstrate certain abilities through the use of problem-solving exercises, role playing, prioritization of a list of tasks, incident simulation, and other exercises. Each candidate is observed by a trained assessment team and scored according to performance. Many experts in the field of human resource management agree that the assessment center is the most realistic means of determining a candidate's suitability for a promoted position.

NFPA 1021, *Standard for Fire Officer Professional Qualifications,* specifies the levels of performance for fire officers. Written in performance terms, this standard requires an individual to demonstrate competence by knowledge and performance.

Many fire departments include educational requirements for officers, such as community college fire science certificates or bachelor's degrees for chief officers. It is not uncommon to find fire departments that seek individuals with graduate-level degrees in public administration or management for the position of fire chief. Many jurisdictions specify completion of the National Fire Academy's Executive Fire Officer program in their job qualifications for chief executive officer.

The fire department administration, as an arm of the municipal administration, has an important role to play in the promotional process. First, it must advise the personnel agency of the qualifications required in any job or rank to be filled, for those instances in which such qualifications have not been previously listed. Second, when a list of successful candidates is received from the personnel agency, the administration must normally advise the promoting authority of the promotions to be made. The usual practice is to fill vacancies from the top of the promotional list, except where the head of the fire department specifies in writing valid reasons for rejecting or passing over an individual.

Such reasons might include a record of serious disciplinary problems, including disobedience of written orders; frequent bad judgment when performing assigned duties; or a record of conflicts with other employees. Personnel records should be available to substantiate such rationale. These problems should be relatively current and not relate to behavior that occurred years ago that the individual has corrected.

Personnel Records. The fire department should maintain a careful and complete personnel record for each member. Such records cover all the pertinent facts of the person's fire service career, from probationary appointment through retirement, and include the original application for employment, all assignments, transfers, promotions, commendations, and records of disciplinary action. The record should also contain information on any special skills an individual possesses that may be useful to the department, as well as the individual's educational background.

In addition to the general record of an individual's service, a training file should be maintained, as covered in NFPA 1401, *Recommended Practice for Fire Service Training Reports and Records.* The file will show training periods and subjects in which the individual has received instruction, such as apparatus operation, emergency medical service, and fire inspection.

A medical history must be kept for each member, showing absences due to sickness and service-related injuries. A new addition to the personnel file is a record of exposure to hazardous materials and infectious diseases. This information provides a historical record of the fire fighter's known exposure to toxic materials or to infectious communicable diseases during his or her employment, as well as any appropriate inoculations he or she has received.

Productivity

Effectiveness in the fire service is difficult to measure. The basic objective of the fire service is the protection of life, property, and the environment. Modern fire service practice involves two major activities: controlling hazards to minimize fire losses and to prevent fires, and dealing with actual fires and emergencies to minimize suffering and losses. It is difficult to assess the number of fires and the amount of suffering or loss fire department activities have prevented. Experience demonstrates, however, that a lack of effective fire prevention and control measures invites disaster.

Likewise, the fact that most fires are suppressed with minimal losses and injuries does not indicate conclusively that an adequate level of fire department service has been provided. Experience shows that major fires and emergencies often arise from a combination of circumstances that are beyond the immediate control of fire department management but that must be dealt with effectively by the department to protect the public.

The fact that most fires are suppressed with minimal losses and injuries does not indicate conclusively that an adequate

level of fire department service has been provided. Nor does the occurrence of a large-loss fire necessarily mean that the fire department is inadequate. Major fires and emergencies often arise from a combination of circumstances that are beyond the immediate control of the fire department, yet it is left to the department to manage the results.

Because local fire losses do not necessarily reflect fire department performance, fire department management must rely on regional and national fire loss experience to help them develop standards for the department. Frequent training and assessment of company effectiveness can also help provide benchmarks for performance on the fireground.

EMS services provided by fire departments range from first responders assisting ambulance crews to actually providing paramedic engine and ladder companies and an ambulance service. Fire departments involved in this aspect of public safety have seen significant increases in the use of personnel and equipment and in community support.

Increased emphasis on domestic preparedness and large-scale disaster response has caused increasing numbers of fire departments to develop hazardous materials teams. Many metropolitan-area fire service agencies are also active in a federal, state, or regional search-and-rescue team with structural collapse rescue capability. Until a large-scale emergency occurs and the value of their services is realized, the productivity of these specialized programs often is measured in training hours, equipment procured, and exercises completed.

Planning

Planning for the future needs of a fire department is the most important job of fire department managers. Without adequate planning, an administrator will find he or she is handling one crisis after another and can never seem to get ahead. Long-range planning has often been neglected by fire department managers, but with budget constraints, it is absolutely essential. The U.S. Fire Administration (USFA) has developed a master planning process, available to local communities, that outlines the steps a community may take to determine long-range goals for its fire department and explains how these goals can be achieved. The NFA Technical Support Program will assist local governments in developing a master planning process.

All departments, small and large, should develop short- and long-range strategic plans. Short-range plans are generally considered to encompass the next five years; long-range plans cover ten or more years. These plans must be flexible and should be continually updated to reflect changes in the community as well as developments within the fire service. The plans should also be known to department membership and the governing authority. Goals drawn from these plans should guide department budgeting, program development, and decision making. (See Section 12, Chapter 5, "Information Management and Computer Technology," for more information on this topic.)

Research

The term *research* is commonly heard in the fire service, yet few fire departments are staffed or financed to support any significant research activity. Most fire departments are relatively small organizations that do not have sufficient personnel to meet their ongoing fire protection obligations, let alone undertake real research into efficient equipment design.

The development of the Internet and the host of resources available online have made research easier. Websites have emerged that are useful to fire-rescue managers, such as the Lessons Learned Information Sharing site, http://www.llis.gov, maintained by the federal government. The Homeland Security Information Network–Emergency Management site, or HSIN-EM, provides a communication conduit for fire service leaders and managers across the country free of cost. It is intended to facilitate planning and operations activities within the fire community of the emergency services sector, according to the National Infrastructure Protection Plan. Countless other information and research sites are available through the Internet. Fire departments without routine, affordable access to the Internet should seek funding to make this critical connection to the greater fire service community and the world.

Few fire departments have been able to do true research into efficient equipment design. The same is true of most fire equipment suppliers. As competitive, small-volume businesses, they do not often generate a profit margin large enough to fund research and development. Fire apparatus builders have focused much of their engineering effort on meeting the increasingly exacting vehicle safety standards of the U.S. Department of Transportation (DOT). NFPA 1901, *Standard for Automotive Fire Apparatus,* updated every four years, also affects fire apparatus design and development.

One area in which fire department research can readily show returns is in fire record analysis, using programs such as the National Fire Incident Reporting System (NFIRS), which collects data from fire departments around the country. This information yields insights regarding hazards and trends, which allow prevention efforts to be targeted more effectively.

Well-analyzed data can be an informational gold mine, as long as the information is collected in a manner that supports analysis. Commercially produced software is available that will analyze a department's dispatch data. The results can help identify problems in response patterns, such as neighborhoods that receive subpar service delivery. Other applications can model or predict the value a new fire station or company could provide, recommend response arrays, and evaluate effective response times. With the proper tools and training, staff can also analyze data and return useful information.

Fire service managers seeking research expertise and resources can call on a range of fire service allies for help. The NFPA conducts research designed to help fire departments and makes this information available to interested parties around the world. The International Association of Fire Fighters (IAFF) Research Department is available on request to assist its local affiliates with problems. The USFA conducts and sponsors research relating to fire service needs.

Management Records and Reports

The fire chief and other administrative officers should have access to a records system that gives them data indicating how

effective the department is at preventing and fighting fires. Complete records of all fires and inspections must be maintained and made available to government officials and the public. All records should be examined in light of their usefulness. A records retention and disposal system should be employed, and a careful review should be made to ensure that the records system meets all legal requirements. (See Section 12, Chapter 5, "Information Management and Computer Technology," for more information on this topic.)

STAFFING PRACTICES

The principal resource of a fire-rescue department is its personnel. In most fire departments, the vast majority of personnel are assigned to the emergency response division. Resource allocation will thus be most effective if all personnel—and particularly those assigned to fire fighting and rescue—are assigned for maximum use. This can be accomplished through careful time-utilization schedules, assigning appropriate portions of work periods to apparatus and equipment maintenance, training, inspections, and other duties expected of the response division. Careful coordination and planning can help create the most effective emergency service delivery program possible.

In some fire departments, a small percentage of personnel are assigned full-time to fire prevention. Typically, these personnel undertake plan review, code enforcement, fire cause determination, public fire education, and similar prevention and enforcement activities. Departments with adequate funding may also assign full-time personnel to perform new and existing code inspections.

Personnel may also be assigned to perform functions that support the operations of the response and prevention divisions. Such functions, which may be grouped together as preparedness activities for the operations of line personnel, include training, equipment and apparatus maintenance, and facilities management. Like fire prevention, the preparedness division also usually comprises a small percentage of a department's personnel.

Factors Affecting Staffing Levels

Staffing levels for fire departments vary considerably and are influenced by such things as the size or risk characteristic of the population protected, population density, fire fighters' work hours per week, response distances, community risk profile, and fire fighter safety. Most fire departments use a three- or four- platoon system that will accommodate a 56 to 42 hour workweek, respectively. A four-platoon system requires about a third more personnel than a three-platoon system. Staffing levels for cities of 250,000 or more population range from 0.5 to 2.9 fire fighters per thousand population, with a median of 1.1 to 1.5 per thousand. Cities in northeastern United States generally have a higher staffing ratio than do cities in the central northern and southern United States, which in turn tend to have higher staffing ratios than cities in the western United States. Communities must assess their needs to determine the level of staffing that meets their requirements. A study conducted with the Dallas, Texas, Fire Department, however, suggests that when staffing falls below four fire fighters per company, fireground effectiveness may be compromised, overtaxing available forces and contributing to higher losses.[9]

Certain fire-rescue service functions place additional requirements on department staffing. Fire departments operating emergency medical service transports need additional personnel, as time spent delivering patients to hospitals could otherwise erode effective fire company strength. In smaller communities, the staffing ratio per population protected may be relatively high because of the need for sufficient on-duty personnel for effective initial attack and rescue operations. This personnel need is especially true in "bedroom communities" where call personnel are not readily available during the workday. Similarly, fire departments in many core metropolitan cities protect more lives and property than population figures reflect. A city of 80,000 may be the business center for an area of 200,000 persons and house a high percentage of low-income groups. The number of high-rise buildings and structures with unusually high square footage to be protected and the frequency of alarms for fires and emergencies should be considered in determining on-duty fire department staffing.

Some very large fire departments may operate with a lower relative strength per thousand population than those in cities of a more moderate size because, with high population densities, these departments have sufficient companies to provide needed coverage while handling working fires. For example, a large city fire department may operate one engine company per 15,000 to 20,000 population and still have a large number of well-distributed fire companies, whereas a city of 30,000 might not be able to muster an effective fire-fighting force with only two engine companies.

Mutual aid plays an important role in providing additional resources. Even the largest jurisdictions rely to some extent on mutual aid from surrounding areas to provide fire-fighting resources on a routine or major emergency basis. Some departments use automatic mutual aid on initial response. Even large cities are making increased use of both regularly assigned and automatic mutual aid. This use is practical especially when companies from neighboring fire departments may be much nearer to an incident than the city's fire companies, and vice versa.

It is frequently impossible for small cities to fully staff all of the fire companies they need to handle working fires throughout the community. In many cases, the population density and the values protected per square mile are relatively low. In such communities, some engine companies may respond with only three persons on duty and ladder trucks with only two. Such low levels of staffing should be reinforced promptly by off-shift or call personnel or by multiple alarm response to ensure adequate operating forces. In some cases, additional apparatus may be assigned to respond, offsetting deficient company strength. In communities with large geographic areas and relatively low concentrations of value, this may be an acceptable arrangement. To promote fire fighter safety, NFPA 1500 recommends that interior fire fighting and rescue operations begin only when four personnel are on the scene. This is a requirement of OSHA as well, with limited exception. In general, each engine company should have a minimum of four fire fighters on duty, including an officer.

Staffing Career Fire Departments

The number and type of fire department emergency response personnel a jurisdiction needs is determined in part by the factors discussed previously in "Types of Fire Departments," such as (1) the financial resources of the community, (2) the availability of on-call or volunteer personnel, (3) the frequency of emergency incidents, (4) the range of services expected from the department, and (5) the type of department preferred by the community.

Other factors, which are elements of a department's Standards of Response Coverage and also influence required staffing, are (1) on-scene operations, which includes fire flow tasks and life safety tasks; (2) critical tasks, which must be conducted in a timely and safe manner to control a fire prior to flashover or to extinguish a fire; (3) the establishment of an adequate effective response force (ERF), which is the minimum staffing and equipment needed to perform the critical tasks; and (4) the ability to reach an emergency scene within a maximum total reflex time, which is the time elapsed from the call receipt to the time the units arrive on-scene.

The primary goal of every fire department should be to arrive at an emergency scene with an adequate number of well-trained and fully-equipped personnel, within the time allotted by a department's response time standard, and in a manner that meets the expectations of the community. This goal is the starting point for determining adequate staffing for a career fire department.

Tours of Duty. Fire departments are traditionally staffed 24 hours a day. The next step in determining adequate staffing is to identify the number of positions that must be covered 24 hours a day throughout the year, plus the number of duty tours, or employee shifts, required for each 24 hour period. If 24-hour shifts are used, there is one duty tour per position per day. With 10 to 14 hour or similar tours of duty, there are 2 per day or 730 per year.

As an example, take a community that has determined that at least 58 officers and fire fighters should be on duty at all times. With a 42-hour-average workweek, including day and night shifts, each shift or group is on duty 182.5 times during a 365 day year. With 58 persons on duty, this requires 42,340 individual tours of duty per year.

This fire department's records show that with vacation, sick and injured leave, and other absences, its fire fighters actually average not 182.5 but 146.5 tours of duty per year. The required 42,340 tours of duty, divided by 146.5 tours worked per person, show that instead of 212 officers and fire fighters, 289 are actually needed to provide a minimum of 58 personnel on duty and cover the anticipated absences. The additional personnel would be distributed among the companies in the district. Even when vacations are carefully scheduled so that only one person from each shift of each company is absent at any given time, off-duty personnel may sometimes have to be used on an overtime basis due to sickness or injury. The budget should allow for contingency overtime as needed to call back members to cover staffing shortfalls as well as major fires and emergencies.

Defining Minimum Staffing. In many fire departments, when an unusually high number of absences occur, stations housing more than one company may be allowed to operate one person below the desired minimum rather than pay overtime, unless the company minimum strength is specified by contract or city ordinance. Other jurisdictions with a defined minimum staffing level may be forced to take units out of service if the funding level cannot support overtime.

Generally, a 42 hour workweek requires not four but five persons per position. Thus, a 20 person company is needed to maintain an average of four on duty. Because this does not allow two members to be away from their shifts at one time, overtime or personnel swaps between companies may occasionally be needed.

With a fire department operating on a three-platoon system with 24-hour duty tours, each platoon covers 122 tours in 366 days (a leap year). It requires 21,208 tours to have 58 officers and fire fighters on duty. The records in this example indicate that the average member works 98 tours per year. Thus, 21,208 divided by 98 requires 216 fire fighters or 72 for each of the three platoons. With a 53-hour maximum workweek permitted under federal labor law (FLSA), however, each member working more than 53 hours in each 28 day work period would exceed the allowable maximum by 3 hours and would be eligible for extra compensation, except possibly when the work cycle is broken by absences.

When minimum company strength of five persons is desired for a 42 hour workweek, most fire companies have 24 persons assigned to the four duty shifts and 28 assigned for approximately every fourth company. In some fire departments where more vacations are scheduled in the summer months, a 4 person minimum may be maintained in the summer and a 5 person minimum maintained in the winter. However, most fire departments prefer to maintain minimum staffing year round rather than attempt to adjust for seasonal trends. If additional personnel are needed during severe winter storms, they are provided on a temporary overtime basis and are paid from the overtime account.

It was customary in the past to allow 10 percent for absences from assigned shifts due to vacations and sickness. Now the figure commonly is 20 percent or more. Vacations have been increased, and employee benefit programs or work contracts often provide for various other compensated absences from duty.

Meeting Minimum Staffing Requirements. The practice of establishing minimum staffing levels for each fire company or duty shift has become widespread in recent decades. It is a policy in many fire departments not to operate engine or ladder companies with fewer than four fire fighters, including an officer, on duty. In rare cases, because of the workload and the population and values protected per company, the minimum is five persons on duty per company. When a company member is sick or injured while another member is on vacation and no on-duty fire fighter is available to cover the absence, the department employs an off-duty fire fighter on an overtime basis to maintain minimum strength.

Labor boards and at least one court have found that minimum staffing agreements or ordinances are reasonable requirements for the protection of the public and personnel. A number of small fire departments that do not attempt to maintain minimum on-duty company strength have established a minimum for the duty shift while employing off-duty personnel to maintain the predetermined minimum effective strength. Such a plan should account for apparatus that must be operated from several fire stations before off-shift or call fire fighters can arrive to assist. In order to meet minimum staffing goals, it is helpful to have a policy that regulates the number of vacancies permitted due to discretionary absences.

As noted above, off-duty personnel may sometimes be used on an overtime basis when unscheduled absences reduce staffing below the minimum level. This use is usually more economical than maintaining a roster that is large enough to prevent these occasions from ever occurring, but if the roster is too small, overtime may cost more than hiring more members. The calculation of staffing levels should thus be made carefully, considering not only scheduled absences but also typical levels of sick, injured, and military leave, temporary reassignment of emergency response personnel to nonemergency functions, and any other factors that can reduce the number of on-duty personnel.

Work Schedules. Most fire fighters who work an average of more than 50 hours per week use a 24 hour tour of duty. Most fire fighters who work 48 or fewer hours per week have day and night shifts; the most common is a 10 hour day shift and 14 hour night shift. When the law states that anyone working more than 40 hours per week will be paid overtime, many fire departments work a 42-hour, four-platoon schedule by paying 2 hours of overtime. Often, this is considerably less expensive than hiring additional personnel, and better teamwork is maintained by keeping crews together on a regular four-shift basis. (The Department of Labor Issues and Collective Bargaining of the International Association of Firefighters has published "The Hours/Schedules Kit," a compendium of various duty shifts and schedules that have been employed by fire departments.)

Occasionally, municipal administrators have suggested that fire fighters be assigned to an 8-hour-day/40-hour-week work schedule similar to police schedules. This schedule has not proven to be practical or desirable. On-duty police staffing properly varies with the time of day and day of the week, as required by demands for traffic control, patrolling, details, and so on. The work involved in fire fighting and rescue requires a team effort, and the team includes platoon chief officers, company officers, apparatus operators, and fire fighters working together on a regular basis. Serious fires and accidents occur at every hour of the day and night and on every day of the week. Thus, the uniform staffing provided by three- and four-platoon systems is essential to effective, timely operations. Work shifts are readily scheduled in seven 24-hour tours of duty per week on a 56-hour average workweek, or fourteen 10- and 14-hour tours of duty per week on a 42-hour average workweek. When the 168-hour calendar week is divided by 8 hour tours, 21 work shifts are required, a number that cannot be used to schedule evenly staffed platoons around the clock.

In most instances where the 8 hour schedule has been proposed, it has been rejected. Very few fire-rescue departments in the entire United States use an 8 hour work shift. The choice between having fire fighters on 24 hour shifts, or reducing staffing or resources by 40 percent to accommodate 8 hour work shifts, means most municipal fire departments can not seriously consider the latter. As the fire service becomes more adept at computerized analysis of emergency incidents and develops a good base of response data, staffing arrangements similar to police staffing may be possible in the future, particularly for EMS personnel. Demand analysis may demonstrate predictable patterns that can be addressed through more flexible staffing levels.

The requirement for overtime has resulted in improved mutual-aid arrangements, as on-duty companies from nearby departments can respond much faster than can off-duty local personnel called back in. Relying on mutual aid in this way also keeps overtime costs down. However, many small fire departments rely heavily on off-duty response on an overtime basis. Usually a minimum of 2- and 4-hour overtime pay is guaranteed for each response. When alarms for structure fires are infrequent, it may be much more economical for a small municipality to contract for overtime response than to provide a fully staffed fire company around the clock. One major drawback to this scheme is increased response times that will adversely affect fire losses.

Staffing Combination and Volunteer Fire Departments

Significant portions of the populations of the United States and Canada live in communities that cannot support career fire-fighting personnel. According to a 2002 study, whereas 40 percent of the U.S. population is served by career-level fire departments, 26 percent of U.S. citizens live in communities or rural areas whose fire departments are staffed entirely by volunteers.[1]

In most small communities, volunteer fire departments are based on a "neighbor helping neighbor" philosophy in which members receive no compensation other than possibly some reimbursement for personal expenses and uniforms. It is estimated that 84 percent of communities with populations ranging from 2500 to 4999, and 96 percent of those under 2500 are served by all-volunteer fire departments.[1] Various states have recognized the contribution made by their volunteer fire fighters by enacting protective legislation and providing statewide training programs, facilities, retirement systems, tax relief, and similar supportive measures.

Volunteers. When they receive an alarm, members of many volunteer fire departments report to assigned fire stations from which they respond with apparatus; other departments allow members to respond directly to the incident. To guarantee an effective working crew, many departments require the first piece of apparatus to respond with at least three members. NFPA 1720, *Standard for the Organization and Deployment of Fire Suppression Operations, Emergency Medical Operations, and Special Operations to the Public by Volunteer Fire Departments,* states that volunteer fire companies should not conduct interior fire-

fighting operations unless at least four trained members are on the scene.

Fire department administrators should periodically review response records to make sure enough members are responding to emergencies at all times and, if this is not the case, should recruit and train new personnel. In an all-volunteer fire department, staff positions are filled by volunteer officers. In other systems, career personnel may be hired to fill fire prevention, training, and/or communications functions.

Career Staff. Employing career fire fighters means a faster response time and greater efficiency. The fire fighters on duty take the apparatus to the fire, and the volunteers go directly to the fire when notified, thus saving an average of about 3 minutes in arrival time. The career apparatus operator normally is in charge of the apparatus and of the fire station, but volunteer officers may direct the fire fighting. One difficulty with this arrangement is that there are few, if any, opportunities for advancement for career personnel.

An arrangement that works successfully is to have the first responding pumper staffed by a career officer, an apparatus operator, and, when staffing permits, an additional fire fighter. This force is supplemented by additional personnel assigned to respond on call. The second-due engine may be staffed by volunteers or paid call personnel, or it may have a career apparatus operator to take the apparatus to the fire, where it is joined by the volunteer or paid call fire fighters. The ladder truck has a career apparatus operator assigned but is staffed at the fire by volunteer or paid call fire fighters. This arrangement permits a reasonably effective initial fire attack that is quickly backed by volunteer or paid call members. In all cases, there should be just one fire department in any jurisdiction, operating under a clearly defined and unified chain of command that is known to all department members.

Teams of Volunteer and Career Staff. In a number of combination fire departments, career fire fighters have complained about being commanded by volunteer officers whom they felt lacked the needed experience and qualifications. All fire officers should meet the appropriate NFPA qualifications for their rank, as many volunteer officers do. When a career apparatus operator is assigned to operate volunteer fire company apparatus, he or she should work under the orders of the volunteer officer of that company on the fireground. It is important that administrators make clear the respective roles and duties of all members, career and volunteer.

As the principal fire protection officer of a community, the chief of the department should be appointed on the basis of qualifications and experience. The increasing legal and technical responsibilities of the job strongly suggest that communities should consider adopting NFPA standards for fire officers and fire fighters as minimum requirements.

Call Fire Fighters

Many fire departments in small communities employ fire fighters who have no regular duty shift in the stations but are paid by the hour or by the incident for response to alarms and drills. Such members are sometimes loosely termed "volunteers," but under federal labor rules they are considered paid employees of the fire department and, as such, are subject to federal wage and hour regulations.

Compensation. In most cases, call fire fighters are local businesspeople and tradespeople who are willing to be part-time fire fighters. The paid on-call members may also be employed by another agency of the jurisdiction, in which case the time they spend on fire department duty may affect their overtime status. Call fire fighters are expected to meet the same standards of performance as career members of the same rank, although they may not be assigned as apparatus operators when there are sufficient career operators on shift duty.

A call fire fighter's service time is based on attendance at fires and training sessions, with a minimum hourly rate specified for response to alarms. Often, on reaching mandatory retirement age, they also receive a prorated pension, based on their years of service and hours of duty. Various methods are used to determine compensation for paid call fire fighters. In many departments, they receive the same hourly wage for their rank as employees who work regular duty shifts.

Another method of compensation is a fixed annual salary based on rank, from which deductions are made for excessive numbers of unexcused failures to respond or train with the assigned companies. Many fire chiefs arrange to excuse members known to be at their regular employment, except in the case of multiple alarm fires. Chiefs should have the authority to dismiss members who frequently fail to respond to fires or to complete required training sessions.

Still another method of compensation is to make an annual appropriation for call fire service, based on past experience, designed to approximate the hourly wage rate for fire fighters. This amount is divided on a regular basis among the call members as determined by individual attendance at fires and training sessions, so that members responding most faithfully receive the largest compensation. Whatever the compensation method used, the fire department should pay for members' insurance, workers' compensation, training, and all protective equipment.

Service Records. Accurate individual service records should be kept in the personnel files of all fire fighters, both career and volunteer. Response and attendance records are also essential, and members who are habitually late in responding should be replaced. Accurate response records can help identify staffing deficiencies and justify hiring additional career personnel. Municipal officials have often believed that because several hundred volunteers' names were on the roster, the fire department had ample strength, when actually most of those listed were no longer active. This type of situation has resulted in serious delays and in the extension of fires that should have been readily controlled.

Senior fire fighters who cannot respond regularly to first alarms may be assigned to operate reserve apparatus or to guide mutual-aid fire companies when serious fires occur. Other senior call members may be assigned to cover the alarm desk when paid apparatus operators are out of quarters.

PROCURING EQUIPMENT AND SUPPLIES

In most municipalities, fire department equipment and supplies are procured through purchasing departments. Items such as office supplies that are common to all departments may be requisitioned from the purchasing agency and charged to the appropriate fire department account. When items are of a specialized nature, such as fire apparatus or fire-fighting tools and equipment, purchasing specifications must be prepared by the fire department, approved by the purchasing department, and advertised for bids. In preparing specifications for such items as fire apparatus and fire hose, current NFPA standards should be followed.

The fire chief, with advice from the apparatus equipment supervisor, should determine whether proposals submitted by bidders meet specifications. In larger jurisdictions, the law requires that a contract be awarded to the lowest responsible bidder. However, bidders frequently take exception to various details in the specifications or offer substitutes. This situation requires that a fire chief determine whether such proposals meet the intentions of the specifications. If they do not, the bids should be rejected. If, however, the proposals conform to the specifications and are within the appropriation, the contract should be awarded. On delivery, new equipment should be tested in accordance with appropriate NFPA standards.

When emergency purchases must be made, it is customary to require bids from several suppliers. If the amount involved is small and funds are available in the appropriate budget item, the fire chief can authorize the expenditure. If funds are not available in the fire department budget, authorization and funds must be obtained from the municipal management or finance officer.

GOVERNMENTAL RELATIONS

Fire departments are but one agency of local government, and much of their success depends on cooperative working relationships with other local, state, and federal agencies. Some of the more important intergovernmental contacts are discussed here.

Building Department

The proper construction and arrangement of buildings is essential to a sound fire protection program. A community's building department is a key component in ensuring quality control in building construction and compliance with the fire protection features of local building codes.

State laws and local ordinances or agreements between fire and building departments increasingly require the head of the fire department to give written approval of specified fire protection features before building and occupancy permits can be issued. Close cooperation is also needed between these departments to control serious fire hazards that commonly are present while buildings are under construction, before the required fire resistance or protection features have been installed. In small communities, the fire chief generally must handle these duties, but in many fire departments, they are some of the responsibilities delegated to the fire prevention bureau.

Law Enforcement Department

Cooperation between the fire department and law enforcement officials is essential. Regular law enforcement response to fire alarms and other emergency scenes is necessary to control traffic and crowds and otherwise support operations. Similarly, fire-rescue departments are frequently called on to respond in support of law enforcement in investigating criminal matters. Such support can include initiating patient care, extricating victims from vehicles, and providing access to roofs. Fire and law enforcement agencies must develop coordinated plans for managing incidents that require the evacuation or closure of areas.

Law enforcement and fire officials must also develop working relationships to deal effectively with criminal investigations of fires. Many areas use fire investigation teams made up of both fire and law enforcement personnel. Many other fire departments employ fire investigators who have received the necessary law enforcement training to obtain "police powers." These personnel undertake the complete investigation to determine fire cause and origin. In these cases, both agencies work together, combining their areas of special expertise in a coordinated effort when arson is suspected.

As partner agencies in public safety, fire and law enforcement agencies must plan and train together. The scope of incidents that require coordination and unified command to be managed successfully is very broad. Heads of public safety agencies should establish mutual goals and plans that can be relied on in any incident, minor or disastrous.

Water Department

Adequate water supplies, including hydrant service, are essential for fire fighting and are the responsibility of the water department. All too often, water authorities have little knowledge of the waterflow requirements of the fire department for various areas and types of property. Thousands of fire hydrants have been set up improperly because water department crews did not understand the proper location and setting of hydrants required for efficient fire fighting. To prevent this, a knowledgeable fire officer should be assigned as liaison with the water authority. In some communities, the fire department is responsible, by ordinance, for determining the location and setting of hydrants.

All hydrants must be serviced regularly and after use, especially in cold weather. After each incident, the fire department should report all hydrants used to the water department promptly. Alert fire departments maintain a list of hydrants in each fire company inspection district with flow data on each hydrant. (In areas where the water distribution system produces fluctuating flows, however, hydrants should not be marked with flow data.) Hydrants should be marked for nighttime visibility. In many communities the development of geographical information systems (GIS) maps has included a layer that shows the location of every hydrant in the jurisdiction. GIS maps available electronically, and those that identify the global positioning system (GPS) location of the hydrants are increasingly common.

Water departments should operate according to nationally recognized standards, such as those published by the Insurance Services Organization (ISO) and the American Water Works Association (AWWA). The fire department liaison officer should

be familiar with the standards and guidance used by the water department. The fire department should work closely with the water department to identify areas of responsibility and authority for matters such as private hydrant maintenance (in shopping centers, etc.), records management, and development planning and zoning issues.

Public Health Department

Local public health agencies are key partners in community risk management. Fire-rescue department officials should be familiar with local public health officials and coordinate disaster preparedness, response, and recovery planning. A department liaison officer should identify a point of contact within the local public health agency with which regular contact can be maintained. The local health agency is also a conduit to state and federal public health authorities. Public health planners can share guidance with department members for handling emerging diseases and other biohazards, as well as information that has been prepared to inform the public of these issues.

Transportation Department

The local department of transportation is responsible for building and maintaining local roads and streets, and is in constant contact with regional, state, and federal department of transportation agencies. Fire-rescue departments should establish and maintain a good working relationship with the local department of transportation, including staying abreast of its short- and long-term plans for the area. During transportation emergencies, the department of transportation is an invaluable resource and should be part of the unified command structure.

Many metropolitan areas have a regional transportation authority that acts as the long-term planning body for the region. The plans developed often include light rail, rail, and bus systems. Understanding in advance what new modes of transportation and vehicles of conveyance will be brought into the area can be important to fire-rescue planners. A liaison to the regional transportation authority can assist in setting realistic objectives in long-term planning.

Domestic Preparedness Department

Since the federal Department of Homeland Security was created in 2002, state and local government offices have also been organized to address domestic preparedness concerns. The primary goal of these offices is to prevent acts of terrorism, but they also prepare for, respond to, and lead recovery efforts following such acts. Fire-rescue departments should be aware of and in conversation with any homeland security office with standing in their jurisdiction. If an information sharing and analysis center (ISAC) has been created, the department should ensure that fire-rescue personnel participate in its activities and receive relevant information as it is developed. The resilience of a community and its ability to rebound following a terrorist attack will likely hinge on the degree to which comprehensive planning and networking occurred prior to the attack. Fire-rescue officials should insert themselves into local and regional antiterrorism preparedness efforts, along with their allied planning partners.

Emergency Management Agency

Many fire departments are organized to operate the local emergency management agency (EMA) as well. As EMAs have become larger and taken on a wider range of services, however, independently organized EMAs have sprung up within local government. Fire-rescue departments should position themselves as a main support agency to the local EMA. Planning and preparedness for natural disasters is often the primary focus of the EMA and fire-rescue planners have experience, equipment, and trained, geographically distributed staff to offer the community when disaster strikes.

Public Education Department

In the realm of fire safety education, the local public and private school systems, the parks and recreation department, and the public library system can augment and support the local fire department's educational activities. If public fire safety educational activities are to be successful, the local fire department must be able to serve as a focal point for other community resources and be able to build partnerships across a wide variety of public and private organizations. The *Learn Not to Burn*® program is one of the NFPA's excellent fire safety education programs with proven results.

The community safety village is a successful concept originally developed in Canada and now becoming more common in the United States. These villages offer a delivery point in the community for programs of safety education and can include a wide range of education programs, including fire, bicycle, pool, pedestrian, driver, and gun safety. The typical village incorporates classroom space and a kid-sized town into a campus that is used as a training ground for practical elements of the safety lessons. The safety village thus allows a range of organizations to collaborate in managing risk and improving community safety.

Human Resources Department

Members of career fire departments are public employees, and, as such, their recruitment and promotion may involve cooperation with the human resources agency, which, in some jurisdictions, is responsible for conducting entrance and promotional examinations. Fire department management should work closely with the human resources or personnel office, which usually manages compensation and benefits programs for the employing authority.

Finance Department

Fire departments should work closely with finance officials when developing and administering budgets. Budgeting is generally very complex, and fire budget documents must be well prepared. After budgets have been prepared and adopted, proper records of expenditures must be maintained and spending must be kept within the adopted budget. Although some fire departments may have a finance officer, liaison with the finance department may be handled by designated staff officers.

Purchasing Department

All purchases exceeding stipulated amounts must be made according to specifications, usually with competitive bidding conducted by the purchasing department. Close liaison is necessary to ensure that specifications are drawn properly and meet fire department needs and that, when bids are opened, any proposals that deviate from specifications are rejected.

Data Processing Department

Increasingly, fire departments are using electronic data processing to keep fire records and payroll records for statistical analysis. Each fire department should have persons knowledgeable in data processing. It may be desirable to appoint one officer to coordinate this activity and to be involved in administrative planning for the department.

Planning Department

Fire departments, particularly those in rapidly growing areas, should maintain a close working relationship with local and regional planning groups, such as the local emergency planning council (LEPC) and the regional transportation authority. These agencies can provide valuable information on growth patterns that will affect the resources of the department and demands on those resources. The plans, studies, and reports prepared by the planning agencies can be used to determine whether more personnel, equipment, or station facilities are needed.

A variety of other sources of information are also available to fire department planners. Local academic institutions may provide resources that can aid in strategic planning. Coalitions of government that act to coordinate local government agencies actions in regional emergencies often develop sector-specific committees that can serve as referent information sources to planners. Recently, regional planning bodies that convene to address domestic preparedness issues, such as urban area security initiatives, have also become available as a planning resource. Astute fire-rescue planners will avail themselves of the entire planning and information community.

SUMMARY

Fire departments have evolved into organizations that provide a wide array of services. Although fire prevention and emergency response continue to form the basis of the service, most departments now provide some level of emergency medical service, and others provide specialized rescue and hazardous materials response. The growing threat of terrorism presents a new challenge to the changing fire service.

There are many common denominators that define a successful fire service organization. The most successful ones, however, have developed and have adjusted to meet the changing needs of their local communities. Although regional differences result in a significant diversity in structure and staffing, volunteer, paid, and combination departments all function in an environment in which their effectiveness depends on successful intergovernmental relationships with many agencies that interact to achieve public safety.

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on the management of fire-rescue departments discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of the current editions of the following documents.)*

NFPA 1001, *Standard for Fire Fighter Professional Qualifications*
NFPA 1021, *Standard for Fire Officer Professional Qualifications*
NFPA 1221, *Standard for the Installation, Maintenance, and Use of Emergency Services Communications Systems*
NFPA 1401, *Recommended Practice for Fire Service Training Reports and Records*
NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program*
NFPA 1620, *Recommended Practice for Pre-Incident Planning*
NFPA 1720, *Standard for the Organization and Deployment of Fire Suppression Operations, Emergency Medical Operations, and Special Operations to the Public by Volunteer Fire Departments*
NFPA 1901, *Standard for Automotive Fire Apparatus*

Chapter 5

Information Management and Computer Technology

Brian P. Duggan

Chapter Contents

Information Technology Networks
Management Applications
Emergency Response and Operational Applications
Internal and Public Communication Applications
Planning, Training, and Research
Integration of Systems

Key Terms

computer-aided dispatch, enhanced 9-1-1, geographic information system (GIS), incident reporting system, information management, information technology, interoperable communications, Learning Resource Center (LRC), local area network (LAN), mobile data terminal, office automation, personnel accountability system, thermal imaging, wide area network (WAN)

As the fire service enters a new age of expanded information, technology continues to evolve rapidly. This digital revolution has produced an unprecedented external force that requires fire service organizations to change and adapt in an environment increasingly focused on the instantaneous exchange of information. Information-based technology continues to expand at an exponential rate. Often technology is initially developed for the military, space program, or the business community and then adapted to benefit the fire service. The trend toward expanding information applications, integration, and mobile connectivity should be anticipated, and new fire service applications that extend beyond those mentioned here should be expected. Examples of developing applications include intelligent transportation systems that will provide responding units with incident-related information and voice integration that will allow computers to recognize and respond to an individual's voice.

Information technology can enhance organizational effectiveness and efficiency by providing rapid access to high-quality information and empower fire department personnel to offer a higher level of service. Information technology has become an organizational necessity and provides a means for the fire service to innovate and adapt in an increasingly digital world. Although it is clear that the fire service needs to learn new technologies, its mission must be to harness and drive the technology as opposed to allowing technology to drive the fire service.

For related information, see Section 3, Chapter 3, "Fire Data Collection and Databases"; Section 3, Chapter 4, "Use of Fire Incident Data and Statistics"; and Section 12, Chapter 13, "GIS for Fire Station Locations and Response Protocols."

INFORMATION TECHNOLOGY NETWORKS

The availability of low-cost personal computers, widespread Internet access, and wireless connectivity provides even the smallest fire service organizations with the ability to utilize many of the applications discussed in this chapter. As price points continue to decline, a wider range of technology will become more available. In some cases this technology will become single-use disposable items that are critical to operational success. Technology has become evident in most aspects of our culture and can complement the mission of the fire service. These applications range from the dispatch of apparatus to training personnel and providing public education and information services to target populations. Figure 12.5.1 shows an example of fire service specific handheld technology. This rugged unit provides mobile wireless computing for a wide range of fire service applications including personnel accountability and building inspection.

As with many public sector agencies, the fire service is facing the reality of increased competition and diminished resources. Like all government units, the fire service has been asked to maintain, and even increase, service levels. Information technology can facilitate new levels of communication and can help integrate services that provide a foundation for quality service delivery

Brian P. Duggan is the fire chief in the city of Northampton, Massachusetts, and has served as the director of fire science programs at Anna Maria College in Paxton, Massachusetts. Chief Duggan also chairs the Fire Chief's Association of Massachusetts Technology Committee and co-directs the Massachusetts Fire Mobilization Plan.

FIGURE 12.5.1 Handheld Technology Specific to Fire Service (Photo provided courtesy of Tripod Data Systems, Inc.)

and innovation. The contradiction of "doing more with less" can be resolved only with improved management practices that result in higher levels of organizational productivity. Information technology can assist the fire service in meeting the increasing challenges of the twenty-first century. Specifically, information technology is being used to support and complement the following fire service functions:

- Administration and office automation
- Emergency management
- Emergency response, operations, and safety
- Enhanced internal and external communication
- Fire prevention public education and community outreach
- Hazard detection
- Research activity reporting
- Resource control and deployment
- Training

Although the extent of automation varies, the development of information technology has become a specialized niche and many larger organizations have hired information managers and Internet specialists to maximize the organization's ability to successfully apply and benefit from information technology. Information technology has produced a focus on enhancing the effectiveness of both internal and external communication. As such, the development of a sound information technology plan that collaborates and coordinates with other agencies is critical to success.

Local Area Networks (LAN) and Wide Area Networks (WAN)

Connectivity and mobile information applications deserve special attention based on the potential of these applications to benefit the fire service. First, internal connectivity provides the ability to rapidly integrate and share information through the use of local area networks (LAN) and intranets by providing a consistent source of enhanced internal organizational communication. Second, connectivity frequently extends beyond a single agency through the use of a wide area network (WAN). For example, every department in a city may be connected and allowed to rapidly share information and communicate through the use of a single WAN. Networks once fed through miles of wire are quickly becoming wireless and as such more versatile.

The Internet

Connectivity can be further extended through the use of the Internet. The Internet—the organized part of which is called the World Wide Web—provides a means of external connection that can facilitate almost instantaneous communication, data transfer, and information exchange across the globe. The Internet is becoming the most frequent portal of organizational contact with the public. At present, most public sector agencies and private companies maintain an easily accessed informational or commerce-based website. NFPA, for example, maintains a home page on the World Wide Web at http://www.nfpa.org. The Internet provides sources of information on any subject. Some of this information can have relevance in supporting programs, establishing contacts with other persons dealing with the same issues, or developing information for research.

As the Internet has expanded it has become a resource that in many ways has replaced text-based reference sources and printed materials. In essence the Internet has become a library of information and as such an indispensable resource. An example of the vast amount of fire service data available through the Internet can be found through the Learning Resource Center (LRC), which is a virtual fire service specific library maintained by the United States Fire Administration. The LRC provides instant access to an extensive quantity of fire service research and publications. This resource can be found on the Internet at http://www.usfa.fema.gov/training/lrc. Those using information from the Internet are cautioned to verify the source and validity of that information because there is no professional oversight as to what is posted other than information posted by technical organizations.

Fire service agencies can use the Internet successfully for an ever-broadening range of communication needs. One example of how the Internet can benefit the fire service is by providing instant access to the current *National Fire Codes*®, which is an option available through a secure portion of the NFPA website. Through this service, the subscriber is ensured access to updated codes. Previously, updates of *National Fire Codes* were mailed out in printed form or on CD-ROM on a regular basis. This use of technology decreases publication costs, enhances the use of current standards, and increases the effectiveness and efficiency of the subscriber.

Other Internet applications include information research, electronic transactions, purchasing, public outreach, voice communication, video transmission, data transmission, and distance learning. The Internet also provides a tremendous potential for the future as technology continues to evolve.

Although the Internet is full of useful information and has become a primary research tool, it also contains hazards. As technology has developed, viruses, unwanted junk e-mail, and unauthorized intrusion into organizational networks have become all too common. Organizations need to be mindful of

these threats and provide appropriate protection through the use of firewalls, secure software, and diligent data backup.

Wireless Connectivity and Mobile Data

Wireless connectivity has become commonplace, and this technology can be utilized to further extend fire service capabilities. Mobile data allow responding units and command personnel to have rapid access to critical address-based information (Figure 12.5.2). Mobile data also enhance the effectiveness and efficiency of event reporting, allowing fire, medical, and inspection reports to be completed in the field and uploaded to a secure server. Clearly this provides a more rapid means of data collection and reduces the time personnel previously dedicated to these administrative functions on their return from an incident or fire prevention activity.

The advantages of mobile data and wireless connectivity are evident both at the incident scene and through the application of technology developed for the business world. Fire service agencies can also use wireless technology to dramatically enhance communication and coordination of nonresponse functions. Examples of this include electronic mail, remote retrieval of department records, and scheduling applications.

The information age has also provided additional tools that can be used to enhance both safety and operational effectiveness. Examples include computer-driven infrared imagery, electronic personnel accountability systems, and command management software.

Many fire departments have automated a wide variety of functions. Integration of several applications allows for the sharing and retrieval of information among previously distant platforms. Fire service information can be shared among databases and linked through the common thread of address-, person-, or resource-based information fields. (For related information, see Section 3, Chapter 3, "Fire Data Collection and Databases," and Section 3, Chapter 4, "Use of Fire Incident Data and Statistics.")

FIGURE 12.5.2 Command Officer Using a Mobile Data Terminal (Photo provided courtesy of Livermore-Pleasanton Fire Department)

MANAGEMENT APPLICATIONS

Information Management

The successful functioning of a fire department's *information technology*—a term that is used here to include computers, software, data, applications, connectivity, and personnel—depends on how that technology is organized, managed, and incorporated into the organization. Because every organization is unique and because technology continues to provide expanded application opportunities, there is no single best way to develop information technology. A critical step that is often overlooked, however, is the development and training of personnel. Organizations often fail to invest in training personnel how to use and benefit from technology. Without the appropriate development and training of personnel, their resistance to the new technology that often impedes the effective deployment of applications should be anticipated.

Information management within an organization is critical to an organization's overall success. Consequently, information systems are valuable organizational components that must be well managed. Many fire departments now have senior staff members who are responsible for the management of information systems.

Organizational Needs vis-à-vis Information Systems

A well-developed information system fulfills a variety of organizational needs:

- Strategic planning
- Resource optimization
- Support of daily operations
- Public outreach and communications
- Internal communication and documentation

Strategic Planning. Strategic planning is the process by which fire service leaders decide how future resources will be allocated or deployed in the delivery of services—for example, how and where facilities, emergency equipment, and personnel will be distributed. Some fire departments have developed sophisticated computer-based models for the development of strategic plans; others have contracted outside resource groups to provide such analyses. Although modeling applications are becoming cost-effective and widely available, most fire departments depend on the statistical information from fire incident and emergency medical reporting systems as a basis for decision making.

Resource Optimization. Resource optimization is the process of maximizing the output or service provided by resources. Therefore, by optimizing resources we can ensure a high level of effectiveness and efficiency. Resource optimization begins with implementation of strategic choices identified through strategic planning. It continues with the use of control information to make tactical and operational decisions consistent with the organization's strategy and oversight that all decisions are being

implemented as intended. Administrative control and automation are necessary in several areas: (1) finance, (2) personnel, (3) fire prevention, (4) fire investigation, (5) fire suppression, and (6) facility management. Control information is often provided as an additional output of systems designed to support administrative operations. In other words, many applications were initiated for administrative utilization. As an additional benefit, this information can often be used to optimize control of resources such as personnel and equipment. For example, a personnel information system developed to increase the efficiency of collecting and tracking data on individual personnel is likely to permit easy tracking of secondary data useful as controls on the entire workforce (e.g., scheduling of needed training). Applications such as a personnel information-gathering system are often adapted from programs originally developed to meet the needs of the business world.

Support of Daily Operations. The majority of fire service applications and information systems are designed to support day-to-day operations. The most common examples of this type of system are computer-aided dispatch (CAD) and enhanced 9-1-1 (E9-1-1). These systems attempt to optimize response by combining the most accurate data about both the emergency situation and resource availability. Other systems support financial management, fire investigation, equipment inventory and maintenance, inspections, permits, and organizational communications.

Public Outreach and Communications. The ability to provide information to the customer is critical to the future success of the fire service. Websites, e-mail, and distance learning provide an electronic means of enhancing outreach and communication within the community. This form of communication engages the community and provides a previously unheard of level of public contact and customer support. Departments often utilize this conduit to provide information about both the organization and life safety.

Internal Communication and Documentation. The systems applications cited earlier operate as systems of information flow and processing. Each requires certain forms of internal communication and documentation. Strategic planning and resource optimization depend on internal communication of goals, objectives, alternative choices and decisions, and documented field experience, activities, and inventories. Operations support requires internal communications of situation-specific facts and decisions based on the interpretation of principles and procedures in light of these facts. Through integration, systems are often packaged as a function of priorities based on systems planning, organizational needs, and these types of situational factors. There are, however, certain recurring patterns to the way information systems are developed and used within fire service organizations. The following are widely used applications of fire department information systems:

- Word processing
- Electronic mail
- Personnel and facilities scheduling
- Spreadsheet and database programs

Resource Control and Deployment

Program and Organizational Performance Evaluation. Program evaluation is the mechanism by which fire service agencies use facts to make choices about actions that will best achieve their goals. Information technology can be utilized to evaluate an individual program or an entire organization's performance. Points of evaluation must be based on a comparative analysis with other similar service-based agencies. The quality of annual performance and service-level reporting often contributes to resource-level determination. Presenting a compelling case to enhance resource levels is based on the ability to extract and present quality data. This analysis can be used to develop benchmarks that identify both the best practices and the average performance. The benchmarking process can provide a tangible performance analysis of often intangible services. For example, through analysis of trends in fire death and injury statistics, an organization can gauge the overall performance or output of its fire prevention and public education programs. Evaluation can also provide information relating to performance-based criteria, such as the evaluation of response times, or to the need for specialized services, such as advanced life support (ALS), hazardous materials response, or technical rescue.

Fleet Management. Vehicles and equipment represent a significant capital investment, provide safety to fire service personnel, and enable the delivery of high-quality emergency services to the community. Fleet management systems provide the information needed for budgeting and controlling these expenditures, as well as for ensuring that the fleet is maintained in a high state of readiness. The need for information about the fire department fleet exists at all levels: strategic, managerial, and operational. To meet this data-intensive need, fleet management systems involve several components, including fleet inventory, equipment inventory, maintenance records, vehicle replacement schedules, fuel consumption, internal billing for vehicle use (e.g., in the case of citywide carpools), repair cost projection, and performance analysis. Most of these components have become common in the majority of fleet management systems.

At the strategic level, information about the existing fleet is needed to plan and budget for vehicle acquisition and replacement. To make sound replacement decisions, accurate information on maintenance frequency, operating costs, age, and so on for each major piece of equipment is needed. Indeed, those decisions are often so complicated and have such significant political overtones that decision-support software (i.e., operations research models) is needed to help analyze and organize these data.

At the managerial control level, fleet managers need computer support to control preventive maintenance intervals, prioritize work in progress, track fuel consumption, and plan for the appropriate staffing of the maintenance facility. If the maintenance staff members are to be effective, they require immediate access to information, such as vehicle performance, repair records, parts inventory, interchangeable parts data, equipment

manuals, and standard repair times. Likewise, administrative services managers need financial data on expenses for budgetary forecasting and control.

Personnel at the operational or task level also need information from a fleet management system. Most important, of course, is the ability to have information on vehicle condition and availability. Although this information is not always provided by the fleet management system per se, dispatchers need to know what equipment is in service and available to respond to a given type of emergency.

Few fire departments develop their own fleet management systems. They either use a commercially available system or a citywide fleet management system. Commercial systems may be difficult to interface directly with other department or city systems. Also, added capabilities, such as vehicle replacement models, may not easily integrate with these systems. Yet, this internal approach can be implemented easily and is cost-effective, especially for fire departments that do not have highly integrated systems.

The citywide approach also suffers from some of the same deficiencies. Since citywide systems are typically designed for standard street vehicles, they may ignore certain features that would be common to fire apparatus and emergency response vehicles. For example, the city system may not have a provision for capturing and maintaining special data on apparatus components, or it may not provide for maintenance records of special equipment unique to the fire service. If these deficiencies are to be eliminated, the fire personnel must actively participate in defining information requirements. When these requirements have been defined, the citywide approach can be worthwhile. As fire service integration advances, fleet management systems that are customized to the specific needs of the fire service are becoming a common part of most fire department records management systems.

Capital Asset and Personnel Planning. The ability to develop and support a capital plan that anticipates service demand has become an extremely technical process that involves several aspects of information technology. This process includes the evaluation of incident type, location history, response time analysis, and the evaluation of resource availability. This information can be used to model station locations, set performance-based goals, determine peak service demand hours, identify service gaps, and forecast personnel, facility, and equipment needs.

EMERGENCY RESPONSE AND OPERATIONAL APPLICATIONS

Computer-Aided Dispatch

Computer-aided dispatch (CAD) is an address- or occupancy-based information application that is oriented toward operations. CAD monitors resource status and optimizes emergency response by rapidly assigning the closest appropriate and available units (Figure 12.5.3). Through integrated CAD systems, resources are tracked, alarms are received, fire stations are alerted,

FIGURE 12.5.3 Dispatcher Using a Multiscreen CAD System (Photo provided courtesy of Geac Public Safety)

information on hazards can be transmitted, and situations are managed. The system's purpose is to support current activity rather than provide managerial control or strategic planning information. However, the functions of CAD systems often go beyond operational support. In an integrated information systems environment, the CAD system may produce nonoperational information in support of other administrative and planning functions.

CAD systems support a multitude of fire service dispatch functions:

- Alarm receipt, fire alarm signal decoding, central station communications management, and so on
- Communications and signaling management: alerting unit/station, two-way exchange of data, paging, electronic mail, radio frequency selection, and coordination
- Emergency medical dispatch (EMD) and other situation-based emergency instruction
- Status maintenance: monitor resources, equipment, personnel, and system supervisor
- Response assignment: dynamic assignment based on current availability and relative location of emergency response resources to incident

Although CAD is usually credited with reducing response time, the payoff is not necessarily in this area. Some departments even report an increase in response time after implementing a CAD system. The real benefits of CAD occur in the coordination of emergency response activity. Thus, rapid recall of information, such as apparatus status and occupancy data, is at least as important as response time.

Implementing a CAD System. Choosing a correct approach to implementing a CAD system is a multifaceted problem. The first facet of the problem is related to policy. In some cases, dispatching is a shared public safety responsibility. In others, regional dispatch centers serve multiple jurisdictions. The organizational situation can have an important influence on other aspects of the approach, as well as on the ultimate usefulness of the system.

Determining the System Scope. A major starting point in CAD development is a decision on the scope of the system—that is, whether the system is to be developed only for CAD or whether it will include other applications. Most departments elect to develop a stand-alone CAD system with the necessary interfaces to other applications, for example, the fire incident reporting system. Others may elect to more closely integrate their CAD system with other computerized record management systems (RMS) in the department. Regardless of how many applications may be bundled together, the CAD operation is the top priority and it is designed to continue to operate even if some of the other applications are temporarily unavailable.

Closely related to the issue of scope is the degree of modularity built into the system. A highly modular system permits the system to be expanded to include enhanced CAD functions, such as alarm system interface and alphanumeric paging, as well as other peripheral applications. It also allows new software to be tested in an off-line mode and operators to be trained without interfering with operations. Modularity is important in all applications, but it is especially critical in CAD systems because the systems are subject to almost constant change.

Using Outside Contractors. An outside contractor is often used to develop a department's CAD system, although internal teams have developed effective systems. If an outside contractor is used, both operations and communications personnel must be extensively involved in developing the system requirements and specifications to ensure that the final system meets their needs. Likewise, when the system is installed, all staff members must be involved so they understand the system design and are properly trained to maintain and operate the system. The importance of properly involving and training personnel cannot be overstated.

Interoperable Communications. Communications is another aspect in selecting an approach. Standard telephone service has typically been used for communications between the dispatch center and the fire stations. Increasingly, other ways are being found to transmit data. The 800 MHz radio frequencies have been used successfully, as have microwave links and dedicated data lines. Alphanumeric pagers, computer terminals in fire apparatus with both paper printouts and liquid crystal display (LCD) readouts, fax machines, voice-over Internet, and cellular telephones are also becoming increasingly popular for dispatching apparatus and communicating with company officers and incident commanders.

The ability to operate on multiple frequencies and coordinate operations between agencies has become increasingly complex. Often agencies even with the same jurisdiction operate on different frequencies. The inability to create seamless controlled interoperable communications is an ongoing challenge within public safety agencies. Technology has expanded to provide the ability to bridge frequencies. These efforts, however, must be planned and managed through a communications plan because this technology can quickly create a dysfunctional situation. Interoperability equipment includes both a computer-based patching capability (Figure 12.5.4) and banks of radios (Figure 12.5.5).

Incident Management Support

The effective and efficient management of significant incidents can tax even the largest fire service organizations. The use of technology to coordinate and manage operations during large-scale events has increased, and many jurisdictions have developed mobile technology platforms that are designed to optimize deployment, coordinate activity between multiple agencies, and provide general incident support services. Figure 12.5.6 shows an incident in which a technology platform provided incident support at a large warehouse fire.

FIGURE 12.5.4 Computer-Based Patching (Photo provided courtesy of the Massachusetts Department of Fire Services)

FIGURE 12.5.5 Banks of Radios (Photo provided courtesy of the Massachusetts Department of Fire Services)

FIGURE 12.5.6 ISU Fire Response (Photo provided courtesy of the Massachusetts Department of Fire Services)

Although some of these platforms, such as the mobile technology platform pictured in Figure 12.5.7, were designed and deployed prior to the tragic events of September 11, 2001, the development of these vehicles, which often serve a large region or multiple agencies, has become commonplace.

The mobile technology platform pictured in Figure 12.5.7 can effectively be utilized to support operations and assist the incident commander. Examples of the technology provided by the mobile platform often include the following:

- Additional communication resources
- Cellular and satellite-based telecommunications
- Coordination of emergency response mobilizations
- Cross-band and multi-agency communications management
- Download of audio and video signals

FIGURE 12.5.7 Mobile Technology Platform Used to Support Large-Scale Operations (Photo provided courtesy of the Massachusetts Department of Fire Services)

- Equipment tracking
- Event logging
- Geographic information systems
- Interface with other agencies and units
- Internet and paging access
- Interoperable communications planning and management
- Scheduling and long-term planning
- Thermal video imaging and projection
- Weather monitoring

Many communities replicate some of the foregoing resources within an emergency operations center (EOC), and these mobile technology platforms offer the unique ability to operate at an incident scene. Because this equipment is complex, it is essential to have a trained overhead team that works with this technology on a regular basis.

Emergency Access Systems

Enhanced 9-1-1 System. Enhanced 9-1-1, or E9-1-1, is a highly reliable emergency phone system that displays the caller's telephone number, address, response district, and other important information automatically on the dispatcher's computer screen, along with dispatch information for fire, police, emergency medical service (EMS), or other emergency responders. This system is invaluable, especially in those cases where the caller is unable to give information fully or clearly because of language barriers, incapacitation, confusion, or excitement caused by the incident, age, or even lack of knowledge of the area. E9-1-1 can have a dramatic effect on reducing response times. Because it identifies the actual telephone location from where the call is placed, it also helps reduce false alarms.

This system has been widely installed throughout the United States. Even more sophisticated systems can provide information concerning previous calls to the same address, hazardous materials stored on site, day care or other life-safety–intensive operations at the address, and other information pertaining to a caller's disability or medical condition that is useful to the responding units.

As E9-1-1 continues to develop, cellular triangulation that maps and identifies the relative position of a caller will be implemented. The development of a caller's location can be accomplished through the use of signal triangulation from multiple cellular towers and integration with geographic positioning systems (GPS). This technology is common within the majority of enhanced 9-1-1 systems and has the potential to provide information that will assist in locating an incident, therefore saving both time and lives. As 9-1-1 systems have become accepted by society, they often become overburdened with less than true emergency calls. In an effort to properly channel these informational calls, over two dozen U.S. cities have developed alternative informational numbers such as 3-1-1 to divert call volume and match the callers to the best resource to address their needs.

Although the Internet and other modern technologies are being used globally, the application of these technologies varies widely. Of more specific interest here is whether and what kind of enhanced emergency access systems are found in countries outside the United States. Australia has a system similar to the

enhanced 9-1-1 system found in the United States. A call (made to 000, the Australian emergency call number) is received by the national telephone company and passed on to the CAD system covering that area, at which point enhancement kicks in with call line identification and cell phone general area information. The system then captures the information for the incident reports. Utilizing the triangulation of cellular signals in concert with geographic positioning systems, the vast majority of enhanced 9-1-1 systems can rapidly determine the geographic location of a caller.

Across Pacific Asia, enhanced emergency access systems range from very sophisticated systems in Singapore and Hong Kong to very basic systems in other parts of Asia. Of significance to the development of such systems are issues pertaining to the infrastructure currently available, especially within relatively underdeveloped countries.

Geographic Information and Positioning Systems

The integration of digital imagery and mapping technology provides a foundation for the development of location-based applications that combine to form a geographic information system (GIS). This address-based information system serves as a valuable tool to many municipal agencies and can provide a central information link between departments if GIS has been developed, integrated, and networked properly. For example, when a new subdivision is proposed, information relative to the water system would be of interest to the building, fire, planning, and water departments. Information on a structure at a given location is of value both to units responding to an emergency and to the community's tax assessor. Consult Section 12, Chapter 13, "GIS for Fire Station Locations and Response Protocols," for more information on GIS.

GIS represents a mapping application that provides several selectable layers of information. Each layer can be included or excluded depending on the specific need—for example, the zoning information layer would not be of value when configuring GIS to provide a map to be used to search for a missing person. GIS offers a previously unknown ability to consolidate information by address. Specific to the fire service, information pertaining to hazards, permits, structure history, water supply, navigation, and topographical land features are routinely utilized.

GIS can also be used to support fire service planning needs, ranging from response time evaluation to station location analysis. Operationally, GIS can be used to support fire service activity at a variety of emergency situations, including hazardous materials situations, wildfires, and weather-related events. Capitalizing on the ability to integrate multiple applications, officials can now anticipate the track of a severe storm or chemical plume and automatically warn residents within the projected path. Through this technology, evacuations can be expedited and residents can be advised to take appropriate action. Previously, these notifications would take hours and consume vast amounts of resources.

Geographic positioning system (GPS) integrates the mapping of GIS with the ability to determine current location (Figure 12.5.8). This technology, originally developed by the military, can provide accurate location information for aircraft or other responding resources. In addition, GPS can aid navigation by providing directions, inclusive of verbal instructions, to a destination. GPS can be updated to provide optimal routing, given changing traffic conditions. These systems have become popular options in many passenger vehicles, and as they become more affordable, they will continue to gain popularity. In the future, GPS will likely be integrated with intelligent transportation systems and provide an automated reflection of current conditions.

Automatic vehicle location (AVL) further links GPS to GIS. AVL provides the dispatch center with the ability to visually monitor a real-time map that shows resource status, speed, and location. As a result, available units that are closest to a situation can be dispatched. AVL enhances resource control and dramatically reduces response time to emergency situations. This technology truly saves lives, reduces loss, optimizes resource deployment, and complements the fire service mission.

Mobile Data

The ability to provide critical information to responding units can be accomplished through the use of wireless computer technology. Through mobile data systems, responding units can obtain situation updates, directions, prefire plans, digital imaging, structure information, hazard information, water-supply configuration, and hydrant locations (Figure 12.5.9).

In addition, the ability to communicate remotely provides rapid access to reliable data and improves the decision-making process. Mobile data can be transmitted through radio systems or cellular technology; at present, the most popular transmission medium is either the use of secure wireless Internet connection or data bursts sent through cellular digital packet technology (CDPD). As communications networks evolve, mobile data communication will increase in speed and will most likely include the use of both satellites and the Internet.

FIGURE 12.5.8 Mobile Geographic Positioning and Mapping Information (Photo provided courtesy of Livermore-Pleasanton Fire Department)

FIGURE 12.5.9 Responding Engine Company Using a Mobile Data Unit (Graphic image provided courtesy of ESRI. Copyright © 1999, 2000 ESRI)

Thermal Imaging

An infrared thermal imagery unit, which detects temperature variations, can penetrate smoke, structural features, and darkness and provide fire fighters with a visual image of reflected temperature (Figure 12.5.10). Light changes indicate temperature variations. This computer-based tool can be harnessed to increase both the ability and safety of fire service personnel. Thermal imagery, the projection of heat images, has several fire service applications, including the following:

- Searching for fire victims
- Searching for hidden fire (in concealed spaces)
- Searching for missing persons
- Identifying malfunctioning equipment
- Identifying fire location
- Providing assistance to other agencies, municipal agencies, and industry

Thermal images can also be transmitted to provide command personnel with improved reconnaissance as they manage a situation from a remote location. The size of thermal imagers continues to decrease and additional technological advances should be expected. Currently thermal imaging has become an affordable technology that continues to evolve. Future enhancements will include the integration of imagers into a fire fighters' turnout gear, color display, levels of warning, and pattern recognition.

Personnel Accountability/Fire Fighter Tracking Systems

The need to track personnel operating at an emergency scene is a basic principle of safe operations. Technology that uses bar code scanning, coded data chips, radio signal transmissions, and personal digital assistant databases assists command and safety personnel with the management of this complex function in less than optimal environments. Currently, automated personnel accountability systems can track personnel assignments, duration of entry, and project air consumption (Figure 12.5.11). These units automatically prompt and record periodic personnel accountability reports. Other systems can be utilized to direct rescue crews toward the location of a lost or injured fire fighter. Although many systems are complex, this emerging technology is becoming easier to use and more cost-effective. The challenge will be to utilize this technology to provide a timely and accurate reflection of operations.

Locating an injured or unresponsive fire fighter has been a difficult task. Automated location systems that provide a directional pointer to the location of a fire fighter in distress can assist a rapid intervention team. Although this technology is currently useful, it should be expected that systems of this type will be enhanced to provide more detailed information.

Hazardous Materials Detection

The ability to detect hazardous conditions is firmly based within technology. As the need to handle hazardous materials has increased, the need to detect chemical, biological, radiological, and nuclear threats has developed a wide array of computer-driven metering systems. As this technology matures, these metering devices are becoming increasingly reliable, more compact, and easier to use.

Digital Documentation

In a litigious society the need to document conditions and actions at the incident scene has dramatically increased. Information technology has facilitated this documentation. Most fire service radio traffic and telecommunications are digitally recorded and time/date stamped. This audio recording of voice communication provides a foundation for event documentation.

Digital Imagery

Both still photographs and video expand the ability to provide professional documentation. These images can enhance post-operational review and serve as a training and evaluation tool. Images can also communicate and market the organization's role and mission and can be used as a tool in public education efforts. Documentation is essential to an effective fire investigation program.

Emergency Medical Services

Most fire departments now provide emergency medical service (EMS). Fire equipment and fire fighters are generally dispatched to perform or support EMS activities. The fire department may or may not be involved in the actual patient transport. Ambulances, whether operated by the fire department, another city agency, or the private sector, are often dispatched by the fire department or public safety dispatch center.

Technology has gained an expanding role within emergency medical services over the last 5 years (Figure 12.5.12). Examples of the utilization of technology range from defibrillators that can correct an improper electrical rhythm within the heart to a pulse oximeter that monitors a patient's oxygen level.

In many jurisdictions, the cost of emergency medical service is billed to the patient. Since this practice represents a substantial revenue source for the city or county, the billing process is the most intensive information system within most EMS systems. Other components of an EMS data system include the following:

- Patient care information
- Treatment protocol and reference material
- Response needs and resource allocation
- Training material

The statistics generated from EMS systems are used in both long-range plans and operational planning and control. Response times, locations of incidents, and unit staffing and deployment patterns are required to plan and budget for resources and determine if the units, personnel, and facilities are being configured appropriately.

In some fire departments, separate systems have been designed to handle both the EMS billing system and the EMS incident records. In other departments, data from the billing system are transferred to the fire incident reporting system from which operational statistics are generated. Having all incident data in-

FIGURE 12.5.12 Wireless Reporting System for Patient Care (Photo provided courtesy of Zoll Data Systems, Inc.)

tegrated into the same database is helpful in studying fire department emergency activity.

A basic EMS report form can be used by fire departments to keep track of their EMS activities and can be amended to reflect their specific EMS reporting needs. Mobile EMS reporting has enabled EMS personnel to quickly access and update patient care records while treating a patient. Many of these systems automatically upload and synchronize billing and patient care records.

Technology and information systems facilitate communication between ambulances and hospitals for the transmission of medical directions and telemetry data for physician evaluation. Mobile incident reporting has also become an accurate means of documentation because the report is completed rapidly. In addition, this technology can reduce the time that personnel dedicate to documentation and administrative tasks because reports are completed prior to returning to a fixed facility. As the use of the Internet and mobile data expands, the development of information technology that can transmit medical images and video to a treating physician should be expected. Technology currently in use concentrates on telemetry (sending heart rhythms and other critical patient care information over radio signals) and EMS incident reporting.

INTERNAL AND PUBLIC COMMUNICATION APPLICATIONS

Easy access to computer technology and the widespread acceptance of advancing technology have propelled the use of electronic communication. This shift in communication methodology provides the fire service with a tremendous opportunity to enhance both internal and external communications. Internally, electronic mail allows consistent and rapid communication to all personnel within the organization. Regular communication with shift personnel is increased with e-mail. A LAN, or intranet, which serves as an internal information network, can store reference material and share organizational information, such as policies and standard operating guidelines.

Externally, e-mail and Internet webpages permit the positive projection of an organization. Through increased communication, an organization can strengthen both community outreach and customer service. A webpage often becomes the most accessible public portal, and fire service agencies should recognize the importance of an Internet presence and develop a website that is reflective of the quality of the organization. The Internet, which has become a conduit for public information, allows the rapid dissemination of information. In its attempt to meet the needs of its customers, effective fire services will seize on this communication medium as a tool to educate and become more responsive to the community.

Public presentations often influence both resource allocation and programmatic success. Although a presentation reflects the ability of the speaker, information technology can add professionalism and provide a technological means to make presentations more effective. By using presentation software such as Microsoft PowerPoint and liquid crystal display (LCD) projection, speakers can augment and customize their presentations with audio, digital imagery, and video enhancements. They can then electronically transfer these presentations via the Internet to create a base for distance-learning applications. For example, a fire service agency may post an automated training program specific to fire safety for the elderly on its website and allow the public to download and view this material.

Administration and Office Automation

The term *office automation* refers to a group of applications that support clerical and managerial activities. These applications include word processing, spreadsheets for financial and numeric data, database development for various record-keeping applications, e-mail, "tickler" systems, teleconferencing and videoconferencing, and personal calendar management.

The purpose of these applications is to make the executive and the clerical worker more effective. Although the same may be said about traditional information systems, the focus here is different. Traditional information system applications are process oriented; office automation, in contrast, is more people oriented. The objective is to make office personnel more productive by allowing them to use computers and other technology as a natural extension of their minds and bodies.

Executives and clerical workers need office automation to cope with the complexities and increased demands of today's office environment. Fire agencies must contend with an explosion of information in the form of reports, forms, memoranda, and computer files. The efficient development and effective management of this information resource strain even the most dedicated staff. The computer, through automation applications, extends human intellectual capabilities and allows office staff to do more. Personnel development is essential to harness the abilities of office automation software suites. As office automation is developed, employee input must be considered. Through focus groups and internal training, consistent ways to maximize the potential benefit of this technology can be developed.

Mobile Connectivity

Mobile connectivity extends beyond prefire planning, reporting, and emergency operations. Remote communication through wireless technology, mobile data terminals, personal digital assistants, and cellular technology is growing in popularity (Figure 12.5.13). For example, through wireless integration, a fire inspector can adjust his or her schedule, retrieve technical data, update prefire plans, review facility history, and document activity without devoting administrative time at the office to perform these tasks. Therefore, through this technology the inspector's effectiveness and efficiency have been dramatically increased. Based on technology, the inspector can recall records, spend more time in the field, and be instantly updated.

Networking

To provide the needed integration while retaining the flexibility for stand-alone units, most fire service organizations are developing network-based systems. These are full-fledged computer systems specifically designed (both in terms of hardware and software) to handle office automation and interface with other public safety technology. The individual office computer is connected to a central server that manages data storage and

FIGURE 12.5.13 Wireless Personal Digital Assistant (Photo provided courtesy of Livermore-Pleasanton Fire Department)

communication. This setup allows the user to have a stand-alone workstation on a desktop that can perform all the office automation functions and still have access to the databases retained on the central network server (Figure 12.5.14).

There are several variations on network design. Depending on how data are captured and utilized throughout the network, various functions can be performed either by the desktop computers, network servers, or a central microcomputer. For example, a desktop computer might be used for word processing as a stand-alone task but be tied to a network system to transmit electronic mail, link to other computers, and make inquiries into CAD databases on a central computer. The network provides the mechanism to integrate all these activities. Based on the risk posed by mechanical failure, file corruption and virus infection-critical data should be backed up on a frequent basis. At least one full system backup should be stored at a remote location to avoid a potential catastrophic data loss if disaster strikes.

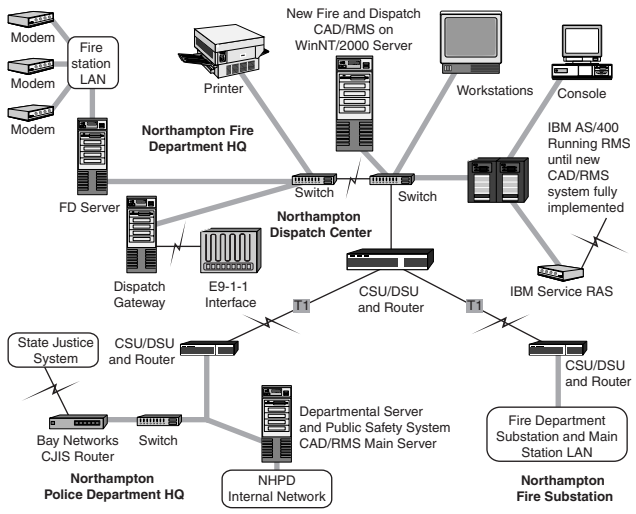

FIGURE 12.5.14 Sample Design for Public Safety Network (Image provided courtesy of Corporation for Public Technology)

Internal Databases

With the advent of desktop and laptop computers, commercial database packages that can develop customized files are becoming the accepted way of gathering information for a fire department. Relational databases not only accomplish one-dimensional tasks but also go much further in their usefulness. The term *relational* means information can be compared in relation to other information; for example, "what if" questions are easily and rapidly answered when data are gathered using a relational database. If a fire chief is asked to cut the budget and the only way to do so is to close a station for some period of time or send fewer engines, he or she can quickly determine the time period when such an action will have the least impact on service to the community. A relational database can analyze incident data to show the best time to close down a station, based on number of alarms, severity of fires, or other criteria the fire chief may want to use to determine the best alternative.

Relational databases, even though created for use on desktop computers, are extremely powerful, highly useful programs. The ease of learning and using these programs has improved dramatically over the past several years, such that most departments, no matter how large or small, would find them valuable tools for all types of information management.

External Databases

Much of the technical and legal information needed by fire departments exists on commercial or governmental databases. These databases are created for general use, and users are charged for access on the basis of either a subscription or a flat hourly rate based on time actually used.

In a very real sense, commercial and governmental databases are a public utility. The source for the information stored in these databases is primarily current technical literature and legal materials. In some databases, abstracts of documents and books are stored; in others, the complete text is stored. For example, *National Fire Codes* is currently available to subscribers through protected electronic access. Numerous firms provide databases. Literally over a million databases, covering various fields, are available today through most technical companies and public communications entities.

The databases of greatest use to the fire service are those dealing with hazardous materials, codes, standards, and legal information. Chemical and hazardous materials databases allow a user to search for a hazardous material by chemical structure, trade name, generic name, CAS registry number, chemical or physical properties, and textual description. These databases can be powerful tools in handling chemical spills, fires involving hazardous materials, and some emergency medical situations.

During the next few years, electronic reference material will become dominant over printed reference material. This growing popularity is based on the increasing ability to rapidly search a large volume of current information.

Fire Service Specific Applications

A variety of programs developed specifically for the fire service exist. Although some perform only one function such as

incident reporting, others provide an entire suite of fire service management applications that can assist with fire prevention, training, budgeting, internal communication, and other functions. As software is selected it should be carefully assessed and matched to the needs of an organization.

One advantage to a comprehensive fire service specific software system is that as data are populated in one area, they are shared throughout the other applications, thus reducing the need for redundant data entry. However, these fire service specific systems often fail to have the capability of easily sharing data with other non–fire service municipal applications. Therefore, many communities have selected separate software packages that can be utilized by several municipal departments that need to share data on a frequent basis.

Financial Applications

Financial applications include those systems that support budgeting, fiscal control, general ledger, accounts payable, and billing. Payroll is sometimes included, although more often it is a part of the personnel system. Billing may also be included in specific systems—for example, billing patients for emergency medical services and billing property owners for removal of illegal brush. (Many high-fire-risk states have ordinances requiring clearing of underbrush to reduce fire intensity and the chance of building involvement.)

The implementation of financial systems in fire departments has been slow, partly because the support of staff functions, such as finance, has been secondary to the support of line activities. In addition, municipality-wide financial systems often preempt those in the individual departments.

Perhaps the most critical need for financial information in the fire department occurs during the yearly budget cycle. The arduous and sometimes politically risky process of allocating resources requires considerable analysis. Decisions must be supported and justified by the kinds of facts best stored and manipulated by a fire service information technology system.

Budget control is also a high priority for fire agencies. Management needs to forecast expenditures to determine if the department is staying within budget. Even if central systems are available for this purpose, they may not provide data in sufficient detail or in a form that is useful to the fire department.

The remaining needs addressed by financial systems are primarily operation oriented: general ledger, billing, accounts payable, and payroll. The last three requirements more often than not are a part of associated applications (e.g., payroll in the personnel system, billing in the emergency medical system, and accounts payable in the procurement system). Manual or automated "bridges" are then provided to integrate general ledger and budgeting systems. The most common design approach to financial systems is a strongly centralized one. This is not surprising in view of the fiduciary responsibility of the chief financial officer in the public sector.

Human Resource Functions

Personnel systems are among the most complex and data intensive of all fire department applications. They may be part of a communitywide personnel system or may be specific to the fire department. Consisting of a number of subapplications, these systems are important in large departments to support the multiple functions of personnel administration, such as basic personnel records management, certification tracking, time and attendance reporting, payroll (sometimes part of financial management), duty schedules, physical fitness and medical records, employee evaluation, training records, position control, badge history and control, and disability/injury analysis. Without computer support for the personnel administration functions, large fire departments would find it difficult, if not impossible, to maintain all the necessary information, and little or no analysis of the collected data would be available.

The operational benefits are obvious. In a 1000 person fire department, a large volume of information is needed to carry out standard personnel functions. Fire fighters must be scheduled and personnel assignments must be balanced daily. Detailed training records are required for each department member. Time and attendance records are necessary for payroll. Employee records must be evaluated and considered for promotion. Overtime hours must be monitored and analyzed. These functions require an efficient way of storing, retrieving, sorting, and evaluating information.

The information that is useful for day-to-day operations also has residual value for strategic planning and managerial control. For example, the roster data may be aggregated in such a way that this information becomes useful for position control or personnel resource planning—that is, controlling the number and rank of personnel assigned to ensure that appropriate staffing patterns are employed. Management may use routine, periodic reports to review time and attendance data in an effort to control excessive sick leave or overtime. However, information required for strategic planning and managerial control typically cannot be fully defined prior to the time it is needed. Therefore, it is useful to have the facility for designing ad hoc inquiries using the operational database to provide information properly tailored to the nonroutine strategic or control application.

At the highest level of design, the approach taken will depend on the relationship of fire department personnel functions to city (or county) personnel functions. For example, the payroll may be prepared by the city from prescribed time and attendance records. In such a case, the fire department may have difficulty developing some of the components of a personnel system.

Another aspect of the design approach is the degree to which the components of the personnel system are integrated. In most cases, the personnel system has been built over several years, with one component implemented at a time, with no overall design providing for integration of files and input. A comprehensively planned system provides for integration, even if the components are implemented separately.

Facility Management

As fire facilities become more complex, technology can be employed to monitor critical aspects of operation. Systems that can be controlled through the use of technology include life safety, backup power, communications, access control, and energy management.

The need for security has increased as fire services have evolved. Ranging from basic facility security to controlled access to narcotics and other medications, controlled access is essential to operations. As such, several access technologies have been developed. Commonly, user name and password combinations will protect information system access, and fingerprint or magnetic card readers can provide access and monitor utilization of facilities and critical equipment.

Energy management systems provide information for control of energy costs, including information about the consumption of electric power, natural gas, and heating oil. In some cases, the use of motor vehicle fuel may be monitored, although this function is more properly a function of fleet management systems. The typical approach to the design of energy management systems is to capture energy billing data, update master files, and make various reports available to administrators. This energy conservation strategy can be maximized through the use of either a relational database or a spreadsheet. More sophisticated approaches include real-time monitoring systems and even real-time energy control. Computer-based evaluation models are also used to assess the impact of conservation measures. The cost of implementing a computerized energy management system can be recovered quickly through increased energy resource efficiency. This technology can control multiple systems to ensure comfort and efficiency and can identify problem areas.

Fire Prevention Applications, Inspection, and Permit Tracking

Fire prevention management information systems are address-based tracking systems for storing fire protection–related information on a community's buildings. The heart of a fire prevention system is a flexible file of properties. The application is useful in planning and managing fire prevention activities, controlling hazardous contents, and prefire planning for fire suppression.

Fire prevention records in many communities still consist of long, often handwritten, forms and narratives filed in individual folders, one for each property. This lack of electronic automation makes it virtually impossible to manipulate data and develop any information on patterns of hazards or violations across the community or for particular property classes.

Even within a file on a single property, it can be difficult to ascertain whether the fire department has been providing the kind of frequency of contact called for by the department's policies, community ordinances, and other state and federal laws and regulations. This difficulty exists because such files are often dumping grounds for any and all papers bearing the property's address. Minor, unofficial correspondence and news clippings may share space with inspection reports, violation notices, and detailed construction plans. Files on properties not covered by the fire prevention code (such as single-family dwellings), on fire education contacts, and on contacts by other agencies (such as the building and housing departments) are generally nonexistent or wholly separate and incompatible with the fire inspection files. Fire incident records are rarely tied to files on the violation and hazard histories that may have caused the fires. In fact, it would be difficult to identify any aspect of a fire department's record keeping that is more in need of refinement and automation than fire prevention. Handheld computers serve as tools to make the fire inspection process more effective and efficient. For example, the TDS Ranger pictured in Figure 12.5.15 makes available applications on fire prevention inspection and records management.

As fire prevention activities are address based, utilizing handheld computers that can retrieve, update, and input property-based information can add to an organization's capabilities. Many of these systems can provide an inspector with a complete history of a property and prevent the need to duplicate data entry. In addition, most of these devices synchronize with a network system and create a database that can be shared with other code compliance agencies.

The first requirement for an adequate fire prevention system is a comprehensive address-based inventory of all properties in the jurisdiction. Such a file is difficult to create. Past studies have shown that, despite conscious efforts, fires are reported in properties that should have been subject to fire inspections but did not appear in the inspection records. These were not new businesses or businesses operating illegally out of homes; they were legitimate businesses of some years' standing that simply had been overlooked.

Although file completeness cannot be guaranteed, it can be improved. Address files should be linked to the fire incident records, preferably through a link to the communities' GIS and CAD systems, so that emergency runs or municipal records to corresponding unlisted addresses will lead to the creation of an inspection file.

Sources for both the initial building inventory and periodic updates are the city's tax records, E9-1-1 database, the build-

FIGURE 12.5.15 Fire Fighter with a TDS Ranger (Photo provided courtesy of Tripod Data Systems, Inc.)

ing department, any inspection agency, and city-owned utilities, such as the water, sewer, and electric departments. Some lists (e.g., the telephone company's Yellow Pages, cross-indexes, and mail carrier routes) tend to be unwieldy or poor sources for finding missing addresses.

The physical fire inspection procedure itself can be a source of effective property list updates. Inspections conducted on a sequential basis allow inspectors to see properties they might miss if they were to organize their routes with strict attention to those properties identified only by the computer.

Once the file is created, it can be used as a basis for organizing and scheduling inspections. The system can be set to print inspection reports for properties scheduled for inspection in any given time period (weekly, biweekly, or monthly), thereby allowing inspectors to plan their work. Likewise, the need for reinspections to check that hazards are abated or other violations corrected can be easily tracked, and missed inspections can be identified. Inspector workloads can be balanced either by the number of inspections or by the total time spent on inspections if statistics are kept on the typical duration of inspections by type and size of property.

Accuracy is important when automating data on buildings in a community. Although the occupants of a building change from time to time, the building itself usually doesn't change much. Some jurisdictions use the Basic Structure Report, Form 903SR, to gather basic information about structures. This form is an excellent way to capture data about buildings that need to be inspected periodically. Furthermore, the information gathered is extremely valuable for prefire planning efforts at that structure.

For all buildings, especially those that contain more than one occupancy, a basic occupancy report provides a way to gather information (e.g., who is using the building) for both inspection and training functions. The best asset of such an information-gathering system is that the data are classified in a uniform manner, based on NFPA 901, *Standard Classifications for Incident Reporting and Fire Protection Data.* With the data classified, it is easy to analyze the data, assess the severity of hazards being reported, and retrieve records for properties that have similar characteristics. This allows a supervisor to prioritize a fire department's inspection functions, based on the hazards present and the severity of the potential fire problem, especially when that department may not have sufficient resources to inspect every building as often as might be desired.

Incident Reporting and Analysis

Incident reporting systems are used to outline operations, document situations, and maintain statistics on fire, medical emergencies, and other emergencies to which a fire department responds. This application is one of the most common uses of information technology.

The methods of capturing data are rapidly changing. Batch data entry, in which a form or forms are completed after each incident and someone other than the person completing the form inputs the data in batches at a computer, has given way to the fire officer entering the data directly at a computer terminal in the fire station or remotely through wireless and mobile data systems.

Departments with a CAD system usually collect at least some of the incident data as a by-product of a CAD operation. These data can then be displayed on a networked computer or on a terminal where data collected at the incident scene can be added by the company officer or officer in charge. Allowing the officer in charge to enter the data directly has the advantage of ensuring completeness and correctness, because the data can be edited as they are entered and mistakes corrected immediately.

Casualty reporting systems are generally subsets of incident reporting systems. As such, they are linked to the incident record so that cause-and-effect studies can be done. Typically, records on fire fighter casualties and civilian casualties are maintained separately, because the information desired or the level of detail is different for the two.

Data on civilians injured at fires are useful for supporting injury reduction programs. These programs can be educational in nature to correct inappropriate behavior or may be focused at either getting unsafe products off the market or redesigned to make them safer. Code and standards developers can use the data from injury reporting to make prudent decisions based on past history. The criteria outlined in codes and standards can help to reduce injuries.

Fire fighters experience a high number of injuries while doing their jobs. Tracking those injuries is important and may involve more than one part of the fire department's information system. Data about the cause and circumstances of the injury can assist in making decisions for additional training, equipment redesign, or operational changes. For example, data collection has revealed that most fatal fire fighter injuries involve a heart attack or vehicle collision and that fire fighters suffer a higher rate of nonfatal injuries per hundred fires at fires that involve abandoned structures than in other properties.

Medical data about the injury are often important for workers' compensation claims. Data on potential time lost are needed to schedule other fire fighters to fill the shift and could affect the overtime budget.

A basic casualty report provides a method of uniformly gathering casualty data for both civilians and fire fighters. This report provides for the classification of much of the collected data so they can be easily summarized and analyzed to support injury reduction programs. This form is not designed to be a medical form for reporting to workers' compensation, although some of the basic data might be applicable to both needs.

Fire Investigation

The investigation of fire incidents needs to be a well-documented and methodical process. Technology such as digital imaging and prefire planning and fire inspection database systems can be a help in investigations. In addition, through GIS, all municipal information on a fire property, on the owner, and on the structure's history can be easily developed.

A number of computer-based data systems have been developed to profile the properties in the neighborhood and assist in identifying arson-prone buildings. The community group or public officials are then able to implement intervention strategies

appropriate for the situation. Much of the early work sponsored by the Federal Emergency Management Agency (FEMA) has led to a developed and tested microcomputer-based arson information management system (AIMS). The system provides both identification of arson-prone buildings and a case management system for fire investigators.

There are many municipal and private databases or record systems that are typically used to support a fire investigation. These sources include data from the fire department incident-reporting system and code-enforcement program, the building department, the assessor's office, the police department crime-reporting system, the prosecutor's office, the tax collector's office, the registry of deeds, mortgage companies, and the insurance industry. Many jurisdictions are choosing to computerize the incident follow-up report in order to increase the information available on significant fires within a jurisdiction. Analysis of this data may reveal patterns showing types of fires that could point to deliberately set fires and other criminal activity.

PLANNING, TRAINING, AND RESEARCH

Emergency Planning

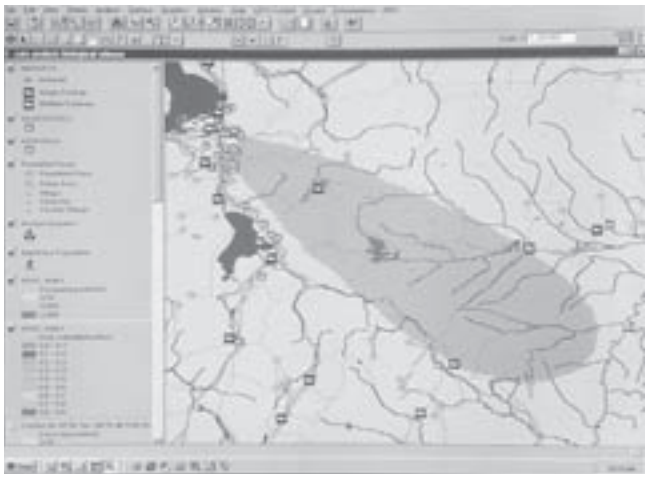
Through GIS and other information technology, emergency personnel can plan for a variety of situations that could affect large portions of a community. Ranging from hazardous materials releases to weather-related events, emergency management systems must be ready to respond to the unforeseen. Most community emergency management plans are currently developed in electronic format and can benefit from integration with other community-based data. Technology allows for hazards to be identified and, through modeling applications and automation, plans can be developed to ensure an appropriate response to a multitude of potential situations (Figures 12.5.16a, b, c). The purpose of such an automated display is for automated notification and evacuation planning.

GIS files can be expanded to include information essential to the emergency management function. Examples of this information include the type, quantity, and location of hazardous materials and the type, frequency, and location of other hazardous activities. The prime difficulty in making a hazard assessment system work is that the situation is dynamic. Types, quantities, and locations of materials may fluctuate widely according to the demands of the business. Annual or even semiannual updating of a central file may be insufficient to give a picture of the community's true hazardous materials profile.

Ownership information on properties can be among the most difficult to obtain. Current ownership is probably not needed until legal proceedings have to be instituted. It is easier and more reliable to check legal ownership in those relatively few cases as they occur than to try to develop and maintain a file on legal ownership for all properties. Knowing who is responsible for the property, however, is important, so that contact can be made in the event of an emergency or to schedule inspections.

Information technology through both the Internet and satellite communication allows the radar monitoring of weather conditions and the projection of the track of events such as tornadoes, flash floods, and blizzards. This technology has saved countless lives by warning the public of a dangerous weather event.

(a)



(b)

(c)

FIGURE 12.5.16 (a) Automated Display of an Evacuation Area Surrounding a Hazardous Materials Incident (b) Automated Modeling and Mapping of a Plume Secondary to a Release of Hazardous Material (c) Automated Path Projection of a Tornado or Other Severe Weather System (Photos provided courtesy of Bradshaw Consulting Services, Inc.)

When weather tracking and other emergency management applications are integrated with automated warning applications, residents can be contacted and given information on the situation. This information may be instructions on whether to seek shelter in place or to evacuate the area.

Through the use of subscription-based Internet calling centers that can quickly distribute thousands of customized voice messages to a targeted population, versatile systems can distribute messages ranging from safety-related messages to instructions on how to shelter in place during an emergency event.

Training and Research

Information technology can provide an exceptional level of support to training, educational, and research activities. Many texts have transitioned to provide CD-ROM study guides, tutorials, and self-paced learning programs. These programs, which focus on the needs of the adult learner, ensure comprehension by requiring students to master lower-level principles before allowing them to proceed to more advanced topics. Therefore, a solid foundation of knowledge is built. The International Fire Service Training Association (IFSTA), for example, offers computer-based and tutorial training for the development of basic fire fighter skills, in accordance with NFPA 1001, *Standard for Fire Fighter Professional Qualifications.* Aircraft orientation and emergency procedures, which crash fire rescue organizations now provide in the form of interactive computer-based training aids, are another example.

These applications are of benefit to fire service personnel because they are a complement to formal training programs. Interactive individual learning can be extended to the evaluation of a student's knowledge, skill, and abilities. Technology has developed realistic incident simulations used to gauge performance or develop a fire officer's confidence and skill (Figure 12.5.17).

Testing and performance during incident simulations and computer-based examinations can be recorded either locally or through secure Internet sites. A fire fighter required to attain a specified performance level can be periodically tested and evaluated through an Internet-based examination. Although this type of testing raises some security issues, these obstacles are being overcome.

FIGURE 12.5.17 Digital Incident Simulation Screen (Image provided courtesy of Digital Combustion, Inc.)

The complexity and specialization of the fire service create the need to use resources outside the organization. Remote locations or entire satellite networks can be reached through distance learning. The Federal Emergency Management Agency (FEMA) and the United States Fire Administration (USFA), for example, have offered online courses of benefit to the fire service.

Through the Internet, new learning opportunities and training materials have become accessible. At present, several fire service websites allow training presentations and materials to be downloaded. The availability of these materials promotes consistency and reduces the program development demands common to local training personnel.

Distance learning is well accepted in the academic environment. Many colleges provide interactive distance learning to enhance the quality of what can be affordably delivered to a remote location, to deliver instruction to smaller audiences, and to increase economy of scale. This interactive instruction is followed by electronic completion of assignments. Several colleges have become paperless institutions with students able to obtain all required materials electronically.

INTEGRATION OF SYSTEMS

Many organizations do not have a systematic approach to the development of information systems. Their approach is piecemeal without an overall plan for the integration of systems. By analogy, an airplane designed in a piecemeal fashion might have three wings, an engine with insufficient power for takeoff, and a fuel tank where there should be cargo or passengers. In short, although each subsystem might fulfill its intended function, the overall system is a failure.

The solution to this problem is information technology planning. As is the case with other organizations, the fire department needs an overall plan for integrating the various component subsystems. All components do not have to be implemented at one time to have a workable system, but a strategic plan for eventual integration and an action plan on how to achieve it are required.

Levels of Integration

Normally, two levels of integration are to be considered. The first is the integration of fire department systems with citywide systems. Considerable benefit can arise from, for example, having a GIS database of occupancy data that can be used by the assessor, tax department, and fire department. In general, however, information resource managers in the fire service should be wary of databases over which they have no control. Nevertheless, the potential benefits are worth the necessary effort in working toward a well-developed multiagency plan. At a minimum, the fire department should think through potential interfaces with city systems and provide the connectivity for future system development. The second level of integration is within the fire department itself where there is significant opportunity for controlling the design of systems, databases, and their interfaces.

Planning Techniques

An organization uses information systems to support strategic planning, managerial control, and operational activities. These activities may be classified into a number of business functions (e.g., scheduling personnel, dispatching, and budgeting). In turn, each function requires a certain subset of the organizational data. Obviously, different functions may require overlapping data subsets. This type of analysis suggests two ways to integrate systems.

Packaging Approach. The first approach to integrating systems is related to the way fire service functions are "packaged" into application systems. For example, a typical entry-level application in a fire department is CAD. In most cases, CAD is implemented on a stand-alone minicomputer. However, the boundary of the system could be expanded to include other records management functions, such as inspections and incident reporting. In the case of inspections, the staff needs information about hazardous materials, occupancy, guard dogs on premises, and so on. In the case of incident data, CAD collects much of the data needed to report fire incident documentation.

Thus, although the focus is still on CAD, the system's boundary would be enlarged to include "subordinate" or supporting functions. The links to supporting functions would be developed as subsystems with their own databases (or files) and have automatic data sharing provided to tie them together.

Data Model Approach. The other approach is based on a data model of the organization. The focus here is on the data and their interrelationships. Whereas the data traditionally have been owned by the application, now the application has become almost insignificant, replaced by transaction sets that update and query the public safety database. In reality, single physical databases are not defined; rather, they are grouped according to some coherent scheme. (Relational databases are appropriate.) Such a scheme should ensure that like entities are grouped together. Although other arrangements are possible, this line of thinking suggests the following groupings:

1. *Personnel database.* Includes data on scheduling of personnel, training, payroll (if not part of the financial system), accidents, assignments
2. *Financial database.* Likely to be citywide in scope; includes data on budgets, flow of funds
3. *Incidents database.* Includes historical data on closed fire and emergency medical incidents
4. *Fire prevention database.* Includes a building inventory and data on occupancy, ownership, hazardous materials; may include arson data
5. *Operational database.* Includes data about incidents in progress; data maintained for relatively short durations; may be moved to incidents database at close of incident or periodically to prevent overloading real-time CAD system with non-real-time data
6. *Supplies and equipment database.* Typically a citywide database; includes supplies inventory and equipment inventory and may include fleet management

SUMMARY

In view of the complexity of information applications, hardware, software, connectivity, and integration, this chapter does not purport to be a complete presentation on fire department information systems and technology. It does, however, attempt to balance technical information with a description of how information technology can be successfully applied to the fire service. Technology continues to evolve at an unprecedented rate; therefore, new applications and innovations beyond those detailed in this chapter should be expected. As new applications develop, they should be evaluated in terms of both reliability and benefit to the fire service.

Technology's increasing interactivity will extend an organization's capabilities. In the fire service, situations are often unforgiving; thus, the reliability of applications is critical. To meet the challenge, organizations should proceed slowly. They should place emphasis on training personnel, evaluating information technology products, and creating a comprehensive technology plan that involves staff members and includes the pilot testing of any new technology. Through this evaluation process, department personnel can ensure that the benefits outweigh the cost and that the best possible applications are selected for the organization.

Chapter 6

Liability of Fire Service Organizations for Negligent Fire Fighting

Maureen Brodoff

Chapter Contents

Negligence in the Fire-Fighting Context
The Fire Service and the Doctrine of Governmental Immunity
Legal Protections for the Fire Service Today
Public Duty Rule as an Added Protection for the Fire Service

Key Terms

discretionary functions immunity, governmental immunity, liability, limited damages, negligence, public duty rule, punitive damages, tort claims act

In 1955 a large quantity of gasoline was spilled onto a city street in Lawrence, Kansas, during the removal of gasoline storage tanks from a gas station. The local fire department was notified and quickly arrived at the scene. In order to determine the extent of the problem, the fire chief who was supervising the scene instructed a fire fighter to touch a cigarette lighter to the ground. Not surprisingly, a conflagration ensued that destroyed several automobiles. In the lawsuit that followed, the court refused to hold the town liable for the foolhardy tactic of its fire chief.*

This case and many others from the period reflect the traditional view that local governments were not liable for their failure to provide effective fire protection. Indeed, even extreme carelessness in fighting fires would not give rise to liability. Today, however, in the field of fire fighting, as with most modern-day endeavors, the historical limitations on legal liability are eroding, and theories of liability are expanding. Fire service legal liability must now, of necessity, be a concern to the fire service.

This chapter describes the general legal principles that are used in analyzing the legal liability of fire service organizations for negligence in conducting fire-fighting activities.† It should be remembered that the law in this area is not uniform but is governed largely by state and local laws and, therefore, varies from jurisdiction to jurisdiction. The liabilities of individual fire service organizations can only be determined by reference to the specific law in its jurisdiction.‡

For related topics, see Section 1, Chapter 4, "Legal Issues for the Designer and Enforcer."

**Perkins v. Lawrence,* 281 P.2d 1077 (Kan. 1955).

†There are many potential types of legal liabilities encountered in the modern fire service. This chapter treats only one—liability for negligent fire-fighting activities—and is intended only as a general introduction to the subject. It does not deal with other types of liability a fire department could owe to members of the public, such as for negligent inspection or automobile negligence. It also does not deal with employment law issues, such as workers' compensation, wrongful termination of employment, and the expanding field of antidiscrimination law, which has had a widening impact on the fire service in recent years. For the interested reader, there are several works designed for the layperson on these and other legal issues relating to the fire service. See, for example, Callahan, T., *Fire Service and the Law,* 2nd edition (National Fire Protection Association, 1987); Hogan, L. J., *Legal Aspects of the Fire Service,* 3rd edition (Amlex, 2000); Schneid, T. D., *Fire Law: The Liabilities and Rights of the Fire Service* (Wiley, 1995); and Grant, N. K., and Hoover, D., *Fire Service Administration* (National Fire Protection Association, 1993).

‡For convenience, this chapter will generally use the terms "fire service organization" or "municipality" in referring to the entity that may bear liability for negligent fire fighting. The reader, however, should be aware that the actual party that is named in a lawsuit alleging negligent fire fighting will vary depending on how the fire service is organized in a particular locale. Most frequently, fire departments are branches of municipal government and, when a lawsuit is brought, it is the city or town that is named in the suit and that is responsible to pay any judgment. In other cases, it may be an independent fire district or a county that is the responsible party. Sometimes individual fire fighters may be named in such suits. Although such individual liability is beyond the scope of this chapter, protections similar to those described here relating to fire service organizations will frequently protect fire fighters from individual liability for simple negligence. See, e.g., *Love v. Detroit,* 2006 WL 964721 (Mich. Apr. 13, 2006); *Willis v. Beaufort,* 143 N.C. App. 106, 544 S. E.2d 600 (N.C. Ct. App. 2001).

Maureen Brodoff is vice-president and general counsel for the National Fire Protection Association.

NEGLIGENCE IN THE FIRE-FIGHTING CONTEXT

As with any other endeavor, particularly one as fraught with danger and uncertainty as fire fighting, things can go wrong. Fires sometimes cause deaths and injury in spite of the best efforts of the fire service. Property damage may result, not only from the effects of fire but also frequently from the activity of fire fighting itself. A tactical decision made in the midst of impending disaster may, in hindsight, turn out to have been terribly wrong. Bad outcomes alone, however, do not make the fire service liable.

The Elements of a Negligence Case

The principal theory of liability used in lawsuits for personal injury and property damage is what is known in the law as negligence.* The law of negligence does not hold a person liable for *any* damage that results from his or her actions, only damage that results from some act of carelessness in circumstances where the actor had some duty to act with reasonable care. This principle can be understood by way of an illustration drawn from an actual case involving allegations of negligent fire fighting.

In 1978 in the city of Lowell, Massachusetts, a fire occurred in and destroyed five brick buildings.† The fire started on the sixth floor of an unoccupied building. This building had a working sprinkler system and, indeed, the system worked properly in the initial stages of the fire. The fire fighters who responded to the fire, however, chose to use the available water source to operate hoses. This reduced water pressure in the sprinkler system, in effect turning it off. There was evidence that good fire-fighting practice would have been to rely on the building's sprinkler system to fight the fire rather than to have diverted the water from the system to fight the fire with hoses. There was also evidence that the sprinkler system, if allowed to operate, would have put out the fire or contained it until it could have been put out by manual means. Instead, because of the choice of the fire fighters to effectively shut off the sprinkler system, the fire eventually engulfed and destroyed five buildings.

In this case, one can see all of the essential elements of a fire-fighting negligence case. First, under the law, all persons generally have a duty, once they undertake to act, to do so with reasonable care. As explained later in this chapter in the discussion of the "public duty" rule, there is some controversy whether fire fighters owe such a duty of care. In this case, however, it was conceded that once the fire fighters undertook to fight the fire, they had a duty to fight the fire with reasonable care.

Second, the fire fighters breached their duty to act with reasonable care. In lay terms, this simply means that they acted carelessly in fulfilling their duty to fight the fire. Reasonable care, in the context of fire fighting, means that level of care that the reasonably prudent fire fighter would use in similar circumstances. Since the evidence in the case showed that proper fire-fighting practice would have been to leave the sprinklers on, turning them off was viewed in the eyes of the law as negligent.

Third, the fire fighters' breach of their duty to reasonably fight the fire caused the destruction of the buildings. From the evidence, if the sprinklers had been allowed to function, the fire would have been contained. In other words, the fire fighters were the legal cause of the destruction of the buildings, because the destruction of the buildings would not have occurred had the sprinkler system been left on, and the consequences of shutting off the system were reasonably forseeable.

Finally, the fire fighters' negligence resulted in damages. In this case, the damages roughly equaled the value of the destroyed buildings and their contents.

Fire Service Negligence in the Caselaw

This case of the turned-off sprinkler system is a good example of what any case of negligence will have to prove in order to be successful; that is, the existence of a duty of care, the breach of that duty, causation, and damages. It is important to remember, however, that this is but one example of what can be alleged as negligent fire fighting. The types of negligence that can be alleged in the fire-fighting context are infinite. Areas of potential liability include fire suppression activities, tactics and strategies, emergency response system failures, operation of fire service vehicles,* hydrant and water supply maintenance, and maintenance of fire-fighting equipment.

Actual cases that have been brought illustrate the variety of claims that creative lawyers can allege. In an Indiana case, for example, it was alleged that a fire service organization was negligent in failing to maintain a sufficient number of fire fighters for the equipment intended to be used.† In the same case, it was also alleged that there was negligence in the service's failure to supervise and train its fire fighters in controlling and extinguishing fires under the conditions encountered in a particular fire. In an Alabama case, negligence was claimed in the failure of a fire department to respond to a house fire because the apparatus operator had gone home sick.‡ In a Maryland case, negligence was alleged in the failure to properly control and extinguish a brush fire that eventually reignited, causing a second fire in which a

*Sometimes other theories of liability are used in suits against the fire service. For example, lawsuits have been brought under a federal law permitting lawsuits for injuries resulting from the deprivation of some civil right. (See 42 U.S.C. § 1983.) These lawsuits require more than allegations of negligence. Typically, they allege some discriminatory action, such as the withholding of adequate fire protection from a minority neighborhood. Lawsuits also sometimes allege deliberate misconduct as opposed to mere negligence. A full discussion of these other theories is beyond the scope of this chapter.

†The fact pattern used for this illustration is drawn from the Massachusetts case of *Harry Stoller & Co. v. Lowell,* 412 Mass. 139 (1992).

*The laws involving the operation of fire service vehicles present something of a special case, since many states have laws aimed specifically at limiting liability for the operation of emergency and fire service vehicles. These statutes vary from state to state. Indiana, for example, provides immunity for the operation of fire service vehicles only when the operator of the vehicle is an employee of the fire service organization and only in the case of authorized emergency vehicles. [See *Indiana Code* § 9-4-1(d).] Other states have additional requirements, such as that emergency sirens or lights be activated.

†See *Hammond v. Cataldi,* 449 N.2d 1184 (Ind. App. 3d Dist. 1983).

‡See *Williams v. Tuscumbia,* 426 So.2d 824 (Ala. 1983).

warehouse was destroyed.* And in a Massachusetts case, it was alleged that fire fighters were negligent in fighting a fire burning at the rear of a house by spraying water on the front of the house where there was no fire.†

In one particularly dramatic case in Alaska, liability was alleged and found for negligent failure to rescue a person stranded in an upper floor of a burning building during a fire. The rescue failed because the ladder used in the attempt was too short to reach the victim's window. Although the court said this fact alone did not constitute negligence, the fire fighters failed to use other commonsense methods of rescue that were available as an alternative. In particular, the court was deeply disturbed that some spectators who had obtained an extension ladder of sufficient length to reach the victim, and who had raised the ladder and started to extend it, were ordered by a fire official to get away from the building and, when they refused to obey, were driven off by fire hoses.‡

Limits on Fire Service Liability

These illustrations would seem to indicate that liability exists around every corner. Although allegations of negligence are easily made, however, not all negligence claims result in a finding that the fire service was liable. There are two broad reasons tending against findings of fire service liability for negligent fire fighting.

The first reason is that allegations of negligent fire fighting are generally more difficult to prove than in the typical negligence case. In a typical negligence case, a party is accused of creating a dangerous situation that resulted in injury. In the typical fire fighter negligence case, the dangerous situation, that is, the fire, already exists when fire fighters enter the picture. A plaintiff, therefore, is usually in a position of having to prove that the fire fighters either made worse or failed to mitigate a harm that they did not cause. This is a difficult task, especially since the unpredictability and destructive power of fire in general often make it difficult to say with any assurance that some other course of action not taken by the fire fighters would have yielded a better result. Thus, as the Alaska case described previously vividly shows, liability is most often found in the extreme case where the conduct of the fire fighters is viewed as foolhardy or outrageous.

The second reason requires some explaining, but it has even greater impact on fire service liability. As discussed earlier, a case of negligence is built by proving that an individual or group by their careless actions violated a duty to act with reasonable care and, thereby, caused damage. If fire fighting were strictly a private enterprise, carried out by and for the benefit of private parties, such proof would be all that was required to entitle the injured party to hold the fire service organization liable to pay for all damages.

Fire fighting, however, is not a private enterprise. It is generally a governmental function carried out by cities, towns, and other governmental units for the benefit of the public. Because of this, the fire service is the beneficiary of an elaborate body of law that has been developed to shield the government from liability, even when it has acted negligently. This law of "governmental immunity" greatly complicates the question of whether and when a fire service organization can be held liable for damages caused by negligent fire fighting.

THE FIRE SERVICE AND THE DOCTRINE OF GOVERNMENTAL IMMUNITY

Until the last 30 or so years, the doctrine of governmental immunity fully protected governments from lawsuits aimed at governmental functions. Under this doctrine, the government as "sovereign" could do no wrong and could not be sued. In the case of fire-fighting activities, it meant that no matter how negligent a fire department might be or how much damage to life or property that negligence might cause, the municipality whose fire fighting had caused the damage could not be sued.

The doctrine of governmental immunity left no remedy to individuals who had suffered grievous injuries as a result of negligent fire fighting or other governmental negligence. As might be expected, the injustice that the doctrine often seemed to impose led to much criticism of the doctrine and calls for reform.

Beginning in the 1970s, the federal government and the states began, either through court decisions or, more often, through the passage of legislation, to severely limit the absolute governmental immunity that governmental entities had enjoyed. The most common type of legislation, now in existence in some form in most states as well as the federal government, is commonly known as a "tort claims act." Each state act is different but, generally speaking, the acts provide that government entities are liable for injury caused by their negligence in the same manner and to the same extent as a private entity. There are important qualifications, however, that provide the fire service with significant protection against liability.

LEGAL PROTECTIONS FOR THE FIRE SERVICE TODAY

Limits on Amount of Damages

Probably the most important protections for the fire service provided by the various state tort claims acts are the limitations they impose on the amount of damages. Thus, although government entities can now be held liable for their negligence just as can a private individual, the amount they can be required to pay has been limited. In Massachusetts, for example, the amount of liability that a municipality can be required to pay if found negligent is limited to $100,000 per claimant. Frequently, there is an overall cap so that, no matter the number of claimants, the total damages awardable for fire department negligence in any one incident cannot exceed a given amount. Vermont, for example, has a limit of $250,000 per claimant with a maximum aggregate liability of $1,000,000 to all claimants arising out of any given occurrence; Maryland has a limit of $200,000 per claimant with

*See *Utica Mut. v. Gaithersburg-Washington Grove,* 455 A.2d 987 (Md. App. 1983).

†See *Cryan v. Ware,* 413 Mass. 452, 469 (1992).

‡See *Fairbanks v. Schaible,* 375 P.2d 201, 206 (Alaska 1962).

an overall cap of $500,000 per occurrence.* A few states provide lower maximum compensation for property damage than for personal injury.† And in North Carolina municipalities are held to have waived their immunity by purchasing liability insurance and can be held liable up to the amount of the purchased coverage.‡ Finally, punitive damages, that is, damages designed to punish the wrongdoer rather than compensate the injured party, are generally forbidden.§

These various limits on liability are highly significant protections for fire service organizations, since they cap damages at an amount that may frequently represent only a small fraction of the damages actually awarded by a jury. Particularly in the area of fire suppression, where mistakes can result in millions of dollars of personal injury and property damage, the tort claims acts provide a great deal of protection against potentially huge damage awards.

Exceptions Specifically Aimed at Fire-Fighting and Related Activities

Several state tort claims acts have exceptions that specifically retain governmental immunity for fire-fighting and related activities. North Dakota, for example, retains governmental immunity for failure to provide adequate fire prevention personnel or equipment, except if gross negligence can be proved.# Illinois retains governmental immunity for any injury caused by the failure to suppress or contain a fire or while fighting a fire.** Kansas, California, South Carolina, and Texas, by statute, and Indiana, by judicial decision, retain immunity for the failure to provide, or the inadequate provision of, fire protection.††

There are other types of specific exceptions that relate to the fire service, as well. Alaska specifically retains governmental immunity for the performance of duties "in connection with an enhanced 9-1-1 emergency system," and for the performance of duties upon the request of or by agreement with the state "to meet emergency public safety requirements."‡‡ Some states retain immunity for claims relating to the provision of or failure to provide emergency services.§§ Also, many states specifically retain immunity for the failure to make an inspection or the making of an inadequate or negligent inspection.* Finally, some states retain such broad general immunity for governmental functions that fire-fighting activities are more or less categorically immune from liability.†

"Discretionary Functions" Immunity

In addition to the exceptions in some states expressly relating to fire-fighting and related activities, there exists in most state tort claims acts another type of exception that provides significant protection for the fire service. This is known as the "discretionary function" exception, and it requires some explanation.

Although, in passing tort claims acts, the lawmakers of the various states wished to make it possible for citizens to obtain compensation for injuries caused by governmental entities, they were reluctant to abolish immunity for all governmental activities. They were concerned that lawsuits might be used to second guess every governmental policy decision and that the constant fear of lawsuits could severely hamper the ability of municipal officials to govern and to freely exercise the discretion of their office. In order to address these concerns, lawmakers created an exception in the tort claims acts that preserved governmental immunity for "discretionary functions."

The typical discretionary functions exception merely states that the tort claims act, and the governmental immunity that it abolishes, simply does not apply to any claim based on a public employee's performance or failure to perform a "discretionary function."‡ What is a "discretionary function," however, and what does it mean in the context of fire fighting? Many legal battles have been fought over the meaning of this exception.

The main problem has been in determining the breadth of the discretionary function exception that, read literally, could be quite broad indeed. The word "discretion" implies, in its essence, the exercise of judgment, and, therefore, a literal interpretation of the discretionary function exception might lead to the conclusion that all conduct involving the exercise of judgment is immune from negligence liability. In addition, since virtually all fire-fighting activities involve the exercise of judgment, even if only concerning minor details, one might conclude that all fire-fighting activities are immune from suit. This, however, is not the case.

Purpose of Discretionary Function Exemption

Courts have generally rejected a too literal reading of the term "discretionary function." They have felt that granting immunity to all acts that involve some exercise of judgment would, in effect, immunize all governmental activity and, therefore, defeat the whole purpose of the tort claims acts, which was, after all, intended to abolish complete immunity. Courts, therefore, have looked to the purpose of the discretionary function exception. It was only intended to protect conduct involving the kinds of broad public policy and planning judgments that governmental

actors need to be able to perform without the constant threat of being sued. In keeping with this purpose, most courts have tended to find immunity, not for all discretionary conduct, but only for conduct that involves "policy making or planning."*

In the context of fire fighting, what does this mean? The legal decisions are far from clear and vary widely in how they treat particular fire service activities. Nevertheless, certain themes emerge.

Administrative Policy Decisions

First, there are aspects of fire service decision making that have an obvious planning or policy basis. These are administrative policy decisions involving the overall structure and makeup of the fire department, the training and equipping of fire fighters, and the allocation of limited fire-fighting resources within the community. They include decisions about the number and location of fire stations, the amount and type of equipment to purchase, the size of the fire-fighting staff, the type and extent of fire fighter training, the number and location of hydrants, or the adequacy of the water supply.†

When lawsuits blame these types of administrative policy decisions for bringing about injury or death, they are frequently dismissed based on the discretionary function exception. For example, a claim that fire fighters were unable to suppress a fire because the nearest fire station was too far away to make timely fire fighting possible would generally fail because decisions about where to locate a fire station are, even if patently unreasonable, protected from liability under the discretionary function exception.

Of course, some courts are more stringent in applying the exception than others. Many courts, for example, will view any broad administrative-level policy decision as categorically immune from liability, without any inquiry into the thought processes of the decision makers. Other courts, however, will require that the fire service organization, in order to claim immunity, present evidence showing that the decision makers actually went through a weighing of policy choices. In a case alleging that fire fighters were not supplied with a particular type of rescue equipment that would have prevented an injury, such a court would, for example, require that the fire service organization show that its failure to provide such equipment was the result of a conscious policy-making decision involving the balancing of competing interests, rather than the result of a simple failure to consider the question whether the equipment was needed.‡

It is clear, therefore, that administrative decisions are generally covered and immune from suit, at least where the decisions involve a conscious weighing of policy considerations. What about operational decisions made in the course of fighting a particular fire? Some have argued, for example, that the initial decision to fight a fire is discretionary, but that all of the subsequent actions in actually fighting the fire are not. Under this view, almost all actual fire suppression activities on the fireground would fall outside the "discretionary function exception" and would, therefore, be subject to potential liability.

This point of view, however, has mostly been rejected. Some courts go so far as to say that all tactical fireground decisions are immune from liability as "discretionary functions."* Most courts, however, have been more selective and have found that, while many decisions taken in the course of fire fighting do not involve policy or planning considerations, some decisions made on the fireground do involve broad public policy choices protected by discretionary function immunity.

Entitlement to Discretionary Function Immunity

How do courts decide whether a fireground decision is entitled to discretionary function immunity? In one recent case, the court looked to whether allegedly negligent fire-fighting decisions were dictated by a statute, regulation, or fire department policy. The case involved a warehouse fire during the course of which the fire department ordered all power to the building turned off. After the fire was extinguished, the fire fighters ordered the power restored, but did so without first either having the electrical system checked or obtaining a permit. The restoration of power resulted in a rekindling of the fire, which then entirely destroyed the building. The municipality argued that the decision to restore the power, even if negligent, was entitled to discretionary function immunity. The court disagreed, however, because there was evidence that the building code as well as fire department policy prohibited restoring power to the building in the way that the fire fighters had done. The court reasoned that, where procedure for the restoration of electrical power was dictated by specific regulations and policies, the decision to restore power was not a matter of discretion and was not, therefore, immune from liability.†

Usually, though, particular fireground decisions are not dictated by a specific rule or regulation. To determine, in these cases, whether a particular operational decision constitutes a discretionary function, courts generally look not at the particular action but at the reasons for fire fighter actions.

To illustrate, consider the case, described earlier in this chapter, of the fire fighters who turned off an operating sprinkler system in an unoccupied building because they wanted to fight the fire with hoses. Their decision to turn off the sprinkler system was clearly negligent, in that good fire-fighting practice would, in the circumstances, have dictated using the sprinkler system to extinguish the fire. The decision to shut off the sprinkler system also did not involve any policy or planning considerations, since the fire fighters simply made a careless decision about how to best fight the fire.

†See, e.g., *Adams v. Tenakee Springs,* 963 P.2d 1047 (Ala. 1998).

‡As examples of the differing approaches used by courts, see and compare *Hammond v. Cataldi,* 449 N.E.2d 1184 (Ind. App. 3 Dist. 1993); and *Waldorf v. Shuta,* 896 F.2d 723, 728-730 (3d Cir. 1990).

*See *Jimenez v. LMA Intern, Ltd.,* 2002 WL 31553547 (N.Y. Sup. October 15, 2002).

†See *Commerce and Industry Ins. Co. v. Grinnell Corp.,* 280 F.3d 566 (5th Cir. 2002).

In slightly different circumstances, however, the decision to shut off a sprinkler system could easily involve a significant policy choice. Suppose, for example, that the fire fighters had decided to shut off the sprinkler system in the unoccupied buildings, not merely to deploy hoses, but to divert the water supplying the sprinkler to fight a fire in a neighboring building that was occupied. The decision to sacrifice the unoccupied buildings in order to devote limited fire-fighting resources to saving lives next door clearly involves policy choices about the relative value of property and human life. Thus, even if the decision to shut off the sprinkler system was ultimately shown to be negligent in that the occupied building could have been saved without diverting water from the sprinkler system, the decision was grounded in an important policy choice, and many courts would rule that it was immune from liability under the discretionary function exception.*

In summary, although the court decisions in this area vary widely from jurisdiction to jurisdiction, it can be said that the discretionary function exception provides immunity to the fire service from liability for most broad administrative-level decision making and for many operational-level decisions as well. Though far from comprehensive, and less than certain in any individual case, the discretionary function exception still provides the fire service with substantial protection from liability.

PUBLIC DUTY RULE AS AN ADDED PROTECTION FOR THE FIRE SERVICE

So far, the liability for negligent fire fighting, although complicated, can be summarized quite simply. Initially, the doctrine of governmental immunity completely protected fire-fighting operations from liability, even if a fire was fought negligently. Today, however, fire service organizations can, in some circumstances, be successfully sued for negligence. The extent to which they can be sued is limited in most jurisdictions by the tort claims acts and the court decisions that interpret them. In general, those acts will, through the discretionary functions exception and other exceptions aimed at protecting fire and emergency services, immunize fire service organizations entirely for some activities. Where immunity is abolished, however, the acts will still provide a cap on damages that can be won against a fire service organization.

Immunity Through Public Duty Rule

If the law preferred simplicity, even of a relative kind, the issue might end here. There is, however, one more important twist: "the public duty rule."

Even though state legislatures have abolished governmental immunity and permitted local governments to be sued in many situations, courts have continued to be sympathetic to the problems of cities and towns and their difficulty in paying even the limited awards permitted by the tort claims acts. Particularly in the area of fire and other public protective services, some courts have expressed the fear that imposing even limited liability for negligence could pose a crushing burden on municipalities, particulary in busy urban areas. As one judge pointed out, in extreme circumstances, such as the Los Angeles riots where there were hundreds of fires and severe obstacles to effective fire fighting, the potential costs of liability could be catastrophic.* This fear has led some courts to develop a judge-made rule to shield the fire service and other public protective services, such as police and inspection. The "public duty" rule offers immunity from negligence liability that goes far beyond the limited immunity retained in the tort claims acts.

Under the public duty rule, fire fighting and other public protective services are viewed as an obligation that governments owe, not to any particular individual, but to the general public as a whole. Based on this view, the public duty rule holds, somewhat paradoxically, that, because fire fighting is for the benefit of all, it is, in effect, for the benefit of no one in particular. Under the rule, therefore, no individual can seek damages for injuries caused by negligent fire fighting because, in essence, the fire service owes no duty to any particular individual to act reasonably.

What is the effect of the public duty rule? Its greatest impact is at the operational level of fire fighting. The immunity offered by most state tort claims acts under the discretionary function exception is quite limited, and most decisions made on the fireground can give rise to potential liability, unless they can be said to involve public policy choices. In states that follow the public duty rule, however, such decisions become largely immune, and any fire-fighting activity, even if negligent and even if devoid of public policy implications, cannot give rise to liability.

Limitations to Public Duty Rule

It would seem that fire service organizations in states following the public duty rule have nothing to fear from lawsuits claiming negligent fire fighting. This is largely true. However, in the law every rule has its limitations and exceptions, and so does the public duty rule.

First, courts that follow the public duty rule limit its protection to the suppression of fires not caused by the fire department itself. Thus, if a fire department negligently caused a fire during a fire training exercise or some other non-fire-suppression-related activity, the public duty rule would offer no protection. Also, a few courts would not apply the public duty rule to protect fire fighters in cases where they aggravated an existing fire as opposed to merely failing to suppress it.† These courts, for example, would provide complete immunity where fire fighters negligently failed to put out an existing fire, because they negligently aimed hoses on the wrong part of the building. They would, however, permit liability where fire fighters took some action that actively made matters worse, as, for example, turning off an operating sprinkler system that, left alone, would have contained the fire.

*See, e.g., *Dahlheimer v. Dayton,* 441 N.W.2d 534, 538–539 (Minn. 1989).

*See *Cryan v. Ware,* 413 Mass. 452, 455 (1992).

†See *Cryan v. Ware, supra,* 413 Mass. 452 (1992).

"Special Relationship" Exception

Second, there is an exception to the public duty rule known as the "special relationship" exception. It holds that, even though fire fighting and other protective services are viewed in general as an obligation owed only to the public at large, a fire or other protective service organization can, by words or actions in a particular case, create a special duty to particular private parties.

How does a fire service organization create for itself this "special relationship," where liability may occur? The special relationship exception has been complicated and often inconsistent in application, and, in practice, courts have been reluctant to apply it to hold the fire service liable.* It seems clear that a fire department does not create a special relationship to an individual property owner merely by responding to the owner's call for assistance and fighting the fire on the property.†

Similarly, the fact that a municipality regularly inspected a factory would usually not, by itself, create a special relationship sufficient to expose the municipality to liability for negligent fire-fighting operations later conducted at the site.‡

Generally speaking, in order to demonstrate a special relationship that could expose a municipality to liability, courts have required a showing that the municipality's fire fighters (or other agents) assumed an affirmative duty to provide a service beyond that generally owed to the public, that the fire fighters knew that failure to perform the duty could cause harm, that the duty was established through direct communication or contact between the fire fighters and the injured party, and that the injured party justifiably relied, to his or her detriment, on the fire fighters to perform the duty they had undertaken.§

Examples of "Special Relationship" Exception

The situations that lend themselves to a finding of a special relationship are best understood by looking at some illustrative cases. In one case, for example, involving a factory fire, factory representatives approached fire fighters at the fire scene and warned them that there were metallic chemical elements stored in the building that were not amenable to water suppression methods. The court found that the warning made directly to fire fighters at the scene created a reasonable reliance on the part of the factory owners that the fire fighters would correctly fight the fire. As a result, a "special relationship" was created, and the municipality could be found liable for the damages that resulted when its fire fighters ignored the warnings, as well as the relevant fire codes, and doused the fire with water.#

Another case involved an inn fire in which a husband who had managed to awaken and escape from the inn desperately tried to return and save his wife when he realized that she had not likewise escaped. As fire fighters arrived at the scene, he began yelling at them to rescue his wife, who could be heard screaming through a wall that the husband had been trying to break through. The fire fighters, however, allegedly did not respond to his pleas, and when he tried to continue the rescue on his own, fire fighters physically restrained him. It was not until 15 minutes following the restraint of the husband that fire fighters began an attempt to rescue the wife. By then it was too late, and the wife perished. Based on these "extraordinary" facts, the court had little difficulty concluding that, when the fire fighters affirmatively prevented the husband from rescuing his wife, they made an implied promise to rescue her themselves, upon which he was forced to rely. A special relationship was thereby created and the municipality could not claim immunity from liability for any negligence of the fire fighters in failing to rescue the wife.*

As the preceding examples illustrate, the public duty rule does not provide complete immunity for fire service organizations. But even apart from the potential liability opened up by the "special relationship" exception and other limitations on the public duty rule, there is yet another reason why fire service organizations in states that observe the public duty rule should not rest with complete ease. The public duty rule has been widely criticized as fundamentally inconsistent with the tort claims acts, because the rule creates immunity where legislatures have sought to remove it. For a time, therefore, a trend appeared to be taking shape to abolish the rule and many states did so.†

The trend stalled, however, and the majority of states that have considered the issue still recognize the public duty rule.‡

---

*Contrast, e.g., the markedly different treatment the court gave police and fire fighters, respectively, in *Cryan v. Ware, supra,* 413 Mass. 452 (1992); and *Irwin v. Ware,* 392 Mass. 745 (1993).

Omaha,* 222 Neb. 293, 301 (1986); *Schear v. County Comm'rs,* 101 N.M. 671 (1984); *Coffey v. Milwaukee,* 74 Wis.2d 526 (1976); *DeWald v. State,* 719 P.2d 643, 653 (Wyo. 1986); *Ryan v. State,* 134 Ariz. 308, 310 (1982); *Commercial Carrier Corp. v. Indian River County,* 371 So.2d 1010, 1015-1016 (Fla. 1979); and *Brennen v. Eugene,* 285 Or. 401, 407 (1979). See also *Hollis v. Brighton,* 885 So.2d 135 (Ala. 2004) and *Ziegler v. Millbrook,* 513 So. 2d 1275 (Ala. 1987) (applying public duty rule to volunteer but not to professional fire departments). See also *Dean v. Childs,* 262 Mich. App. 48, 58–59, 684 N.W. 2d 307 (2004) and *Willis v. Beaufort, supra,* 143 N.C. App. at 108–109 (applying public duty rule to police but not to fire protection services).

‡See, e.g., *Yates v. Mansfield Bd. of Edn.*, 102 Ohio St.3d 205, 808 N.E.2d 861 (Ohio 2004); *Babcock v. Mason County Fire Dist. No. 6,* 144 Wash.2d 774, 30 P.2d 1261 (Wash. 2001); *Stata v. Waterford, supra,* 225 A.D.2d 163. *Shore v. Stonington,* 187 Conn. 147 (1982); *Randall v. Fairmont City Police Dep't,* 186 W. Va. 336 (1991). As many as 21 states and the District of Columbia have been cited as following the traditional public duty rule. Excluding Michigan, which, as indicated in the previous note, no longer recognizes the public duty rule for fire-fighting activities, these states include California, Connecticut, Hawaii, Illinois, Indiana, Kansas, Maryland, Minnesota, Missouri, Nevada, New Hampshire, New York, North Carolina, Ohio, Pennsylvania, Rhode Island, South Carolina, Utah, Washington, and West Virginia. See *Jean v. Commonwealth,* 414 Mass. 496, 518 n.1 (1993) (O'Connor, J., concurring).

And at least one state, Massachusetts, has, following court abolition of the rule, revived it by incorporating it into the state tort claims act.* It is safe to say, therefore, that the public duty rule, in many states, still offers fire service organizations a large measure of immunity.

SUMMARY

The degree to which the fire service may be exposed to liability for negligent fire fighting depends, to a large degree, on the law of the state in which the fire service organization is located. Although all states have abolished to one degree or another the total governmental immunity from negligence lawsuits, the amount of protection that remains varies among jurisdictions. In all states, however, it is important to remember that, even in the absence of complete immunity, there are still significant protections offered the fire service. Although the principles defy easy summarization, the following, in general, can be said.

1. In virtually all states, fire service organizations will be protected from suits criticizing broad administrative policy decisions of fire department and municipal administrators. Thus, suits claiming injuries resulting from bad policy decisions about the placement or number of fire stations, the size of fire department staffs, and the adequacy of funding for fire department activities will generally be prohibited under the "discretionary functions" exception or similar legal principles contained in the torts claims acts or caselaw of most states.
2. In the majority of states, fire service organizations will generally be liable for injuries for negligent fire fighting when the claims are based on bad operational decisions made on the fireground about how to fight a particular fire. Even operational decisions, however, will sometimes be protected under the "discretionary functions" exception, particularly where those decisions involve public policy choices.
3. In the minority of the many states that still follow the "public duty" rule, fire service organizations will be protected from negligence suits, even those involving operational decisions, unless the department or its employees have by words or deed created a "special relationship" with an injured party, thus creating a duty beyond that owed to the public as a whole.

The trend of recent years has been to hold fire service organizations liable when fire fighters have acted negligently. This trend, however, is far from complete. As the preceding discussion shows, limited immunity still exists both in the discretionary function exception and in the persistence of the public duty rule, which, despite much criticism, continues to show vitality in many statews. In addition, the caps on damages that exist in all states will continue to serve to soften the impact of negligence cases on the fire service. The explosion of liability that has occurred in all areas of the law in recent years has had only mixed results when it comes to the fire service.

Chapter 7

Safety, Medical, and Health Issues and Programs

Revised by
Murrey E. Loflin

Chapter Contents

Evolution of Safety and Health Legislation
NFPA Standards
Definition of Safety Officer Roles
Risk Management
Risk Management Model
Incident Command System (ICS)
Blending Incident Command Systems
Communication Issues
Incident Scene Rehabilitation

Key Terms

fire fighter safety, incident command system, industrial fire brigade, infection control, occupational safety and health, rehabilitation, risk management, safety officer

Over the past 35 years, positive changes have emerged in fire service, as fire fighters have increasingly applied occupational safety and health concepts to the practice of our profession. Vast improvements with protective clothing and protective equipment, apparatus and vehicles, command and control of emergency operations, health maintenance, and numerous other components have improved fire fighter safety and health. One method for gauging the effectiveness of a national fire fighter occupational safety and health program is fire fighter fatality and injury statistics, and those numbers are beginning to move downward. This trend indicates that an emphasis on occupational safety and health is becoming a standard part of fire department operations and activities. However, there is still an incredible amount of work ahead for the fire service regarding occupational safety and health. In years past, the fire service had the distinction of being the most hazardous occupation in the country. Slowly, the fire service is losing this pronounced title and taking pride in conducting safe and effective operations. The number of fire fighter fatalities has averaged approximately 100 per year for the past 15 to 20 years. Since 1977 when fire fighter fatality statistics began to be tracked by the National Fire Protection Association (NFPA), the number reached a high of 173 fatalities in 1978 and a low of 75 in 1992 (Table 12.7.1). Progress has been made in the fire fighter safety and health arena, but there is still opportunity for improvement.

The fire service is beginning to understand the necessity and rationale for developing, implementing, and maintaining a proactive, comprehensive occupational safety and health program. However, many fire service personnel still do not subscribe to the safety and health philosophy. Tradition plays a major role in this lack of understanding of fire fighter safety and health. Although the struggle is far from over, the fire service is learning the lesson that safety is good business.

This chapter outlines the history of safety and health legislation as it applies to fire departments and describes relevant NFPA standards and requirements within the context of that history. The chapter concludes with a description of the risk management program that is detailed in NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program.*

For related topics, see Section 12, Chapter 1, "Planning for Public Fire-Rescue Protection"; Section 12, Chapter 8, "Effect of Building Construction and Fire Protection Systems on Fire Fighter Safety"; and Section 12, Chapter 9, "Fire and Emergency Services Protective Clothing and Protective Equipment."

EVOLUTION OF SAFETY AND HEALTH LEGISLATION

On December 29, 1970, the Occupational Safety and Health Act of 1970 (Public Law No. 91-596) was signed into law by President Richard M. Nixon. The Occupational Safety and Health Act had an effective date of April 28, 1971. Coauthored by Senator Harrison A. Williams (D-NJ) and

Murrey E. Loflin is the director of fire training for West Virginia University Fire Service Extension. He has served in the fire service for over 28 years. He is a secretary of the NFPA Fire Service Occupational Safety and Health Technical Committee and a member of the Incident Management Professional Qualifications Technical Committee.

TABLE 12.7.1 Fire Fighter Fatalities and Injuries, 1977–2006

Year	*Total Fatalities*	*Career*	*Volunteer*	*Injuries*
1977	157	70	82	NA
1978	173	64	101	NA
1979	125	58	57	NA
1980	138	61	69	NA
1981	136	58	65	103,340
1982	128	51	67	98,150
1983	113	54	51	103,150
1984	119	43	59	102,300
1985	128	55	66	100,900
1986	119	50	55	96,450
1987	132	49	68	102,600
1988	136	43	81	102,900
1989	118	43	65	100,700
1990	107	26	62	100,300
1991	108	36	66	103,300
1992	75	24	44	97,700
1993	79	21	55	101,500
1994	105	34	38	95,400
1995	98	30	59	94,500
1996	96	27	65	87,150
1997	99	31	59	85,400
1998	91	33	49	87,500
1999	112	37	71	88,500
2000	103	28	58	84,550
2001	103/443	25/365	66	82,250
2002	97	29	50	80,800
2003	106	26	58	78,750
2004	105	29	65	75,840
2005	87	25	54	80,100
2006	89	23	46	83,400

Note: 9/11 fatalities are listed separately for 2001.
Source: NFPA, August 2006.

Congressman William Steiger (R-Wis), the Occupational Safety and Health Act is referred to as the Williams-Steiger Act or the Williams-Steiger Occupational Safety and Health Act. Prior to the passage of the Occupational Safety and Health Act, legislation for general industry was intermittent and grossly inadequate. Most states had little or no safety and health legislation, inadequate safety and health standards, insufficient staffing, and inadequate enforcement procedures. Budgets were poorly funded. In turn, the occupational fatality rate was greater than 14,000 employees killed and 2.2 million suffering work-related injuries annually in the late 1960s. Prior to 1970, the federal legislation for occupational safety and health was erratic. Efforts were directed more toward specific interests than the widespread coverage, as designated in the Occupational Safety and Health Act.

When the Occupational Safety and Health Act of 1970 was enacted, each state was given the opportunity to develop its own safety and health plan. Under the Occupational Safety and Health Act of 1970, the federal Occupational Safety and Health Administration (OSHA) has no direct enforcement to ensure that state and local governments comply with safety and health standards, such as the OSHA Bloodborne Pathogens standard for public employees.

State Plans and Programs

Twenty-four states and two territories have established and maintain an effective and comprehensive occupational safety and health program for public employees. These state plans must meet or exceed the requirements of federal OSHA. OSHA gives each state 6 months from the publication date of any new federal final standard to adopt a similar state standard. All fire departments, whether state, county, or municipal, in any of the 24 states or two territories that have an OSHA plan agreement in effect have the protection of the minimal acceptable safety and health standards mandated by federal OSHA.

The following 24 states and two territories have state OSHA plans that cover public employees:

Alaska	Michigan	South Carolina
Arizona	Minnesota	Tennessee
California	Nevada	Utah
Connecticut	New Jersey	Vermont
Hawaii	New Mexico	Virgin Islands
Indiana	New York	Virginia
Iowa	North Carolina	Washington
Kentucky	Oregon	Wyoming
Maryland	Puerto Rico	

Section 18 of the Occupational Safety and Health Act of 1970 encourages states to develop and operate their own job safety and health programs. OSHA approves and monitors state plans and provides up to 50 percent of an approved plan's operating costs.

There are currently 24 states and jurisdictions operating complete state plans (covering both the private sector and state and local government employees) and 4—Connecticut, New Jersey, New York, and the Virgin Islands—covering public employees only. Eight other states were approved at one time but subsequently withdrew their programs. States must set job safety and health standards that are "at least as effective as" comparable federal standards, though most states adopt standards identical to federal standards. States have the option to promulgate standards covering hazards not addressed by federal standards.

Inspection and Consultation. A state must conduct inspections to enforce its standards, cover public (state and local government) employees, and operate occupational safety and health training and education programs. In addition, most states provide free on-site consultation to help employers identify and correct workplace hazards. Such consultation may be provided either under the plan or through a special agreement under Section 21(d) of the act.

Awareness of Laws and Standards. Regardless of whether a department is mandated to comply with the requirements under the Occupational Safety and Health Act or not, it is a good practice to do so for the protection and welfare of personnel. With

more emphasis being placed on health and safety, fire and EMS agencies are now more aware of pertinent laws and standards.

Laws and standards are a critical and significant part of the operations of any emergency services organization. Administrators must remain knowledgeable and compliant with current safety and health regulations. As managers responsible for the delivery of customer services, we must have a thorough understanding of the laws, standards, and regulations that govern the safety and health of members relating to response and actions at the emergency scene.

Regulations for Fire Brigades

With the development of occupational safety and health standards for general industry, there were applicable requirements for the fire service in 29 Code of Federal Regulations (CFR) 1910.156, Industrial Fire Brigades. This standard contains requirements for personal protective equipment, training, respiratory protection, and the use of fire-fighting equipment. Basically, this was the fire service's introduction to safety and health requirements. Attitudes toward safety and health in the fire service have been gradually changing as occupational safety and health requirements have improved over the past 20 years.

Fire Service Processes for Occupational Safety and Health

Federal and/or state laws now regulate components of the fire service occupational safety and health process, which include the following:

- Development of an occupational safety and health program
- Facility safety
- Training and education
- Protective clothing and protective equipment
- Respiratory protection
- Infection control
- Health maintenance

The risk management process must be recognized as a vital component of ensuring the success of the fire department's occupational safety and health program (see the section entitled "Risk Management"). Before dealing with specific risk management programs, it is important to understand the requirements of relevant NFPA codes.

NFPA STANDARDS

NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program,* and Related Standards

This document was intended to function as an umbrella for future standards developed by the Fire Service Occupational Safety and Health Technical Committee. The true advancement of fire fighter safety and health can be tied to the development of NFPA 1500, which was passed at the NFPA Annual Meeting in 1987. The standard was approved at the Standards Council Meeting in July 1987 and was published with an effective date of August 1987. Prior to the comment period of NFPA 1500, no standard had generated this many public comments (1200). NFPA 1403, *Standard on Live Fire Training Evolutions,* generated approximately 1000 comments during the Report on Comments in 1985.

After the initial passage of the standard in May 1987, issues that surfaced focused on incident management, infection control, and health maintenance. Task groups were appointed and work was initiated to begin development of the following standards: NFPA 1561, *Standard on Emergency Services Incident Management System;* NFPA 1581, *Standard on Fire Department Infection Control Program;* and NFPA 1582, *Standard on Comprehensive Occupational Medical Program for Fire Departments.* Also a complete rewrite of NFPA 1501, *Standard for Fire Department Safety Officer* (renumbered to NFPA 1521 during the 1992 revision cycle) was initiated as the requirements of this document had not changed significantly since its inception in 1977. Additionally, the technical committee addressed the continued development of NFPA 1500 to improve on the initial requirements addressed in the 1987 edition of the document. Two additional standards developed were NFPA 1583, *Standard on Health-Related Fitness Programs for Fire Fighters,* and NFPA 1584, *Recommended Practice on the Rehabilitation of Members Operating at Incident Scene Operations and Training Exercises.*

NFPA 1501, *Standard for Fire Department Safety Officer* (now NFPA 1521)

The initial standard that promoted health and safety for fire fighters was NFPA 1501, approved in 1977. The technical committee responsible for the development of NFPA 1501 was dissolved by the NFPA Standards Council and a new technical committee was officially formed in 1983. The scope of the Fire Service Occupational Safety and Health Technical Committee was to address the development of a comprehensive fire service occupational safety and health program.

Evolution of Standards in the 1990s

The issues that surfaced during the public proposal period of NFPA 1500 included the need to identify methods for achieving competencies for fire fighter, driver/operator, fire officer, and safety officer job functions and the need to establish training and education mandates for achieving and maintaining certifications.

Staffing for fire apparatus was also an issue. During the Report on Comment Period, a public comment was submitted to identify the minimum staffing on fire apparatus. The public comment led to a vote at the NFPA Annual Meeting in May 1992 in New Orleans. The issue was taken to the Standards Council for consideration. The staffing requirements remained in the annex under emergency operations.

During the 1997 revision cycle, additions to NFPA 1500 included recommendations on administrative and operational risk management and on conducting fire fighting operations during the incipient stages of an incident (for the initial rapid intervention crew). This crew required sufficient personnel to

conduct an "initial operation" in an atmosphere that was either potentially or actually immediately dangerous to life and health (IDLH).

The Occupational Safety and Health Administration defines an IDLH atmosphere as one that poses an immediate hazard to life or produces immediate irreversible debilitating effects on health. This issue, which was discussed and debated during the subsequent revision to NFPA 1500, coincided with OSHA's public review process of 29 CFR 1910.134, Respiratory Protection, which contained the mandates for the "Two in/Two out" requirements. The citing of fire departments caused a great deal of confusion and resistance among the fire service leaders and the governing bodies they reported to. Not until the revised NFPA 1500 was passed in May 1997, and OSHA issued its rules in January 1998, was the inconsistency resolved. The 1997 edition of NFPA 1500 included material that provided a comparison of the requirements 29 CFR 1910.134, Respiratory Protection, and those included in NFPA 1500 including the medical requirements.

FIGURE 12.7.1 Assessing Risk as Part of the Incident Management System (Photo courtesy of Fairfax County Fire and Rescue Department, Fairfax, Virginia)

Developments in the Twenty-First Century

Evolution of NFPA 1500. The fourth edition of NFPA 1500 was approved at the NFPA 2001 fall meeting and was issued by the Standards Council with an effective date of January 31, 2002. Changes were made based on input from NFPA Data Analysis and Research Division, NFPA fire investigation reports, and the National Institute on Occupational Safety and Health (NIOSH) Fire Fighter Fatality Investigation reports. The changes were made to the standard relating to personal protective clothing and equipment, fire apparatus, training requirements, medical requirements, and several other areas. The Fire Service Occupational Safety and Health Technical Committee working with several other NFPA technical committees developed a complete section that outlines the requirements for a fire department respiratory protection program. The standard provides the user and the enforcer one source in which to develop and implement a comprehensive respiratory protection program.

The 2007 edition of NFPA 1500 was approved at the annual meeting in Orlando, Florida, in June 2006 with an effective date of August 17, 2006. The 2007 edition is a complete revision of the standard, which includes a change in chapter titles, revisions to each chapter based on fire fighter fatality data analysis and reports, and requirements in the chapters addressing the operations of fire apparatus, protective clothing and protective equipment, and emergency operations. Annex material for each chapter was completely reviewed with necessary changes made.

NFPA 1561, *Standard on Emergency Services Incident Management System.* The 2005 edition of NFPA 1561 was prepared by the Technical Committee on Fire Service Occupational Safety and Health, acted on at the NFPA 2004 Fall Meeting, and issued by the Standards Council.

The first edition of this document was issued in 1990 to support requirements in NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program,* requiring fire departments to conduct emergency operations within an effective incident management system (Figure 12.7.1). The committee realized that the safety aspects of an effective and efficient command and control were as important as the operational coordination and effectiveness of the system. In developing this document, the committee examined several incident management systems and variations thereon that were in use in different fire departments and related organizations. The committee determined that, in addition to requiring the use of an incident management system, there should be performance criteria for the components of a system that contribute directly toward safety and health objectives and developed the standard to specifically address those concerns.

The 1995 edition expanded the areas of accountability, use of rapid intervention crews (RIC) for rescue of members, and interagency cooperation and recognized that incident management includes more than fireground operations. The 2000 edition expanded the document to reflect the mainstream utilization of incident management systems. The title of the document was changed to *Standard on Emergency Services Incident Management System* to reflect the fact that all emergency service organizations should use an incident management system. In the 2002 edition, the committee focused on areas of risk management, communications, roles and responsibilities of the Incident safety officer (ISO), rapid intervention crews, and defined command structures. In addition, new annex material was added to assist the users of the standard.

Following the issuance of the 2002 edition, a Tentative Interim Amendment (TIA) was issued to add annex material on position descriptions and roles, responsibilities of command, and general staff positions within an incident management system. This edition expands the TIA and incorporates it into the body of the standard. The response and operational capabilities of the emergency response community are required to be managed through an incident command system. The revisions in the 2005 edition of the standard address specific issues such as incident management teams, unified command, the roles and responsibilities of the incident commander (IC), and command and general staff functions.

DEFINITION OF SAFETY OFFICER ROLES

As previously stated, NFPA 1501, *Standard for Fire Department Safety Officer,* was the association's first fire service safety document. Although other standards dealt with protective clothing, fire apparatus, and other issues related to the fire service, NFPA 1501 was the first to specifically address fire fighter safety and health. The first two editions (1977 and 1982) of this standard addressed areas dealing primarily with the roles and responsibilities of a fire department safety officer. These roles were vague and were interpreted differently from user to user. The committee struggled to make this document a useful tool for the fire department and to make it play a more significant role in fire fighter safety.

Expanding Roles of the Safety Officer

With the appointment of the Fire Service Occupational Safety and Health Technical Committee in 1983, NFPA 1501 was assigned to this new technical committee. During the revision between the 1987 and 1992 editions, a movement began within the fire service to expand the roles and responsibilities of the safety officer. With the revision of the 1992 edition of the standard came a change in the numbering of the standard. This was done to be consistent with other standards developed by the technical committee. The role of the fire department safety officer was divided into two distinct positions—the incident safety officer (ISO) and the health and safety officer (HSO). Note that with the advent of the national incident management system, the term *safety officer* is the correct title for this position on the command staff. NFPA 1521 uses the term *incident safety officer* to distinguish the positions.

Training of Safety Officers

While the technical committee was revising and expanding NFPA 1521, fire service subject matter experts and curriculum developers at the National Fire Academy in Emmitsburg, Maryland, were developing two new courses based on these two distinct roles of the safety officer. These two 16-hour courses, Incident Safety Officer and Health and Safety Officer, outlined the basic requirements and roles and responsibilities of each position. The course included activities that emphasized the decision-making processes each position requires and provided instruction on how to read and utilize NFPA standards, federal laws, and rules and regulations. These two courses were offered to the fire service beginning in early 1996 and were updated in 2003.

These two courses continue to be two of the National Fire Academy's most popular courses. The specific roles for the incident safety officer and health and safety officer within a fire department's occupational safety and health program are a critical component in making the health and safety programs work. In some small or medium-sized departments, one person may be assigned the responsibilities of both positions, which usually leads either to that individual being overworked and frustrated or to the program not being implemented at all.

Roles and Responsibilities of the Health and Safety Officer

Health and safety officers must have a knowledge and understanding of pertinent laws, codes, and standards. Their responsibilities and functions include the following:

- Ensure that training and education programs relating to fire department operations are conducted
- Manage an accident prevention program
- Develop procedures for accident investigation and review
- Maintain records and conduct data analysis pertaining to fire fighter fatalities, injuries, occupational illnesses, health exposures, and accidents
- Review apparatus and equipment specification
- Conduct facility inspections to ensure compliance with applicable codes and standards
- Manage the health maintenance program to ensure compliance with NFPA 1582, *Standard on Comprehensive Occupational Medical Program for Fire Departments*
- Serve as liaison to various internal and external committees that influence the department's occupational safety and health program
- Serve as a member of the department's Occupational Safety and Health Committee
- Serve as the department's infection control officer or maintain a liaison with the infection control officer
- Ensure that the department has a critical incident stress management program
- Ensure that fire fighter safety and health issues are addressed during the post-incident analysis process

Roles and Responsibilities of the Incident Safety Officer

Standard operating procedures define criteria for the response or appointment of an incident safety officer position. The functions of the incident safety officer include the following:

- Serve as the safety officer of the command staff
- Monitor conditions, activities, and operations to determine whether they fall within the criteria as defined in the fire department's risk management plan
- Ensure that the incident commander establishes an incident scene rehabilitation tactical-level management unit during emergency operations
- Monitor the scene and report the status of conditions, hazards, and risks to the incident commander
- Ensure that the fire department's personnel accountability system is being utilized
- After receiving the incident action plan from the incident commander, provide the incident commander with a risk assessment of incident scene operations
- Ensure that established safety zones, collapse zones, hot zone, and other designated hazard areas are communicated to all members present on scene
- Evaluate motor vehicle scene traffic hazards and apparatus placement and take appropriate actions to mitigate hazards

- Communicate to the incident commander the need for assistant incident safety officers due to the need, size, complexity, or duration of the incident
- Ensure that a rapid intervention crew meeting the criteria in Chapter 8 of NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program,* is available and ready for deployment
- Where a fire has involved a building or buildings, advise the incident commander of hazards, collapse potential, and any fire extension in such building(s)
- Evaluate visible smoke and fire conditions and advise the incident commander, tactical-level management units officers, and company officers on the potential for flashover, backdraft, blowup, or other fire events that could pose a threat to operating teams
- Monitor the accessibility of entry and egress of structures and the effect they have on the safety of members conducting interior operations
- Ensure compliance with the department's infection control plan and NFPA 1581, *Standard on Fire Department Infection Control Program,* during emergency medical operations
- Ensure that incident scene rehabilitation and critical incident stress management are established as needed at emergency medical operations, especially mass casualty incidents

Roles and Responsibilities of the Hazardous Materials Incident Safety Officer

The hazardous materials incident safety officer should meet the requirements of NFPA 472, *Standard for Professional Competence of Responders to Hazardous Materials Incidents.* The functions of the hazardous materials incident safety officer include the following:

- Attend strategic and tactical planning sessions and provide input on risk assessment and member safety
- Ensure that a safety briefing, including an incident action plan and an incident safety plan, is developed and made available to all members on the scene
- Ensure that hot, warm, decontamination, and other zone designations are clearly marked and communicated to all members
- Meet with the incident commander to determine rehabilitation, accountability, or rapid intervention needs; for long-term operations, the hazardous materials incident safety officer should ensure that food, hygiene facilities, and any other special needs are provided for members

Roles and Responsibilities of the Incident Safety Officer for Special Operations Incidents

The individual who serves as the incident safety officer for special operations incidents should have the appropriate education, training, and experience in special operations. The functions of the incident safety officer for special operations incidents include the following:

- Upon notification of a member injury, illness, or exposure, immediately communicate this information to the incident commander to ensure that emergency medical care is provided
- In the event of a serious injury, fatality, or other potentially harmful occurrence, request assistance from the health and safety officer
- Prepare a written report for the post-incident analysis that includes pertinent information about the incident relating to safety and health issues; the incident safety officer for special operations incidents participates in the post-incident analysis
- Include information about issues relating to the use of protective clothing and equipment, personnel accountability system, rapid intervention crews, rehabilitation operations, and other issues affecting the safety and welfare of members at the incident scene

RISK MANAGEMENT

Risk Management During Emergency Operations

According to NFPA 1500, the management of risk during emergency operations is a critical factor for ensuring the safety and health of fire fighters. In order to have effective operational risk management, the following components need to be part of the incident command system:

- Routine evaluation of risk in all situations
- Well-defined strategic options
- Standard operating procedures
- Effective training
- Full protective clothing and protective equipment
- Effective incident management and communications
- Safety procedures and the use of an incident safety officer
- Rapid intervention crew(s)
- Adequate resources
- Incident scene rest and rehabilitation
- Regular re-evaluation of conditions
- Pessimistic evaluation of changing conditions
- Experience based on previous incidents and critiques

Using Risk Management Principles

The incident command system starts with the arrival of the first department company. The first company to arrive integrates risk management into the routine functions of incident command. As indicated in NFPA 1500, the concept of risk management should be utilized on the basis of the following principles:

- Activities that present a significant risk to safety of members should be limited to situations in which there is the potential to save endangered lives.
- Activities that are routinely employed to protect property should be recognized as inherent risks to the safety of members, and actions should be taken to reduce or avoid these risks.
- No risk to the safety of members should be acceptable when there is no possibility to save lives or property.

As indicated in the second item just listed, "actions should be taken to reduce or avoid these risks." Identifying potential safety concerns to members and taking actions to reduce risks to fire fighters are without a doubt two of the most important things that can be accomplished.

Reducing Risks. The following are just some of the ways to reduce the overall risks to members operating at the scene of emergency incidents:

- Written guidelines should be established and used that provide for the tracking and inventory of all members operating an emergency incident.
- All members operating in an emergency are responsible to actively participate in the department's personnel accountability system.
- The incident commander should be responsible for the overall responder accountability for the incident. The incident commander should initiate an accountability worksheet at the beginning of the incident and maintain the system throughout the operation.
- The incident commander should maintain an awareness of the location and function of all companies assigned to an incident.
- The incident commander should implement branch directors and division, group, or sector supervisors when needed to reduce the span of control for the incident commander.
- Branch directors and division and group supervisors should directly supervise and account for companies operating under their command.
- Company officers are accountable for all company members, and company members are responsible to remain under the supervision of their assigned company officer. Members should be responsible for following the personnel accountability system procedures, which should be used at all incidents.
- The incident command system should provide for additional accountability responders based on the size, complexity, or needs of an incident. The implementation of division, group, or sector supervisors can assist the incident commander in this area by reducing the span of control.
- The incident commander should provide for control of access to the incident scene.
- A department should adopt and routinely use a standard responder identification system to maintain accountability for each member assigned to an incident. There are several accountability systems used during structural fire fighting.
- The personnel accountability system should provide an accounting of those members actually responding to the scene on each company or apparatus.
- The incident command system should include standard operating guidelines that use emergency traffic communication to evacuate responders from an area where imminent hazard is found to exist and to account for their safety.

Emergency Traffic. The fire department standard operating procedure provides direction in the use of clear text radio messages for emergency incidents. The standard operating procedure should use emergency traffic as the designator to clear the radio traffic. "Emergency traffic" can be declared by the incident commander, division or group supervisor, or member in trouble or subject to emergency conditions. Clear text should be used to describe the emergency conditions present. Examples of emergency conditions that could occur include the following:

1. "Fire fighter down"
2. "Fire fighter missing"
3. "Fire fighter trapped"
4. Serious conditions—"all members evacuate the building"
5. Change in conditions—"wind changed direction from north to south"
6. Hazard identification—"power line has energized a fence to metal roof"
7. Change in tactics—"change from offensive to defensive"

When a member has declared "emergency traffic," that person should use clear text to identify the type of emergency, change in conditions, or tactical operations. The member who has declared the "emergency traffic" should conclude the condition by transmitting "all clear, resume radio traffic" to end the emergency situation or to reopen the radio channels for communication after announcing the emergency message.

Retreat Policy. A fire department should have an operational retreat policy. In addition to an emergency traffic radio message, fire departments could use an additional signal, such as an apparatus air horn, to cause an evacuation of responders. Some departments have incorporated a series of three 10-second short blasts on an air horn with a 10-second silence between each series of blasts of an air horn. For fire departments that adopt this system, it is very important for the incident commander to select apparatus away from the command post to reduce the possibility of missing radio messages while the air horns are sounding.

Personnel Accountability Report. The incident commander should conduct a personnel accountability report (PAR) from each division or group supervisor whenever there has been an announcement of a change in conditions that could create an unsafe operation. When a division or group supervisor is requested to conduct a PAR, this supervisor is responsible for reporting on the accountability of all companies or members working within his or her area of responsibility. (A position description that addresses fire fighter Incident Safety and Accountability Guideline is available from FIRESCOPE and is published in the ICS 910 publication.)

Officer Responsibilities

An incident safety officer should be designated by the incident commander whenever the incident commander cannot perform this vital function due to the size or complexity of the incident. At an emergency incident where activities are determined by the incident safety officer to be unsafe or to involve an imminent hazard, the incident safety officer should have the authority to alter, suspend, or terminate those activities. The incident safety officer should immediately inform the incident commander of any actions taken to correct imminent hazards at the emergency scene. At an emergency incident where an incident safety officer identifies unsafe conditions, operation, or hazards that do not

present an imminent danger, the incident safety officer should take appropriate action through the incident commander to mitigate or eliminate the unsafe condition, operation, or hazard at the incident scene.

The incident safety officer should be designated by the incident commander and be integrated with the incident management system as a command staff member. The incident safety officer should survey and monitor the scene and report the status of conditions, hazards, and risks to the incident commander. The incident safety officer can have designated assistant safety officers based on the need, size, complexity, or duration of the incident.

The incident commander should be provided with reports of elapsed time-on-scene at emergency incidents in 15-minute intervals from the emergency service organization communication center until reports are terminated by the incident commander. Members operating in hazardous areas at emergency incidents should operate in crews of two or more.

Deployment

Initial Crew. In the initial stages of an incident where only one crew is operating in the hazardous area at a working structure fire, a minimum of four individuals is required, consisting of two individuals working as a crew in the hazard area and two individuals present outside this hazard area who are available for assistance or rescue at emergency operations where entry into the danger area is required. The standby members should be responsible for maintaining a constant awareness of the number and identity of members operating in the hazardous area, their location and function, and time of entry. The standby members should remain in radio, visual, voice, or signal line communications with the crew. The initial stages of an incident should encompass the tasks undertaken by the first arriving company with only one crew assigned or operating in the hazardous area.

The following examples from NFPA 1500 indicate how a fire department could deploy a team of four members initially at the scene of a structure fire:

- The team leader and one fire fighter could advance a fire-fighting hoseline into the IDLH atmosphere, and one fire fighter and the pump operator become the standby members.
- The team leader could designate the pump operator to be the incident commander. The team leader and one fire fighter enter the IDLH atmosphere, and one fire fighter and pump operator remain outside as the standby members.
- The two fire fighters could advance the hoseline in the IDLH atmosphere, and the team leader and pump operator remain outside as standby members.

Assignment of Additional Resources. Once a second crew is assigned or operating in the hazardous area, the incident should no longer be considered in the initial stages, and at least one rapid intervention crew/company should comply with the following requirements: (1) on-scene members designated and dedicated as rapid intervention crew/company, and (2) on-scene members performing other functions but ready to redeploy to perform rapid intervention crew/company functions.

The assignment of any responders as members of the rapid intervention crew/company should not be permitted if abandoning their critical task(s) to perform rescue clearly jeopardizes the safety and health of any member operating at the incident. As the incident expands in size or complexity, which includes an incident commander's requests for additional resources beyond the fire department's initial attack assignment, the dedicated rapid intervention crew/company (RIC) should on arrival of these additional resources be either one of the following: (1) on-scene members designated and dedicated as rapid intervention crew/company, and (2) on-scene crew/company or crews/companies located for rapid deployment and dedicated as rapid intervention crews.

During fire fighter rescue operations, each company should remain intact. At least one dedicated rapid intervention company should be in the standby mode with equipment to provide for the rescue of members who are performing special operations or for members who are in positions that present an immediate danger of injury in the event of equipment failure or collapse.

When more than one rapid intervention crew is deployed, consider implementing a rescue group supervisor to manage the multiple rapid intervention companies and to coordinate any rescue attempts when in the deployment mode. Whenever a rapid intervention crew is deployed, the incident commander should designate another rapid intervention crew in the standby mode to provide for fire fighter safety.

Additional areas that are also very important in reducing risks to members include the following: effective training, rest and rehabilitation, continuous evaluation of changing conditions, and past experience.

NFPA 1581, *Standard on Fire Department Infection Control Program*

Emergency Medical Services. As the fire service has expanded its role, the fastest-growing service it provides is that of emergency medical services (EMS). For fire departments that provide a level of emergency medical service, that service constitutes more than 60 to 70 percent of their responses. The fire service provides different models and levels of this service. Included are the basic first responder level, as outlined by the medical regulatory agency; the basic emergency medical technician level (EMT-B); the intermediate level (EMT-I); and the paramedic level (EMT-P). At both the intermediate and paramedic levels, regulatory agencies may allow certain procedures based on need, training, and local medical protocol. The models of service delivery may include treatment and transport at all levels; treatment at all levels with a combination of public, private, or third-party transport; and treatment with only private transport.

In any of these models, the fire service uses largely dual-trained cross-role fire fighters. Many departments now require members to have some level of emergency medical training and certification before they apply for a position within the department.

Exposure to Disease. With these increased roles and services come increased risks. The risks within this context include com-

municable and infectious disease. The fire service members providing patient care place themselves at risk at an incident scene, but some of these same risks are found in the facilities in which they live and work. NFPA 1581, 1992 edition, was part of the plan of developing standards that could have a significant and immediate impact on fire fighter health and safety. The standard outlined a program that would afford fire fighters a level of protection if they complied with documented practices regarding the following:

- Wearing protective clothing
- Being immunized and vaccinated
- Adhering to an exposure reporting system
- Cleaning and disinfecting clothing and equipment
- Acquiring needed training

Important to note is the fact that when the standard was being issued, there was an outbreak of the AIDS virus, the initial hepatitis B vaccines were being developed, and the fear of fire fighters becoming infected and possibly dying was ongoing. The federal government moved quickly, under the auspices of the Centers of Disease Control and Prevention (CDC), and OSHA developed regulations on protecting emergency response personnel and health care workers (Figure 12.7.2). The Ryan White Act spelled out protection, notification, and confidentiality issues regarding communicable and infectious diseases.

Cleanup. One important aspect of infection control is the cleaning and disinfecting of protective clothing and protective equipment. This cleanup includes the proper cleaning and disinfecting of protective clothing and equipment, a separate room and laundry facilities to accomplish that, a clean work area in the kitchen to wash and prepare meals, and clean and properly spaced living quarters. The 1992 edition of NFPA 1581 provided the initial requirements. The 1995 edition contained those additional requirements and updates on vaccinations and immunizations, facility safety, and worker protection. The 2000 edition has continued along those same avenues and expanded into other areas, including updating the CDC regulations, updating the immunization and vaccination list, expanding the list of infectious and communicable diseases, and developing requirements for cleaning and disinfecting apparatus and vehicles. This standard, along with NFPA 1999, *Standard on Protective Clothing for Emergency Medical Operations,* is an asset to being better educated regarding the hazards of infectious and communicable diseases. The fire service needed an educational venue to explain to fire fighters that the protective clothing they wore at an incident scene contained contaminants that might be harmful. The possibility for such cross-contamination is real and the fire service needs the education component. Even if the station does not have in-house cleaning capabilities, the fire department is required to clean the fire fighters' protective clothing every 6 months at a minimum. The issue is for fire fighters to protect themselves so that they can continue to provide service to the citizens we serve.

NFPA 1582, *Standard on Comprehensive Occupational Medical Program for Fire Departments*

Fire fighter medical requirements were originally included as a component of NFPA 1001, *Standard for Fire Fighter Professional Qualifications.* In 1988 the Occupational Safety and

FIGURE 12.7.2 Emergency Response Personnel Protecting Himself While Providing Patient Care (Photo courtesy of Fairfax County Fire and Rescue Department, Fairfax, Virginia)

Health Technical Committee and the Professional Qualifications Technical Committee formed a working subcommittee whose mission was to write a medical requirements standard for both candidate and incumbent fire fighters. This committee, which was composed of occupational medical physicians, fire service personnel at all levels, fire service instructors, and representative fire service organizations, realized early in the process that medical evaluations for fire fighters are an important component of an overall occupational medical program.

Medical Condition of Fire Fighters. The first edition of the standard, issued in 1992, outlined medical requirements that were categorized into A and B conditions. Category A conditions would preclude someone from either becoming a fire fighter or from continuing in a position that included primarily fire suppression. This decision caused difficulty because most fire departments had only one entry portal into the service and that was as a fire suppression fire fighter. An additional complication emerged as fire departments created "light-duty positions" or moved personnel into other positions that had no job description.

Fire department physicians or those hired to perform medical evaluations had no fire fighter job description or task analysis on which to base the medical evaluation and, thus, determine the medical condition necessary to be a fire fighter. Consequently, this raised questions on who was being "accommodated" in order to maintain his or her status as a fire fighter. Although some departments made this practice part of a labor agreement, other departments considered it part of the routine procedure. This issue led to some problems while the 1997 edition of the standard was being written. The technical committee physicians realized that when they examined fire fighters, certain areas within the standard were critical, based on how the 1992 edition was being interpreted.

They identified the following areas as ones that needed greater emphasis and clarification: cardiovascular, neurological, vision, hearing, and metabolic processes. Thus, the committee sought out specialists in those areas to assist them in rewriting the standard.

Americans with Disabilities Act. Concurrently, litigation, citing NFPA 1582, was brought forward regarding the use and interpretation of the Americans with Disabilities Act (ADA). The implementation and interpretation of the ADA law created confusion on how this law impacted employment factors of hiring and promoting within the fire service. The committee worked toward revising the standard and further defining areas by developing a sample job task analysis, a sample job description, an annex that included discussion regarding ADA, and a sample physician's checklist. In the 1997 edition, all these changes were made and the medical requirements were updated. Medical technology changes constantly; the standards-making process, however, cannot keep up with these changes.

The committee members, along with outside physicians, worked within the confines of a short revision cycle to continue to refine the five identified areas in the 1997 edition. Additionally, the committee realized that the work being done by the National Institute for Occupational Safety and Health (NIOSH) in its fire fighter fatality investigations as well as documentation from NFPA Fire Analysis and Research Division would assist it in the future as revisions to NFPA 1582 were being made. The 2000 edition of the standard, therefore, reflects some of those revisions, especially in the areas of diabetes, hearing, and cardiovascular disease.

Common Medical Problems. Statistics tell us that almost 50 percent of fire fighter fatalities are cardiac related and almost 50 percent of those had previous cardiac-related problems. The commonsense approach would be to medically evaluate these personnel annually and try to diagnose these conditions in the early stages and treat them before they occur. Recall that the purpose of an occupational safety and health program is for the fire fighter to leave the profession in the same condition as when he or she entered it. Fire fighting is a hazardous occupation.

In addition to cardiac-related problems, other medical problems are also characteristic of the profession, including a high incidence of cancer, especially of the liver, kidney, colon, prostate, and lung. Screening for these and other occupationally related diseases is a component of an occupational medical program and is included as part of the medical evaluation program.

Role of the Fire Department Physician. The fire department physician plays a significant role in managing the fire department's occupational medical program. Many fire departments that cannot afford their own physicians have grouped together to contract with either a physician or local HMO. Some smaller departments may utilize the physician as a regular member of their fire-fighting force. In any case, the physician oversees the program, reviews medical exams and evaluations, recommends follow-up or specialist exams, and works in conjunction with the health safety officer and the health fitness coordinator.

The 2003 edition addressed the issues of medical care and evaluation of both candidates and incumbents within a fire department; these issues have been discussed in numerous NFPA standards. The initial discussion and mandatory medical requirements were contained in NFPA 1001. Members of both committees have broken significant ground in providing a standard that the user—the fire department physician—can understand. The physicians on the committee have developed a physician guidance text that provides a link between the essential job tasks of a fire fighter doing manual fire suppression and the medical requirements in the standard. This will assist the user in determining, based on medical evaluations, if someone can do the essential job tasks.

Occupational Medical Program. In addition, the standard has delineated the document to address those medical issues of a candidate seeking to become a fire fighter and those incumbents currently performing the tasks of fire fighting. This standard does not differentiate among volunteer, paid-on-call, part-time, and career fire fighters—the tasks are the same. Since the committee has changed the title of the standard to reflect a comprehensive occupational medical program, it has included references to the IAFC-IAFF Joint Wellness Initiative and to NFPA 1583. These two documents outline a health-related fit-

ness program that is medically validated against this edition of NFPA 1582. Although the cost of medical exams continually increases, the organization must weigh the initial costs versus long-term job related illnesses, injuries, and fatality costs. Fire departments spend a lot of money on preventive maintenance of apparatus and equipment; however, that is an inefficient use of resources if they do not have medically qualified personnel to operate them and to respond to emergency incidents.

NFPA 1583, *Standard on Health-Related Fitness Programs for Fire Fighters*

As part of a fire department occupational health and safety program, NFPA 1500 includes text requiring a physical performance program as well as a fitness program. The committee struggled to provide a standard on physical performance requirements that would be required for both candidates and incumbents alike. This standard was doomed from the outset. There was considerable discussion among the technical committee members, as well as litigation within the United States, regarding the validity and content of physical performance testing. Trying to develop a set of physical test skills related by task analysis to the profession of fire fighting and then to validate that test was difficult at best.

The committee skipped a cycle and with a great deal of angst reached consensus on a document that was passed by the NFPA membership and then subsequently appealed to the association's Standards Council. It was returned to the technical committee by the Standards Council and withdrawn from the system after a unanimous vote from the committee members in 1997. The technical committee initiated a new document in the summer of 1997.

Joint Fire Service Wellness Program. As this proposed NFPA standard was withdrawn, a group of 10 cities within North America began work on a joint fire service wellness program. This program, supported and endorsed by the International Association of Fire Fighters (IAFF) and the International Association of Fire Chiefs (IAFC), included Phoenix, Arizona; New York, New York; Los Angeles County, California; Seattle, Washington; Calgary, Alberta, Canada; Austin, Texas; Charlotte, North Carolina; Indianapolis, Indiana; Fairfax County, Virginia; and Metro-Dade County, Florida. IAFF officials from each local, fire chiefs from each city, and fire department physicians worked on this program, which was introduced at both Fire Rescue International and the IAFF Redmond Symposium in 1999. This program has been used successfully by these 10 departments, as well as others across the world. It is a great example of a joint labor-management initiative that benefits all of the fire service.

The Fire Service Occupational Medical and Health Technical Committee began work on a health-related fitness program for the fire service, which initially did not have widespread support from the fire service. Many saw this effort as a revisit of the physical performance test versus what it really was—namely, a standard containing the components of an overall health-related fitness program for the fire service. Managed by both the fire department physician and the health fitness coordinator, this standard has nutrition, wellness, and fitness components that may be accomplished in a number of different ways. The program, as outlined in the standard, is similar to the program developed by the IAFF/IAFC Joint Labor/Management Wellness Initiative.

Fitness Testing. The 10 cities in the initiative then began work on a physical performance component that would be used to test candidates wishing to seek employment in the fire service profession. The testing process was developed with the assistance of the U.S. Department of Justice. The job tasks were validated for the 10 cities, the testing mechanism and props were developed, and then the test was run using incumbents from each department. This test, called the Candidate Performance Agility Test (CPAT), was introduced at both Fire Rescue International and the IAFF Redmond Symposium in 1999. The validity developed within the 10 cities required each to provide a job task analysis and a job description based on that analysis in order to validate the CPAT test for their municipality. The validation process is not a "one size fits all" for those who choose to utilize it. Municipalities must go through the same process as did the 10 cities and validate the CPAT individually. The IAFF has developed a Peer Fitness Training Program that assists those municipalities that wish to use the CPAT.

NFPA 1584, *Recommended Practice on Rehabilitation of Members Operating at Incident Scene Operations and Training Exercises*

The 2003 edition of NFPA 1584 was prepared by the Technical Committee on Fire Service Occupational Medical and Health and acted on by NFPA at its November Association Technical Meeting held November 16–20, 2002, in Atlanta, Georgia. It was issued by the Standards Council on January 17, 2003, with an effective date of February 6, 2003.

The Technical Committee on Fire Service Occupational Medical and Health has responsibility for this document. The members of the committee have developed standards in areas of incident management, occupational medical programs, fitness evaluation, fire department safety officer, and infectious disease control programs. These standards fall under the umbrella of NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program,* 2002 edition. An integral component of both an occupational safety and health program and incident scene management is an organized approach for fire department members' rehabilitation at incident scene operations.

The concept of incident scene rehabilitation has been discussed and utilized throughout the fire service in various sizes and configurations. Many departments have utilized material from the United States Fire Administration, as well as material from emergency medical services. Progressive departments have shared their "lessons learned" in the development of this document. This recommended practice establishes the minimum level of criteria for developing and implementing a rehabilitation process for fire department members at incident scene operations and training exercises. This recommended practice provides for the rehabilitation of members operating within an

incident management system rehabilitation component, including but not limited to, the following:

- Medical evaluation and treatment
- Food and fluid replenishment
- Relief from climatic conditions
- Rest and recovery
- Member accountability

RISK MANAGEMENT MODEL

NFPA 1500 requires the development, implementation, and use of a written risk management plan. This plan must consider all fire department activities, operations, and standard operating procedures to ensure that a comprehensive approach is the focus. The health and safety officer is the primary person responsible for this document but must seek assistance as this plan covers all aspects of the fire department.

The risk management model presents a systematic approach for identifying and planning for the control of risks. This methodical process for making decisions can be utilized not only for the nonemergency risks that all organizations must address but also for the risks associated with the response to and mitigation of an emergency incident. The factors at each incident will always vary, but as we have known for years, continual training in all aspects of the approach will yield the best, most consistent results possible.

Five Steps

The model has five primary components, or steps, which serve as a foundation for this process. Each one depends on information generated by the previous step, so it is important to evaluate each one before moving on to the next. The following five steps are discussed in detail in the next sections:

1. Identifying risk
2. Evaluating risk
3. Establishing priorities or prioritization
4. Establishing risk control techniques
5. Monitoring

For each step in the process, it is important to record performance criteria, suggestions, and recommendations. These data will provide the elements that formulate a written risk management plan. The number of pages in the plan has no impact on the plan's effectiveness. Once created, the plan should be periodically updated (at least annually). Consider it a dynamic process, not a static event with a single written record. Keep the plan current based on conditions, circumstances, and experience.

Identifying Risk. The first step of the risk management model involves identifying what could go wrong. To make this identification it is useful to compile a list of all emergency and nonemergency operations in which the department participates. The intent is to plan for the worst but hope for the best. There are many sources to assist with this identification process. The first, and possibly the most effective, is the department's loss prevention data. Seek input and ideas from department personnel, other health and safety officers, jurisdiction risk managers, trade journals, professional associations, and other service providers. When using ideas or information from other fire departments or organizations, simply consider local circumstances when formulating the list.

Evaluating Risk. Once the risks are identified, they can be evaluated from both a frequency and severity standpoint. Frequency addresses the likelihood of occurrence. Typically, if a particular type of incident (e.g., back injuries) has occurred repeatedly, these incidents will continue to occur until effective control measures are implemented.

Severity addresses the degree of seriousness of the incident and can be measured in a variety of ways, such as time away from work, cost of damage, cost of and time for repair or replacement, disruption of service, or legal costs. Using the information gathered in the identification step, the risks can be classified based on severity.

Establishing Priorities. Taken in combination, the results of the frequency and severity determinations will help to establish priorities for determining action. Any risk that has a low probability of occurrence (frequency) but has serious consequences (high risk or severity) deserves immediate action and would be considered a high-priority item (Figure 12.7.3). Nonserious incidents with a low likelihood of occurrence are a lower priority and can be placed near the bottom of the "action required" list.

Establishing Risk Control Techniques. At this point in the process, risks have been identified and evaluated, so it is time to find solutions. There are several approaches to take, including risk avoidance, implementation of control measures, and risk transfer.

In any situation, the best choice is *risk avoidance,* which simply means to avoid the activity that creates the risk. In an emergency services organization, risk avoidance frequently is impractical. Lifting a stretcher presents a serious back injury risk, but you cannot avoid this risk and still provide effective service.

An example of a situation in which avoidance has been very practical is the widespread, hopefully universal, use of sharps containers. The risks associated with recapping needles are well documented; therefore, recapping is no longer an ac-

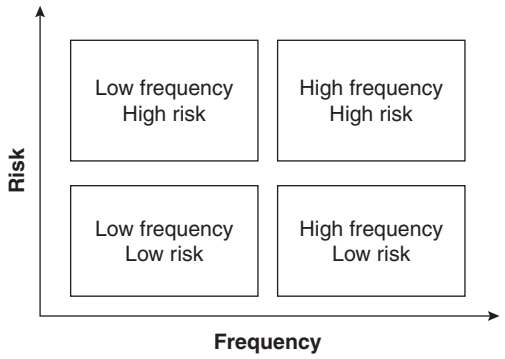

FIGURE 12.7.3 Risk Management Graph

cepted practice. This risky behavior can be avoided through the proper use of a sharps container.

The most common method utilized for the management of risk is the adoption of *effective control measures.* Although control measures will not eliminate the risk, they can reduce the likelihood of occurrence or mitigate the severity. Safety programs, ongoing training and education programs, and well-defined standard operating procedures (SOPs) are all effective control measures.

Some typical control measures instituted to control fireground injuries include accountability, use of full protective clothing, a mandatory respiratory protection program, training and education, and competent standard operating procedures. These control measures coupled together make an effective program that ensures safe fireground operations.

Risk transfer can be accomplished in two primary ways: physically transferring the risk to somebody else or through the purchase of insurance. For a fire or EMS organization, the transfer of risk may be difficult if not impossible. However, an example of risk transfer would be contracting out the operation and maintenance of helicopters for use by responders. The risks associated with those activities have been transferred to a private contractor.

The purchase of insurance transfers financial risk only and does nothing to affect the likelihood of occurrence. Buying fire insurance on a fire station, although highly recommended for protecting the assets of the department, does nothing to prevent the station from burning down. Therefore, insurance is no substitute for effective control measures.

Monitoring. The last step in the process is risk management monitoring. Once control measures have been implemented, they need to be evaluated to measure their effectiveness. Any problems that occur in the process have to be revised or modified. This final step ensures that the system is dynamic and will facilitate periodic reviews of the entire program.

The intent of the risk management plan is to develop a strategy for reducing the inherent risks associated with fire department operations. Regardless of the size or type of fire department, every organization should operate within the parameters of a risk management plan. This is a dynamic and aggressive process that must be monitored and revised annually by the health and safety officer.

Operational Risk Management

In order to address operational risk management and reduce level of risk during emergency operations, several components need to be incorporated into this process. Many components have a positive impact of reducing risk during fireground operations or any other type of emergency including as discussed in the section that follows.

INCIDENT COMMAND SYSTEM (ICS)

In the early 1970s, southern California experienced several devastating wildland fires. The overall cost and loss associated with these fires totaled $18 million per day. This multijurisdictional disaster was the impetus for the development of an improved interagency incident management system known as the incident command system (ICS). The incident command system is one of the beneficial results of a federally funded project called FIRESCOPE that was convened after these fires and whose charter was to examine various aspects of interagency response to incidents.

FIRESCOPE

The Fire Resources of California Organized for Potential Emergencies (FIRESCOPE) incident command system is primarily a command and control system delineating job responsibilities and organizational structure for the purpose of managing day-to-day fire and rescue operations. It also is flexible enough to manage catastrophic incidents involving thousands of emergency response and management personnel.

National Interagency Incident Management System (NIIMS)

This incident command system was developed by the wildland community in order to provide a common system for wildland fire protection agencies at the local, state, and federal levels. The NIIMS organization includes the Bureau of Land Management, the Bureau of Indian Affairs, the U.S. Fish and Wildlife Service, the U.S. Forest Service, representatives of State Foresters, and the National Park Service. NIIMS consists of the following five major subsystems that collectively provide a total systems approach to risk management:

1. The incident command system, which includes operating requirements, eight interactive components, and procedures for organizing and operating an on-scene management structure
2. Training that is standardized and supports the effective operations of the National Interagency Incident Management System
3. A qualification and certification system that provides personnel across the nation with standard training, experience, and physical requirements to fill specific positions in the incident command system
4. Publications management that includes development, publication, and distribution of NIIMS materials
5. Supporting technologies such as orthophoto mapping, infrared photography, and a multiagency coordination system that supports NIIMS operations

FIRESCOPE Model Incident Command System

Since the development of the incident command system, the fire service has experienced several challenges in understanding its application. As a result, inconsistencies in the system began to develop; other hybrid systems came into existence, further distancing a common approach to incident command. A single incident management system is critical for effective command and control of major incidents. At these incidents, a single department may interface with other agencies on the local, state, and federal levels. In order to reduce the inherent confusion that

may be associated with larger-scale incidents, a common command system must be used.

Need for a Single Approach

Recognizing the challenges that were occurring in the fire service in applying a common approach to incident command, the National Fire Service Incident Management System Consortium was created. Developed in 1990, its purpose is to evaluate an approach to developing a single command system. The consortium consists of many individual fire service leaders, representatives of most major fire service organizations, and representatives of federal agencies including FIRESCOPE. One of the significant outcomes of the work done by the consortium was the identification of the need to develop operational protocols within the incident command system, so that fire and rescue personnel would be able to apply the incident command system as one common system. In 1993, as a result of this, the IMS consortium completed its first document: *Model Procedures Guide for Structural Firefighting.*

FIRESCOPE adopted this in principle as an application to the Model FIRESCOPE Incident Command System. The basic premise is that the organizational structure found in the FIRESCOPE Incident Command System now is enhanced with operational protocols that allow the nation's fire and rescue personnel to apply the incident command system effectively, regardless of the area in the country to which they are assigned. The National Fire Academy (NFA), having adopted the FIRESCOPE Incident Command System in 1980, has incorporated this material in its training curriculum and will continue to reach the thousands of fire service personnel with one common incident command and control system.

It is important to note that the FIRESCOPE Model Incident Command System has had other applications or modules similar to the structural fire-fighting applications that have been in place for some time. These create a framework for other activities to operate in and further enhance the use of the incident command system. Examples are the multicasualty, hazardous materials, and the urban search and rescue applications.

The Federal Emergency Management Agency (FEMA) formally adopted the FIRESCOPE Incident Command System as the incident management system for any federal response required by the agency. Since then, several other federal agencies have adopted the FIRESCOPE Incident Command System.

Evolution of the Incident Command System

The concept of the incident command system (ICS) was developed more than 30 years ago in the aftermath of a devastating wildfire in California. During 13 days in 1970, 16 lives were lost, 700 structures were destroyed, and over 1.5 million acres burned. The overall cost and loss associated with these fires totaled $18 million per day. Although all of the responding agencies cooperated to the best of their ability, numerous problems with communication and coordination hampered their effectiveness. As a result, Congress mandated that the United States Forest Service design a system that would "make a quantum jump in the capabilities of Southern California wildland fire protection agencies to effectively coordinate interagency action and to allocate suppression resources in dynamic, multiple-fire situations."

The California Department of Forestry and Fire Protection; the Governor's Office of Emergency Services; the Los Angeles, Ventura, and Santa Barbara County Fire Departments; and the Los Angeles City Fire Department joined with the United States Forest Service to develop the system. This system became known as FIRESCOPE .

In 1973, the first FIRESCOPE Technical Team was established to guide the research and development design. Two major components came out of this work, the incident command system (ICS) and the Multi-Agency Coordination System (MACS). The FIRESCOPE ICS is primarily a command-and-control system delineating job responsibilities and organizational structure for the purpose of managing day-to-day operations for all types of emergency incidents. By the mid-seventies, FIRESCOPE agencies had formally agreed on ICS common terminology and procedures and conducted limited ICS field-testing. By 1980, parts of ICS had been used successfully on several major wildland and urban fire incidents. It was formally adopted by the Los Angeles Fire Department, the California Department of Forestry and Fire Protection (CDF), and the Governor's Office of Emergency Services (OES) as well as endorsed by the State Board of Fire Services.

Also during the 1970s, the National Wildfire Coordinating Group (NWCG) was chartered to coordinate fire management programs of the various participating federal and state agencies. By 1980, FIRESCOPE ICS training was under development. Recognizing that FIRESCOPE training could also satisfy the needs of other state and federal agencies in addition to the local users for which it was designed, the NWCG conducted an analysis of FIRESCOPE ICS for possible national application.

Widening the Application of ICS

By 1981, the incident command system was widely used throughout southern California by the major fire agencies. In addition, the use of the incident command system in response to nonfire incidents was increasing. Although FIRESCOPE ICS was originally developed to assist in the response to wildland fires, it was quickly recognized as a system that could help public safety responders provide effective and coordinated incident management for a wide range of situations, including floods, hazardous materials accidents, earthquakes, and aircraft crashes. It was flexible enough to manage catastrophic incidents involving thousands of emergency response and management personnel. By introducing relatively minor terminology, organizational, and procedural modifications to FIRESCOPE ICS, the NIIMS ICS became adaptable to an all-hazards environment.

Although tactically each type of incident may be handled somewhat differently, the overall incident management approach still utilizes the major functions of the incident command system. The FIRESCOPE board of directors and the NWCG recommended national application of ICS. In 1982, all FIRESCOPE ICS documentation was revised and adopted as the National Interagency Incident Management System (NIIMS). In the years since FIRESCOPE and the NIIMS were blended, the

FIRESCOPE agencies and the NWCG have worked together to update and maintain the Incident Command System Operational System Description (ICS 120–1). This document would later serve as the basis for the NIMS ICS.

National Incident Management System (NIMS)

The way this nation prepares for and responds to domestic incidents is changing. It will not be an abrupt change; best practices that have been developed over the years are part of this new comprehensive national approach to incident management known as the National Incident Management System (NIMS). Developed by the Department of Homeland Security and issued in March 2004, the NIMS will enable responders at all jurisdictional levels and across all disciplines to work together more effectively and efficiently.

One of the most important best practices that has been incorporated into the NIMS is the incident command system (ICS), a standard, on-scene, all-hazards incident management system already in use by fire fighters, hazardous materials teams, rescuers, and emergency medical teams. The ICS has been established by the NIMS as the standardized incident organizational structure for the management of all incidents.

In Homeland Security Presidential Directive-5 (HSPD-5), President Bush called on the Secretary of Homeland Security to develop a national incident management system to provide a consistent nationwide approach for federal, state, tribal, and local governments to work together to prepare for, prevent, respond to, and recover from domestic incidents, regardless of cause, size, or complexity.

On March 1, 2004, after close collaboration with state and local government officials and representatives from a wide range of public safety organizations, Homeland Security issued the NIMS. This system incorporates many existing best practices into a comprehensive national approach to domestic incident management, applicable at all jurisdictional levels and across all functional disciplines.

The NIMS represents a core set of doctrine, principles, terminology, and organizational processes to enable effective, efficient, and collaborative incident management at all levels. To provide the framework for interoperability and compatibility, the NIMS is based on a balance between flexibility and standardization. The recommendations of the National Commission on Terrorist Attacks upon the United States (the "9/11 Commission") further highlight the importance of ICS. The commission's report recommends national adoption of the ICS to enhance command, control, and communications capabilities.

BLENDING INCIDENT COMMAND SYSTEMS

There were several efforts to "blend" the various incident command systems. One early effort was in 1987 when NFPA undertook the development of NFPA 1561, then called *Standard on Fire Department Incident Management System.* The NFPA committee quickly recognized that the majority of the incident command systems in existence at the time were similar. The differences among the systems were mainly due to variations in terminology for similar components. That NFPA standard, later revised to its present title, *Standard on Emergency Services Incident Management Systems,* provides for organizations to adopt or modify existing systems to suit local requirements or preferences as long as they meet specific performance measurements.

National Fire Service Incident Management System (IMS) Consortium

Recognizing the continuing challenges occurring in the fire service in applying a common approach to incident command, the National Fire Service Incident Management System (IMS) Consortium was created in 1990. Its purpose was to evaluate an approach to developing a single command system. The consortium consisted of many individual fire service leaders, representatives of most major fire service organizations, and representatives of federal, state, and local agencies, including FIRESCOPE and the Phoenix Fire Department. One of the significant outcomes of the consortium's work was an agreement on the need to develop operational protocols within ICS, so that fire and rescue personnel would be able to apply the ICS as one common system.

In 1993, the IMS consortium completed its first document: *Model Procedures Guide for Structural Firefighting.* As a result, FIRESCOPE incorporated the model procedures, thereby enhancing its organizational structure with operational protocols. These changes enabled the nation's fire and rescue personnel to apply the ICS effectively regardless of what region of the country they were assigned to.

The NIMS provides a consistent, flexible, and adjustable national framework within which government and private entities at all levels can work together to manage domestic incidents, regardless of their cause, size, location, or complexity. This flexibility applies across all phases of incident management: prevention, preparedness, response, recovery, and mitigation. The NIMS provides a set of standardized organizational structures—including the ICS, Multi-Agency Coordination Systems, and public information systems—as well as requirements for processes, procedures, and systems to improve interoperability among jurisdictions and disciplines in various areas.

Department of Homeland Security

The Department of Homeland Security recognizes that the overwhelming majority of emergency incidents are handled on a daily basis by a single jurisdiction at the local level. However, the challenges we face as a nation are far greater than the capabilities of any one community or state but no greater than the sum of all of us working together. There will be instances in which successful domestic incident management operations depend on the involvement of emergency responders from multiple jurisdictions, as well as personnel and equipment from other states and the federal government. These instances require effective and efficient coordination across a broad spectrum of organizations and activities. The success of the operations will

depend on the ability to mobilize and effectively utilize multiple outside resources. These resources must come together in an organizational framework that is understood by everyone and must utilize a common plan, as specified through a process of incident action planning. This will be possible only if we unite, plan, exercise, and respond using a common NIMS.

When Homeland Security released the NIMS on March 1, 2004, Secretary Tom Ridge and Under Secretary Brown specifically highlighted compliance with the ICS as being possible fairly quickly. They recognized that in some cities, the fire and police departments have worked together using ICS for years. In other places, only the fire department has used ICS. Although law enforcement, public works, and public health were aware of the concept, they regarded ICS as a fire service system.

The NIMS ends this discrepancy because HSPD-5 requires state and local adoption of NIMS as a condition for receiving federal preparedness funding. Although ICS was first pioneered by the fire service, it is, at its core, a management system designed to integrate resources to effectively attack a common problem. This system is not exclusive to one discipline or one set of circumstances; its hallmark is its flexibility to accommodate all circumstances. Some purists may claim that a particular application of ICS is not consistent with the NIMS. Yet we need not approach ICS with the same mathematical precision used by an engineer. We are changing the culture of organizations and first responders at all levels of government. As long as implementation of ICS is consistent with the basic principles expressed in the NIMS, we will have made significant progress. Further refinements can be achieved over time based on experience with its use.

COMMUNICATION ISSUES

Emergency incidents involving fire fighter fatalities demonstrate that, despite technological advances in two-way radio communications, important information is not always adequately communicated on the fireground or emergency incident scene. Communication is integral to incident scene operations; it is the key to fire fighter safety and survival (Figure 12.7.4).

Fatalities and Injuries

Inadequate fireground communication is repeatedly cited as a contributing factor in many of the incidents through the United States Fire Administration Fire Fighter Fatality and Major Fires Investigation. Communication problems are continually cited as one of the four contributing factors in fires and emergency incidents in which fire fighters are killed or injured. Despite the obvious importance of effective communication on the emergency scene, only a limited amount of published research exists.

There are several United States Fire Administration investigation reports that cite communications-related issues as part of the "lessons learned" component. These investigatation reports include the following:

- *Wood Truss Roof Collapse Claims Two Fire Fighters, Memphis, TN*
  Two fire fighters operating an interior attack line were killed at this fire after a church roof collapsed.
- *Indianapolis Athletic Club Fire, Indianapolis, IN*
  Two fire fighters were killed on the third floor of a nine-story mixed-use building during a fire.

FIGURE 12.7.4 Communication as an Integral Part of Accountability (Photo courtesy of Martin Grube, Virginia Beach Fire Department)

- *Four Fire Fighters Die in Seattle Warehouse Fire, Seattle, WA*
  Four fire fighters were killed in a collapse at an arson fire in a warehouse.
- *Two Fire Fighters Die in Auto Parts Store Fire, Chesapeake, VA*
  Two fire fighters were killed after a roof collapse in a retail auto parts store.

Table 12.7.2 describes several key factors that create problems during emergency operations for fire fighters and continually surface during fire fighter fatality and injury investigation reports.

Standards for Radio Communications

NFPA 1561, *Standard on Emergency Services Incident Management System,* requires the fire department to develop standard operating procedures for radio communications, which address use of protocol and terminology at all types of incidents. There are definitive procedures in NFPA 1561 regarding radio communications, the incident management system, and emergency operations.

These procedures include the following:

- Clear text should be used.
- A radio channel should be provided for dispatch, and a separate tactical channel provided to be used initially during the incident.
- When a division or group is implemented, the fire department should provide a dispatch channel, a command channel, and a tactical channel.
- The fire department should provide the necessary number of radio channels relating to incidents with multiple tactical channels and the complexity of these incidents.
- Standard terminology will be established for transmitting information, strategic modes of operation, situation reports, and emergency notification of imminent hazards.
- The fire department should have procedures for the announcement of emergency conditions, which is termed "emergency traffic," as a designation to clear radio traffic.
- "Emergency traffic" should be declared by the incident commander, tactical level management component, or member who is in trouble or subjected to an emergency condition.
- Standard operating procedures should exist for telecommunicators (dispatchers) to provide support to emergency incident operations.
- Telecommunicators should be trained to function effectively within the incident command system and should

TABLE 12.7.2 Communications Issues

Key Issues	*Comments*
Unsuitable equipment	The chief communication problem reported by fire fighters and company officers is the difficulty with communicating from inside a fire when using full personal protective equipment, including SCBA. The majority of portable radios currently used by fire departments are not suited for the task.
Portable radios needed for all fire fighters	Despite some technical limitations, portable radios are a proven lifesaver during fires and emergency incidents. Portable radios should be considered a critical item of personal protective equipment similar to SCBA. *Ideally, every fire fighter working in an IDLH atmosphere should have a portable radio with an emergency distress feature.*
Little attention paid to human factors	There is available literature pertaining to the impact of human factors on effective fireground communication. Furthermore, while fire departments devote substantial time to manipulative skill training, relatively little training is provided to help fire fighters develop stress-tempered communications skills.
Importance of active listening	All fire fighters on an emergency incident should actively monitor their radios for important information at all times, not just when specifically queried. Communications should be emphasized as an essential part of fire fighters functioning as a tactical team, not just operating as individual entities.
Standard message formats and language	Fire departments can enhance fireground communications by creating standard message formats and using keywords consistently. Plain English is usually preferred over codes, especially when transmitting a complex message.
Tiered message priority	Keywords to prompt immediate action can be tiered based on their priority; for example, "Mayday" signals a life-or-death situation, whereas "Urgent" may be used to signify a potentially serious problem. Such message headers prompt the crew's listening priorities and radio discipline.
Attention to cultural factors	If necessary, fire fighters are not usually reluctant to circumvent the chain of command to report critical safety issues. There may be greater hesitation to communicate problems in completing an assigned task. However, this is usually due to a lack of situational awareness and not a fear of reprisal from other members. Studies on fire fighter communications show that sometimes the culture of bravery in the fire service is reflected in a reluctance to communicate quickly enough when help is needed. Repeated situations of this nature must be investigated by the department.

meet the requirements of NFPA 1061, *Standard for Professional Qualifications for Public Safety Telecommunicator.*
- The incident commander should be provided with elapsed time-on-scene information at emergency incidents in 10-minute intervals from the communications center.

INCIDENT SCENE REHABILITATION

The fire department should develop standard operating procedures that outline a systematic approach for the rehabilitation of members operating at incidents. Provisions addressed in these procedures should include medical evaluation and treatment, food and fluid replenishment, crew rotation, and relief from extreme climatic conditions. This program should outline an ongoing rehabilitation for simple or short-duration incidents as well as a process to transition into the rehabilitation needs of a large or long-duration incident.

Emergency Medical Service

Medical evaluation and treatment in the on-scene rehabilitation area should be conducted according to emergency medical service (EMS) protocols developed by the fire department in consultation with the fire department physician and the EMS medical director. If advanced life support (ALS) personnel are available, this level of EMS care is preferred.

The incident commander should consider the circumstances of each incident and initiate rest and rehabilitation of members in accordance with the fire department's standard operating procedures and with NFPA 1584 and Chapter 8 of NFPA 1500.

The incident scene rehabilitation group or division should include emergency medical care. The minimum level of emergency medical care available should be at least basic life support care. The assignment of an ambulance or other support crew to the rehabilitation function is essential during long-duration or heavy-exertion incident operations. This crew can assist with rehabilitation functions as well as be available to provide immediate basic life support needs for members. However, the advanced life support (paramedic) level of evaluation and treatment must be available quickly to ensure the proper level of care.

Analysis of Weather Conditions

Weather factors during emergency incidents can have a severe impact on the safety and health of the members. When these factors combine with long-duration incidents or situations that require heavy exertion, the risks to members increase rapidly. The fire department should develop procedures, in consultation with the fire department physician, to provide relief from adverse climatic conditions. Typical rehabilitation considerations for operations during hot weather extremes include the following:

- Moving fatigued or unassigned members away from the hazardous area of the incident
- Removing members' personal protective equipment
- Ensuring that personnel are out of direct sunlight
- Ensuring that there is adequate air movement over personnel, either naturally or mechanically
- Providing members with fluid replenishment, especially water
- Providing medical evaluation for personnel showing signs or symptoms of heat exhaustion or heat stroke

Typical rehabilitation considerations for operations during cold weather extremes should include the following:

- Moving fatigued or unassigned members away from the hazardous area of the incident
- Providing shelter from wind and temperature extremes
- Providing members with fluid replenishment, especially water
- Providing medical evaluation for members showing signs or symptoms of frostbite, hypothermia, or other cold-related injury

The incident safety officer should ensure that the incident commander establishes an incident scene rehabilitation tactical-level management unit during emergency operations as required by NFPA 1521, *Standard for Fire Department Safety Officer.*

Rehabilitation Division or Group

This component should be established in a safe environment away from the hazardous area of the incident. The resources needed at the rehabilitation tactical level management unit should include an environment to limit temperature stress, medical equipment, and adequate medical staff. Items that can assist in limiting temperature stress in cold environments include heat, blankets, and protection from the wind. For hot weather, items should include adequate shade, fans, air conditioning, and misting systems. Food and hydration needs include water and oral fluids, food, broth, and fruit. Also, for hydration, a 50/50 mixture of water and an electrolyte replacement drink can be provided. Medical equipment should include blood pressure cuffs, stethoscopes, oxygen, cardiac monitors, thermometers, and intravenous fluid and supplies.

SUMMARY

Fire fighting and the delivery of other emergency services continue to be a hazardous occupation. Significant improvements and advancements have been made in terms of fire fighter safety and health. The process starts with the development of a written risk management program. The risk management plan serves as documentation that risks have been identified, evaluated, and prioritized and that a reasonable control plan has been implemented and monitored. Other critical components that are needed to ensure the safety and health of our members include training and education, protective clothing and equipment, safe vehicle operations, use of an incident management system, an aggressive health maintenance program, and facility safety.

A considerable effort needs to be focused on the issues of fire fighter fatalities, debilitating fire fighter injuries, and occupational illnesses. Moreover, specific emphasis needs to address improvements with incident scene communications, personnel accountability of fire fighters, operation of fire department vehicles responding to an incident, and medical conditions of fire fighters.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on safety, medical, and health issues and programs discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

Chapter 8

Effect of Building Construction and Fire Protection Systems on Fire Fighter Safety

Revised by
Glenn P. Corbett

Chapter Contents

General Concerns
Simplified Principles of Building Construction
Building Codes and Building Construction Classification
Specific Concerns

Key Terms

building code, building collapse, building construction (types of), compartmentation, concrete, fire fighter safety, fire resistance, noncombustible construction, ordinary construction, timber

Fire department personnel have a very strong interest in building construction. They must fight fires in buildings, from those under construction to those built hundreds of years ago. Some building methods encountered are long forgotten, but the hazards still exist. For example, a reference to tile arch floors would be difficult to find in modern architectural texts, yet there are thousands of them still in existence and they do present a specific hazard.

This chapter looks at the fire department's involvement in and concerns about various aspects of building construction. For the safety of those they serve as well for their own safety, fire fighters must understand simplified principles of construction, be familiar with the building codes and building construction classification, and be actively involved in pre-incident planning. These activities will make fire fighters aware of issues regarding structural integrity, water supply, and so on when they arrive at the fire scene.

A number of sections and chapters in this handbook deal with aspects of building construction. Relevant chapters include all the other chapters in Section 12 as well as Section 1, Chapter 1, "Challenges to Safety in the Built Environment"; Section 1, Chapter 2, "Fundamentals of Structurally Safe Building Design"; Section 11, Chapter 4, "Fire Hazards of Construction, Alteration, and Demolition of Buildings"; Section 19, Chapter 1, "Types of Building Construction"; Section 19, Chapter 2, "Structural Integrity During Fire"; and Section 19, Chapter 3, "Structural Fire Safety in One- and Two-Family Dwellings."

GENERAL CONCERNS

Fire department functions related to building construction include the following:

- Reviewing and approving plans for fire protection features in new construction in cooperation with the building department. In some cases, the fire department has absorbed the building department.
- Making regular inspections that, among other functions, check on the reliability of code-specified fire protection features—both passive features, such as fire walls and the fire doors that protect openings in the fire walls, and active features, such as fire suppression systems. A most

Glenn P. Corbett, P.E., is an associate professor of fire science at John Jay College of Criminal Justice in New York City; technical editor of *Fire Engineering* magazine; an assistant chief of the Waldwick, New Jersey, fire department; and serves on the Fire Code Advisory Council for the state of New Jersey. He is the coauthor of *Brannigan's Building Construction for the Fire Service,* Fourth Edition. He has served as the administrator of engineering services for the San Antonio, Texas, fire department and as a fire protection consultant for the Austin, Texas, fire department.

important function is ensuring that code-required life safety features, such as exit facilities, are fully usable as intended.

- Making pre-incident planning surveys to assemble and record information vital to the incident commander at a fire scene. It is most important that the information be retrievable instantly at the fire scene. A foremost purpose of pre-incident planning is to identify situations that are or can become hazardous to fire fighters. Some hazards may be sufficiently serious as to call for defensive fire-fighting tactics (i.e., exterior attack with no entry into the building). Examples would include fires involving dilapidated or abandoned buildings, posttensioned concrete in buildings under construction, and unprotected load-bearing steel.
- Acquiring knowledge of building construction. This is important in investigations of the origin, cause, and extent of serious fires.

The geodesic dome of the U.S. exhibit at Expo '67 in Montreal is pictured in Figure 12.8.1. Some architectural writers, unaware of the entire story, still praise this dome. It accommodated a huge number of visitors. After it was turned over to the city of Montreal, a workman accidentally touched a torch to the plastic covering. It totally burned in 10 minutes. The framework stands today as a monument to a tragedy that, by great good fortune, did not happen.

The planked ceiling conference room shown in Figure 12.8.2 is another example of a type of construction that should be avoided. This room is decorated with a virtual lumberyard of planks overhead. It is possible that the planks are treated to be flame resistant. In any case, fire involving the desks and chairs might cause failure of the hangers, usually set in lead anchors, allowing the planks to fall.

SIMPLIFIED PRINCIPLES OF BUILDING CONSTRUCTION

The fire officer should have knowledge of the principles of construction and the proper terms for various building elements.

FIGURE 12.8.1 Geodesic Dome at Expo '67 in Montreal (Source: Photo by D. Lion)

FIGURE 12.8.2 Heavy Fire Load in Conference Room of Fire-Resistive Building

Errors in principles or terminology can adversely affect the credibility of sound fire protection recommendations. Further, court testimony may be fatally discredited on cross-examination.

Some of the more important principles of construction include the following:

- Construction is primarily designed to resist the force of gravity and other stresses such as wind and snow loads under normal conditions.
- The supporting system of a building is composed of many elements designed to transfer the building load to the ground.
- Exposure to fire is not a normal condition and design provisions are made in some types of construction to protect the gravity-resisting (structural) elements from failing when exposed to fire. Unprotected structural elements can result in early and unexpected failure leading to partial or full collapse.
- Contents, not construction elements, typically drive the growth, intensity, and spread of fire; however, combustible construction elements can both contribute to the fire and lead to collapse.

Gravity and Building Collapse

If fire fighters are in, on, or adjacent to a structure when it fails, injury or death can result. Difficult and dangerous rescue efforts might be required. Only seconds may elapse between the time it is recognized that fire fighters should evacuate a structure and the failure of the structure.

In evaluating the hazards of building construction under fire conditions, the entire path of the load to ground must be considered. The parts of the system that can be the quickest to fail, such as connections or unprotected supporting elements, need to be considered. For example, laminated heavy timber beams may have substantial fire resistance but be supported by unprotected steel columns or cables that can result in failure. Lightweight timber trusses that can support the loads of roofs and floors generally have their parts held together with nail plates (sometimes called gusset plates). Exposure of nail plates

to fire can char the wood into which they are nailed, releasing the plates and resulting in collapse.

When the incident commander on the scene of a building fire determines that the *structure* is involved in or affected by the fire (e.g., unprotected steel), the announcement should be made that all fire fighters be alert for and report any evidence of potential failure. Fire departments should have an easily recognized signal that means immediate evacuation of a structure. Multiple short air horn blasts and a distinctive Mayday radio signal broadcast on all radio channels should be used. All units should acknowledge the radio announcement.

Evacuation drills should be carried out during routine training activities to overcome any reluctance of fire fighters to abandon their equipment except those tools that might be needed to get out and withdraw. The proudest ships in the navy conduct regular "abandon ship" drills.

Failure on the part of command officers to understand the principles of construction and their repercussions can cause fire fighter injuries and deaths. For example, a cantilever beam can be compared to a seesaw. It is supported in position by connections in the interior of a building. If these connections fail because of fire, the extended portion of the beam, and whatever it supports, will fall. In lieu of a cantilever, a suspended beam may be used. To the building designer, there is little difference in whether the reaction goes downward through a column or upward through a tension member, such as a cable to the wall. However, if the connection fails, the suspended beam becomes an unsupported cantilever and can fall on fire fighters.

In Figure 12.8.3, for example, tendons providing lateral support for the structure will be posttensioned in several increments as the building grows taller. They remain exposed until the building is finished. They will fail at 800°F (427°C) and thus collapse the structure, possibly causing fire fighter deaths. Wooden falsework and other combustibles provide sufficient fuel.

In another example (Figure 12.8.4), the cold drawn steel cable that supports the tram car loses its tensile strength at 800°F (427°C). Many of the stations are made of wood, which could provide sufficient fuel for a destructive fire.

FIGURE 12.8.3 Tendons Providing Lateral Structural Support

FIGURE 12.8.4 Steel Cable at Ski Station

Building Reaction to Fire

All structures have some resistance to fire-caused collapse. This can informally be described as *inherent* fire resistance, as distinguished from *legal* or code-specified resistance. The inherent fire resistance of one structure may be absent in another similar structure. Direct experience with this fire resistance, whether personal or organizational, is not transferable from one structure to another. Simply put, "What you know may not be so."

Through experience the fire service has developed some understanding of and criteria for inherent fire resistance. However, estimates of "safe time" in buildings on fire are invalid because the time elapsed since the start of the fire is rarely known. In particular, fire fighters must understand that a fire resistance rating of 2 hours, for example, does not guarantee 2 hours of safety. A structural element or wall with a fire resistance of 2 hours might not last 2 hours in actual fire conditions. It can fail sooner or last longer. In addition, failure of a single key element may cause a massive collapse. Many times fire fighters risk life and limb without knowing the degree of risk involved. Generally accepted indications of imminent collapse—softening, water flowing between bricks, smoke pushing from mortar joints, strange noises—are grossly inadequate, even for older buildings. If they are relied on solely to protect fire fighters from collapse in today's different, lighter buildings, disasters can certainly result.

Contents

The problems of structure fires cannot be isolated from the structure's contents. Most building fires originate in contents. Fires involving building contents can destroy noncombustible structures and damage fire-resistant structures. The hazard of today's fast-burning, high heat release rate contents is a major problem.

Occupancy classifications found in building codes in some cases provide a general indication of the combustibility of contents (e.g., factory occupancy, moderate hazard storage occupancy, etc.) but must not be relied on for fire-fighting operations. Materials with high rates of heat release and/or rapid flame spread can be found in many occupancy types.

As long ago as 1975, the Society of Fire Protection Engineers (SFPE) warned that "A high rate of fire development can create a condition that may tax or overpower traditional fire defenses. Defenses of the past, both passive and active (evacuation, alarm, ventilation, and manual fire control), have not been designed by engineer or code to anticipate this hazard. This is primarily a furnishings problem. Many occupancies (residences, office buildings, theaters, hospitals) are being affected."[1]

Other Hazards

A building involved in fire presents other serious hazards to fire fighters. Fire can spread in void spaces with little or no external evidence and burst out unexpectedly and increase in intensity when a nearby breach admits oxygen. Buildings of otherwise noncombustible or fire-resistive construction may have combustible interior finish on floors, walls, and ceilings that can contribute to rapid fire spread.

When live fire training is conducted in most typical training school structures, the hazards of collapse, hidden fire, and highly combustible interior finish are absent. There have been serious accidents during live fire training in abandoned buildings when these hazards were present. It is important to have adequate classroom instruction on these issues, followed by preincident planning exercises for the hazards of individual major buildings and general building construction.

BUILDING CODES AND BUILDING CONSTRUCTION CLASSIFICATION

Types of Building Construction

Building codes classify buildings according to the type of construction and the fire resistance of the various load-bearing and non-load-bearing elements, such as exterior and interior walls, columns, beams and girders, and floor and roof construction. NFPA 220, *Standard on Types of Building Construction,* describes five types of construction. The fire resistance requirements as determined by NFPA 251, *Standard Methods of Tests of Fire Resistance of Building Construction and Materials,* will vary depending on the building element being considered. The details can be found in Section 19, Chapter 1, "Types of Building Construction." The types of building construction include the following.

Type I. Structural members of approved noncombustible or limited combustible materials with specified fire resistance ratings (exterior bearing walls 4 or 3 hours, etc.).

Type II. Structural members are the same as Type I but with lower or no fire resistance rating.

Type III. Exterior walls and structural members that are part of exterior walls are of approved noncombustible or limited combustible materials; and interior structural members, including walls, columns, and so on, are entirely or partially made of wood; no fire resistance rating greater than 2 hours.

Type IV. Exterior and interior walls and structural members that are portions of such walls are of approved noncombustible or limited combustible materials. Other interior structural members, including walls, columns, floors, and roofs, should be of solid or laminated wood without concealed spaces; no fire resistance rating greater than 2 hours. Note that wood timbers used in Type IV construction are assumed to have "inherent" fire resistance due to their mass and do not have a fire rating.

Type V. Exterior walls, bearing walls, columns, beams, floors, roofs, and so on are entirely or partially made of wood or other approved combustible materials; structural members may have a 1 hour rating or be nonrated.

Bearing in mind that the current classification has varying fire resistance requirements within a given type, the traditional or common terms associated with the NFPA 220 and *NFPA 5000®, Building Construction and Safety Code®*, "construction types" include the following:

Type I: Fire resistive
Type II: Noncombustible
Type III: Ordinary
Type IV: Heavy timber
Type V: Wood frame

These traditional classifications are very general and may not fully describe the fire resistance characteristics of any specific building. In addition, some buildings include several types of construction, particularly when additions have been made to older buildings. Some typical variations include the following:

- The construction of wood frame buildings has changed over the years. Prior to 1940, many multistory buildings were built with vertical framing members that created continuous void channels extending from the foundation to the attic space. This type of construction was referred to as "balloon construction" and allowed fire to spread upward rapidly through the exterior walls, sometimes without being detected by fire fighters. Balloon construction practice was replaced with construction in which each floor comprised a platform extending to the building perimeter. Platform construction cut off the vertical spread of fire. Although wood frame buildings with truss floors may be structurally considered as platform frame construction, the presence of horizontal floor voids interconnected vertically by plumbing voids can result in concealed fire spread similar to balloon frame construction.
- Brick buildings may be partially load-bearing brick or brick/block masonry on some walls and brick veneer over wood bearing walls on others. In some cases, the lower floor(s) are of masonry and the upper floors are brick veneer. Brick veneer may be applied over steel or concrete.
- Heavy timber buildings may have potentially dangerous departures from the ideal "mill construction," which is designed in all aspects to resist collapse from fire.
- Noncombustible buildings may have many combustible features, such as roofs, balconies, overhangs, and combustible materials in metal deck roof systems. Noncombustibility does not necessarily mean resistance to collapse.

• Fire-resistive buildings can have deficiencies that compromise the concept of compartmentation. For instance, large-area concrete floors require expansion joints. In a fire at a U.S. Postal Service Parcel Post Facility in New York City, there were large open areas that were pierced with many unprotected vertical openings; these openings consisted of conveyor belt systems, spiral mail chutes, duct systems, and flush floor openings.[2] In another example, melting aluminum expansion joints in the McCormick Place fire in Chicago dropped to the floor below, igniting combustible materials.[3] Ducts and wiring penetrations can provide paths for the spread of fire and smoke. It is not uncommon for fire barriers to be compromised after buildings are occupied. Inspection of compartmentation in new construction and after modifications and maintenance is important to achieve reliable compartmentation.

Fire-rated elements may vary greatly in materials. The test used, NFPA 251/ASTM E119, *Standard Test Methods for Fire Tests of Building Construction and Materials,* may give equal time rating to a wall of steel studs and plaster and a wall of wood and gypsum. However, S. H. Ingberg, who developed the concept of applying NFPA 251/ASTM E119 to wood structures and is considered the father of the fire resistance testing methods of the National Bureau of Standards (now the National Institute for Standards and Technology), issued the following warning:

> We must particularly distinguish between the fire resistance of a combustible and a noncombustible structure. While they may be equivalent in time, there is a world of difference in the protection afforded as it concerns the individual building, the hazard to nearby structures, and the hazard to life.[4]

Wood Frame Structures

The most prevalent construction material in the United States and Canada is wood. Wood can carry structural loads such as columns and beams. In older buildings, there are huge quantities of nonstructural wood used as lath to support plaster. Wood is also used for decoration and interior trim. A wooden interior in a restaurant in a high-rise building provided such a fierce fire that the fire department was unable to reach three trapped civilians, who finally jumped to their deaths.

For over 150 years, attempts have been made to render wood fireproof or noncombustible with no success. Wood can be surface treated to render it ignition resistant or reduce its surface flame spread. One method is to paint wood with an intumescent coating, which swells up like a marshmallow when heated, retarding ignition and the spread of flame. One problem in using this method to reduce the hazard of installed wood paneling is its untreated reverse side.

Wood can be rendered fire retardant by drawing out the sap and moisture and replacing it with chemicals. Fire-retardant-treated (FRT) wood is just that—fire retardant. It is still combustible.

In recent years, the dimensions of wooden structural members have been reduced and specialized wood structural members have been introduced. The removed wood had provided some inherent fire resistance due to its additional mass. Using sawn or laminated two-by-four lumber or flakeboard in wooden I-beams has reduced the mass of these wooden beams. These lighter beams can be expected to fail earlier in a fire,[5] because as soon as the web starts to burn, the strength of the beam is degraded.

In the construction of wood-frame row-type dwellings, no fire protection provision is resisted more than parapeting fire walls to separate the units. Parapeted fire walls present a special problem to the builder because they require skilled craftsmen to flash the wall properly to prevent leaks. It is much easier to place shingles on a flat, unbroken roof.

Plywood. Some years ago the practice of laying a 4 ft (1.2 m) sheet of ignition-resistant plywood on each side of a fire wall that did not penetrate the roof was adopted in lieu of parapeting. The treated plywood is supported on untreated, lightweight wood trusses, which are subject to early failure. Plywood, laid over the top of masonry fire walls, can delaminate and/or raise up and pass fire over the top of the wall. Furthermore, plywood over a rough-cut, concrete-block fire wall can be difficult to seal against the passage of fire, smoke, and hot gases.

In an attempt to prevent this extension, some codes specified a 4 ft (1.2 m) roof section of fire-retardant-treated plywood to be laid lengthwise along each side of the fire wall. Some of the chemicals used in the treatment reacted to heat and humidity and destroyed the plywood. Thousands of roofs required replacement.[6,7] In at least one jurisdiction, the underside of the replaced roofs is covered with a 4-ft (1.2-m) wide layer of gypsum board along the fire wall line. In the nineteenth century, plastering was used in an attempt to provide fire resistance to wood columns. Rot occurred under the plaster.

Wood Framing with Gypsum Board. Another method of protecting wood from fire is found in floor and ceiling assemblies and wall sections that combine wood framing with gypsum board membranes. A number of such floor and ceiling assemblies have received fire resistance ratings of 1 hour or more after being subjected to the NFPA 251/ASTM E119 test. One problem is that this fire resistance test was developed for floors of homogeneous, noncombustible materials, which were essentially the same from top down and bottom up. The one-way test in which the fire is applied from the bottom of a floor/ceiling assembly may not adequately determine fire resistance in a fully developed fire where the development of flashover can create severe temperatures developed at floor level, sometimes quite early in the fire.

As illustrated in Figure 12.8.5, in the NFPA 251/ASTM E119 test, the floor is exposed to fire only from below. Real fires, however, are different in that a fully developed compartment will involve a floor from the top down. Real fires may also start within the floor assembly itself, and in the case of wood trusses, may easily spread horizontally and vertically throughout a building's void spaces.

Trusses. The difficulty with fire fighters accepting the 1 hour resistance rating as indicating a degree of safety is even more serious in the case of lightweight gusset-plate trusses. When solid wood floor joists are used, each joist can act as a firestop, thus slowing the progress of the fire through the floor construction. In the case of a truss, the entire floor void, along with its

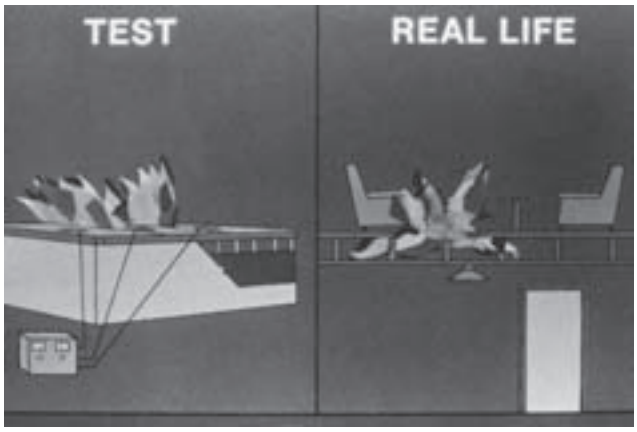

FIGURE 12.8.5 Spread of Test Fire Versus Real Fire

air supply, is available to the fire as soon as fire enters the void. The lightweight members of the truss are of small kindling-like dimensions. The voids can extend over sizable areas.

There are no fire-rated designs for firestopping (preventing vertical fire spread) or draftstopping (preventing horizontal fire spread) in the truss voids of frame buildings. The accepted practice of employing gypsum board is subject to improper installation and inspection, often due to a lack of appreciation of the purpose of draftstopping. Draftstopping is difficult to install and may be ineffective in preventing the extension of fire to adjacent truss voids, particularly when postconstruction penetrations are present. For example, firestopping is at the mercy of any worker with a pipe or cable to run (Figure 12.8.6).

Early collapse of a structure in which fire has penetrated into the truss voids is highly likely. A three-story, trussed-floor apartment house in San Antonio, Texas, collapsed moments after fire fighters evacuated the building. The fire started when a flammable liquid accidentally spilled on a floor, leaked down into the truss void, and ignited.[8]

A dangerous situation can result when trusses are permitted to extend from the floor voids on either side of a stairway to support the platform of a stairway that may serve as the single exit for the occupants and access for fire fighters. Incomplete firestopping can lead to fire spread and subsequent collapse.[9]

FIGURE 12.8.6 Firestopping Affected by Postconstruction Penetration

In another design the extended trusses may support a balcony that can be an area of refuge for occupants or provide entry for the fire department. A piece of gypsum board, plywood, or flakeboard may be used as firestopping to separate the floor void from the balcony void. There are no data indicating that such firestopping is adequate, particularly when it is penetrated for utilities. Casualties could result as fire units attempt to rescue occupants over ground ladders while the fire burns unchecked in inaccessible floor voids.

In one type of truss, the gusset plates and diagonal tension members were stamped from one piece of steel. If a fire causes a floor to collapse, the floor can fall on the floor below, causing it to collapse also because the tension members buckle out of the wood. Another new type of truss uses only finger joints and glue to hold the truss together.

Fire burning down into the floor void can come up on the other side of a rated wall, thus making dubious the concept that compartmentation is provided when a "rated wall" meets a "rated floor."[10] A ceiling light fixture can cause a fire that starts in the truss void. The fire can extend unnoticed from the truss void into the void between the plywood sheathing and the brick veneer and then back into the floor voids above. A collapse can result. In addition to collapse and fire spread, the truss floor provides a void in which carbon monoxide can accumulate.

Heavy Timber

The features of heavy timber construction that contribute to fire fighter safety are heavy masonry and brick walls; heavy dimensional timber used for columns and beams; heavy, thick wooden floors, which collapse only after many hours of fire fighting; and the lack of concealed spaces. However, it is dangerously inaccurate to consider building code–defined heavy timber construction as the equivalent of true mill construction.[11] Heavy timbers are slower to reach sustained burning than lighter wood members. This has lead to the term *slow burning* being applied to buildings of masonry exterior walls and timber interiors. Such a building is expected to retain its structural stability for a long time when subjected to a fire. Unfortunately, the slow-burning characteristic sometimes becomes long burning, so there is no merit to slow burning once the fire department can no longer remain in the building and must operate defensively.

The original concept of heavy timber construction, or mill construction, employed timber columns. Where the column intersected the floor girder, it should have been replaced by a solid cast-iron pintle, which passes through a hole in the girder. (A girder is any beam that supports other beams.) The small cross section of the pintle would cause it to be protected by the mass of wood girder. However, this procedure was ignored in many buildings. Some heavy timber buildings have cast-iron columns that may fail early in a fire. Where these columns pass through the floor girder, there is no reduction in size of the column. As a result, two "half moons" of the timber rest on a shelf protruding from the column. Failure of the shelf, or the loss of a

small amount of wood around this column, will cause the floor to fall.

Rehabilitated buildings may be fitted with unprotected steel columns, which can fail early in a fire. Sometimes Lally columns (steel columns filled with concrete) are used. In the nineteenth century, Lally columns were often cast iron and were drilled to release the steam from the concrete. Current columns may not be drilled and could explode when heated because of the steam generated when the concrete core is heated and releases water.

Heavy timber, slow-burning, or mill construction buildings should be carefully examined for these potentially disastrous weaknesses, which make invalid the assumption that the building will retain its stability for any appreciable time. Six Worcester, Massachusetts, fire fighters died in a heavy timber building that had been a cold storage warehouse. A complicated layout and smoke from cork and plastic insulation caused fire fighters to become lost. The building had not been pre-incident planned, and the stability of heavy timber buildings was immaterial to the outcome.

Plank and beam construction is sometimes called *western framing*. The typical 16 in. (406 mm) spacing of floor beams may be considered too boxlike and unattractive. Except in the roughest construction, a ceiling is installed to hide floor or roof beams. A take-off from heavy timber construction provides residences, churches (Figure 12.8.7), and other public buildings with an aesthetically pleasing interior by eliminating the ceiling and exposing the wood structure. Many churches are of plank on laminated wood beam or arch construction, often a fast flame spread potential. Heavy beams, widely spaced, are spanned with heavy tongue-and-groove planks instead of floorboards. The wood surface is planed smooth. Often a clear lacquer is used as a finish. This has the excellent advantage of eliminating void spaces. However, fire may still spread rapidly over these wood surfaces.

Long heavy timbers may be in short supply or are not available. It is common practice to splice timbers to attain the proper length. Laminated arches are commonly shipped in sections to be field spliced. A properly designed spliced timber will carry its load adequately in normal use but may fail disastrously in a fire. The arches of a Florida jai alai fronton were of spliced laminated timbers. Although the timbers were burned only moderately, the arches fell apart because the heated metal of the splice connections simply burned away the wood to which they were attached.[12]

Many old buildings are being adapted to other uses. Dropped ceilings provide huge voids through which hidden fire can travel (Figure 12.8.8). Nailing up "fire-rated" gypsum board does not solve the fire extension problem. As shown in Figure 12.8.9, a peaked truss roof is being erected to change the roofline of a flat-roofed building. The old combustible built-up roof covering was left in place. The exhaust duct was not extended through the new roof. Ventilating the new roof would be hazardous and useless. For additional information on timber construction, see Section 19, Chapter 2, "Structural Integrity During Fire."

Ordinary Construction

Ordinary construction is the term applied to buildings of usually combustible interior with load-bearing masonry exterior walls.

FIGURE 12.8.8 Dropped Ceiling Being Added

FIGURE 12.8.7 Church with Plank on Laminated Wood Beam Construction

FIGURE 12.8.9 Peaked Truss Roof Being Added (Source: David Harlow)

Originally, such buildings had brick or stone exterior walls and wood floors. The brick or stone walls were often required by law to limit fire spread from building to building in cities. In most building codes, the area of the city required to have construction that limits fire spread is defined by the "fire limits." In more recent times, in addition to brick and stone construction, exterior masonry construction may use brick and clay tile composite, brick and block composite, cast-in-place concrete, concrete block, hollow clay tile, and adobe.

Brick. Brick is attractive but expensive. Many buildings that appear to be of brick construction are actually a single layer of brick veneer on the face of a wood building. Brick veneer can be applied to any surface. Brick or stone veneer may be used to rehabilitate an old building. Imitation stone veneer is made of concrete cast in molds.

Brick veneer is totally dependent on the basic structure of the building for stability. If the supporting structure is damaged, the veneer may fall down. A veneer building is not a masonry building. It should be described by its basic construction type, for example, wood frame, steel, or concrete.

In the past it was possible to easily see the difference between brick masonry and veneer, because in solid masonry some brick courses were turned to show the ends (headers), whereas the others were laid lengthwise (stretchers). The development of the masonry wire truss has made it possible to lay all the bricks as stretchers, so the difference between masonry and veneer is no longer obvious.

The following are some causes of masonry wall collapse:

- Many brick walls are not totally brick. It was common practice to insert wood lintels over windows and doors. In many buildings, wood beams were laid in the wall to provide a level surface for floor beams and to tie the wall together lengthwise. When this wood burns out, a collapse is certain. This can be determined only by thorough pre-incident analysis.
- Water-soluble sand-lime mortar was universally used until 1880, was partially used thereafter for many years, and is still used today in the rehabilitation of older brickwork. This type of mortar can be washed out by weather or by hose streams. The loss of mortar to water leaks can cause some collapses when there is no fire.
- Although lightweight steel bar joists can fail early in a fire, first they will elongate. Elongating steel can push down masonry walls.
- Collapse of wood floors was early recognized as a hazard to the masonry in which the floor beams were imbedded. Collapse of floors can precipitate wall collapses. The beams may act as a lever pulling down the brick wall. In some areas builders corbelled out a ledge. The beams were set on the ledge, so that when they fell, the wall was undisturbed. In other cases, a "fire cut" (Figure 12.8.10) was required at the ends of wooden beams. In these beams, a 45 degree cut was made on the end, so that the top was shorter than the bottom. Thus, the beam could fall out of the wall without acting like a lever and disturbing the brickwork. Since wood is removed, the fire-cut beam may collapse earlier than would a beam solidly set into the wall. In some building renovations, fire-cut wooden beams that had sagged over time were simply turned over to provide an upward camber; thus, a minimal amount of wood was bearing on the wall. Another method uses beam boxes, which are cast-iron boxes laid in the brick wall to accommodate a girder. When the girder fails, the box remains in place and the wall is not affected.
- The impact load of debris from a wall collapse can cause the collapse of adjacent buildings with possible loss of fire fighters' lives.
- Unreinforced masonry buildings are liable to collapse in earthquakes, which is a concern to fire fighters who respond to earthquakes.
- Old masonry buildings have been renovated for other uses. Many have included the conversion of old downtown residences into commercial buildings. In many cases, the floor loads from files, safes, and merchandise can be much greater than that which previously existed. These heavier loads can place additional stress on the floor construction as well as the supporting wall construction. Commercial buildings may also represent higher fire loads than did the original residences.
- Some older masonry buildings were built with interior walls of balloon frame construction. Fire in such a wall spreads freely from floor to floor and into the floor voids. The wall is structural, and its damage can precipitate an interior collapse.
- More substantial buildings were built with interior masonry structural walls. Since the practical span of wooden beams was only about 25 ft (7.6 m), there were many small interior rooms. In many cases, walls have been removed to enlarge the interior space. The heavy masonry above was supported on a steel beam that, in turn, was supported by cast-iron columns, usually unconnected to the beam. The connection is vulnerable to any lateral thrust. Such an arrangement provided the larger space needed for a coffee shop in the century-old Vendome Hotel in Boston. Nine fire fighters died in 1972 when the beam-column arrangement failed.[13]

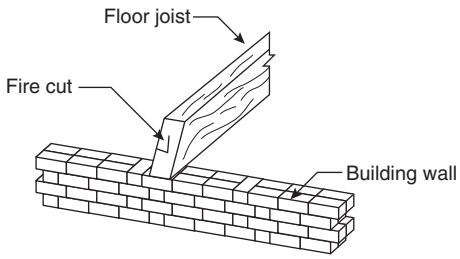

FIGURE 12.8.10 Cutaway Diagram of a Fire Cut on the End of a Wood Floor Joist

Beliefs About Construction. Beyond these indications, there are other dangers associated with building construction that the fire service needs to be concerned with. Some widely accepted beliefs regarding construction-related issues are open to question. Some of these beliefs may prove fatal to fire fighters or others at the fire scene.

One rule of thumb attempts to specify how far out from the building a wall would fall depending on its height. In other

words, to be safe from collapsing walls, fire fighters must be as far away from the wall as the wall is tall. This informal guideline is of doubtful validity: even if true for most of the wall, some bricks and timbers may land much farther out than anticipated.

Collapse of masonry walls is sometimes attributed to contraction caused by cold water hitting hot bricks. This theory is unproved. The greatest amount of water thrown in a defensive attack is directed through windows, not onto a wall. Considering the low heat transmission rate of brickwork, it is likely that the brick is at best only slightly cooled by the water.

Many older buildings have an outer layer of finished brick, which may be a veneer. A hose stream hitting such a wall can get behind the finished brick, tear the bricks off the surface, and endanger persons below.

The interior of ordinary construction buildings is almost completely of combustible construction. Where steel is used it may be left unprotected or enclosed in combustible voids that provide no protection from heat. The fire department may be completely unaware of the hazard of the hidden steel. Another major hazard of the voids that has been noted is the potential for hidden fires.

Alterations of the interior may leave hazardous floor conditions. For example, when a stairway is relocated, the former opening is rarely restored to a strength equal to that of the original floor. This presents a weak floor through which fire fighters can fall. In another example, the roof of the precast tilt slab concrete building shown in Figure 12.8.11 was fire damaged. Because the roof is vital to the stability of the building, the contractor's first move was to replace the tormentors, which braced the walls before the roof was in place. For more detailed discussions, see Dunn.[14]

Noncombustible Construction

Noncombustible construction is a building code term that unfortunately may not be literally true. Fire departments should be aware of what the local code permits under this heading. It is possible that substantial combustible components, such as a wooden balcony or roof or a combustible metal deck roof, are included in a noncombustible building. The fact that a material is noncombustible is not necessarily significant in reducing the fire loss or in reducing hazards to fire fighters. The two common materials of noncombustible construction are steel and concrete.

Steel. Steel is an extremely strong material. Heavy loads can be carried on light structural steel elements. Because of the small mass of the steel, all but very heavy members elongate as they are heated. Steel beams will elongate 9 in. (229 mm) in 100 ft (31 m) at about 1000°F (538°C).[15] This can be sufficient to push out wall panels and cause toppling. Elongating steel has pushed down many walls in this fashion. At slightly higher temperatures, steel reaches its collapse range. Collapse of steel roofs supporting the sprinkler piping can cause sprinkler system failures, resulting in massive destruction in several warehouse fires.

As steel trusses (like those shown in Figure 12.8.12) are heated, connecting ties can transmit undesigned torsional load to other trusses. This may result in failure of trusses away from the fire area. Four fire fighters died in Pennsylvania in the collapse of a "concrete" building in which the floor was supported by unprotected steel columns.[16] These unprotected steel struts could be loaded to twice the limit for permanent structural steel, thus lowering the failure temperature. A fire in combustible materials, often present in excavations, could cause the steel to fail. The adjacent structures could then collapse into the excavation.

Extreme caution should be the rule at any fire where unprotected steel is being heated. The potential consequences are not always evident. Pre-incident planning should be thorough, and limits should be set on fire-fighting procedures to ensure safety of personnel.

Concrete. Concrete is strong in compression but weak in tension. Plain concrete, usually found in the form of concrete

FIGURE 12.8.11 Fire-Damaged Roof

FIGURE 12.8.12 Unprotected Steel Struts

blocks, is used for compressive loads. Reinforced concrete is a composite material. Steel is incorporated into the concrete to provide the tensile strength. By definition, a composite material is one in which both elements must act together to carry the load. A failure of the bond between the steel and concrete destroys the composite nature and strength of the structural element.

Unlike steel, which needs to be protected from fire by an insulating covering, concrete can be inherently fire resistive. The resistance to fire is accomplished by the nature and thickness of the concrete itself. However, it is impossible to distinguish fire-resistive concrete from that which is merely noncombustible by simply looking at the concrete member.

Non-fire-resistive concrete has no specific fire resistance requirement and can fail early in a fire, even when exposed to only modest heat. No valid assumptions can be made as to when fire-exposed, non-fire-resistive concrete will fail. If the building is of monolithic construction, however, the load may be redistributed throughout the building, and a general collapse is unlikely. However, local collapse may cause injuries from falling concrete or from fire fighters falling through holes.

Precast concrete tilt slab buildings are now commonly used for warehouses and factories. Many of them are the equivalent of several stories high to accommodate high-rack storage. The integrity of the roof is vital to the tilt slab building. Failure of the roof can result in collapse of the tilt slab walls.

The roof may be carried on several types of beams. Most common are wood, steel bar joists, and concrete pretensioned tee beams.

Concrete tee beams would not generally be rated fire resistive unless the building was required to be fire resistive. If the concrete below the bottom tendon spalls off, the cold drawn tendon, which typically fails at 800°F (427°C), is exposed to the fire, and the beam is subject to failure.

A Metropolitan Dade County, Florida, fire lieutenant lost his life when prestressed tendons in tee beams in a carpet warehouse roof were heated to failure and the beam(s) collapsed. Massive reinforced concrete, fire-resistive multistory buildings have a good fire record. However, there have been cases of serious destruction, usually during long-duration, high-intensity fires. A recent fire in a concrete building loaded with tires caused heavy damage. A long-burning fire in the top floor of the Military Records Center near St. Louis, Missouri,[17] caused considerable elongation of the roof, which resulted in columns being torn off either the roof or the floor. After the fire, the top floor was removed.

Massive concrete is a substantial heat sink. The heat that is stored in the concrete is not available to extend the fire. However, the retained heat in the concrete may cause serious health hazards to fire fighters during operations and overhauling.

In posttensioned concrete buildings, the load is carried on the tendons (Figure 12.8.13). As a result, a failure of a tendon in a fire can lead to the failure of the building. Finished posttensioned concrete buildings cannot be distinguished by appearance from conventional reinforced concrete buildings. They are very different, however, with respect to fire operations. Spalled concrete can expose the tendons, resulting in failure. It is not safe to drill through a posttensioned floor to attack a stubborn fire on a floor below because the drill might cut a tendon and cause collapse. A hole alongside a tendon might permit the tendon to heat to failure. To cut large holes with jackhammers would be extremely hazardous in a posttensioned building.

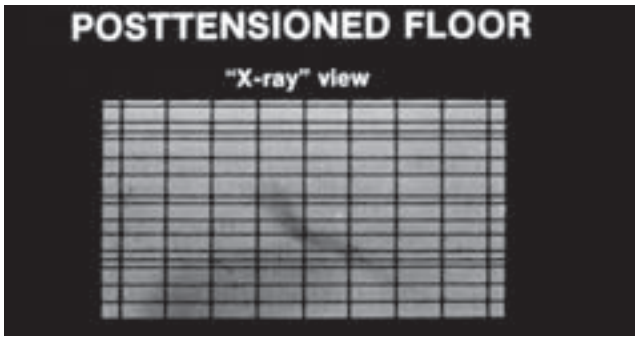

FIGURE 12.8.13 Location of Tendons in Posttensioned Concrete

Concrete Buildings Under Construction. The extraordinary rescue and body recovery operations required at the Oklahoma City, Oklahoma, bombing in 1995[18] could be repeated at a fire in a concrete building under construction if conventional fire-fighting tactics are followed.

When concrete buildings are under construction, the loads of freshly poured floors and structural elements are supported on temporary forms that are either combustible or, if made of steel or aluminum, subject to fire-caused failure. A massive failure of forms dropping one floor on another is almost certain to cause progressive collapse of several floors, possibly all the way to the ground.

In such cases, the command decision process should be the opposite of the traditional method. Traditionally, fire fighters rush into the structure and withdraw only when it is determined that the structure is unsafe. In the case of fire in concrete forms, which support thousands of pounds (kilograms) of concrete, it may be advisable to stay out until a decision can be made as to whether it is safe to enter the structure or even be near it.

On October 30, 2004, the top five stories of a 10 story parking garage collapsed in Atlantic City, New Jersey. Composed of both precast and sitecast concrete structural members, a column at or underneath the tenth floor (that was being poured) failed, trapping 24 construction workers. Three of them were killed.[19]

The situation in the case of posttensioned concrete construction is even more serious than it is for conventional reinforced concrete. Until the tendons are tensioned and the cables are stretched, the entire weight of the concrete, even hardened and dry to the touch, is supported on the concrete forms. If the forms burn, the entire floor or floors dependent on them will fall, possibly precipitating a total collapse. In 1974 a 14 story, posttensioned concrete structure under construction in Cleveland, Ohio, totally collapsed when fire attacked the forms. The fire chief, aware of the hazard, had kept the fire fighters out of the collapse area.

In 2000, a three-section, posttensioned, residential high rise was under construction in Key Biscayne, Florida.[20] Fire in exterior construction material spread to construction material in the interior. The fire department, cognizant of the posttensioned concrete hazard, adopted a defensive mode; that is, a no-entry mode. Many tendons were exposed to the fire, and three units were so damaged that they were demolished. It took several days for the explosive demolition contractor to prepare a safe plan for placing the explosives.

Fire fighters need to be aware that moisture remains in the concrete used to fill steel columns (Figure 12.8.14). In the nineteenth century, Lally columns were drilled to vent the steel. In a fire, the trapped moisture can heat until it becomes steam under sufficient pressure to cause the columns to explode. The explosion is not only dangerous itself but also can weaken the structure.

Fire-Resistive Construction

The major components of fire-resistive buildings are required to be similar to building components that have been subjected to the NFPA 251/ASTM E119 test. Test results are stated in the time to the last full hour (or half hour) the assembly withstood the assault of the test fire. Thus, a column might be rated as having "1-hour fire resistance" or a floor-ceiling assembly as having "2-hour fire resistance."

There may be no specific relationship between the time given in the rating and the time to failure of the structure in a real fire, however. There are many variables that affect the time a structural element can withstand fire exposure. The limit of confidence that one can have is that a 4-hour fire-resistive building is more fire resistive than a 2-hour fire-resistive building or that a 1-hour fire-resistive building is less fire resistive than a 2-hour fire-resistive building.

Fire-resistive buildings generally fall into the following three classes, corresponding roughly to the time they were built:

1. During the period 1880 to 1920, emphasis was on the building itself. Floors were of tile arch with or without protection of the steel beams. Vertical opening protection was not even considered. Fire resistance consisted of whatever the architect thought proper, because there were few requirements for fire resistance in the building codes. There are many such buildings still in use.

2. From 1920 to 1945, many building components were rated fire resistive in accordance with the ASTM E119 test. Steel frames were fireproofed with concrete. Floors were cast-in-place concrete. Stairways and elevators were generally enclosed. Fire and occupant loads were low because of limited floor areas due to the need for natural light and air. Many exit stairs were designed to provide an atmospheric break between the floor and the stairway, thus providing exit stairs that did not become contaminated with smoke. Sprinklers were generally not provided except for such buildings as the headquarters of the National Board of Fire Underwriters and high-rise factory buildings in New York City as a result of laws passed in the wake of the Triangle Shirtwaist fire. Only a few cities had high-rise buildings of this type. The Empire State Building represents the zenith of this type of fire-resistive construction.

3. From 1945 to present, many changes have occurred in building construction techniques. Air conditioning and fluorescent lighting have made extensive floor areas possible. Compartmentation in the form of full height partitions (found in older high-rise buildings and beneficial for slowing fire spread) have been replaced by short cubicle partitions. The increase in height and floor area has permitted a huge increase in occupants. Timely evacuation is difficult. Air conditioning may require nonoperable windows. Building height can generate strong stack effects, which can become a serious factor in smoke movement.

FIGURE 12.8.14 Concrete-Filled Steel Tube Columns

Combustible Metal Deck Roofs (CMDRs)

The so-called built-up roof of tar and layers of roofing material generally covered in stone is capable of self-sustained combustion when installed on metal decking, irrespective of contents. Such a roof is called a combustible metal deck roof (CMDR). If it is looked at it from below, the tar, which turns to gas when heated, is not visible, and the bar joist and corrugated steel void appear to be noncombustible. Frank Brannigan discovered the problem in 1946 at a fire in the Marine Corps Depot of Supplies in Norfolk, Virginia, and developed a tactical solution whereby heavy caliber streams were directed to the steel decking from a safe location to chill the steel and thus solidify the gas-generating tar. This technique was applied successfully at another fire in 1948. Until the total destruction of the General Motors Transmission Plant in Livonia, Michigan, in 1953, with a loss of $70,000,000, the problem of CMDRs remained largely unapprised.[21] Tests at Factory Mutual showed that 800°F for 5 minutes on the underside of the metal deck produces a self-sustaining fire.[22]

The U.S. Atomic Energy Commission had two roof deck fires in buildings with only minor combustible contents and developed the fixed protection solution, that is, automatic sprinklers to cover the underside of the roof, irrespective of the contents. The U.S. Air Force suffered a $170,000,000 loss at Tinker Field,[23] and the General Services Administration

suffered a severe loss in Fort Worth, Texas,[24] both caused by contractors cutting through the CMDR to install skylights. It is unsafe and useless for fire fighters to try to ventilate a combustible metal deck roof manually. Tests at Factory Mutual showed that a 56 ft^2 (5.2 m^2) vent was required to vent a small structure with no contents.[25]

Six Dallas fire fighters, planning to ventilate the roof of a store with a CMDR, fell into the fire when elongating steel bar joists pushed down a concrete block wall. Fortunately, they were near the edge and were recovered.[26] Twenty St. Paul, Minnesota, fire fighters were evacuated from a store with a CMDR 60 seconds before it collapsed. Two Memphis fire fighters were not so lucky when a CMDR in a retail store collapsed on them in 2003. An alternative to CMDRs is to install a Factory Mutual Type I roof or a UL "classified roof," which will not sustain independent combustion.

If there is a significant fire load, the height of the steel above the floor is no guarantee of stability during a fire. After the devastating 1967 McCormick Place Exhibition Hall Fire in Chicago, tests at Underwriters Laboratories Inc. showed that failure temperatures were reached in steel 30 ft (9.2 m) above the floor a few minutes after the fire started.[27]

Hose streams can cool steel being heated by the fire if a safe operating position is available. If the steel is elongating, it will retract to its original length when cooled. If it has started to fail, it will solidify in the shape it had reached. Contrary to a once-prevalent myth, the water does not cause the distortion of the steel. For a full explanation of the origin of the "don't put water on hot steel" myth, see Brannigan.[28]

SPECIFIC CONCERNS

The following areas of concern for the fire service relate, directly or indirectly, to fire fighter and public safety. There are no "minor" deficiencies in buildings being attacked by fire. Any single deficiency may contribute to loss of life or the destruction of the building.

Alarms and Staff Training

Building staff should be properly trained. A potential and, at times, fatal error is for a security guard or maintenance personnel to go to the floor from which the fire alarm has been received—thus walking right into the fire. The lone fatality in the spectacular 1988 First Interstate Bank fire in Los Angeles was the maintenance person who went to the fire floor to investigate.[29] Further, a guard went to the alarm floor of the One Meridian Plaza fire in Philadelphia, Pennsylvania, and barely escaped death.[30]

Sometimes personnel are temporary employees who have not had adequate instruction in their duties and responsibilities. Fire department personnel should inspect buildings during the night shift and question employees as to the actions they would take in the event of a fire alarm or for reported smoke.

Building staff has reset alarms to prevent the alarms from being transmitted to the fire department. This was a factor in a 12 fatality fire in the Westchase Hilton Hotel in Houston, Texas, in 1982.[31]

Delayed alarms can be due to a mistaken management perception that the arrival of the fire department is bad publicity. A policy of charging for false alarms should be carefully monitored to determine if it results in nontransmission of alarms.

Pre-Incident Planning

A thorough study of a target building should be made before the action pre-incident plan is developed. The fire department's pre-incident plan should examine each building as an individual problem. Problems and/or deficiencies in areas noted below may be present in buildings. Most were factors in serious fires.

The World Trade Center had been regarded as a significant advance in reducing weight and cost of high-rise buildings. There are serious questions as to the effectiveness of the "fireproofing" (insulation would be a better word) methods used as well as concerns about lack of compartmentation and "robustness" of shaft enclosures. Fire departments should review the final report of the National Institute of Standards and Technology's National Construction Safety Team investigation of the World Trade Center disaster.[32]

Automatic Sprinklers

Full automatic sprinkler protection, properly maintained, is a proven fire protection measure that can provide reasonable assurance of occupant and building fire safety. However, sprinklers can be inoperable. The fire department should carefully monitor the maintenance and shutdown of sprinkler systems. Special precautions and watch service should be required during periods of sprinkler impairment.

In many cases, building codes permit exceptions from or reductions in code provisions if sprinklers are installed. If the sprinklers are turned off when the building is occupied, it may be in violation of the code provisions.

Water Supply

The water supply system should be carefully checked for possible failures. Examples of water supply problems include water supply pumping system disconnection. At the time of the First Interstate fire, this was the case. Also, falling glass may cut lines supplying standpipes. Improperly marked standpipe connections have also been a major factor at fires.

Compartmentation and Structural Integrity

A fire-resistive building is generally designed to provide for compartmentation and structural integrity in a fire. Unfortunately, the design may be flawed or the construction faulty. Changes after the building was occupied may compromise the value of the compartmentation or structural integrity.

Compartmentation. Early fire-resistive design did not include compartmentation. It was believed to be sufficient that the building was "fireproof." Several disastrous fires in fire-resistive buildings proved the concept of "fireproof" to be faulty, and compartmentation became required. The following are points of failure in compartmentation:

- Many early fire-resistive buildings are still undivided and allow the passage of smoke and toxic gases throughout the structure.
- Floors are penetrated for wiring and other services. The openings are not always properly protected to restrict the passage of heat and smoke. Due to unprotected openings in floors, fire-resistive buildings can resemble a sieve to smoke and gases. The handful of fiberglass stuffed into the opening will not stop smoke and gases. Figure 12.8.15 illustrates penetrations to a floor.
- The reliability of horizontal compartmentation separating floors into fire areas or smoke compartments can be questioned. The wall may remain intact, but there may be utility openings through the walls that are not properly sealed.
- Fire barrier doors into stairways and between fire areas are required to have door closers and latches. These may be removed or doors found blocked open for convenience. This problem occurred at a high-rise apartment house that had both interior stairway doors propped open. A fast-spreading fire erupted, filling the stairs with heat and smoke. Four occupants died. It took almost 200 fire fighters to subdue the fire and to evacuate the tenants.[33]
- Automatic door closers are often made ineffective, generally for the sake of convenience. For example, it can be tempting to remove closers in a high-rise residence for seniors to allow residents to visit neighbors "for a moment." It is possible that the occupant of the apartment in which the fire occurs exits, leaving the door standing open. In such cases the hallway can fill with fire, and fire fighters could find it dangerous and sometimes impossible to advance the hose lines, particularly if the wind is blowing into the apartment. Few people have any concept of the heavy fire load and high rate of fire growth of today's furniture.

The best solution for the conflict between inconvenience and a potential hazard not understood by occupants is to have such doors equipped with magnetic latches. When the door is opened the electromagnet holds it open. Any fire alarm cuts the current to the electromagnet and the door closes. For smoke barrier doors in hallways, a detector is provided on both sides of the door. Some door closers have a smoke detector incorporated in the closer. Closers that incorporate only a fusible link are not effective for life safety since deadly quantities of gases can pass before heat operates the fusible link.

FIGURE 12.8.15 Unprotected Floor Penetrations

Structural Integrity. The structural integrity of a building may depend on how the fire resistance was achieved. The following are issues in structural integrity:

- Buildings with tile arch floors may not provide protection for the steel beams. In later buildings, skewback tiles were provided to protect the steel.
- Steel floor and ceiling assemblies using suspended ceilings are common. Unfortunately, ceiling tiles are easily removed and integrity is hard to maintain. The ceiling voids can allow smoke and fire to pass.
- Permitting steel columns to be unprotected in the plenum space is particularly dangerous. Failure of the ceiling membrane would subject the column to fire temperatures. The heating of only a short length of a column to failure temperature could have costly, or even catastrophic, effects on the building.

Spray-on fireproofing used asbestos fibers for many years. The health hazard of asbestos fibers now requires its removal. A most important question is what, if anything, is done to fire-protect the steel when the asbestos fireproofing is removed.

Flame Spread

Fire departments should be aware of the presence of combustible interior finish, such as plywood and combustible acoustical tile, in buildings. Older acoustical tile was made of compressed wood fibers and will burn furiously. It is usually installed on wood stringers, which enables burning on both sides of the tile. If it is applied with glue, the adhesive can add significantly to the rate of burning. This was discovered in the investigation of the Hartford Hospital Fire in 1961, in which 16 people died.[34] The combustible tile was glued to a suspended gypsum board ceiling that was surface-treated with a flame retardant. When the tile was tested, the adhesive caused a very rapid flame spread. When new tile is installed, it will probably need to meet flame spread requirements. However, there may be no requirement that the old tile be removed (Figure 12.8.16).[35] A very serious potential hazard is created if old combustible tile is left in place when a new "code-approved" suspended ceiling is installed below it.

Similarly, flame spread was a significant factor in the February 2003 Station nightclub fire in West Warwick, Rhode Island, which killed 100 people. Polyurethane foam soundproofing, installed around a platform used by musical performers, was ignited by indoor pyrotechnics. The entire room flashed over in 90 seconds.[36]

Other Areas of Concern

Construction in Occupied Buildings. Buildings can be partially occupied before construction is finished. Many major remodeling projects are carried on in occupied buildings. The fire department should be aware of any such construction. Special permits should be required for any construction after the certificate of occupancy is issued. A typical construction fire in

FIGURE 12.8.16 Old Combustible Tile Retained Above a New Suspended Ceiling

such a building can be a serious threat to the safety of all the occupants.

Lightweight Construction. The almost complete change from sawn lumber to gusset plate wood trusses and wood I-beams has profoundly changed the fire suppression environment. Tactics learned and experience gained on sawn joist and rafter buildings are not transferable to truss buildings. The truss floor introduces a new hazard, which creates a floor void in which carbon monoxide (CO) gas can accumulate.

Vacant Buildings. Large commercial and manufacturing buildings may be vacant due to remodeling for "adaptive use," lack of a tenant, upcoming demolition, or even abandonment by the owner. Sprinklers can have been shut off or removed. Open construction shafts can make vacant buildings one huge fire compartment. As demonstrated by a 1999 fire in a warehouse in Worcester, Massachusetts, which claimed the lives of six fire fighters, searching for homeless people and fighting fires in vacant buildings can be extremely dangerous.[37]

Added Roofs. New roofs can be constructed over the original roof to control leaks (rain roof) or for aesthetic reasons. These present serious problems in fire fighting. Harlow[38] provides detailed information.

Stadiums. Stadium fires in Texas and Georgia focused attention on the severe difficulties faced in fighting fires in the luxury "sky boxes." The potential for flaming plastic windows falling onto occupied combustible seats in the arena below is a serious risk. Fire departments should perform realistic risk assessments and, where indicated, require fire protection improvements.[39]

SUMMARY

This chapter presents the highlights of the problems that the effects of building construction present to fire suppression forces. Further detailed information can be found in *Building Construction for the Fire Service* and in the references cited. Knowledge and experience with building construction methods and materials can help improve fire department safety and efficiency.

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on the effect of building construction and fire protection systems on fire fighter safety discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 13, *Standard for the Installation of Sprinkler Systems*
NFPA 220, *Standard on Types of Building Construction*
NFPA 241, *Standard for Safeguarding Construction, Alteration, and Demolition Operations*
NFPA 251, *Standard Methods of Tests of Fire Resistance of Building Construction and Materials*
NFPA 252, *Standard Methods of Fire Tests of Door Assemblies*
NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials*
NFPA 5000®, Building Construction and Safety Code®

Chapter 9

Fire and Emergency Services Protective Clothing and Protective Equipment

Bruce W. Teele

Protecting fire fighters, law enforcement officers, hazardous materials technicians, emergency medical personnel, technical rescue personnel, and other emergency responder personnel from the expected exposures and hostile operating environments that emergency operations pose is a complex issue. The following are key facets in minimizing emergency responder injuries and deaths:

- Thorough training of officers, supervisors, and response personnel
- Considerable medical and physical requirements and health maintenance
- A detailed and well-functioning incident management system
- Adequate staffing
- Closely supervised operating teams or crews
- Company/team/crew cohesiveness
- Clear and concise standard emergency operational procedures
- State-of-the-art personal protective equipment (PPE), including protective ensembles, clothing, and equipment that are consistently and properly used

Much has changed in these areas during the past several decades, and more must be done in the future. Emergency responder organizations should stay well informed of developments in all of these areas and provide the information and training to their personnel to keep them as current and informed as possible. Emergency responder personnel need to realize their human limitations and the dangers they face during operations in hostile environments. They must also understand that the inherent safety of participating as a member of a team in a well-planned operation under a safety-driven incident management system does far more for their safety than just relying on the PPE they use.

For related topics, see "Section 12, Chapter 7, "Safety, Medical, and Health Issues and Programs"; Section 12, Chapter 8, "Effect of Building Construction and Fire Protection Systems on Fire Fighter Safety"; and Section 12, Chapter 16, "Fire Department Apparatus and Equipment."

NFPA INVOLVEMENT

Historical Background

In the early 1970s, the National Fire Protection Association (NFPA) became directly involved with fire service safety issues through its technical committees and new standards. The effort began with the Technical Committee on Fire Department Equipment. This committee established a Sectional

Bruce W. Teele is senior emergency services safety specialist at NFPA. He serves as the staff liaison for the Technical Correlating Committee and the eight technical committees of the Project on Fire and Emergency Services Protective Clothing and Equipment.

Committee on Protective Equipment for Fire Fighters to specifically address these issues. Their documents were directed toward equipment standards.

The sectional committee developed a new document on respiratory protective equipment, and the association membership adopted NFPA 19B, *Standard on Respiratory Protective Equipment for Fire Fighters,* on May 17, 1971. This new standard prohibited the use of filter-type canister masks for protection of fire fighters from the products of combustion and allowed only self-contained breathing apparatus (SCBA) for fire fighter respiratory protection. This action was the direct result of fire fighters dying while wearing filter-type masks during fire-fighting operations. At least one court decision found that filter-type canister masks and other respirators that only filtered the atmosphere and did not provide a source of noncontaminated breathing air were inappropriate for use by fire fighters, as they did not provide protection from the known and expected respiratory hazards that fire fighters encounter during fire-fighting operations.

The second document from the sectional committee, NFPA 19A-T, was a tentative document (a preliminary document that is no longer a part of NFPA's codes and standards development process) that was the first to address protective clothing for structural fire fighting. Although NFPA 19A-T never became a standard, it was the basis for a future document on the same subject, NFPA 1971, *Standard on Protective Ensembles for Structural Fire Fighting and Proximity Fire Fighting.*

In 1974, NFPA restructured the sectional committee as a separate and full technical committee for PPE. This new committee, the Technical Committee on Protective Equipment for Fire Fighters, was no longer under the direction of the Technical Committee on Fire Department Equipment. It assumed the responsibility for NFPA 19B and developed a new document, NFPA 1971, which was adopted on November 18, 1975. This document has been followed by a series of documents on PPE for structural fire fighting, proximity fire fighting, wildland fire fighting, hazardous materials emergencies, emergency medical operations, and special operations. The committee was renamed in 1988 as the Technical Committee on Fire Service Protective Clothing and Equipment.

Because of the continuing increase of the types of PPE being addressed by the committee and the areas other than fire fighting in which the committee was involved, NFPA created a Project on Fire and Emergency Services Protective Clothing and Equipment in late 1994. It is structured with a technical correlating committee managing the project and seven technical committees now responsible for electronic safety equipment; respiratory protection equipment; and for protective ensembles, clothing, and equipment for emergency medical services; hazardous materials; special operations; chemical, biological, radiological, nuclear (CBRN) terrorism incidents; proximity fire fighting; structural fire fighting; and wildland fire fighting; and for the selection, care, and maintenance of the PPE. Within this project, there are currently 15 active documents and more under development or in the planning stages.

In 1973, NFPA established the Technical Committee on Fire Service Occupational Safety and Health. This was the first NFPA committee to focus on the issues of the safety and health of fire fighters instead of just the PPE. In its early years, the committee considered many issues and then wrote a document, NFPA 1501, *Standard for Fire Department Safety Officer,* that was adopted on May 18, 1977.

NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program*

The committee produced NFPA 1500, which became effective on August 7, 1987. NFPA 1500 was developed as an umbrella document, encompassing an entire fire department safety and health program. NFPA 1500 became the first nationally recognized consensus standard to address fire service occupational safety and health. It was the first national document on safety and health to be written by the fire service and fire service interest groups for the fire service. Prior to NFPA 1500, any safety and health measures had to be based on general industry standards and regulations that either did not adequately address fire service problems or were difficult to impose on a nonindustry agency.

The fifth edition of NFPA 1500 became effective in August 2006. NFPA 1500 is the fire services organizations' requirements, as it has the criteria for fire departments and fire fighters, rather than the product requirements that manufacturers must meet. NFPA 1500 is the document that makes it happen, as it requires fire departments to have, and fire fighters to use, protective clothing and equipment.

NFPA 1500 requires the provision and use of protective ensembles, clothing, and equipment that are certified as compliant with the appropriate NFPA PPE standard(s) for the intended application. The basis of the requirements is to provide for the protection of fire fighters who are responsible for various fire-fighting and other emergency operations. The fire department is required to provide the appropriate protective clothing and protective equipment for the task and operation.

The fire department is also required to ensure that the PPE is properly utilized and maintained. Accordingly, each fire fighter is to be provided training in the use and limitations of protective clothing and equipment.

OSHA INVOLVEMENT

In addition to NFPA 1500, in the United States there are federal and state regulations, generally under the federal Occupational Safety and Health Administration (OSHA) or the state equivalent, that include protective clothing and equipment as well as other safety and health issues.

OSHA first addressed fire service occupational safety and health in 1980 when it issued regulation 29 CFR 1910.156, the "fire brigades regulations." Although the federal OSHA regulations did not apply to state and local government employees, states that have federally approved state OSHA plans were, and still are, required to cover state and local government employees.

However, when OSHA issued regulation 29 CFR 1910.120 on hazardous materials emergency response, the U.S. Congress directed the Environmental Protection Agency (EPA) to issue identical regulations that would apply to state and local govern-

ment employees as well as volunteers in all 50 states. This EPA regulation is 40 CFR 311, which was issued June 23, 1989. Both 29 CFR 1910.120 and 40 CFR 311 include a mandatory reference requiring fire departments to be compliant with 29 CFR 1910.156. Therefore, wherever fire departments also respond to any type of hazardous materials incidents, the OSHA/EPA regulations apply to all operations for all fire departments in the United States whether career, career/volunteer combination, or all volunteer.

NFPA PPE STANDARDS

Two different types of PPE standards produced in the NFPA codes and standards development system are product standards and user standards.

Product Standards

Product standards specify the requirements to which manufacturers produce their PPE, and certification organizations inspect, evaluate, and test the product to determine compliance. All product standards are written to the extent possible in terms of performance requirements with pass/fail criteria and specific testing methods to evaluate each performance. These standards also have a chapter on design requirements covering those items that cannot be defined in performance criteria but must be inspected and evaluated by the certification organization in order to determine product compliance.

All product standards require manufacturers to have their product "certified as compliant" with the applicable NFPA PPE standard in order to claim the product meets the standard. Certification is a very important part of the PPE product standards as it gives a reasonable degree of confidence to end users and purchasers that the product they are purchasing or using has been found to meet the requirements of the standard and has been certified as such. The certification program includes an independent third-party certification organization that is accredited to certify PPE; evaluates and tests the product in accordance with the applicable NFPA PPE standard; applies labeling, listing, and follow-up programs for the product; and administers periodic product recertification and quality assurance programs for the manufacturer. The certification program is addressed in further detail later in this section.

User Standards

User standards specify requirements for the emergency responder organizations and personnel who purchase and use the PPE. These standards are written to assure the correct and safe use of the PPE and the proper selection, care, and maintenance of PPE. NFPA 1500 specifies which types of PPE are to be used for various emergency operations and that the PPE must be certified as compliant with the appropriate product standard. A new type of user standard now specifies the process of selection, care, and maintenance for different types of PPE. The first two standards in this series are NFPA 1851, *Standard on Selection, Care, and Maintenance of Protective Ensembles for Structural and Proximity Fire Fighting,* and NFPA 1852, *Standard on Selection, Care, and Maintenance of Open-Circuit Self-Contained Breathing Apparatus (SCBA).*

These selection, care, and maintenance (SCAM) standards specify requirements for segments of the organization's overall PPE program as required by NFPA 1500 by reference to the SCAM standards. The SCAM standards also specify the procedures for selecting PPE both prior to purchase and, in some cases in which different types of PPE could be used, prior to use, as well as the proper care, cleaning, maintenance, repair, storage, and removal from service or retirement of PPE. These SCAM standards are intended to provide enhanced safety for users by assuring that the PPE remains in optimum condition for user protection.

THIRD-PARTY CERTIFICATION PROGRAM

All NFPA PPE standards for emergency responder personnel require that the PPE be certified in accordance with the certification program specified in each standard. The certification program is an essential means of ensuring the quality of emergency responder PPE.

Certification includes an accredited, independent third-party certification organization that evaluates and tests the product in accordance with the applicable NFPA PPE standard and, on determining that the product does meet the requirements, permits the manufacturer to affix the certification organization's label, symbol, or other identifying mark to the product, indicating compliance. This is called the *labeling* portion of certification. The certification organization must also provide a listing service in which the organization publishes lists of products by specific type or model that have been evaluated, tested, and labeled as compliant products. This is called the *listing* portion of certification. In the *follow-up* portion of certification, the certification organization makes random periodic reviews of the manufacturing process and evaluates and tests the continuing production process to assure that the product remains compliant.

In addition, the certification organization reviews and monitors the manufacturer's quality assurance program. Manufacturers are required to be registered in accordance with the ISO 9001 quality control standard. Some may claim that following the ISO quality control requirements only means the manufacturer documents everything whether good or bad, that it is just a paper project. But when the manufacturer has certified a product as being compliant with an NFPA PPE standard, quality control is evaluated against the PPE standard so that the manufacturer and the certification organization, which monitors the quality assurance program, can always know the status of the product and can quickly identify any problems that could affect product certification. The certification organization also provides annual recertification of the product in which key tests are conducted to assure that the product remains compliant.

All items of emergency responder protective clothing and equipment that are claimed to be compliant with the appropriate NFPA standard *must* carry the label, symbol, or other identifying mark of the certification organization. Any PPE item that does not bear the label or mark of a third-party certification organization is *not* compliant with the appropriate NFPA

standard, regardless of the claims or statements that are made by the manufacturer, distributor, advertisement, or the garment or product label.

Requests for bids and purchase specifications should require the manufacturer to submit appropriate evidence of certification of the specific product and model that the manufacturer is bidding on. When releasing purchase specifications to solicit bids, purchasers should obtain copies of listings of certified PPE from certification organizations to assist in their review of bids received. These listings are the certification organizations' documents identifying which products have been tested and found to be in compliance with various standards. In all cases, purchasers should verify directly with the certification organization that the specific product and model certification are still valid *before* the purchase contract is signed or the purchase is made. After purchase, questions regarding the certification of any PPE item should be addressed to the indicated certification organization. Details of the certification and the labeling of PPE can be found in each NFPA product standard on protective ensembles, clothing, and equipment.

CLEANING AND MAINTAINING PPE

In all cases, the manufacturer's instructions for cleaning and maintaining its PPE must be followed. The manufacturer is required to provide specific printed or video cleaning and maintenance instructions with each item of PPE sold in order to be certified as compliant with the NFPA PPE standard. These instructions must be consulted and followed because failure to do so may reduce the protective qualities of the PPE or negate warranties. When the manufacturer's instructions for cleaning and maintenance that were provided with each new PPE item cannot be found, the product manufacturer should be contacted directly to obtain a new set of instructions.

The PPE selection, care, and maintenance (SCAM) standards mentioned earlier further specify the system for the organization's PPE program and how frequently inspections, cleaning, and maintenance must be performed. Recommendations (nonmandatory) for cleaning procedures are given if the manufacturer is no longer available to provide these instructions. Each SCAM standard states that whenever a difference occurs between the manufacturer's instructions and the SCAM standard, the manufacturer's instructions shall be followed.

Clean PPE reduces safety and health risks. It is recommended that PPE be cleaned frequently to reduce the level of, and bodily contact with, contaminants. Cleaning should prolong the life of the protective garments and help maintain the performance. Decontamination may not be possible when protective garments are contaminated with chemical, radiological, or biological agents. When decontamination is not possible, garments should be discarded in accordance with local, state, and federal regulations.

PPE is composed of a combination of materials. Each of these materials has unique characteristics, capabilities, and weaknesses. Even fabrics inherently flame resistant can have this characteristic negated by improper care and use.

Chlorine bleach must *not* be utilized for any PPE cleaning, decontamination, or disinfecting. Some components of PPE lose their physical integrity on exposure to chlorine bleach. Other components will actually lose their flame-resistant properties and thermal insulation capability on exposure to chlorine bleach. In any case, the protection provided by the PPE will be compromised.

Storage of PPE in direct sunlight, even for short periods of time, will substantially reduce protective qualities; the effects of such a reduction might not be visually apparent. Ultraviolet (UV) degradation will destroy or reduce the useful life of the PPE item. Color fading or color change often indicates that the garment has experienced UV degradation.

STANDARDS ON PPE FOR FIRE-FIGHTING OPERATIONS

Protective ensembles, protective clothing, and protective equipment for fire fighting are currently covered by two standards: one for structural fire-fighting protective ensembles and for proximity fire-fighting protective ensembles, and one for wildland fire-fighting protective clothing and protective equipment. These standards provide protection from physical hazards as well as thermal and environmental hazards and are designed to protect fire fighters against exposure to the hazards associated with each type of fire-fighting operation. The performance requirements are not intended to establish the limitations of the fire fighter's working environment but are intended to establish material performance requirements based on empirical field data and laboratory testing.

Proper sizing is an important part of the protection provided by PPE garments. PPE garments that fit properly allow air retention in the composite and the air adds insulation. Garments that are too tightly fitting squeeze air out and reduce the insulative qualities. Garments that are too loose or too tight can prevent the fire fighter from being able to reach, pull, climb, crawl, straddle, or jump and will contribute to fatigue. Improperly fitting garments are safety hazards as they do not permit the wearer to function with as little interference as possible. Sizing must also take into consideration the minimum overlap of two-piece ensembles (coat and trousers instead of a one-piece coverall style) to assure that there is no gap in the protection where the two elements meet. This overlap of protection must be provided in all working positions, including standing straight, crouching, crawling, reaching overhead, and stretching front, back, and side to side.

The preferred method of sizing is to measure persons individually for their PPE garments or ensemble. This assures a proper and safe fit for chest, shoulders, arms, waist, thighs, legs, and garment overlap areas of the fire fighter who will be wearing the garments. Another method used with standard stock garments is numerical sizes that are based on increments of chest and waist measurements, such as 32, 34, 36, 38, and so on. It can give individuals who conform to standard sizing measurements an effective fit in many situations; however, the garment overlap areas must be carefully considered. Yet another sizing method uses general sizing indicators such as S/M/L/XL/XXL. This sizing method is very general and the least accurate, combines a larger increment of chest and waist measurements in each size range, and is not recommended.

Some of the testing that the materials, components, composites, and ensemble elements for fire-fighting PPE are subjected to include the following: flame resistance, thermal stability, thermal insulation, convective heat resistance, radiant heat resistance, total heat loss capability (breathability), durability, dexterity, grip, electrical insulation, corrosion, abrasion, compression, cut, puncture, penetration, impact, energy absorption, retention, water penetration, viral penetration, and common liquids resistance.

Excessive Protection

One point of view about fire-fighting protective clothing is that it allows fire fighters to overextend themselves, thus getting into positions that are more likely to cause injury—positions that they would not be able to get into if they were not wearing such "sophisticated" clothing. Some think that the advanced protective clothing does not allow fire fighters to "feel the heat" and better judge their environment.

Fire fighters who overextend are not operating under close or adequate supervision or in an incident command system that controls the position, function, and safety of all operating teams. The advanced protective clothing can allow fire fighters, who are operating safely within the incident command system, to be able to perform more effectively.

Some advocate different levels of protection for various parts of the same protective ensemble. This is alleged to allow the fire fighters to "feel the heat" in areas of the body that are sensitive to heat but are believed to be not as severely exposed to the fire environment.

All parts of the fire fighter's body are sensitive to heat and equally exposed during most active operations and especially when conditions unexpectedly change. The philosophy of NFPA PPE standards has been to provide protection from the expected environment during proper, supervised operations and, if conditions deteriorate rapidly, to provide a margin of time for fire fighters to escape uninjured or with survivable injuries. The fire fighter must be afforded equal protection throughout the ensemble to reduce the possibility of injury or limit the severity of the injury.

Regardless of the level of protection afforded by any protective clothing, anything *except bare skin* can allow fire fighters to overextend, further enforcing the position that all operations must be managed by the incident command system and that fire fighters operate only under direct supervision within that system. Individual fire fighters who operate alone and not as a member of a company or a team, who operate without direct supervision, or who operate outside of the incident command system (a situation frequently called "freelancing" in the United States) cannot be permitted if safety is to be achieved.

The ability to judge heat buildup can differ depending on what fabrics the fire fighter is wearing. The level or intensity of heat that can be sensed in one garment may feel entirely different in another garment that was manufactured using different fabrics or component layers. There is not a single "measure of heat buildup" that can be applied to all protective garments. Likewise, it is impractical to rely on exposed human body parts to indicate heat exposure, as skin begins to burn at relatively low temperatures (about 135°F [57°C]) after a short exposure. It is actually a cultural issue and a training issue for the fire fighter to become familiar with how a particular ensemble transmits heat.

Heat Stress

Another viewpoint is that the thermal insulation of the protective clothing causes more injuries, due to heat stress, than lighter weight but less protective garments. Some positions state that these injuries are the result of the protective clothing.

Heat stress cannot be addressed by only the garment materials but must be approached from several factors that equally affect it. Simply put, the problem is protecting fire fighters from a very hostile environment in which thermal insulation is required and attempting to reduce heat stress to as low a level as possible.

In mild and moderate environments and at low and moderate work levels, differences in PPE garment materials are likely to have an appreciable effect on heat stress. In the most stressful situations of high-temperature environment or high work rates, PPE garment materials are unlikely to make any significant improvements in tolerance time. In addition to the total heat loss testing and material specifications, heat stress must also be addressed through other means.

Fire fighters spend considerable time in other than high heat environments and at other than high work levels. Relief can be provided from heat buildup inside protective clothing in mild and moderate environments and at low and moderate work levels, and NFPA PPE standards are addressing some of the garment and fabric issues of heat stress with a total heat loss test that measures the breathability of garments. This requirement is currently being met by use of breathable membranes in the PPE garment composite that do not compromise the other required protection.

For garments to be protective from the hostile thermal environment, thermal insulation is needed. Garments alone cannot keep a fire fighter both cool and comfortable and provide adequate thermal insulation necessary for fire-fighting operations in hostile thermal environments. All of the factors affecting stress and heat stress must be evaluated, including fire fighters' age, physical condition, and individual metabolism as well as how fire fighters are managed during incident operations.

Fire fighters who are operating in high-temperature areas or at high work rates must be cared for. These crews must be periodically rotated to allow rest, cooling, rehydration, monitoring of physiological conditions, and other measures as necessary. Simply reducing the insulation or weight of the protective garments will not benefit fire fighters and will not have any meaningful effect on heat stress. The entire spectrum of heat stress and stress-related problems must be fully addressed by the fire department.

Structural Fire-Fighting PPE

Thermal Environment. The PPE for structural fire fighting has been developed over the years after careful consideration of the expected thermal environment. The types of fire involvement and the general range of conditions and maximum exposure durations that might occur are shown in Table 12.9.1.

TABLE 12.9.1 Thermal Classification—Structural Fires

	Occurrence	*Height and Duration of Temperature and Thermal Radiation*
Class I	In a room or enclosed area that has been involved after the fire has been knocked down	Environmental temperatures up to 104°F (40°C) and thermal radiation up to 0.05 W/cm^2 for up to 30 min
Class II	When a small fire is burning in a room or enclosed area	Environmental temperatures from 105 to 203°F (41 to 95°C) and thermal radiation from 0.050 to 0.100 W/cm^2 for up to 15 min
Class III	When a fire in a room or enclosed area more completely involves the contents	Environmental temperatures from 204 to 482°F (96 to 250°C) and thermal radiation from 0.100 to 0.175 W/cm^2 for up to 5 min
Class IV	During ignition of fire gases, a backdraft, or flashover in a room or enclosed area	Environmental temperatures from 483 to 1500°F (251 to 815°C) and thermal radiation from 0.175 to 4.200 W/cm^2 for about 10 sec

Source: Adapted from http://www.cdc.gov/niosh/npptl/pdfs/ProjectHEROES.pdf.

Although achieving these exposure durations could be possible, most situations have other factors that can dramatically affect the durations. Two of many factors are preheating of the PPE at lower-class conditions prior to the higher-class exposure and effects (both positive and negative) on the thermal environment caused by fire-fighting operations. In any case, structural fire fighting is not designed to give full protection for the exposure durations sequentially through each class environment.

Because the thermal environment can change extremely rapidly during structural fire-fighting operations, the wearing of full ensembles is required for all operations when the fire is not under control and for many "under control" operations.

Protective Ensembles Used by the Fire Department of New York. In February 1995, the New York City Fire Department (FDNY), the largest fire department in the United States, required all of its 11,228 fire fighters to be equipped with and to wear both protective coats and protective trousers, rather than just protective coats with boots, for all fire-fighting operations. In 1996, FDNY required protective hoods also be worn with full protective clothing. FDNY's statistics for 1993 through 2005 show a significant reduction in burn injuries (Table 12.9.2) and time lost due to burn injuries (Table 12.9.3).

Over the years, other fire departments have also reported reductions in burn injuries when the change was made to full PPE from only protective coats worn with boots.

Protection for Structural and Proximity Fire Fighting Operations. The product standard for structural proximity fire fighting PPE is NFPA 1971, *Standard on Protective Ensembles for Structural Fire Fighting and Proximity Fire Fighting* (formerly NFPA 1971, *Standard on Protective Ensemble for Structural Fire Fighting* and NFPA 1976, *Standard on Protective Ensemble for Proximity Fire Fighting*). This structural fire-fighting protective ensemble consists of the following elements: garments (coat and trousers), hoods, helmets, gloves, and footwear. Figure 12.9.1 from NFPA 1971 shows helmet test areas and landmarks for sample helmets that are conditioned through exposing the area to be impacted/penetrated to a radiant heat source.

TABLE 12.9.2 Reduction in Burn Injuries

	Burn Injuries		
	1993	*2005*	*Change*
Ears	185	43	–76.76%
Face	176	98	–44.32%
Hand	189	64	–66.14%
Head	76	25	–67.11%
Knee	355	43	–87.89%
Arm	283	52	–81.63%
Leg	162	45	–72.22%

The 2007 edition of NFPA 1971, the seventh edition, introduced *optional requirements* for protection from chemical, biological, radiological, and nuclear (CBRN) terrorism agents (chemicals, biological agents, and radiological particulate) that could be released as a result of a terrorism attack. These optional requirements can be selected by fire departments that are concerned about first response of their personnel to terrorism

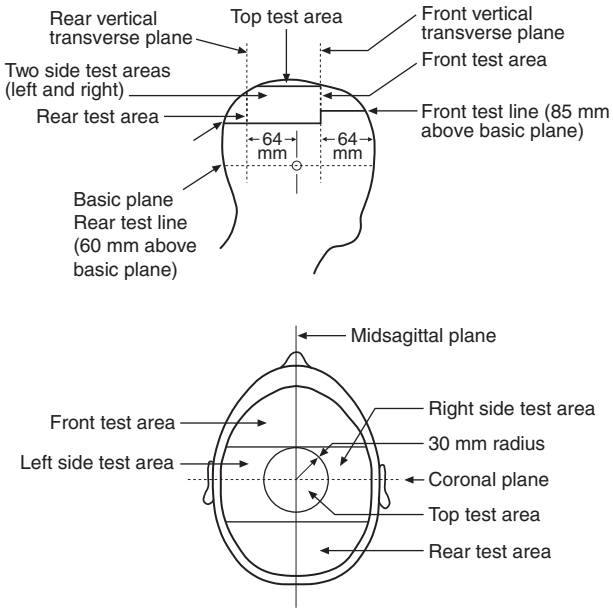

FIGURE 12.9.1 Helmet Test Areas and Landmarks (Source: NFPA 1971, *Standard on Protective Ensembles for Structural Fire Fighting and Proximity Fire Fighting,* Figure 8.1.6.1, 2007, p. 1971-42)

incidents where "normal" fire-fighting protective ensembles offer little or no protection from CBRN terrorism agents. These optional requirements can also be selected where supplementary protective ensembles that are certified as compliant with NFPA 1994, *Standard on Protective Ensembles for First Responders to CBRN Terrorism Incidents,* for protection from CBRN terrorism agents are unlikely to be provided to the vast majority of fire-fighting first responders.

The CBRN optional protection can only be applied to an entire ensemble, including the specified CBRN SCBA for that ensemble, and cannot be applied to individual ensemble elements. The design and performance of the entire ensemble including the CBRN SCBA provide the CBRN protection for the wearer and depend on the proper use of the entire ensemble to accomplish this. No combination of individual ensemble elements short of the entire assembled ensemble will give CBRN protection.

These optional CBRN requirements apply to both structural fire-fighting protective ensembles and proximity fire-fighting protective ensembles and are built into the construction of the "basic" fire-fighting protective ensemble elements, so that nothing has to be added to or subtracted from the basic fire-fighting protective clothing in order to achieve the protection from CBRN terrorism agents. The optional CBRN requirements do not decrease any of the protection for the fire-fighting environments in which these ensembles are used.

Protective Clothing and Equipment (PPE). The use of "full structural fire-fighting protective clothing and equipment" (PPE), certified as compliant with the NFPA 1971, is required by NFPA 1500 for all structural fire-fighting operations. Full PPE includes the previously mentioned ensemble elements, as well as SCBA certified as compliant with NFPA 1981, *Standard on Open-Circuit Self-Contained Breathing Apparatus (SCBA) for Emergency Services,* and PASS (personal alert safety system) certified as compliant with NFPA 1982, *Standard on Personal Alert Safety Systems (PASS).*

The user standard for structural fire-fighting PPE is NFPA 1851. This standard embraces the selection process for purchasing new PPE and the inspection, cleaning, care, repair, and removal from service of "in-service" PPE.

Specialized Fire-Fighting PPE

Approach Fire-Fighting Operations. There are other fire-fighting operations in which personnel can be exposed to very high levels of radiant heat and in which proximity PPE is not suitable. Approach operations are generally limited to incidents at fixed facilities that produce high levels of radiant heat and also produce conductive, convective heat but also include operations conducted at greater distances from the fire so that the principle thermal hazard is the radiant heat. Such operations usually consist of personnel "approaching" the fire area in order to position and set up unstaffed delivery points for exposure protection or application of cooling or extinguishing agents onto the fire area, such as master streams, and then withdrawing from the area affected by the radiant heat.

Radiant heat protection is necessary for personnel involved in such operations, but protection from convective and conducted heat is generally not necessary because personnel are not exposed to significant thermal hazard due to the distance from the fire at which they perform the operations. Lighter weight and more flexible approach protection can permit the personnel to expeditiously complete their functions and withdraw with less stress.

Entry Fire-Fighting Operations. Entry fire-fighting operations are extraordinarily specialized operations at fires that produce extreme levels of conductive, convective, and radiant heat. Entry fire fighting should not be confused with structural fire fighting. In structural fire fighting, fire fighters enter into a structure in which there is a fire in order to search for and rescue victims and to confine and extinguish the fire in the smallest possible area. They do *not,* however, *enter into the flames.*

In entry fire-fighting operations, in contrast, personnel actually *enter into the flames.* These operations are generally limited to incidents at fixed facilities where the need is known beforehand and tasks have been pre-incident planned. Frequently employees of the facility who have been specially trained and equipped perform the operations. Entry is made in order to perform critical tasks. These tasks might include opening or closing valves or operating other controls that will likely result in control of the fire with no other way possible to control the fire without performing these tasks. Because of the scope of these operations, highly specialized thermal protection from exposure to extreme levels of conductive, convective, and radiant heat is necessary for persons involved in such extraordinarily specialized operations. Such entry PPE is specifically designed for the particular situation in which it will be used and for the known

and expected hazards. There are no standards for entry PPE due to the unique individuality of each set of PPE.

Proximity Fire-Fighting Operations

Proximity fire-fighting operations are specialized operations that can include the activities of rescue, fire suppression, and property conservation at incidents involving fires producing very high levels of radiant heat, as well as conductive and convective heat. Proximity fire-fighting operations include fires involving bulk flammable liquids, bulk flammable gas, bulk flammable metals, commercial or military aircraft, and similar situations that release high levels of radiant heat.

Specialized thermal protection from exposure to high levels of radiant heat, as well as thermal protection from conductive and convective heat, is necessary for persons involved in such operations. Although fire fighters do not make direct entry into flame, they need such protection because of the scope of these operations and because of their closeness to the fire when conducting these operations. These operations are usually exterior operations but might be combined with interior operations. Proximity fire fighting is not structural fire fighting but might be combined with structural fire-fighting operations. Proximity fire fighting is not entry fire fighting.

The product standard for proximity fire-fighting PPE is NFPA 1971, *Standard on Protective Ensembles for Structural Fire Fighting and Proximity Fire Fighting* (formerly NFPA 1976, *Standard on Protective Ensemble for Proximity Fire Fighting*). This protective ensemble standard consists of the following elements: garments (coat and trousers), helmets, shrouds, gloves, and footwear.

The use of full proximity fire-fighting protective clothing and equipment certified as compliant with NFPA 1971 is required by NFPA 1500 for all proximity fire-fighting operations. Full PPE includes the previously mentioned ensemble elements, as well as SCBA certified as compliant with NFPA 1981, and PASS certified as compliant with NFPA 1982.

Wildland Fire-Fighting PPE

Wildland fire-fighting operations are exterior operations incidents involving fires in natural ground cover, woods, trees, and other such vegetation. Such operations expose fire fighters to radiant heat, to some conductive and convective heat, and to many physical hazards.

Wildland fire-fighting PPE includes garments for upper and lower torso protection, overgarments, helmets, gloves, footwear, and fire shelters. The PPE is not presented as a total ensemble but as individual items that the incident commander can pick from in order to select the best combination for the particular incident conditions. The minimum necessary to meet the requirements of NFPA 1500 includes a fire shelter and protection for head, torso, hands, and feet.

Wildland fire fighting is the one fire-fighting operation in which respiratory protection is not required. At this time, some wildland fire-fighting organizations do use respiratory protection devices, usually of the air purifying respirator (APR) type or the powered air purifying respirator (PAPR) type. (See a more detailed discussion of wildland fire-fighting respiratory protection in the following respiratory protection section.)

The product standard for wildland fire-fighting PPE is NFPA 1977, *Standard on Protective Clothing and Equipment for Wildland Fire Fighting.* The use of PPE certified as compliant with NFPA 1977 is required by NFPA 1500 for all wildland fire-fighting operations. The PPE includes, as a minimum, the protective shirt, pants, helmet, gloves, and footwear (Figure 12.9.2). In addition, PASS certified as compliant with NFPA 1982 is also required.

STANDARDS ON PPE FOR RESPIRATORY PROTECTION

Self-Contained Breathing Apparatus (SCBA)

Self-contained breathing apparatus (SCBA) are required for all fire-fighting operations except wildland fire-fighting operations, as well as for any emergency incident operations where IDLH (immediately dangerous to life and health) atmospheres or oxygen-deficient atmospheres exist or are anticipated, including CBRN terrorism incidents, confined space rescue, hazardous materials emergencies, and certain technical rescue operations.

Both SCBA and supplied-air respirators (SAR, also called "airline respirators") are of the "atmosphere supplying respirator" family in which the respirator supplies the user with breathing air from a source independent of the ambient atmosphere.

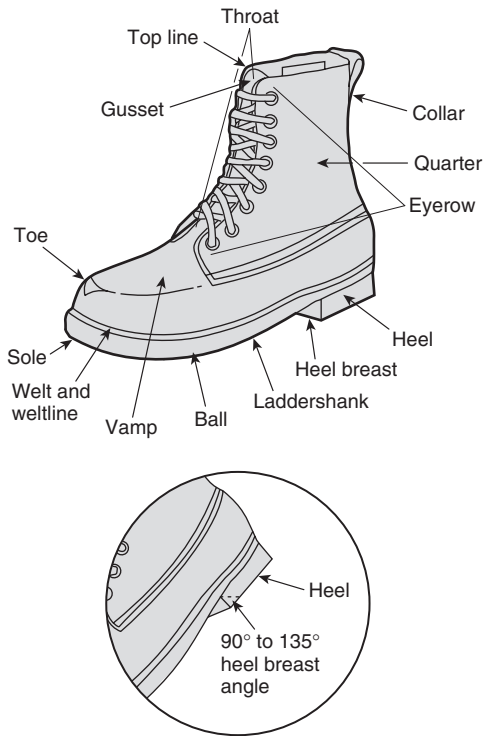

FIGURE 12.9.2 Footwear Terms (Source: NFPA 1977, *Standard on Protective Clothing and Equipment for Wildland Fire Fighting,* Figure 6.4.3, 2005, p. 1977-27)

SARs provide breathing air from a source that is *not* designed to be carried by the respirator user, while SCBA provide breathing air from a source that *is* designed to be carried by the respirator user. Where SARs incorporate a continuous air-line breathing air supply, and the SAR component is an integrated part of an SCBA that has a rated service time of at least 30 minutes, such SCBA/SAR can be used by emergency responders for extended duration operations, or for an increased exit time from the hazardous atmosphere.

There are two types of SCBA: open-circuit and closed-circuit. Open-circuit SCBA are respirators from which exhaled breath is vented to the atmosphere and is not rebreathed; closed-circuit SCBA are respirators in which exhaled air is rebreathed by the wearer.

Positive-Pressure and Demand SCBA

Positive-Pressure SCBA. All SCBA are classified as either positive pressure (also called pressure demand) or demand. OSHA regulations and NFPA standards require use of only positive-pressure SCBA for any IDLH or potentially IDLH atmospheres including structural fire-fighting operations. The use of demand SCBA for such operations is prohibited. The use of only positive-pressure SCBA became mandatory in the United States on July 1, 1983.

During normal use of positive-pressure SCBA, a positive pressure during inhalation and exhalation is maintained inside the facepiece in relation to the ambient atmospheric pressure. This positive pressure reduces the inward leakage of a contaminated atmosphere around the perimeter of the facepiece, but the positive-pressure feature cannot be construed to take the place of proper facepiece fitting and fit testing for each user. The positive-pressure feature cannot and will not compensate for any interference with the facepiece-to-face seal, such as from beards or other facial hair or from facial deformities, from eyeglass temple bows or straps, or from any other condition that passes through the area where the facepiece seals with the face, thereby preventing a proper facepiece-to-face fit.

Demand SCBA. Because demand SCBA operates on the principle of requiring negative pressure (inhalation) to initiate and maintain breathing airflow, OSHA regulations and NFPA standards do not permit use of demand SCBA for fire-fighting or other IDLH operations. The danger of the atmosphere surrounding the facepiece (the contaminated atmosphere) being drawn into the SCBA facepiece is significant.

Open-Circuit SCBA. Of the two types of SCBA, open-circuit is the SCBA where the exhaled breath is vented to the atmosphere and is not rebreathed. Open-circuit SCBA use an expendable source of breathing air that is stored under pressure in a cylinder. The breathing air is made available to the user through a regulator that automatically functions to reduce high air-storage pressures to lower usable pressures and to supply this breathing air to the user.

Open-circuit SCBA use compressed breathing air cylinders and are available in pressure systems from 2216 psi (15,279 kPa), 3500 psi (28,132 kPa), to 4500 psi (31,027 kPa). Regardless of the system pressure, all SCBA should be equipped with carbon filament or composite breathing air cylinders that are rated with a 30-minute or greater service life. The advantage of the carbon or composite breathing air cylinders is a significant lower weight achieved by the cylinder design. High-pressure systems have smaller cylinders that have less bulk and provide a smaller profile than a conventional pressure cylinder. Whereas the 2216 psi (15,279 kPa) cylinders can provide a rated service time of 30 minutes, the 3500 psi (28,132 kPa) cylinders can provide a rated service time of 45 minutes, and the 4500 psi (31,027 kPa) cylinders can provide a rated service time of 60 minutes.

Closed-Circuit SCBA. The second type of SCBA, closed-circuit, is the SCBA in which the exhaled air is rebreathed by the wearer. These SCBA recirculate the user's exhaled gas. The exhaled breath passes through an exhalation hose and through a carbon dioxide absorber, where the carbon dioxide is removed. Then it enters a breathing chamber, where it is mixed with additional oxygen from an oxygen source that is stored under pressure in a cylinder, and it is then available for inhalation. Closed-circuit SCBA can have a rated service life from 30 minutes to 4 hours.

OSHA and National Institute of Occupational Safety and Health (NIOSH) Regulations

Respiratory protection standards in the United States have recognized that unknown types and quantities of toxic elements of the products of combustion encountered during fire fighting do not allow the selection of different respiratory protective equipment for different exposures, as is often the case in the industrial environment. These atmospheres are classified as IDLH and require SCBA for respiratory protection.

OSHA has utilized National Institute of Occupational Safety and Health (NIOSH) and other OSHA regulations to establish minimum requirements for fire fighter respiratory protection. The OSHA *Fire Brigade Regulations,* 29 CFR 1910.156, requires the use of only positive-pressure SCBA that are certified by NIOSH under 42 CFR 84 and have a minimum rated service life of at least 30 minutes. OSHA requires that only positive-pressure SCBA be used during all structural fire-fighting operations; at all hazardous materials incidents; in oxygen-deficient atmospheres; in areas such as sewers, confined spaces, and silos; and wherever a hazardous or oxygen-deficient atmosphere may exist.

Nothing can be allowed to be in or pass through the area where the facepiece-to-face seal is made. Therefore, beards, drooping mustaches, long or wide sideburns, or other facial hair at any point where the face seal with the respirator facepiece is to occur or the wearing of eyeglasses with temple bows or straps are prohibited for persons who are required to use SCBA. OSHA has ruled (February 15, 1990) that ". . . these conditions have been shown to prevent a good facepiece-to-face seal, so that use of an SCBA by a person with any of the noted conditions (i.e., beards, drooping mustaches, long or wide sideburns, and other facial hair, temple bows/straps) is in violation of OSHA regulation 29 CFR 1910.134 (e)(5)(i), *regardless of what fit test measurement can be obtained.*" In addition, persons with conditions

such as severe skin pitting, loss of teeth, facial deformities, skull caps or head gear, or any other conditions or devices that prevent a proper facepiece fit are prohibited from using SCBA. SCBA manufacturers offer special prescription lens/frame assemblies that can be affixed inside the facepiece and do not affect the facepiece-to-face seal.

Breathing Air Cylinder U.S. Department of Transportation (DOT) Regulations

Compressed gas cylinders for breathing air are regulated in the United States by the Department of Transportation (DOT). U.S. federal regulations for the construction, testing, and maintenance of compressed gas containers are contained in 49 CFR 178, Subpart C. These DOT specifications apply to steel SCBA and large storage cylinders only. Cylinders constructed of manganese/steel and conforming to the preceding DOT specifications are designated by a DOT3A marking on the cylinder. Steel cylinders constructed of chrome alloy steel and meeting DOT specifications are designated by a DOT3AA marking on the cylinder, followed by the marked cylinder service pressure.

There are no specifications outlined in 49 CFR for composite cylinders. Therefore, the DOT developed special certifications known as "exemptions." DOT authorized composite cylinders to have a maximum service life indicated in the exemption. Most exemptions specify that composite cylinders have a maximum life of 15 years, but newer composite cylinders can have a longer designated service life. Composite cylinders that have a maximum life of 15 years are prohibited from being refilled after 15 years from the original hydrostatic test date. All U.S. retest facilities performing requalifications on composite cylinders are required by DOT to have a current copy of the cylinder's exemption available and must follow its instructions and conditions. DOT, which is the regulatory authority in the United States, specifies the cylinder requalification frequency of every 3 years for composite cylinders and the cylinder requalification frequency of every 5 years for all-metal cylinders. The organization/cylinder owner and retest facility are required by DOT to know how often to have the requalification performed. At this writing, DOT is considering changes to the requalification schedule for all cylinders, so changes to the previously noted cylinder requalification frequencies may be announced.

NFPA 1981, *Standard on Open-Circuit Self-Contained Breathing Apparatus (SCBA) for Emergency Services*

SCBA Design. The product standard for respiratory PPE is NFPA 1981. The basic design and function of the SCBA must be certified by NIOSH in accordance with 42 CFR 84 as being positive pressure, having a rated service life of at least 30 minutes, and weighing no more than 35 lb (16 kg). Labeling of the SCBA must include the NIOSH certification plate and a certification organization's label denoting compliance with NFPA 1981.

SCBA Testing. Airflow performance testing measures the airflow that the SCBA can supply (Figure 12.9.3). Airflow must be provided to the wearer at 100 L/min volume without the facepiece pressure going negative during both inhalation and exhalation. The 100 L/min airflow exceeds the NIOSH certification requirement of 40 L/min volume.

Thermal cycle testing evaluates the proper function of the SCBA when exposed to various temperature extremes and tem-

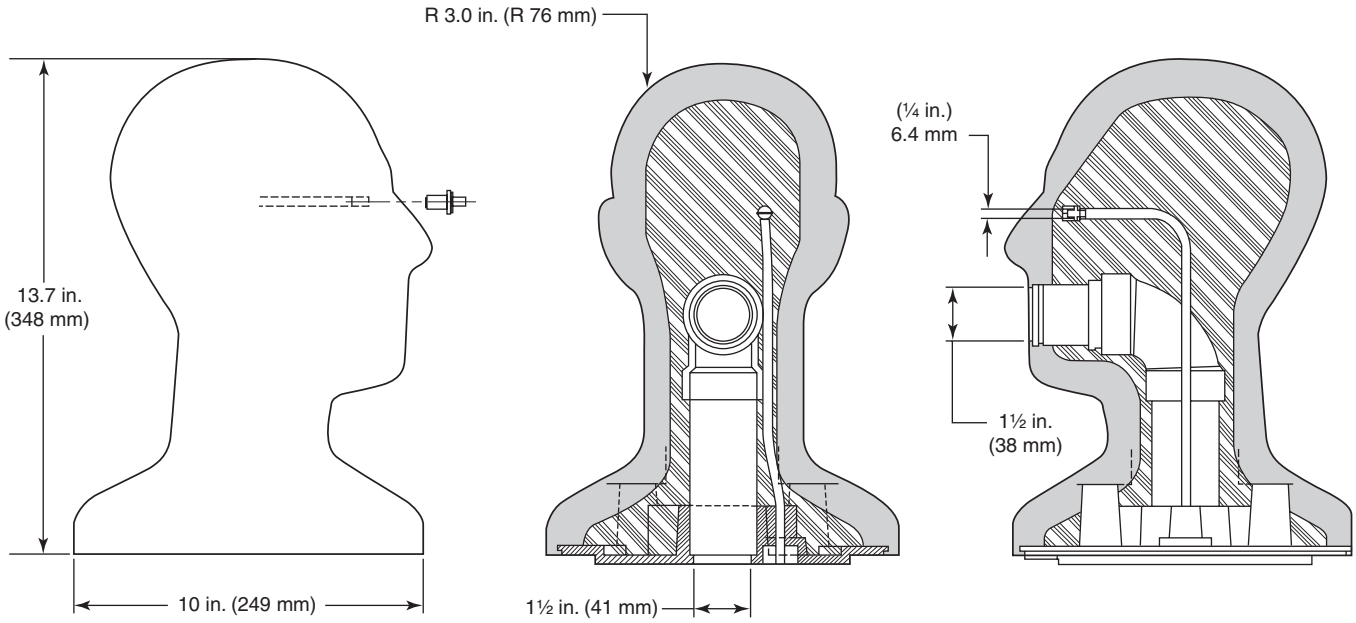

FIGURE 12.9.3 Test Headform (Source: NFPA 1981, *Standard on Open-Circuit Self-Contained Breathing Apparatus (SCBA) for Emergency Services,* Figure 8.1.4.1, 2007, p.1981-23)

perature cycles through a series of four tests (cold-cold, hot-hot, cold-hot, and hot-cold).

Total heat and flame testing is tested for the entire SCBA. The SCBA, while mounted on a mannequin and attached to a breathing machine operating at 40 L/min, is conditioned for 15 minutes in a 203°F (95°C) oven. Immediately following the conditioning, the SCBA breathing rate is increased to 100 L/min and then exposed to a direct-flame contact that engulfs the entire SCBA for 10 seconds at temperatures between 1500°F to 2102°F (816°C to 1150°C), with an average mean of peak temperature at 1742°F (950°C). After this exposure, the SCBA is subjected to a drop test. Through the entire testing, the SCBA must operate as required by the standard, must not show any afterflame of the SCBA and all components beyond 2.2 seconds, must not shift from the proper mounting on the mannequin, and the facepiece lens must not obscure vision greater than 20/100.

SCBA are required to be equipped with a second independent End of Service Time Indicator, a heads-up display (HUD) that provides alerts and warnings on remaining breathing air supply, and a voice communications system in addition to the speaking diaphragm. Other performance requirements test for vibration and shock resistance, corrosion resistance, particulate resistance, fabric flame resistance, fabric heat resistance, and facepiece lens abrasion.

SCBA Certification. The 2007 edition of NFPA 1981, the sixth edition, introduced the major change of requiring all emergency services SCBA to also be NIOSH certified as CBRN SCBA in accordance with the NIOSH *Statement of Standard for NIOSH CBRN SCBA Testing.* This requirement will provide respiratory protection for CBRN terrorism agents (specified chemicals, biological agents, and radiological particulate) that could be released as a result of a terrorism attack.

Although major metropolitan areas may be more likely targets of a terrorist event, emergency responders from smaller communities away from urban areas could be called on to respond to urban areas where the emergency services have become overwhelmed by a terrorist incident and require assistance. Terrorists themselves may reside in small communities while they await their opportunity to strike. They may have the chemical, biological, or nuclear material in their possession, making the possibility of exposure greater for small rural areas. Terrorist attacks aside, CBRN-certified SCBA offers greater protection for the emergency services for a very minimal cost.

Protection from CBRN. CBRN protection offers verification of enhanced protection for emergency responders that is not otherwise available. Without CBRN protection evaluation, no SCBA components are tested for permeation, penetration, corrosion resistance, or other detrimental effects from exposure to toxic industrial chemicals during hazardous materials incidents and hazardous chemical warfare atmospheres. *NIOSH benchmark testing of non-CBRN hardened SCBA against CBRN agents demonstrated that chemical warefare agents (CWA) could cause catastrophic failures within minutes of exposure.*

The selection of the test challenge agents by NIOSH for CBRN protection was based on a comprehensive review of available technical data and consultations with other government agencies (e.g., Departments of Defense, Justice, Energy, etc.). Various chemical data lists were analyzed, including lists from EPA, ATSDR, NFPA 1994, U.S. Army Center for Health Promotion and Preventative Medicine (USACHPPM) Technical Guide 244, and classified sources. This review established a total of 151 toxic industrial chemicals and chemical warfare agents as potential candidates for challenge agents. The candidate agents were evaluated for permeation (molecularly diffusing through material) and penetration (seeping through interfacing components) characteristics as part of a review of their physical properties. This evaluation concluded that sarin (GB) and sulfur mustard (HD) could be selected as the two representative agents for the penetration/permeation test for the complete listing of 151 CWA and toxic industrial chemicals (TICs) due to their physical properties and molecular structure. NIOSH is unaware of any data that indicate the CBRN-certified SCBA provide less protection against TICs than their industrial counterparts.

The evaluation for CBRN protection provides verification and assurance that the component and material combinations in the approved SCBA configurations provide high resistance to permeation and penetration of hazardous atmospheres of toxic industrial chemicals and materials into the breathing air. This assurance is of importance to all responders who are subject to exposures of any hazardous industrial chemicals and materials.

Additional Safety Requirements. In addition to the CBRN requirement, new requirements were added to increase the safety to the users of emergency services SCBA and to better assure the proper functioning of the SCBA including the following:

- New breathing air cylinder retention requirement within the mounted position
- Mechanical voice diaphragm performance requirement increased to 80 percent minimum score at 5 ft (153 cm) distance
- New voice communications system with at least an 85 percent score at 10 ft (305 cm) distance
- New independent pressure gauge that would not be affected by failure of the HUD
- New water immersion requirements for electronic devices that are part of the SCBA that must function properly and remain watertight after exposures to 350°F (177°C) for 15 minutes and water submersion to 5 ft (1.5 m)
- New low power capacity requirements for electronic devices to assure that such devices will continue to function properly for at least 2 hours following activation of the lower power signal

The product standard for breathing air is NFPA 1989, *Standard on Breathing Air Quality for Fire and Emergency Services Respiratory Protection.* This standard provides requirements for breathing air quality of the overall respiratory protection program required by NFPA 1500. It covers testing frequency; qualifications for laboratories performing breathing air quality verification testing; breathing air quality levels for oxygen, carbon monoxide, carbon dioxide, condensed oil, and particulate content; hydrocarbon content; water concentration; and determination of odors.

The user standard for SCBA is NFPA 1852. This standard embraces the organizations' program for respiratory protection, the selection process for purchasing new SCBA, and the inspection, cleaning, care, repair, and removal from service of "in-service" SCBA.

Wildland Fire-Fighting Respiratory Protection Considerations

Wildland fire fighting is the only fire-fighting operation in which respiratory protection is not yet required. Concerns exist regarding the actual dangers of short- and long-term exposure to the products of combustion from wildland fires. Studies of air samples collected on wildland fire fighters and workers indicate potential for hazardous exposure (e.g., respirable particulate, carbon monoxide, formaldehyde, and acrolein). The health implications of short-term exposures and the potential health effects of long-term exposures are being studied.

It is current practice to consider wildfire smoke not IDLH, even though human health hazards have not been quantified. As a prudent practice, wildfire smoke exposure should be reduced. Fire fighters and crew supervisors should consider the level of smoke exposure of the tasks to be performed before committing personnel to action. Mitigation efforts could include short work periods, removal of crews from areas of heavy smoke concentration, rest periods with smoke-free air, or use of respiratory protection. Although SCBA offers the most complete respiratory protection, SCBA is not practical for use by wildland fire fighters who work for extended periods in remote locations. The weight of an SCBA, its limited use time, and breathing air cylinder recharging logistics make it impractical for use by wildland fire fighters.

A high-efficiency particulate air (HEPA) filter-equipped, air-purifying respirator could be considered an option for the filtration of respirable particles from the air to be breathed. The addition of sorbents to remove selected gases and vapors (e.g., P100 high-efficiency particulate filter plus organic vapor [OV] and acid gas [AG]) could also be an option when greater exposure is anticipated, as in a direct attack on a fire. Particulate respirators remove the irritation and make breathing seem easier, but they do nothing to protect from carbon monoxide (CO).

Any respirator being considered for use by wildland fire fighters must be NIOSH certified. Care should be exercised in the use of NIOSH-certified respirators because they have not been tested for heat resistance and flammability of the filter medium and have not been evaluated for their ability to provide protection from the products of combustion of wildfires.

STANDARD ON PPE FOR PERSONAL ALERT SAFETY SYSTEMS (PASS)

Personal alert safety systems (PASS) encompass devices that are known by several names, including personal distress alarm devices, personal distress locators, personal alarm locators, personal alarm monitors, and personal alarm devices. The concept of PASS involves several distinct features. The alarm signal must be able to be activated manually by the user. The PASS must also contain a sensor that senses movement or the lack of movement. The alarm signal must be capable of being activated automatically through interaction with the sensor under a specified series of events. PASS must also have a prealarm signal to prevent false alarms by alerting the user that the sensor has not sensed motion of the user and has activated the automatic alarm signal sequence.

Despite popular belief that PASS are a required part of "fire fighters' SCBA," PASS are not required to be (but can be) integrated with SCBA. PASS can also be a stand-alone device worn on part of the emergency services person's protective clothing. PASS can also be integrated with several items of protective clothing or equipment to enhance the sensing abilities over a wider area of the body, locate the sounders where the users can better differentiate between signals from their PASS and from other PASS, and disperse the weight and power sources over a greater area.

Automatic Notification

Emergency response personnel can become incapacitated during operations and might not be noticed by other members of the crew. These personnel may be aware that they need assistance and may be able to manually activate the alarm. If they are suddenly stricken, however, the automatic alarm must activate and call for assistance. Fire fighters, especially, can become trapped or disoriented in fire-fighting situations and can lose contact with others in their crews. They frequently behave in a disoriented manner as they attempt to escape. This scenario is particularly associated with fire fighter deaths caused by smoke inhalation. Even with the use of SCBA, fire fighters face similar dangers if they operate beyond the time limits of their breathing air supply.

Emergency services personnel need the capability to contact other workers at the emergency scene when they are in need of assistance. Equipping each member assigned to an emergency operation with a portable two-way radio is one approach, but automatic notification that could summon help if the member became incapacitated would still not be provided by today's portable radios.

Applicability of PASS

Although PASS are generally associated with fire fighters for use during emergency operations, PASS protection applies to all emergency services personnel who operate in hazardous environments where they could become entrapped or incapacitated and need assistance. Hazardous materials, emergency medical, technical rescue, skilled trades, and even, for certain operations, law enforcement personnel should use PASS where their safety and well-being can be easily compromised. Confined space, structural collapse, extrication, limited access, complicated area or building layouts and floor plans, and atmospheres that could become IDLH are some of the many emergency operations working environments where PASS should be used.

NFPA 1982, *Standard on Personal Alert Safety Systems (PASS)*

The product standard for PASS is NFPA 1982. PASS performance requirements test for intrinsic safety, corrosion resis-

tance, case integrity, temperature cycling resistance, temperature shock resistance, dust and particulate resistance, immersion and leakage, radiant heat resistance, flame resistance, impact resistance, retention system durability, and water drainage.

National Institute for Occupational Safety and Health (NIOSH)

During the work on the fifth edition of NFPA 1982, the committee addressed reports from the National Institute for Occupational Safety and Health (NIOSH), Division of Safety Research, regarding its investigations of fire fighter fatalities where there was evidence that the PASS alarm signal failed to function or was not heard by other personnel in the area and in some instances that there was water ingress to the electronic components that would diminish or cancel the alarm signal. The National Institute for Standards and Technology (NIST), Building and Fire Research Laboratory, partnered with NIOSH to characterize the performance of PASS devices in the fire-fighting environment. NIST determined that exposure to high-temperature environments caused the loudness of the alarm signal to be reduced. This reduction in loudness may cause the alarm signal to become indistinguishable from background noise of the emergency scene. Initial laboratory testing by NIST highlighted that this sound reduction may begin to occur at temperatures as low as 300°F (150°C). All PASS devices that were evaluated experienced significant alarm signal degradation at temperatures between 300°F and 500°F (150°C to 260°C). As the PASS cooled, the alarm signal on most of the units returned to preexposure sound levels.

NIOSH and others also noted that water ingress did occur or could have occurred in several cases, causing the alarm signal to cease to function with any effectiveness, but that after the PASS electronics dried, the alarm signal might again function.

These issues and others caused significant changes to the requirements, including the following:

1. Water immersion requirements and testing where PASS are exposed to 350°F for 15 minutes and then to water submersion in 4.9 ft (1.5 m) and also for 15 minutes for each of six cycles. It is then tested to determine that all PASS signals and electronic data logging function properly. Following this, PASS are reimmersed in the test water with the power source compartment(s) open for 5 minutes, and the electronics compartment is opened and examined to determine no water ingress.

2. High-temperature resistance and functionality requirements and testing procedures where PASS are exposed to 500°F (260°C) for 5 minutes. The PASS alarm signal must function at or above the required 95 dBA sound level for the required signal duration, electronic data logging must operate properly, and no part of the PASS can show evidence of melting, dripping, or igniting.

3. Tumble-vibration requirements and testing in which PASS are tumbled in a rotating drum for 3 hours and the PASS alarm signal must function at the required 95 dBA sound level and electronic data logging must operate properly

4. Requirements to prevent muffling of the alarm signal where PASS are evaluated in five positions (face down with arms extended, supine left, supine right, fetal right with knees drawn to chest, and fetal left with knees drawn to chest), and the alarm signal must function at or above the required 95 dBA sound level in each of the positions

Limitations of PASS

Users of PASS, whether or not the PASS were certified as compliant to editions of NFPA 1982 prior to the 2007 edition, are cautioned that PASS can fail to sound the alarm signal at the 95 dBA sound level, sound the alarm signal at an insufficient volume to make it audible from background noise on the emergency scene, or not sound the alarm signal at all. PASS could also have alarm signal muffling, water ingress, and vibration issues, all of which can negatively affect the ability of PASS to function properly and signal for help.

Despite PASS, there have been too many fire fighter fatality incidents in which fire fighters became entrapped, lost, or disoriented while performing interior structural fire-fighting activities. In these incidents, many of the fire fighters were wearing PASS devices but had failed to turn them on. The current edition of NFPA 1982 requires automatic activation of PASS, including remote activation, tethering, and integrating PASS with SCBA so that the PASS will be automatically activated when the air supply is turned on.

PASS cannot substitute for an individual's common sense, just as it cannot substitute for an active incident management system, close supervision of operating crews, communications, and a functional and adequate personnel accountability system to ensure that the assignment and location of each fire and emergency services personnel are known at all times. Although the addition of a PASS device does not guarantee safety, it is an important component to the fire fighter's personal protective ensemble.

STANDARDS ON PPE FOR EMERGENCY MEDICAL SERVICES

When emergency services personnel perform emergency medical services (EMS) or otherwise might be exposed to blood or other body fluids, these personnel must be provided with EMS PPE. OSHA regulation 29 CFR 1910.1030, issued March 6, 1992, sets the requirements for all emergency responders, health care workers, and others for appropriate actions to prevent contact with blood-borne pathogens.

Appropriate Clothing and Equipment

The U.S. Centers for Disease Control and Prevention (CDC) *Guidelines for Public Safety Workers* discusses the selection and use of appropriate clothing and equipment during medical emergencies. CDC recommends that disposable gloves be worn by all personnel prior to initiating any emergency patient care tasks involving exposure to blood or body fluids. Extra pairs of gloves should always be available. For multiple victims, gloves should be changed between patient contacts.

Gloves contaminated with blood or other body fluids to which universal precautions apply should be removed as soon

as possible, taking care to avoid skin contact with the exterior surface. The use of gloves does not eliminate the need to wash hands after emergency medical incidents. Hand washing is one of the most important elements of infection control.

Masks, eyewear, and gowns should be present on all emergency vehicles that respond or that might respond to medical emergencies or victim rescues. These items should be donned by all personnel prior to any situation in which splashes of blood or other body fluids to which universal precautions apply is likely to occur. Finally, contaminated gloves should be placed and transported in bags that prevent leakage and disposed of properly. In the case of reusable gloves, they should be cleaned, disinfected, and stored properly.

Because of the risk of salivary transmission of other communicable viruses and bacteria (e.g., herpes simplex and Neisseria meningitides, respectively) and the risk of HIV and hepatitis B and C transmission during artificial ventilation of victims, the use of mechanical respiratory-assist devices, such as bag-valve masks and oxygen-demand valve resuscitators, or pocket mouth-to-mouth resuscitation masks (i.e., double lumen systems), designed to isolate emergency response personnel from victims' blood and blood-contaminated saliva, respiratory secretions, and vomitus, is strongly recommended.

NFPA 1999, *Standard on Protective Clothing for Emergency Medical Operations*

The product standard for EMS PPE is NFPA 1999, which is the only standard, both from within and outside the emergency responder community that includes performance tests to ensure that each type of PPE has a barrier against penetration of blood-borne pathogens. The standard requires penetration resistance to body fluids and blood-borne pathogens that personnel can be exposed to during EMS functions. The EMS PPE barrier materials, including seams, are exposed to a bacteriophage suspension of a liquid inoculated with *E. coli* C bacteria for 1 hour. Materials are tested in both directions and cannot allow any penetration of the bacteriophage. EMS PPE items must also meet performance requirements for liquidtight integrity, material strength, physical hazard resistance, seam strength, and closure strength.

NFPA 1999 covers EMS PPE items, including garments, both full and partial, upper and lower torso protection; three types of gloves, examination gloves for patient care, work gloves for situations that pose higher physical hazards such as extrication, and cleaning gloves for handling and cleaning contaminated EMS equipment; footwear; and face protection. EMS PPE must provide the barrier protection to whatever parts of the body they cover. Although no partial protection is allowed for the EMS PPE item, the items might be configured to cover only part of the upper or lower torso, such as arms with sleeve protectors, torso front with apron-styled garments, face with faceshields, and so on.

EMS PPE face protection must meet requirements for liquidtight integrity in those areas of the facewear that are designed to provide biological protection.

For mass casualty incidents where civilian victims could self-present at medical care facilities without having been decontaminated by emergency services personnel at the incident scene, medical first receivers should have PPE protection so they can function and give care without themselves becoming victims. All of the PPE covered by NFPA 1999 will provide blood-borne pathogen protection for these personnel as well.

NFPA 1581, *Standard on Fire Department Infection Control Program*

The existing user document is NFPA 1581. (There is no PPE SCAM document at this time.) This standard is a comprehensive document on infection control and requires that the organization provide EMS PPE for each of its members for use while performing EMS operations. EMS PPE includes single-use gloves, fluid-resistant clothing, pocket masks, splash-resistant eyewear, respiratory-assist devices, approved sharps containers, and leakproof bags. It also establishes standard operating procedures for the selection and use of the appropriate EMS PPE for the specific hazards of each incident.

STANDARDS ON PPE FOR HAZARDOUS MATERIALS OPERATIONS

Anyone involved in a hazardous materials incident must be protected against potential hazards. The purpose of PPE is to shield or isolate individuals from the chemical and physical hazards that may be encountered during hazardous materials responses. Structural fire-fighting protective clothing and equipment, even when certified to the NFPA standard, provide little or no protection against hazardous materials and should not be used for hazardous materials incidents.

EPA Levels of Protection

The EPA has outlined four levels of hazardous materials protective clothing and respiratory protection: A, B, C, and D. The EPA defined these levels of protection primarily for workers at hazardous waste sites, where emergency conditions do not usually exist. These levels are commonly, and often inappropriately, utilized by emergency responders.

Although EPA levels of protection might be used as the starting point for ensemble selection, each ensemble must be appropriate for the specific situation. Ensemble design or configuration alone is not sufficient to ensure adequate protection. In other words, just having the right components to form an ensemble is not enough. The EPA levels of protection do not define what performance the selected clothing or equipment must offer.

Degree of Coverage

For emergency response, the only acceptable types of protective clothing are fully encapsulating suits, or totally encapsulating suits, and nonencapsulating or "splash" suits combined with accessory clothing items, such as chemically resistant gloves and boots. These descriptions apply to how the clothing is designed and do not apply to performance.

Hazardous materials protective ensembles should completely cover both the wearer and the wearer's respiratory pro-

tection. Wearing SCBA or other respiratory equipment outside the ensemble exposes it to the contaminated environment. SCBA used in hazardous materials emergency response is generally the same as that for fire fighting. In general, respiratory protective equipment is not designed to resist chemical contamination and should be protected from these environments.

NFPA Standards

The two product standards for hazardous materials emergencies PPE are NFPA 1991, *Standard on Vapor-Protective Ensembles for Hazardous Materials Emergencies,* and NFPA 1992, *Standard on Liquid Splash-Protective Ensembles and Clothing for Hazardous Materials Emergencies.*

NFPA 1991 requires that SCBA be worn on the inside of vapor-protective suits. NFPA 1992 allows liquid splash-protective suits to be configured either with the SCBA on the inside or the outside. However, it is strongly recommended that respiratory equipment be worn inside the ensemble to prevent its failure and to reduce decontamination problems.

The chemical resistance data provided by the manufacturer of the ensemble should be studied. Technical data packages are required to be provided by the manufacturers of protective ensembles that are certified to NFPA 1991 or NFPA 1992. Manufacturers of vapor-protective ensembles provide permeation-resistance data for their products, and manufacturers of liquid splash-protective garments provide penetration-resistance data for their products. Data should be provided for every primary material in the ensemble, including the suit or garment, hood, visor, gloves, and boots.

Permeation data should include the chemical name, breakthrough time (how soon the chemical permeates), permeation rate (the rate that the chemical comes through), and system sensitivity (comparison of test results from different laboratories).

Ensemble or ensemble element materials that show no breakthrough or no penetration to a large number of chemicals are likely to have a broad range of chemical resistance. If there are specific chemicals within the response jurisdiction that have not been tested, the manufacturer should be asked to supply test data on these chemicals.

The manufacturer's technical data package should document all the features of the ensemble and describe what materials are used in its construction. It should cite specific limitations for the suit and what restrictions apply to its use. Procedures and instructions should be supplied for at least donning and doffing, inspection, maintenance, storage, decontamination, and use.

Vapor-Protective Ensembles

NFPA 1991 covers vapor-protective ensembles that are designed to provide "gastight" and "liquidtight" integrity and are intended for response situations where no chemical contact is permissible or where the exposure is unknown. These ensembles now provide the mandatory requirements for CBRN protection at terrorism incidents where no chemical contact is permissible or where the exposure is unknown. Formerly, this was covered in the 2001 edition of NFPA 1994, *Standard on Protective Ensembles for Chemical/Biological Terrorism Incidents,* Class 1 ensemble requirements.

Performance testing includes permeation resistance to a specific battery of chemicals and gases selected as representative of the classes of chemicals encountered during hazardous materials emergencies. Vapor-protective ensembles must resist permeation by the hazardous materials present during a response. Permeation occurs when chemical molecules diffuse through the material, often without any evidence of chemical attack. Permeation resistance is measured in terms of breakthrough time of at least 1 hour or more. Chemical permeation resistance must be met for each chemical specified in ASTM F1001, *Standard Guide for Selection of Chemicals to Evaluate Protective Clothing Materials.* Any additional chemicals or specific chemical mixtures for which the manufacturer is certifying the ensemble must meet the same permeation performance requirements. Additional performance testing includes gastight integrity, liquidtight integrity, overall suit function and integrity, suit ventilation rate, and physical durability.

Liquid-Splash Protective Ensembles and Protective Clothing

NFPA 1992 covers liquid splash-protective ensembles that are designed to protect emergency responders against liquid chemicals in the form of splashes but not against continuous liquid contact or chemical vapors and gases. Liquid splash-protective ensembles and clothing can be used for protection with liquid chemicals that do not present vapor hazards. Materials that prevent liquid penetration can still allow chemical permeation since this PPE does not offer gastight performance, even if duct tape is used to seal clothing interfaces.

NFPA 1992 specifies a battery of liquid chemicals that are representative of the classes of liquid chemicals likely to be encountered during hazardous materials emergencies. Liquid splash-protective ensembles are for use only for protection from liquids with low vapor pressures and with no known skin absorption toxicity. Liquid splash-protective suits cannot be used for known or suspected carcinogens.

Performance testing includes penetration resistance to a specific battery of liquid chemicals selected as representative of the classes of chemicals that are encountered during hazardous materials emergencies. Penetration resistance is measured in terms of penetration resistance time. A chemical penetration resistance time of at least 1 hour or more must be met for each of the specified chemicals. Any additional chemicals or specific chemical mixtures for which the manufacturer is certifying the ensemble or clothing must meet the same penetration performance requirements. Additional performance testing includes liquidtight integrity, overall suit function and integrity, and physical durability.

Chemical, Biological, Radiological, Nuclear (CBRN) Incident PPE

Called weapons of mass destruction (WMD) by the military community, these or similar CBRN agents are expected to be used in attacks against civilian populations by terrorists. On the civilian side, these agents may take a different form and different concentration than WMD agents in battlefield conditions and are called CBRN terrorism agents.

First Responders. Civilian emergency response personnel will most likely be the first responders to see and be exposed to these terrorism agents. Support from federal government agencies, including the military, will be delayed due to several reasons, the least of which are not assembly and deployment time, transportation time to the incident site, or being committed to similar simultaneous attacks on military installations. Local fire departments, police and other law enforcement agencies, hazardous materials response teams, and emergency medical services providers will be the civilian response.

It is incorrect to view these local government agencies as the "first responders" if that is understood to mean they are involved in only the initial stages. Even though they will be the first to respond, they will remain the responders throughout the duration of the incident. Although, in the United States, state and federal agencies may respond, they will be present to assist and support the local jurisdiction and not to assume command and take over the operation and all the problems.

Because CBRN terrorism agents are intended to injure, incapacitate, or kill large numbers of persons, it is obvious the responders must rapidly identify such situations and protect themselves so that they may help others. PPE does exist for civilian responders to these incidents, and more PPE will be available as the technology progresses. Little of the current military WMD PPE can "transfer" to civilian responders as it is designed for military scenarios where it is used under significantly different environments, operations style, supervision, and deployment conditions.

Limitations to Protection. Civilian emergency response organizations must instruct their personnel that although existing PPE for fire fighting, EMS, or hazardous materials operations might provide some low level of dermal protection for a very short exposure, there is no evaluation or procedure to determine how much protection would be offered by each "in-service" PPE. The fact is that "in-service" (i.e., "used") PPE that is not certified as providing CBRN protection most likely will not provide any protection at all, or might provide only a few seconds of limited protection before the wearer could face severe or lethal exposures. The same problem exists for law enforcement agencies whose normal everyday PPE is not capable of protection from CBRN exposures.

NFPA 1994, *Standard on Protective Ensembles for First Responders to CBRN Terrorism Incidents.* NFPA 1994 is the product standard for CBRN terrorism incident PPE. Although this standard still covers the requirements for three classes of ensembles, the former NFPA 1994 Class 1 ensemble is now covered in the requirements of NFPA 1991.* NFPA 1994 now covers Class 2, Class 3, and Class 4 protective ensembles for CBRN terrorism incidents.

The 2007 edition is the second edition of NFPA 1994. As noted, NFPA 1994 no longer specifies a Class 1 ensemble, but has left the designation "Class 1" vacant. A new Class 4 ensemble was added to provide particulate protection for emergency responders to incidents where no chemical or biological agent is identified but where a particulate threat is present (including "white powder" incidents).

The CBRN protection requirements of NFPA 1994 apply to all emergency first responders at CBRN incidents. Individual agencies (law enforcement, emergency medical, medical first receivers, fire, hazardous materials, and skilled trades) need to define the operations for which their personnel are trained and develop detailed purchase specifications to assure the ensembles are designed to best support their operational needs while providing the CBRN protection.

All Class 2, Class 3, and Class 4 CBRN protective ensembles are required to be certified with a specific respirator certified by NIOSH as a CBRN SCBA, a CBRN APR, or a CBRN PAPR, or multiple CBRN respirators.

NFPA 1994 ensembles are intended to be pristine ensembles maintained in their own package until needed for use. They are intended to be single-exposure PPE and then discarded. These protective ensembles are intended for protection of fire, law enforcement, emergency medical, skilled trades, and other emergency services personnel responding to CBRN terrorism incidents or for emergency services personnel exposed to victims, materials, or the general incident environment during assessment, extrication, rescue, decontamination, triage, and treatment operations.

Ensemble Classes. The three classes of ensembles were developed for use in environments that can be generally described by considering the following:

- Exposure and delivery method
- Potential for skin contact
- Contaminant identification and concentration level
- Persistency (longevity) of the contaminant
- Threat of contamination and cross-contamination

Selection of the appropriate class ensemble must be based on a thorough risk assessment of the incident.

Class 2 and 3 ensembles are designed and tested for permeation resistance to chemical warfare agents and liquid industrial chemicals but at lower exposure rates commensurate with the intended protection level for the respective class. Class 4 ensembles are designed and tested for particulate inward leakage.

All ensembles are tested at exposure rates commensurate with the intended protection level for the respective class, inward leakage of exhaust valves, overall ensemble function and integrity, and for burst strength, puncture propagation, seam strength, closure assembly strength, visual acuity of facepiece or visor, maximum suit airflow, and cold weather performance.

NFPA 1991 (as discussed earlier) also specifies chemical and biological protection requirements for vapor-protective ensembles.

*Class 1 ensembles, the highest level of protection from vapor and liquid IDLH hazards, are intended for use at known or suspected CBRN incidents where the identity or concentration of the vapor or liquid is unknown, where most victims appear dead or unconscious and not ambulatory, or where liquid contact is expected, and no direct skin contact or inhalation can be permitted. These ensembles are now covered exclusively by NFPA 1991 vapor-protective ensembles. This high level of protection would be selected at incidents where exposure of personnel at these levels will result in the substantial possibility of immediate death, or immediate serious injury or illness, or the severe impairment of the ability to escape.

STANDARDS ON PPE FOR SPECIAL OPERATIONS

Technical Rescue Operations

PPE for technical rescue operations, including urban search and rescue (USAR), provides protection from physical, environmental, thermal, electrical, chemical flash fire, chemical splash, and blood-borne hazards. Technical rescue operations are commonly performed at incidents involving building/structural collapse, machinery or vehicle accidents, confined space entry, trench/cave-in rescue, and rope rescue. These operations include the functions of victim search, extrication, rescue, body recovery, and site stabilization.

Technical rescue PPE includes garments, helmets, gloves, footwear, and eye and face protection. The clothing portion of these ensembles might also be part of other PPE elements, such as a layer(s) or portion(s) of certain fire-fighting PPE, EMS PPE, and station/work uniforms.

The product standard for USAR and other technical rescue PPE is NFPA 1951, *Standard on Protective Ensembles for Technical Rescue Incidents.* The 2007 edition is the second edition of NFPA 1951. The document's title has been changed to *Standard on Protective Ensembles for Technical Rescue Incidents* to clarify that the standard applies to all emergency services organizations that perform technical rescue incident operations and not just to urban search and rescue (USAR) teams of state or federal governments. It embraces the broader audience of emergency responders for which these types of protective ensembles are developed to provide protection from the expected hazards common to these operations.

This edition specifies requirements for the following three different types of technical rescue ensembles:

1. A *utility* ensemble that provides protection from physical hazards and provides a basic flame resistance for the ensemble and the elements of the ensemble and provides a high level of "breathability" for the ensemble to aid in reducing heat stress for the wearers
2. A *rescue and recovery* ensemble that provides all the physical protection of the *utility* ensemble and in addition a blood-borne pathogen barrier to afford protection from infection from injured or deceased victims
3. A *CBRN* ensemble that, in addition to all the protections of the *utility* and *rescue and recovery* ensembles, also provides limited protection from chemicals, biological agents, and radiological particulates during terrorism incidents where chemical warfare agents or weapons of mass destruction could be used

It remains the choice of emergency services organizations to select the appropriate ensembles for the protection of their emergency responders based on the expected and anticipated technical rescue incidents to which their respective organizations will or could respond.

These ensembles do not apply to PPE for any fire-fighting operations or hazardous materials operations outside of CBRN incidents, due to the severity of those specific exposures. The standard also does not apply to PPE for wilderness search and rescue, water and swiftwater rescue, contaminated water diving, or cave rescue operations.

NFPA 1951 provides performance testing, depending on which ensemble is being evaluated, for total heat loss of garments, tear strength, fabric breaking strength, seam strength, and resistance to abrasion, corrosion, liquid penetration, flame, blood-borne pathogen, limited flash fire, and CBRN agents.

Life Safety Rope Operations

The life safety rope and system components covered by the NFPA PPE standard addresses a type of rope and system that are used to support the weight of emergency responder personnel and civilians during rescue, fire fighting, and other emergency operations, as well as during training for such operations.

Life safety rope is not a utility rope used to secure, raise, lower, or support equipment or machinery. Life safety rope and the system components are not intended for industrial fall situations or for recreational uses and are also not intended for lead climbing, mountain rescue, or cave rescue operations.

Life safety rope is not a dynamic rope; it is a static, low-stretch rope intended for use where the fall factor will not be greater than 0.25. The types of rope covered in the NFPA PPE standard are life safety rope, escape rope, and throwlines. Life safety rope is classified as light use or general use, depending on the minimum breaking strength.

Escape rope is a single-purpose, one-time use, emergency self-rescue (or self-escape) rope and not considered a life safety rope. A throwline is a one-person rope intended to be thrown to a person during water rescue or to tether rescuers entering the water.

The types of system components covered are auxiliary equipment including ascending devices, buckles, carabiners, descent control devices, load-bearing connectors, rapid links, rope grab devices, and snap-links; belts including escape belts and ladder belts; hardware including portable anchors, pulleys, and rings; Classes 1, 2, and 3 life safety harness; and software including anchor straps, pick-off straps, rigging slings, and webbing.

The product standard for life safety rope PPE is NFPA 1983, *Standard on Life Safety Rope and Equipment for Emergency Services.* NFPA 1983 provides performance testing of life safety rope, escape rope, throwlines, life safety harness, belts, auxiliary equipment, hardware, and softwear and includes breaking strength, minimum and maximum elongation, dynamic drop, static load, tensile, corrosion resistance, diameter, melting resistance, and colorfastness.

SUMMARY

Personal protective clothing and equipment play an essential role in the safeguarding of emergency personnel against the hazards of fire fighting. All NFPA product and user standards, including manufacture, cleaning, maintenance, and fit, must be adhered to in order to ensure effectiveness of protection. Fire fighters must be trained in the proper use of PPC and PPE and must also be informed of their limitations. PPC and PPE alone cannot ensure safety from hazardous exposure and must be considered only

one factor in a defense system that includes physical fitness, well-planned emergency procedures, and teamwork.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on fire and emergency service protective clothing and protective equipment discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program*
NFPA 1581, *Standard on Fire Department Infection Control Program*

External Training Sources
Training Safety
Training Records

Key Terms

blood-borne pathogen, distance learning, education, fire fighter safety, fire service instructor, Hazardous Waste Operations and Emergency Response (HAZWOPER) Standard, job performance requirement (JPR), learning, live fire training, National Fire Academy training

This chapter is an overview of the broad challenge of providing training for fire and emergency service personnel. The challenge includes a continuous need for training throughout an individual's career. Changes in technology constantly affect the lives of fire fighters in many ways. New hazards evolve and create risks to the public and fire fighters, but technology also provides new ways to deal with the risks. Training helps sort out the differences.

Acquiring and maintaining a high level of training in fire and emergency service personnel is more than a matter of efficiency; it can at any moment become a matter of personal survival. When a fire fighter responds to an emergency incident, a situation is already out of control. With a shortened time to think things through, rapid emergency response makes effective training more important.

In a world of highly specialized medical, legal, and other types of professionals, fire fighters must also remain generalists ready to respond to a bewildering variety of emergency incidents. The next emergency response could be for a residence fire or a high-rise fire, a hazardous materials spill or an explosion, a vehicle rescue or a swiftwater rescue. The response could require checking on a smell of smoke, fighting a raging fire that threatens a structure's stability, or handling a terrorist incident with mass casualties. The call could be for a rescue in an underground confined space or high on the side of a cliff. Training for each response is complex, and the skills needed must already be learned before the current emergency.

For related topics, see Section 4, Chapter 1, "Human Behavior and Fire"; Section 12, Chapter 2, "Organizational Benchmarking and Performance Evaluation"; and Section 12, Chapter 14, "Fire Rescue Stations and Fire Service Training Centers."

NEED FOR TRAINING

Personal Training

Health Education. The difficulty of maintaining a public service for 24 hours every day and the potential need to respond to unlimited types of service requests every day should be ample motivation for fire and emergency service personnel to expect and deliver a high level of training. Even as the number of reported fires has decreased in the last 25 years,[1] the number of medical calls has increased. And even as the number of civilian deaths and injuries has decreased, the number of fire fighters who die or are injured on duty has remained at a level that is too high. Analysis of fire fighter deaths and injuries reveals a long list of training needs that should be addressed, and all of them should be revisited periodically.

Jerry W. Laughlin is assistant executive director at the Alabama Fire College. He is a former fire fighter and previously was editor at *Fire Command* and *Fire Engineering* magazines. He has served as NFPA staff liaison to the technical committees developing the fire service professional qualifications standards. He is currently pursuing a doctorate in higher education administration at the University of Alabama.

Between emergency alarms, there is a need for wellness training to increase the physical fitness of emergency responders. Almost half of all fire fighter deaths on duty are from sudden cardiac incidents.[2] There is ample medical evidence that known risk factors contribute to this high number of deaths.[3] Some risk factors cannot be changed, such as male gender and increasing age. However, most heart attacks suffered by fire service personnel are preventable. Wellness training that addresses modifiable risk factors is not difficult or expensive. Risk factors that can be influenced by training, diet, and exercise between emergency responses include smoking, high blood cholesterol, high blood pressure, physical inactivity, being overweight or obese, and diabetes.

Transportation Safety. Responding to emergency calls has the inherent risks of transporting personnel and equipment in heavy vehicles moving through other traffic. Training is clearly needed to improve awareness of these risks and to improve the skills needed to operate emergency vehicles. NFPA statistics show that "firefighters are more likely to die traveling to or from a fire than fighting one, and motor vehicles pose a greater hazard than flames."[4] Almost all of these vehicle deaths can be prevented by training personnel to operate emergency vehicles safely.

Although the fireground is as dangerous as it ever was, incident by incident, the decreasing total number of fires has been associated with a lower number of fatalities on the fireground over the last 25 years. Now less than a third of fire fighter deaths occur on the fireground.[5] However, it is again clear that the number of fire fighter deaths and injuries on the fireground could be reduced further through training.

Skill Sets. A single "routine" fire emergency incident calls for a complex set of fire fighter skills, and all fireground activities must be completed in rapid succession under stressful and physically demanding conditions. Without retraining, skills deteriorate. Continuing training is necessary to keep these important skills ready for instant use. A fire in the upstairs bedroom of a two-story house provides many examples of the complexity of needed fire fighter skills. Personnel must be trained and equipped to conduct a search for residents who may have been incapacitated by the fire or smoke. If a victim is found, training in emergency medical response is critical. Other personnel must be trained to rapidly provide water to quench the fire, using knowledge of water locations and skills for operating fire department pumps, hose, and nozzles. Other personnel must be trained to assess the buildup of heat and harmful smoke inside the structure and know how to make the right decision about ventilating the heat and smoke through a hole cut in the roof above the fire. All of these complex tasks must be coordinated by an incident commander trained in each of the different tasks, in the responsibilities of command, and in the details of overseeing all of the tasks underway at the same time.

It is clear that the tasks are not only numerous and complex but also highly specialized. Pump operators must have the experience needed to anticipate water needs at the fire. Every fire can have different hydraulic requirements, and the operator must be trained to adjust to every variable. The chemistry of fire and the nature of building construction must be considered by the person intending to ventilate a roof. Individuals must be well trained to use these numerous and specialized skills almost automatically. The success of every task on the fireground can be affected by how quickly the tasks can be completed. The speed of completing the tasks is affected by the level of training.

NFPA Requirements. National standards of competency further specify a personal need for training. NFPA 1500*, Standard on Fire Department Occupational Safety and Health Program,* requires training in many areas. An entire chapter of NFPA 1500 addresses training and education requirements as a department responsibility and as a personal responsibility. Paragraph 5.1.9 states: "As a duty function, members shall be responsible to maintain proficiency in their skills and knowledge, and to avail themselves of the professional development provided to the members through department training and education programs."[6]

Training as an Obligation to the Community

Communities choose to provide emergency response services for protection of the entire community. Communities then have expectations that the services will be available and effective when they are needed. In turn, fire and emergency service personnel have an obligation to develop and maintain appropriate skills. When a citizen's life, family, or property is threatened, fire fighters who perform well under these difficult conditions will earn the highest respect and admiration for the fire department, and community support of the department will be strengthened. But when fire fighters are not trained well enough to perform as expected, community respect and support can disappear. Many times the difference is in the training that the responders have received.

Training is not a one-time event. Knowledge and skill levels must be repeated in order to be maintained. Given the variety of incidents that a fire department may face, many types of fires are not frequently encountered. It is the same with hazardous materials that may be released. Each incident can be significantly different, and considerable time can elapse between similar incidents. Experience alone, therefore, is not enough to keep skills well practiced and ready for instant use. Continuing training is required to prevent degradation of skills.

In addition, new challenges can emerge as manufacturers invent ways to combine chemicals to develop useful new products. During the transportation and storage of chemicals that occur before they are combined, the chemicals can burn, explode, or escape their containers and thereby endanger the populace. If a leak or explosion occurs, fire fighters and hazardous materials response teams must respond. The evolving use of chemicals is yet another situation that forces emergency responders to stay well trained. In addition, fire departments must also be ready to respond to terrorist incidents, which requires even more training.

Federal Requirements

Training increases fire fighter safety, helps fire fighters meet the community's expectation for effective emergency response, and prepares fire fighters for the evolving world around them

that presents frequent new challenges. Training is also mandated by federal requirements. These rules are the result of demonstrated problems that have adversely affected the public or the emergency responders. Three important requirements relate to hazardous materials, respiratory protection, and communicable disease.

Hazardous Materials. The Occupational Safety and Health Administration (OSHA) developed hazardous materials regulations to increase safety in hazardous waste operations and related emergency response. Called HAZWOPER and officially designated as 29 CFR 1910.120, this federal regulation details the requirements of employers and responders to plan for and safely respond to emergency incidents. Training is specified for anyone who might respond: "Training for emergency response employees shall be completed before they are called upon to perform in real emergencies. Such training shall include the elements of the emergency response plan, standard operating procedures the employer has established for the job, the personal protective equipment to be worn and procedures for handling emergency incidents."[7] Refresher training is also specified: Employees trained under these requirements "shall receive annual refresher training of sufficient content and duration to maintain their competencies. . . ."[8]

Respiratory Protection. Fire fighter respiratory protection is required in federal regulation 29 CFR 1910.134. The regulation stipulates that employers, including fire departments, must provide breathing protection and training "when such equipment is necessary to protect the health of the employee. The employer shall provide the respirators which are applicable and suitable for the purpose intended."[9] The employer must also create a written respiratory protection program that includes "training of employees in the respiratory hazards to which they are potentially exposed during routine and emergency situations."[10]

Communicable Disease. The blood-borne pathogen federal regulation is intended to protect fire fighters and other employees from infections that could result from contact with another person's blood. This is Code of Federal Regulations number 29 CFR 1910.1030. For anyone who could have occupational exposure to blood-borne pathogens, the employer must provide precautions. Again, training is required: "Employers shall ensure that all employees with occupational exposure participate in a training program which must be provided at no cost to the employee and during working hours."[11] The training must be provided annually. Paragraph (g)(2) lists the training requirements.

State Requirements

Although every state might be expected to offer or encourage training for emergency responders, some states have specific requirements. Washington State, through the Department of Labor and Industries and the Washington Industrial Safety and Health Act, places clear responsibility for training on the employer fire department as follows: "The employer shall provide training and education for all members commensurate with those duties and functions that members are expected to perform. Such training and education shall be provided to members before they perform emergency activities. Fire service leaders and training instructors shall be provided with training and education which is more comprehensive than that provided to the general membership of the fire department."[12]

A further Washington State example addresses training frequency: "The employer shall assure that training and education is conducted frequently enough to assure that each member is able to perform the member's assigned duties and functions satisfactorily and in a safe manner so as not to endanger members or other employees. All members shall be provided with training at least annually. In addition, members who are expected to perform interior structural fire fighting shall be provided with an education session or training at least quarterly."[13] Live fire training in Washington is required to conform to NFPA 1403, *Standard on Live Fire Training Evolutions.*[14]

Other states also mandate that NFPA 1403 requirements for live fire training be followed. For example, Florida enacted such a law after suffering fire fighter fatalities during two live fire training incidents.[15] (See the section in this chapter entitled "Training Safety.") Through its Firefighters Occupational Safety and Health Act, Florida has long required fire fighter employers to "provide training and education for all fire fighters and supervisory personnel commensurate with those duties and functions that such fire fighters and supervisory personnel are expected to perform. Such training and education shall be provided to fire fighters and supervisory personnel before they perform any emergency activities or other activities requiring such training."[16] In other words, before a fire fighter can respond to any emergency, training must already have been provided. The law also states that the fire fighter must be able to perform any activity in a satisfactory and safe manner.

ORGANIZATION OF TRAINING DELIVERY

It might be argued that training for career and volunteer fire departments should be identical because fire behaves in the same way regardless of the kind of fire department that responds. There is merit in this argument, but real-world economics often results in different funding levels for a large-city career department and a rural volunteer department. Different funding levels, when they are present, affect the availability of instructor training, equipment purchases, and time devoted to training. Of course, there can be exceptions in which a volunteer department has greater funding and more commitment for training than a nearby career department. But the complexity of a large city always creates the necessity, if not the funding, for a more varied training program.

Career Departments

A career fire department has the ability to offer and mandate training in ways that a volunteer fire department might not. Larger departments are more likely to have the funding resources to maintain a complete fire training bureau with multiple instructors, ample technical and audiovisual equipment, and realistic training simulators. Smaller departments usually

have at least one individual dedicated to training activities for the department.

Career departments in large cities have the added challenge of a more variable fire and emergency risk. Transportation hubs can have a very high exposure from the large volumes of hazardous materials being stored or shipped into, out of, and through them. Most waterfront developments add more specialized risks while at the same time limiting access. In large cities, public assembly events are more likely to occur. Training must be made available to address these and other normal hazards of cities. With the usual higher funding for training in career departments, any failure to provide ample training would invite embarrassing press questions and public resentment concerning the funding that was invested but not used effectively.

Volunteer Departments

Volunteer fire training has its own unique challenges. Volunteer members have the added burden of a full-time job that often interferes with sufficient time for training. Volunteer departments protecting rural communities may have a very low level of response activity, which is fortunate for the community but allows fire-fighting skills to degrade from lack of frequent activity or practice. This in turn makes training extremely important.

Volunteer fire fighters often have fewer average years of experience in fire fighting compared to career fire fighters. The volunteer nature of their service and the demands of other primary jobs and families on limited free time make it harder for volunteers to sustain their service over many years. Training in the basics of fire fighting is a constant need in many volunteer departments, which can interfere with another vital need for specialized training in a variety of hazards that may be present even in a small rural community. Because the needs for training are so great and funding can be low, volunteer fire departments must be innovative to find ways to fund and offer continuous basic training. There is no excuse for any fire department lacking trained members to protect the public.

Comprehensive Training

A fire department's training program can be full service and comprehensive, minimal, or nonexistent, depending on available funds and the training orientation of the fire chief. A minimal or nonexistent training program should not be acceptable. Reports from the National Institute for Occupational Safety and Health (NIOSH),[17] describing the lessons learned from fire fighter fatalities in the United States, repeatedly list prevention warnings that indicate insufficient training. Each warning that follows is from a NIOSH report and describes actions that should have occurred but did not and contributed to a fire fighter fatality. Each of the following represents a training failure:

- "Instruct and train firefighters on initiating emergency traffic (Mayday—Mayday) when they become lost, disoriented, or trapped."
- "Ensure firefighters are trained to recognize the danger of operating above a fire."
- "Train on the SOPs, the incident command system, and lost firefighter procedures with mutual aid departments to establish interagency knowledge of equipment, procedures, and capabilities."
- "Ensure that firefighters from the ventilation crew and the attack crew coordinate their efforts."
- "Develop, implement, and enforce standard operating procedures (SOPs) on the safe operation of emergency vehicles which include the use of seat belts."
- "Ensure that all drivers of fire department vehicles receive driver training at least twice a year."
- "Ensure that the Incident Commander conducts a risk-versus-gain analysis prior to committing firefighters to the interior and continually assesses risk versus gain throughout the operations."
- "Ensure that firefighters train with thermal imaging cameras (TIC) and they are aware of their proper use and limitations."

These lessons from actual incidents demonstrate that any department needs a full-service comprehensive training program to best prepare its members for the dangerous conditions that they face. A fire department that cannot train its members to stay safe also cannot live up to the expectations of the community that depends on an effective response by the fire department.

Many fire departments have some training needs that are similar, such as the basic operation of water delivery, forcible entry, ventilation, use of personal protective equipment, and obvious others. Department needs can also be diverse according to the characteristics of the community protected. An urban department will have different training needs compared to a rural department. A community with heavy industrial risks requires different training than a community with mostly residential structures.

ENSURING QUALITY INSTRUCTION

Instructor Attributes

When a fire department commits to a full-service comprehensive training program to best protect its members and citizens, it will be necessary to consider the qualities of an instructor in order to adequately plan the training program and implement individual training classes. When the NFPA national standard on fire instructor professional qualifications, NFPA 1041*, Standard for Fire Service Instructor Professional Qualifications,* was first developed, it reflected on one message of the influential Wingspread fire service meeting in 1966: "Professionalism begins with education." The NFPA 1041 technical committee concurred and stated that "the quality of any educational program is only as good as its instructional staff."

The professional levels of competence of fire service instructors are the subject of NFPA 1041, which presents the following three levels of progression:

- A Level I instructor "has demonstrated the knowledge and ability to deliver instruction effectively from a prepared lesson plan, including instructional aids and evaluation instruments; adapt lesson plans to the unique requirements of the students and authority having jurisdiction; organize the learning environment so that learning is maximized; and

meet the record-keeping requirements of authority having jurisdiction."

- A Level II instructor is someone who, in addition to meeting Instructor I qualifications, "has demonstrated the knowledge and ability to develop individual lesson plans for a specific topic including learning objectives, instructional aids, and evaluation instruments; schedule training sessions based on overall training plan of authority having jurisdiction; and supervise and coordinate the activities of other instructors."
- A Level III instructor is someone who, in addition to meeting Instructor II qualifications, "has demonstrated the knowledge and ability to develop comprehensive training curriculum and programs for use by single or multiple organizations; conduct organization needs analysis; and develop training goals and implementation strategies."

A comprehensive full-service training program should have instructors who meet the requirements of this national standard to at least Level I. That means they have received training on the nature of instruction and have passed the standardized exam to demonstrate competence according to the national standard.

A certified fire service instructor has been exposed to learning opportunities related to communication skills, components of a lesson plan and how to use one, how to prepare and maintain training records, the laws of adult learning, learning styles, methods of instruction, organizing the learning environment, operation and maintenance of instructional equipment, test administration, skills checklists, the need for feedback, and the requirements of educational confidentiality.

It is possible for an experienced fire service instructor to be competent without the formal process of certification, but certification ensures that an individual's competence has been evaluated by more than one person. The best combination is experience and certification of competence to the established national standard of performance.

Nature of Learning

A proper training session is much more than someone standing up and talking about a fire service subject. Even being an expert in a fire service subject does not mean that the expert understands or is automatically good at instruction. Effective training instruction does depend in part on the instructor's subject matter knowledge and skills, but effective instruction also must consider the general principles of learning and the particular needs of adult learners. This statement sums up a body of educational research: "There is increasing evidence that the effectiveness of learning can be determined by the methods used to teach. In other words, the way material is presented has an effect on how well you understand and remember it."[18] Certainly the material must be understood and remembered so that it can be used when it is really needed during an emergency on the fireground.

Individuals in a group of seemingly similar fire fighters from a single department can differ significantly in how they learn best. This does not mean that instruction must be tailored for every variation in individual learning style. However, awareness of these learning style differences can increase the chances that the instruction can be tailored so that is actually useful to the greatest number of individuals who need to learn something new. Therefore, the subject matter expert does need to be aware of learning styles.

So-called laws of learning also can help the instructor to appreciate different impacts on learning. Many laws of learning were studied by Edward Thorndike in the 1920s and 1930s and have been further developed and confirmed through educational research in various other settings. Although they may have differing names,[19] these laws can be applied generally to the fire service.

Law of Exercise. The law of exercise is already frequently applied to the fire service. It states that a person learns best and retains information longer when there is a chance for meaningful practice and repetition during the learning. People learn by doing. Instructors use repetition, but they also make sure that the right skills are being practiced and that the practice is followed by positive feedback.

Law of Effect. When the instructor gives positive feedback following a student's demonstration of correct skills, the law of effect is being used. It states that learning is better when it results in satisfying consequences. This can include praise or any other type of reward that the student values. A positive effect is also present when the adult learner can immediately see the benefits from training. To a lesser extent, this law can have an undesirable result: If the attempt at learning is associated with negative feedback and frustration, learning can be weakened and less likely to persist. This can also be called the law of reinforcement.

Law of Relevance. Other researchers realized that learning is more effective when shown to be highly relevant to the learner's life and work. Fire service training generally follows this approach. Realistic training has higher relevance, which makes it tempting to provide for live fire training, but the overriding safety requirements should not be forgotten.

Law of Response Level. Students may sometimes grumble about their workload, but this law provides that students do only as much as is required of them. It states "learners master skills and knowledge at the level at which they are required to respond during the learning process." This should motivate instructors to maintain high standards and not let any training activity be performed casually, since people will tend to operate at the same level used in training.

Law of Emotional Learning. This law works well in the fire service training environment. It states that when learning events are accompanied by intense emotions, the learning will tend to be longer lasting. This law fits with highly realistic and even stressful training conditions. A variation is the law of intensity, which states that using an intensely vivid or realistic stimulus in learning will more likely result in a change of behavior. There is a limit to the application of this law. When the training scenario becomes too intense, it can become dangerous and interfere with learning.

Law of Expectations. This law states that learner attitudes affect what and how much they actually learn. They are more likely to learn when they expect the learning to be positive. This expectation can be influenced by personal history, course format, attitudes of fellow students, and instructor attitudes. Situations where students and instructors do not want to participate in the training usually result in low levels of learning.

Law of Recency. This law reminds us that recent learning is stronger than earlier learning. Memory deteriorates, which is why frequent retraining is necessary. Information and skills that are not being repeated are being replaced by whatever has been happening more recently.

This sample of the laws of learning makes the point that instructors can be more effective when they understand the fundamental conditions of the learning process. Fire service training may be mandatory, but the good instructor will not make it seem that way. Results are what count. As more schools are being held accountable for the learning of their students, they have started to change their emphasis from just teaching a subject to ensuring that actual learning takes place. This approach is also appropriate for training fire and emergency service personnel. Since the training often involves critical safety messages for fire fighters, it is clear that the instructors should not be satisfied with merely teaching a class; they must use various forms of assessment to ensure that the members are learning.

Evaluation of Learning

A weakness of much in-service fire training is that too often no effort is made to ensure that some learning has occurred and that some behavioral change will take place. In-service training is rarely accompanied by any testing to measure what was learned. The best evidence of learning comes from testing the subject knowledge or skill before starting the instruction and then retesting after the instruction. Comparison of the two results is a measurement of what was actually learned during the class.

Criterion-referenced testing is intended to measure what a person has learned compared to a specific body of knowledge (criteria). The learning can be measured by multiple-choice questions, fill-in-the-blank questions, demonstration, or performance of the skill that has been taught to ensure that it can be accomplished correctly. This kind of testing is included in certification courses for instructors, which again shows the value of formal instruction for instructors. It is unfortunate and potentially fatal for fire fighters to discover during an emergency incident that they did not actually learn some important material in a previous lecture.

Proper evaluation of learning does take extra time, but undiscovered substandard learning can be much more costly. Another aspect of evaluation is that care must be taken to make sure that the evaluation is accurate and valid. The importance of accurate evaluation of learning applies especially to certification courses where there can be serious consequences for failing the criterion-referenced test. State fire training agencies have the means to statistically check the accuracy of the tests they use. Taking the time and effort to properly evaluate learning is an obligation for any instructor or training program.

Education Versus Training

The terms *education* and *training* have different meanings, although they are often used interchangeably. The differences are more important as fire agencies become more complex and need more analytical management skills to build on the technical skills of manual fire fighting.

Fire and emergency training is designed to increase proficiency in a particular skill. Training can also be applied to increasing knowledge in a particular area. It starts with a performance objective that can be described specifically. It ends with the trainee being able to demonstrate an ability to perform according to the stated objective or, if the performance objective is not met, the instructional activity can continue. This can be described as a training loop, in which the instructor provides information input, the student is tested to demonstrate learning, and the instruction is revised as necessary to provide the proper input. A fire fighter certification class is an example of training.

Education is learning that provides the student with a foundation of general knowledge that helps in problem solving and effective thinking. Education involves learning to think and reason. Pursuing a college degree, with core courses in English, math, history, and psychology, is education, even when study in the major subject area results in increasing specific knowledge and skills. The overall process is education when it contributes to efficient analysis techniques.

Although they are different, education and training can be combined. Training by itself, when measured and successful, transfers established facts and skills. Then a behavior, such as ventilating a fire scene, is predictable within a generally defined range. Training by itself can be described as reflexive. The mental functions required to put training techniques into practice could be considered relatively passive when compared to educational analysis. Education provides ways for the student to further analyze and understand why and what kind of ventilation is appropriate for varying conditions. Fire scenes are not always confined to the defined range covered in the ventilation training. There could be, for example, unique reasons why ventilation is not the correct solution in a particular situation. With broader education combined with training, the fire fighter or fire officer can better observe and apply critical thinking and reach informed conclusions.

Education and critical thinking become increasingly important as an individual advances in rank within a fire department. College attendance is not the only way to acquire education, but it is the most efficient way. Improved critical thinking can be the result of long years of experience, but not everyone grows at the same rate from the same experiences.

National Fire Academy Superintendent Dr. Denis Onieal believes that the educational component is most important in considering the fire service as a profession. "Many feel that the distinguishing characteristics of a profession," he writes, "are years of formal education, approval of an accrediting board, and continuing education requirements."[20] Onieal calls for combining our localized systems of training and education into a national one in order to demonstrate a more convincing professionalism. He would integrate the following four existing parts:

1. Training systems now available through local and state agencies and the National Fire Academy (NFA)
2. Standardization of the education systems now available through 2-year and 4-year colleges and universities and through NFA
3. Independent assessment of skills now available through the Pro Board and IFSAC
4. Broader reciprocity among systems of training and education

INTERNAL TRAINING PROGRAMS

Recruit Training

Recruit training is the basic staple of fire service training. Although some fire fighters transfer in from other departments, the typical candidate is completely new to the fire service. Training for this individual must start at the beginning. Although it has been noted that different types of departments in different communities will have different overall training needs, the basic recruit training of any fire fighter should be the same. A fire in one room of a one-story home requires the same response skills whether the department is career or volunteer, suburban or rural.

The recognized standard of fire fighter performance when the duties are primarily related to structural fires is NFPA 1001, *Standard for Fire Fighter Professional Qualifications.* Most state fire training agencies and progressive fire departments use this standard for developing a recruit training course. The standard describes the minimum job performance requirements for fire fighters in the duty areas of communications; fireground operations; rescue operations; and prevention, preparedness, and maintenance. For the recruit fire fighter, there are 19 listed job performance requirements in the duty area of fireground operations, each with related requisite knowledge and skills.

NFPA 1001 also includes an annex with information on how to use the job performance requirements (JPRs) in curriculum development and training design and evaluation. According to Annex B: "The statements contained in this document that refer to job performance were designed and written as JPRs. Although a resemblance to instructional objectives might be present, these statements should not be used in a teaching situation until after they have been modified for instructional use. JPRs state the behaviors required to perform specific skill(s) on the job, as opposed to a learning situation. These statements should be converted into instructional objectives with behaviors, conditions, and standards that can be measured within the teaching/learning environment. A JPR that requires a fire fighter to 'ventilate a pitched roof' should be converted into a measurable instructional objective for use when teaching the skill."

In-Service Training

In-service training sessions are conducted during the normal departmental work shift. Depending on the equipment available as instructional aids, any type of fire service training can be done on an in-service basis. The understanding is that any emergency call or any administrative assignment coming from higher authority will take precedence, and the training will be interrupted until the emergency or the other assignment is completed. When interruptions occur, training effectiveness can be reduced. The in-service instructor is usually from within the department or may be an officer or other member of the crew receiving training. This arrangement has the advantage of being economical, since no additional costs are incurred by instructors who are already on the payroll. A disadvantage is that the training session can suffer from distractions that interfere with learning. Members of the public may enter the station during the training with questions for the officer or some member of the crew. The station phone may ring. After returning from an emergency call, the training may be cut short due to meals or previously scheduled assignments. Some good training can occur in an in-service setting, but it is not the ideal arrangement.

Specialized Courses

The nature of specialized training often involves more detailed planning, special equipment not available at each station, or multiple crews receiving the same training at the same time. Specialized courses are often conducted at a central location such as a training bureau. Rather than a shift supervisor conducting the training, as during in-service training, specialized courses may require specialist instructors. Examples of specialized courses are new training procedures that must be extended to all personnel in a short time frame (such as the adoption of the National Incident Management System), training for new equipment being brought into the department (such as an aerial device or a thermal imaging camera), and highly technical courses (such as surface water rescue or hazardous materials response).

Training for each of these examples should also include a method of assessment to confirm that the intended learning actually occurred and that the training was worthwhile. Also important for specialized courses is to add documentation of this specialized training to the permanent training record of every individual participating in the session (see the section in this chapter entitled "Training Records").

Special Operations Training

Numerous public events remind us of ever-present dangers that call for special operations training for incidents that are outside the realm of routine fire and emergency service duties. Examples can be seen in such diverse incidents as terrorist attacks, major transportation accidents involving hazardous materials spills and explosions, and natural episodes such as hurricanes and multiple tornadoes. Although such incidents occur infrequently, when they break, the demands on fire and emergency services can be the most challenging and expensive situations where the highest level of training is required.

The events of September 11, 2001, provide grim reminders of the threat of overwhelming terrorist incidents using weapons of mass destruction. The Oklahoma City bombing is evidence that the threats can be internal to a country as well as external. In any event the training preparation is the same. Federal funding has provided extended training opportunities, but it remains to be seen if permanent lessons have been learned about training and preparedness. The 9/11 Commission report expresses

concern that "We learned that the institutions charged with protecting our borders, civil aviation, and national security did not understand how grave this threat could be, and did not adjust their policies, plans, and practices to deter or defeat it." Will the fire service be better trained and better prepared next time?

Transportation of hazardous materials across the United States is routine but still results periodically in multiple fatalities. In 2004 and 2005, there were train derailments in South Carolina and Texas that resulted in the spillage of the same dangerous chemical, chlorine. Fire departments protecting communities along these railways did not have comprehensive response training complying to the requirements of NFPA 472*, Standard for Professional Competence of Responders to Hazardous Materials Incidents.* Transportation of chemicals may be normal, but emergency service response to spills of any dangerous chemical is not yet normalized. Much work is still to be done to train these responders.

Successive hurricanes force home the importance of special operations training for responding to major natural disasters. At the same time the range of needed training has greatly expanded. From hurricanes like Katrina, responders learned of the importance of backup systems for communications, basic supplies such as batteries, and personnel accountability. A hurricane is an example of the need for multiagency training, since the response will involve multiple overlapping jurisdictions.

Training Classrooms, Buildings, Grounds, and Equipment

It has been mentioned that during training, learning is reduced when there are distractions during the instruction. Distractions can include the occurrence of unrelated physical and noisy activities in the vicinity of the instruction that draw the attention of the student away from the instruction. Ringing phones, fire department radios, and normal fire station activity are examples. For many reasons, classroom training sessions need a proper classroom environment. Trying to conduct classroom-type instruction in an open fire station engine room is difficult. A separate classroom is preferred, with desks or tables for writing, audiovisual equipment, adequate lighting and ventilation, and access to the tools that might be part of the instruction.

NFPA 1402*, Guide to Building Fire Service Training Centers,* provides valuable information for functional and safe training environments. This document addresses facility components and planning considerations, classroom needs, drill tower construction and use, special structures for live fire and smoke training, and space and equipment for outside training activities. Mobile training units are also discussed.

Classrooms and Libraries. For classrooms, NFPA 1402 states that "classroom size is dictated by the number of students and the type of training to be conducted." The guide serves to remind users of some important considerations for training facilities without being overly restrictive. Most hands-on skills training requires more space than instruction that is lecture only. Audiovisual equipment to supplement instruction is important. A good instructional facility will have functional seating and writing surfaces, with a common example being tables and stacking chairs for greater flexibility. Lighting and ventilation need to be adjustable to maintain a comfortable learning environment.

A library of fire-related books and magazines is an essential part of fire service training. The library should include references for departmental regulations, procedures, and history. Copies of national standards should be included. Computers and Internet access are becoming common to all libraries.

Realistic Training Simulations. Drill towers, smoke rooms, and live fire training structures are expensive to build properly, but they are important for training in basic fire fighting. Training towers and smoke and burn rooms allow realistic training simulations that help build confidence in fire fighters. The height of the tower should be typical of the buildings found in the locale, according to NFPA 1402. The value of realistic training simulation also introduces an extra responsibility to consider safety during this training (see the section later in this chapter entitled "Training Safety"). NFPA 1402, paragraph 8.18, recommends that "consideration should be given to the need for an observation/control tower in order to monitor various training functions from one location."

To reduce the frequency of disruption of training due to department emergency response, equipment used for training should be exclusively for training. Otherwise, the training of out-of-service personnel would be interrupted if in-service equipment is taken out of the classroom to respond to an emergency. This is a waste of time that is more costly than the purchase of equipment dedicated for training purposes.

High-Tech Training Center. Most training centers have been in existence for many years. They may be intended to serve a single department's needs, or several departments in a county or region may cooperate to maintain a training center. Most state-level training centers have also been in existence for many years. One of the newest and most comprehensive training centers has been built for the Tarrant County College Fire Service Training Center in Fort Worth, Texas. This 23-acre, $18 million complex with a realistic, all-hazard cityscape provides an impressive number of scenarios for realistic training. This training center calls itself a "high-tech theme park for firefighters."[21] Figure 12.10.1 shows fire fighters engaged in realistic training exercises.

The cityscape at the college is indeed a small city with built-in associated hazards designed to allow challenging training while maintaining safety controls. There are residential, commercial, warehouse, and high-rise structures that add realism to training for size-up, exposure protection, and apparatus placement. A train derailment and 18-wheeler truck fire scenarios can be used, and there are sites for trench and confined space rescue. The center may have the only controlled swiftwater rescue site anywhere available for fire service training.

One of the main motivations for the training center design was to provide a live fire training environment without the safety risks of acquired structures. As a result, the Tarrant County College Fire Service Training Center is one of the largest computer-controlled, gas-fired facilities in the world, according to the school. It features six separate live fire buildings.

FIGURE 12.10.1 Realistic Training Exercises (Courtesy of Tarrant County College)

In addition to the real-world props across the property, there is a 48,000 ft^2 (4460 m^2) classroom and administration building. A high-tech command and control center occupies the third floor, where operators can program, initiate, and monitor all training activities. Control has been emphasized throughout the complex. At the swiftwater site, the "river" flow can change from 80,000 gallons per minute (302,400 L/min) to a trickle with the turn of a switch.

The price tag of the Tarrant County College Fire Service Training Center means that the fire service cannot expect to see these facilities popping up everywhere, but it does represent what is possible in realistic training.

EXTERNAL TRAINING SOURCES

State Fire Training Agencies

Many states have designated an official agency to provide training for fire and emergency personnel throughout the state. In most cases there is a similar legislative authority, but there are significant differences in how state fire training agencies are funded. Fire fighter training is mandated in some states and is voluntary in others. With more funding, state fire agencies typically are able to offer more services.

The earliest state training programs focused almost exclusively on the basic skills of using hose and ladders and operating fire pumpers. Since fire departments in larger cities usually had staff to operate their own training sections, state fire training was often aimed at smaller departments that did not have the resources for a separate training staff. Individual state instructors, many of them retired fire fighters from larger cities, commonly traveled around a state and offered skills training to rural fire departments. The training was informal and the quality varied, depending on the experiences and abilities of the instructor.

Concerns about the adequacy and inconsistency of fire department training activities began to be expressed more forcefully by fire service leaders in the late 1960s. These concerns led to more calls for a set of performance standards to be used for acceptable levels of training and professionalism. Today, the core of most state fire training agencies involves more formal courses based on national standards rather than state or individual preferences.

Starting in the 1980s, state agencies began increasing use of NFPA's national professional qualifications standards to guide training. The use of a national standard was an idea that state political leaders could understand and support and has been accompanied by a rise in the funding for and importance of state certification authority and national accreditation. The organization of state training directors is the North American Fire Training Directors (http://www.nftd.org).

Certification. Certification in state training programs implies valuable benefits for students and for the departments sending the students for training. Certification is a written assurance to the student, the sponsoring fire chief, and the home community that the student conforms to specified requirements. Students should understand the different meanings of certification so that they can assure themselves that they are getting the training that they and their departments need.

The basic meaning of certification may be represented by a certificate of attendance, which usually indicates only an assurance that the student was present when a course of instruction was presented. With a certificate of attendance there is no automatic assurance as to the specific content of the course. There is no measurement of actual learning, such as an exam. One may infer the course content from the title, and there may be a course outline, but there is no accountability for skills learned. A student's experience in class could be passive with limited learning, but the student might still qualify for a certificate of attendance. To be more informative, this certification should specify the length of attendance in the course.

When a course has more requirements than simple attendance and it includes an examination of some kind to measure learning, the result for successful students who demonstrate minimum learning may be a certificate of completion. A person evaluating such a certification would need to know how course completion was defined. A fire training course might include requirements for demonstrating both knowledge and

skills, so someone evaluating a certificate of completion needs a way to clarify exactly what was completed. Another factor for evaluating a certificate of completion is the authority of the individual or agency issuing the certification. Someone's mother could physically issue a printed certificate, but her authority and credibility would be evaluated as weak. On the other hand, when an authorized state agency issues a certification of completion, the credibility of the course content can be judged as higher.

Certification to national standards has additional advantages and credibility. Ideally, this certification provides written assurance that a recognized national standard of performance has been met. This assurance should be the result of successful completion of a test based on the national standard. The highest credibility for a certification to national standards is when the certification is accredited.

Accreditation. Accreditation in the fire service is a system of evaluating the certifiers. The award of accreditation to a state fire training agency is a written seal of approval according the definition of accreditation. Creation of an accreditation system in the fire service was an important quality assurance step in making fire service training more valid and reliable. By observing other professions, fire service leaders in the 1960s who wanted to eliminate the unevenness of many training courses based on personal preferences proposed the National Professional Qualifications System, which was created in 1972.[22] Professional qualifications standards for specific fire-fighting job categories were the next step. Under their own authority, states could certify that individuals had been trained and were known to meet the requirements of the national standard.

The best assurance that the state program indeed meets the national standard is demonstrated when the state actions are evaluated by an independent third-party organization to ensure quality and eliminate politics or favoritism. The first national accrediting organization, set up by the Joint Council of National Fire Service Organizations, was the National Board on Fire Service Professional Qualifications (Pro Board, http://www.theproboard.org). A later accrediting organization, the International Fire Service Accreditation Congress (IFSAC, http://www.ifsac.org), grew out of Oklahoma State University. Both evaluate state fire training courses based on the same national standards from NFPA.

As a result, the accredited certification has the highest credibility and provides full disclosure to students about the definition of their certification. For example, a student awarded fire investigator certification from an accredited state fire training agency has assurance that he or she has demonstrated successful completion of tests measuring the knowledge and skills as specified in the national standard, NFPA 1033*, Standard for Professional Qualifications for Fire Investigator,* and that the state certifier has been checked by the independent third-party Pro Board and IFSAC and confirmed as having properly assessed the student's competency.

The Pro Board and IFSAC accrediting organizations use the national professional qualifications standards to accredit certification for the following subjects and levels (new subjects and levels may be added according to demonstrated need):

NFPA 472: Hazardous Materials Response for Awareness, Operational, Technician, Incident Commander
NFPA 1001: Fire Fighter I, II
NFPA 1002: Fire Apparatus Driver/Operator for Pumper, Aerial, Tiller, Wildland, Airport Rescue and Firefighting, and Mobile Water Supply Apparatus
NFPA 1003: Airport Fire Fighter
NFPA 1006: Technician Level for Rope Rescue, Surface Water Rescue, Vehicle and Machinery Rescue, Confined Space, Structural Collapse Rescue, Trench Rescue, Subterranean Rescue, Dive Rescue, and Wilderness Rescue
NFPA 1021: Fire Officer I, II, III, IV
NFPA 1031: Fire Inspector I, II, III; Plan Examiner I, II
NFPA 1033: Fire Investigator
NFPA 1035: Fire and Life Safety Educator I, II, III; Public Information Officer; Juvenile Firesetter Intervention Specialist I, II
NFPA 1041: Fire Service Instructor I, II, III
NFPA 1051: Wildland Fire Fighter I, II; Wildland Fire Officer I, II; Wildland/Urban Interface Protection Specialist, Coordinator
NFPA 1061: Public Safety Telecommunicator I, II
NFPA 1071: Emergency Vehicle Technician I, II, III
NFPA 1081: Fire Brigade Member for Incipient Industrial, Advanced Exterior Industrial, Interior Structural Industrial, Industrial Fire Brigade Leader
NFPA 1521: Health and Safety Officer, Incident Safety Officer

Federal Training Sources

National Fire Academy. The *America Burning*[23] report in 1973 documented the serious nature of the nation's fire problem and concluded that fire prevention and control should remain primarily local responsibilities. However, the commission appointed to study the federal fire problem at that time also recommended a new federal government agency "where the Nation's fire problem is viewed in its entirety, and which encourages attention to aspects of the problem that have been neglected" (p. x). Also recommended was the establishment of a "National Fire Academy for the advanced education of fire service officers and for assistance to state and local training program" (p. xi).

The National Fire Academy (NFA) has completed more than 30 years of operation and has won the respect of the fire service. Its educational courses are offered at the resident facility in Emmitsburg, Maryland, and throughout the nation in cooperation with state and local fire training organizations. Some courses are offered in distance learning formats. Leaving basic training to local fire departments and state fire training agencies, NFA resident courses deliver "specialized training courses and advanced management programs of national impact"[24] in an intensive learning environment.

Emergency Management Institute. Training to minimize the impact of natural and technological disasters on the American

public is the emphasis of the Emergency Management Institute (EMI). Its intended audience includes the fire service, but it serves the broader world of emergency management personnel in federal, state, and local governments and also volunteer organizations and other public and private sector representatives. EMI shares the campus of the National Fire Academy in Emmitsburg, Maryland. Courses are taught in residence at EMI and also in the states. Nonresident courses taught in the states are through cooperative agreements with state emergency management agencies.

Office of Domestic Preparedness. The United States Department of Homeland Security Office of Domestic Preparedness (ODP) "provides tailored training to enhance the capacity of states and local jurisdictions to prevent, deter, and respond safely and effectively to incidents of terrorism involving weapons of mass destruction."[25] ODP training is aimed at the full range of first responders, not just fire and emergency medical services.

ODP began in 1998 as a part of the Justice Department, but it was transferred to the Department of Homeland Security in 2002. Other federal training activities were transferred within Homeland Security with the title of Office of State and Local Government Coordination and Preparedness (SLGCP). This office administers the Assistance to Firefighters Grant Program. Grant funds can be used for a variety of fire service needs, including training.

Where the National Fire Academy specifically works with state fire training agencies and local fire departments to extend the outreach of NFA courses, OPD and SLGCP have a narrow coalition of training partners for the development and delivery of its training programs. A recent trend has begun to place more emphasis on partnering with more state and local fire agencies to meet the needs of first responder training.

Colleges and Universities

Individuals in fire and emergency services, as with individuals in any technical and managerial field, are increasingly valuing opportunities for higher education in fire protection and emergency medicine. Colleges and universities have been increasing these opportunities through a wider choice of college-credit courses and through additional degree and certificate programs at all levels.

Associate Degree. Community colleges have long been a source for associate degree programs in fire science technology and fire program administration. An associate degree is becoming more common as a requirement for fire department promotion to higher levels of advancement. When not tied to promotion consideration, some fire departments give value to higher education at the associate degree level by offering salary increases when the degrees are work related. A fire science technology degree also prepares an individual for a career in other areas of fire protection. A fire administration associate degree is especially helpful for someone seeking promotion, or it can be used to qualify for positions in fire safety organizations.

Associate degree fire science programs in community colleges combine study in general education subjects such as English, math, and chemistry with specialty fire protection courses such as fire hydraulics, hazardous waste operations, and building construction as related to fire suppression. Associate degree administration programs include the same general education programs and combine them with more management courses. Some programs may allow limited credit for fire department experiences. More formal programs often allow credit for previous state fire training accredited certifications. Some fire service management programs include teaching such certification courses as Fire Officer III and Fire Officer IV as part of the degree curriculum.

Bachelor's Degree. Universities in all parts of the United States now offer bachelor's degrees related to fire protection. Many are created to allow easy transferability of fire protection associate degrees from community colleges. Bachelor programs may also have several types of specialization, some with application in fire departments and some with application in other areas of fire protection. One state university bachelor's degree in fire protection has options for fire protection administration, fire protection engineering technology, fire and explosion investigation, industrial safety and risk management, and safety and industrial relations. There are also many opportunities for master's and even doctoral degree programs in fire protection that did not exist even 10 years ago.

Distance Learning Opportunities

Distance learning via the Internet has greatly expanded options for fire and emergency training. The fact that virtually every community college and university offers some classes online demonstrates how mainstream this relatively new format has become. The widespread success of online learning suggests that colleges and universities have found it to be successful. This is backed up by educational research showing that measurable student learning and student satisfaction with online courses can be equal to the learning and satisfaction in regular classroom courses.

Online learning can be especially important to adult learners. The typical advantages of online learning often fit closely with adult situations. A training course taught online means that the work of learning can be accomplished at home and on the weekends, so that the adult with a full-time job and family responsibilities does not have to juggle scheduled classes that may require an inconvenient commute. Online learning requires the same effort as classroom learning, but the schedule flexibility may be a critical consideration.

Not all fire and emergency service training can be provided in an online learning format. A fire fighter training course featuring many skill development requirements may not ever be feasible online, but an accredited certification course for Fire Officer I has already been conducted online by a state fire training agency.[26]

Not all online learning courses are created equal. Much variety exists in the educational value of courses labeled as online learning. Some nonrecommended online learning formats allow a single student to work alone without any deadlines for assignments, and the course content may be nothing

more than a textbook placed online for student reading. The learning is expected to occur simply from the student flipping the pages and reading the material online. Student satisfaction and completion rates in these courses are not as high as in other formats.

College and university online courses often follow a common format that has many of the successful features of a classroom course. About 80 percent of college and university online courses use similar course management software interfaces, named Blackboard and WebCT, to present online information to students. The course is presented in a normal semester or quarter time frame, and students participate in the class together, although at a distance. Research on this format shows good educational results. One particular benefit comes from student interaction, although again from a distance and in writing. Research shows that important learning, whether in a classroom or online, comes from student interaction during group discussion about the course content.

Training Companies

For-profit training companies have increased their offerings of training opportunities for fire and emergency personnel, even to the level of college courses. For-profit companies competing with colleges to provide technical training are usually big operations with a regional or national reach. In the fire service, the company may be just one or a few instructors with prior fire department experience or specialty experience. For-profit training can be seen with specialty areas in technical rescue, water rescue, and hazardous materials response.

The quality of for-profit training companies depends on the technical and instructional experience of the trainer. When such courses do not usually claim to fully address any national standard and the training company lacks independent third-party accreditation endorsement, anyone contracting for training must make an extra effort to be sure of what training is needed and what quality can be delivered.

Fire Service Organizations

In the United States and other countries, the following not-for-profit associations provide a valuable service to the fire service community in terms of training and other resources:

- The International Association of Fire Chiefs (IAFC, http://www.iafc.org) is an international trade association of fire chiefs. Membership is restricted to upper-level officers in fire departments. IAFC provides a large annual conference and trade show along with an advisory service and publications for its members. This organization also operates the Chief Fire Officer Certification project.
- The International Association of Fire Fighters (IAFF, http://www.iaff.org) is a national labor union representing career fire fighters throughout North America. Extensive advisory and training services are offered to its members with a focus on fire fighter health and safety.
- The International Fire Service Training Association (IFSTA, http://www.ifsta.org) is an advisory group to Fire Protection Publications, a division of Oklahoma State University. Membership is by invitation only. The group reviews and revises the extensive fire service training materials issued by Fire Protection Publications.
- The International Society of Fire Service Instructors (ISFSI, http://www.isfsi.org) is a trade association of individuals engaged in or interested in fire service training. The society provides conferences, seminars, and some training materials for its members and others.
- The National Fire Protection Association (NFPA, http://www.nfpa.org) is a public advocacy association that primarily develops voluntary consensus standards. Many of those standards apply to the fire service and provide valuable technical guidance. In addition, NFPA provides training materials and staff resources in support of fire and emergency service training.
- The National Volunteer Fire Council (NVFC, http://www.nvfc.org) is an organization whose membership is made up of delegates from state volunteer fire service organizations. It also has individual fire departments and fire fighter memberships. The organization is primarily engaged in lobbying for volunteer fire service issues but does provide some valuable training programs and resources.

There are typically several fire service organizations in each state and province that mirror the work of associations at the national level. State and local fire fighters, fire chiefs, fire instructors, and other associations vary in their commitment to training, but nearly all have some resources to offer.

TRAINING SAFETY

Injuries and Fatalities

Fire fighter injuries and fatalities during training in the last 25 years suggest that instructors can forget that a realistic training scenario can have disastrous results when safety is not a paramount consideration. Guidance for realistic but safe training can be found in NFPA 1403*, Standard on Live Fire Training Evolutions.* Development of this document started after numerous training deaths occurred across the United States, especially the tragic deaths of two fire fighters in 1982 during live fire training in Boulder, Colorado, using an abandoned wood-frame building. Rapid fire spread across a combustible low-density fiberboard ceiling, an inadequate water supply, inadequate exits, and a general lack of planning for the potential dangers contributed to these fatalities. The first edition of this standard was in 1986, with revisions following as more experience was gained in subsequent years.

Unfortunately, the availability of this safety guidance sometimes has been overlooked or ignored, with continued disastrous results. Three more fire fighters died in a live fire training exercise in 1987 in Milford, Michigan. Multiple fires had been set in an old frame house in an attempt to create a realistic fire scenario for training. The scenario, with a lack of planning, insufficient paths of escape, inadequate water supply, and large amounts of accelerants, was not in compliance with NFPA 1403. Four area fire departments took part in this exercise, but safety was not a sufficient priority to prevent the unanticipated flashover that occurred with fire fighters still inside.

Failure to follow the requirements of this important standard continues. The following newspaper and magazine headlines remind us of the consequences:

- "Instructor Suspended over Death of Trainee"[27] (Maryland)
- "Apparent Flashover at Controlled Burning Traps, Kills Delaware Asst. Chief"[28]
- "Iowa Firefighter Brothers Burned During Training"[29]
- "Career Lieutenant and Fire Fighter Die in a Flashover During a Live-Fire Training Evolution"[30] (Florida)
- "Volunteer Fire Fighter Dies and Two Others Are Injured During Live-Burn Training"[31] (New York)

The foregoing Florida headline incident from 2002 occurred in a vacant concrete-block dwelling. A fire in the structure was started to accompany search and rescue training. As a result, the two fire fighters in the training exercise did not have a ready water supply. As in the Boulder and Milford fatalities, there were insufficient paths of escape. This incident had designated safety officers and a rapid intervention team, but the fuel load contributed to a flashover only 3 minutes later. Four instructors positioned inside the structure to serve as interior safety officers were able to exit successfully, but the fire lieutenant and fire fighter in the training exercise died from smoke inhalation and thermal injuries. Now state law in Florida requires that training fires be in compliance with NFPA 1403.

The foregoing New York headline incident from 2001 forced a wider fire service audience to become aware of NFPA 1403 when the fire department officer supervising the training exercise was charged with felony counts of manslaughter and assault. The fire fighter trainee who died was 19 years old. The training officer was later convicted of criminally negligent homicide. During sentencing the judge said, "This was not an accident. This was a series of bad decisions, decisions that should never, ever have been made." Now the state offers two programs to prevent a reccurrence of this type of incident: "Live Fire Training Safety" and "Conducting Live Fire Training Evolutions." Both reference NFPA 1403.

Maintaining Controlled Training

NFPA 1403 explains its purpose with this statement: "The ongoing training of fire fighters is the cornerstone of good fire protection in today's world. However, the benefits derived from live fire training can be negated by the injuries and deaths suffered by fire fighters under unsafe and poorly supervised training conditions." Separate chapters address ways to maintain controlled training in acquired structures and in gas-fired and non-gas-fired training center buildings, using exterior props, and using exterior Class B fires.

The chapter on acquired structures for live fire training is especially important because the most preventable injuries and fatalities occur in acquired structures. It calls for students to have prior training to help them understand safety issues and recognize normal and abnormal fire behavior. The structure itself must undergo special preparations to minimize factors that contribute to uncontrolled burning. Fuel loads are limited. Prior to beginning any training fire, participants in a live fire exercise must become familiar with the building, the exit arrangements, and the plan for the training. Adequate water supplies must be available, and training instructors must be available in sufficient numbers to supervise the burn. Flammable or combustible liquids are not allowed to fuel the fire in these exercises.

TRAINING RECORDS

Training activities must be recorded and updated for easy retrieval. They provide a source of information for effective management decisions for planning and budgeting. Records document and guide professional development for all fire and emergency service personnel. Such records show who has had and who needs training for certification and recertification, internally and externally obtained education, and general compliance with personnel performance standards.

Fire training records are also important to meet various legal and statutory requirements, such as those from the Occupational Safety and Health Administration (OSHA). Fire department records are generally public documents, and citizens or members of the press may have the right to access these public records. But some records, such as test questions and employee personal training records, are not freely available to the public. However, these records are subject to disclosure through a court order or, in some cases, through written permission of the employee. The fire department or emergency agency must have clear-cut guidelines to spell out public access and to prevent the unnecessary and illegal disclosure of confidential information. Other NFPA standards also specify accurate and complete training records, including NFPA 1403 and NFPA 1500.

Guidance for record keeping is available in NFPA 1401, *Recommended Practice for Fire Service Training Reports and Records.* Separate chapters address elements and types of training documents, legal aspects of record keeping, and evaluating the effectiveness of the training records system.

Training elements generally include information about the who-what-when-where-why of training for each individual member of the organization. Every type of training that a department offers should be documented by records. Records may be used to identify, investigate, evaluate, or solve various problems. A resulting report should follow five steps as outlined in NFPA 1401 and summarized here as follows:

1. State the purpose and scope of the report.
2. Outline the method or procedure followed.
3. Present the essential facts.
4. Analyze and categorize the facts.
5. State the conclusions and recommendations from the analysis.

Besides the individual records of all training, NFPA 1401 presents five types of training reports that are often compiled. These include an inventory of training apparatus and equipment, plans and costs for needed training improvements, a periodic report on the evaluation of all probationary fire fighters, a monthly summary of all training division activities, and an annual report of activities with projected plans for the upcoming year.

SUMMARY

Training for fire and emergency service personnel should be varied and continuous. It is not only required by numerous federal and state regulations, but it is also the expectation of the people who finance public fire protection. Beyond these considerations, every fire department should make training a moral priority to protect the health and safety of its members. Finally, every fire fighter should demand an ongoing and comprehensive full-service training program to ensure that fire fighters can protect themselves and be ready to provide assistance to anyone else.

There are many sources for necessary training, including federal, state, and local agencies. When the training is provided by the local fire department, its leaders should ensure that the instruction offered concentrates on the right kind of learning and verifies learning through measured assessment. If a fire department, career or volunteer, is not using established national standards as the basis for its training, fire fighters or citizens should demand an explanation.

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on training programs for fire and emergency service personnel discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 472, *Standard for Professional Competence of Responders to Hazardous Materials Incidents*
NFPA 1001, *Standard for Fire Fighter Professional Qualifications*
NFPA 1002, *Standard for Fire Apparatus Driver/Operator Professional Qualifications*
NFPA 1003, *Standard for Airport Fire Fighter Professional Qualifications*
NFPA 1006, *Standard for Rescue Technician Professional Qualifications*
NFPA 1021, *Standard for Fire Officer Professional Qualifications*
NFPA 1031, *Standard for Professional Qualifications for Fire Inspector and Plan Examiner*
NFPA 1033, *Standard for Professional Qualifications for Fire Investigator*
NFPA 1035, *Standard for Professional Qualifications for Public Fire and Life Safety Educator*
NFPA 1041, *Standard for Fire Service Instructor Professional Qualifications*
NFPA 1051, *Standard for Wildland Fire Fighter Professional Qualifications*
NFPA 1061, *Standard for Professional Qualifications for Public Safety Telecommunicator*
NFPA 1071, *Standard for Emergency Vehicle Technician Professional Qualifications*
NFPA 1081, *Standard for Industrial Fire Brigade Member Professional Qualifications*
NFPA 1401, *Recommended Practice for Fire Service Training Reports and Records*
NFPA 1402, *Guide to Building Fire Service Training Centers*
NFPA 1403, *Standard on Live Fire Training Evolutions*
NFPA 1451, *Standard for a Fire Service Vehicle Operations Training Program*
NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program*
NFPA 1670, *Standard on Operations and Training for Technical Search and Rescue Incidents*

Chapter 11

Industrial Fire Loss Prevention

Revised by
Michael Snyder

Chapter Contents

Fire Risk Management
Fire Prevention and Control Program Management
Loss Prevention Program Motivation and Development
Management Loss Prevention and Control Program Framework
Quality Grading of Management Loss Control Programs
Emergency Organizations and Industrial Fire Brigades

Key Terms

emergency management, fire prevention, fire risk management, hazard identification, hot work, industrial fire brigade, industrial loss prevention, insurance, local emergency planning committee (LEPC), pre-incident planning, process safety, risk assessment, risk management

Fire and explosion loss consequences, which can involve property damage, business interruption, life safety hazards, environmental issues, damage to corporate image, and reduced future profitability, present a major threat to corporate goals and survival. Recognition of these consequences has prompted the development of fire and explosion loss prevention programs and emergency response organizations in many commercial and industrial organizations.

For related topics, see Section 3, Chapter 7, "Fire Hazard Analysis Techniques"; Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 9, Chapter 6, "Welding, Cutting, and Other Hot Work"; Section 11, Chapter 4, "Fire Hazards of Construction, Alteration, and Demolition of Buildings"; Section 12, Chapter 9, "Fire and Emergency Services Protective Clothing and Protective Equipment"; Section 17, Chapter 8, "Explosion Prevention and Protection"; and Section 20, Chapter 18, "Industrial Occupancies."

FIRE RISK MANAGEMENT

Fire risk management can be defined as the systematic application of management policies, procedures, and practices to the tasks of analyzing, assessing, and controlling fire risk in order to protect employees, the public, the environment, and company assets while avoiding business interruption (Figure 12.11.1). The typical priorities in fire risk management involve the following:

- Identifying and evaluating fire and explosion hazards/risks
- Developing programs and assigning management responsibilities to manage the identified risks
- Establishing emergency organizations to control fire and explosion incidents that do occur

Hazard Identification

A fire or explosion hazard can be defined as a characteristic of a system, plant, or process that represents a potential for an unplanned event leading to undesirable losses. The key words in this definition are "undesirable losses." Hazard identification is the process of recognizing hazards that can pose significant undesirable losses. Hazard identification should be a continuous activity in the evaluation of new materials, plant additions, and production modifications, as well as the continuing inspection and evaluation of existing facilities.

Resources, including various chapters within this handbook, many NFPA standards, and Internet websites such as those maintained by the United States Chemical Safety and Hazard Investigation Board, and the United Kingdom's Health and Safety Executive describe fire hazards in major industries and special process hazards based on current technology and past loss experience.

Michael Snyder, P.E., CFPS, is EHS development manager with Dow Corning Corporation in Midland, Michigan. He serves on the Industrial Fire Protection Section Board.

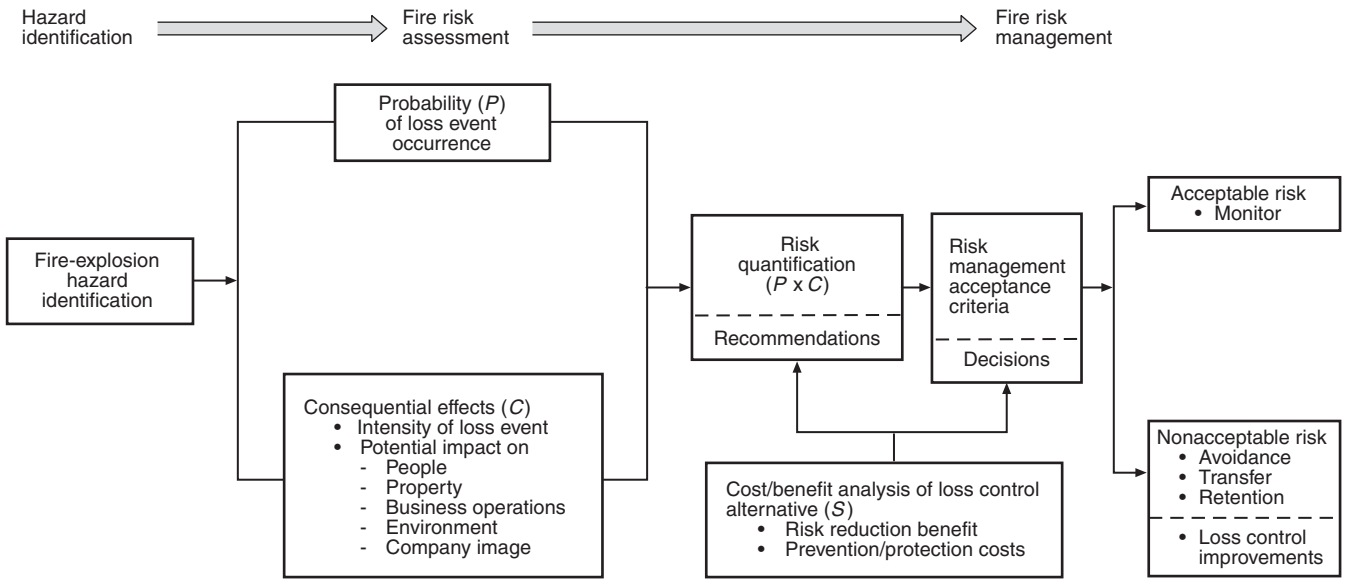

FIGURE 12.11.1 General Framework for Industrial Fire Risk Management

Risk Assessment

The risk assessment process consists of both identifying risks and estimating the probability and magnitude of potential fire and explosion losses. In recent years, there has been an increase in the use of formalized risk assessment methods to support decisions on fire safety issues. Predictive methods that integrate statistical data, deterministic models, and expert opinion increasingly are being used. The primary steps in fire risk assessment include the following:

1. Identification of the fire events that could lead to significant loss
2. Quantification of the fire risk—that is, probability of fire or explosion event occurrences and loss consequences—for the generated fire loss scenarios
3. Development and evaluation of alternative fire prevention and/or fire protection strategies (recommendations) to reduce the fire and explosion risk
4. Measurement of the estimated change in fire and explosion risk (difference in probability and/or consequences) associated with the alternatives

Addressing Probabilities. One of the most difficult tasks in the risk assessment process is addressing probabilities. Fire risk reflects both the probability of fire occurrence and the loss consequences of the fire. In both factors there is an element of uncertainty that must be recognized. Approaches for determining the probabilities of values for fire event occurrences are detailed later. If valid data on fire loss event frequencies are available and applicable, then probabilities can be extracted from this source. Often objective data sources are scarce. To evaluate the application of historical data, it is necessary to look at the following, both for the source of the data and for the situation under consideration:

- Design standards and quality
- Inspection methods and quality
- Maintenance philosophy and quality
- Operational philosophy and quality
- Safety standards and enforcement

If historical data sources are not available for the loss event(s) of interest, probabilities can be evaluated using inferential judgment based on available loss-trending information, such as equipment failures, human error, ignition sources, loss control elements, and damageability factors. Good sources of information include the NFPA Fire Analysis and Research Division and United Kingdom's Health and Safety Executive website.

Subjective estimation processes should be documented and should involve the best judgment a fire protection expert can make based on knowledge of contributing factors from past fire losses, site-specific evidence of loss control deficiencies, and exposed values. A very good reference on equipment failure data sources and application precautions is the AIChE's Center for Chemical Process Safety (CCPS) book entitled *Guidelines for Process Equipment Reliability Data, with Data Tables*[1] as well as the publicly available Process Equipment Reliability Database maintained on the CCPS website.

Quantifying Fire Loss. The physical intensity of fire-explosion consequences can be quantified in terms of the expected energy released (heat exposure, smoke and/or corrosive gas contamination, explosion blast overpressures, etc.), the area involved, and the duration of the fire. Probabilistic engineering assessment—and, in some situations, deterministic fire-explosion modeling tools—are utilized to aid the evaluation process. The *SFPE Handbook of Fire Protection Engineering*[2] provides information on various analytical techniques that can be used in this evaluation.

Once the intensity and duration of the potential fires have been quantified, the impact on both direct and indirect loss potential must be assessed. Direct losses include damage to buildings, equipment, and contents. Indirect losses include business interruption, liability for injury or death, environmental contamination, and damage to company image. For most quantification studies, loss potential is expressed in equivalent monetary terms.

Assessing Risks. The type of risk assessment conducted depends on the significance of the decision, the complexity of the problem, and the time and cost limitations. Routine code-compliance problems can often be handled by simple choices. Complex problems involving new technologies or high-hazard operations require application of more detailed risk assessment and decision analysis methods. Whatever method is used for the risk assessment, it is critical that the assessment is well documented and maintained in an easily accessible format to ensure that complete information is available for routine reviews of the assessment and to be readily available in the event that details of the assessment are questioned by either management or a regulatory authority.

Risk Management

Risk management addresses the value judgments involved in establishing acceptable levels of risk and methods of handling identified risks. The acceptable risk decision-making process is based on specific organizational goals and generally includes (in any order) the following:

- Profit (competitive market position)
- Protection of company assets (major loss exposures)
- Continued company operation (business interruption)
- Continued growth (expansion)
- Humanitarian concerns (employee and public safety)
- Community goodwill (potential embarrassment)
- Legal requirements (liability, building codes, etc.)
- Insurance company requirements
- Environmental concerns

If the risk is acceptable, no immediate action may be necessary, but monitoring for changes that could increase the risk must be done. If the risk is unacceptable, then decisions must be made about how to deal with the risk.

General options available to the risk management decision maker for handling fire and explosion risk exposure include the following:

1. Avoiding the risk by nonparticipation in risky operations
2. Reducing the risk through improved design or use of alternative manufacturing processes
3. Transferring the risk by purchasing insurance to cover potential losses
4. Financing alternative risk transfer arrangements such as captive or corporate funded reserves (self-insurance)
5. Providing loss control improvements
6. Developing a risk management program that includes a combination of the foregoing options

The sixth option generally provides a cost-effective approach for reducing fire loss potential and reducing the risk funding requirements for options 3 and 4. *Risk-Informed, Performance-Based Fire Protection* by T. F. Barry provides a detailed discussion with examples on the subject of risk and industrial fire protection.[3]

An important part of fire risk reduction is the development, implementation, and monitoring of comprehensive loss prevention and control programs. Written documentation should be provided for programs and updated periodically based on the major opportunities for risk reduction.

Recognition of Fire Risk Reduction Opportunities

Figure 12.11.2 illustrates a fire sequence event tree. It depicts primary areas of opportunity for reducing fire risk through implementation of fire loss prevention programs and emergency response organizations.

Initiating Fire. The likelihood of initiating fire events is reduced when fire hazards are adequately identified and evaluated and when quality fire prevention programs are developed, implemented, and audited. Equipment failure rate minimization via good mechanical integrity programs, human error reduction through effective procedures and training practices, and ignition

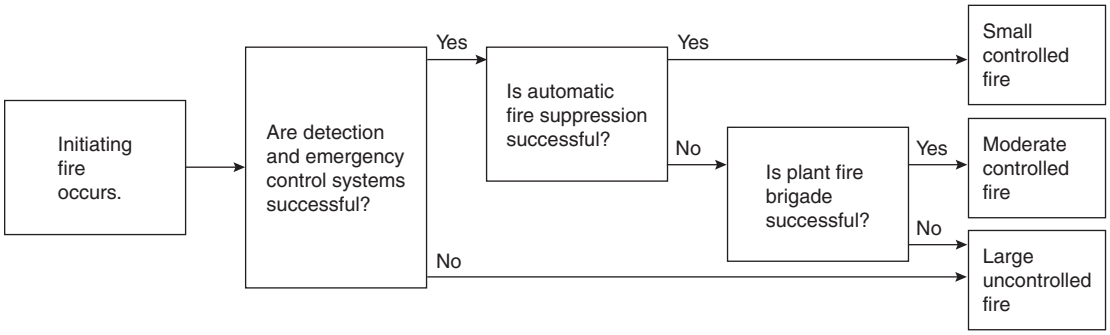

FIGURE 12.11.2 Fire Sequence Event Tree

control procedures such as hot work permits and safe practices all contribute to the overall reduction of initiating fires.

Detection and Emergency Control Success. Rapid detection of fires is the key to reducing the incident magnitude, duration, and the resulting physical damage as well as losses from business recovery time. Prompt detection and intervention through process control systems and successful automatic fire suppression may quickly control incipient fires and prevent them from progressing to large fires that create significant damage.

Process controls can also be used to prevent flammable chemical releases from igniting by quickly isolating flammable releases, thereby stopping the flow of fuel to the atmosphere. Activation of fixed water spray systems can disperse vapors or, with foam water spray, cover and suppress vapors to prevent ignition or control small fires. The prompt response of a well-trained and well-equipped industrial fire brigade can assist the process controls and fixed systems to control the release and limit the size of an emergency fire incident.

Computerized process controls, with extensive emergency shutdown features, are prevalent in large facilities such as refineries, petrochemical plants, and power generation facilities. Process control systems are also prevalent in smaller facilities such as compressed gas cylinder filling, paint spraying, and plywood manufacturing.

Automatic Fire Suppression. Programs related to the inspection, testing, and maintenance of fire protection systems such as sprinkler systems, fire pumps, foam water protection systems, and special extinguishing systems, such as gaseous agents and dry chemicals, improve the reliability of the fire suppression system. Properly designed, effective, and reliable automatic fire suppression systems can quickly control an incipient fire and reduce life safety and property damage exposures.

To ensure that automatic fire suppression systems remain fully functional, it is essential to establish and maintain a fire protection system impairment program that contains the following three aspects:

- Identification and notification of the impaired system
- Minimization of the impairment
- Provision of contingencies (i.e., shutdown of operations, fire watch, use of portable equipment)

The historical collection of large loss fires contains too many examples of situations in which a fire starts in a facility that had an improperly managed fire protection system impairment, which allowed a minor fire to grow, uncontrolled, into a fire resulting in catastrophic loss.

Industrial Fire Brigade Response Success. Industrial fire brigades provide a number of functions at industrial facilities. In addition to providing manual fire suppression support and backup to automatic fire systems, fire brigades assist in the development of prefire planning with responding public fire departments, employee emergency evacuations, and salvage operations following fire incidents. Other duties can include plant fire safety inspections, fire extinguisher training, fire equipment maintenance, and overall emergency coordination. Fire brigade organization and training are discussed later in this chapter.

FIRE PREVENTION AND CONTROL PROGRAM MANAGEMENT

Today few companies, in the face of severe global competition and the high cost of capital, could survive a major loss. Over the years, it has become apparent that people can substantially aid in the minimization of losses. It has been statistically demonstrated by major property insurance companies that the factor with the largest effect on the size of a loss by fire or explosion is what people do or fail to do.

Due to the numerous interfaces between the various engineering disciplines, as well as maintenance and operational programs, it is essential to place the responsibility for the fire protection program with a single individual or small group with direct access to top management. This individual must have sufficient authority to delegate responsibilities affecting plant fire protection across engineering discipline and departmental lines and even across separate divisions, such as engineering, plant services, utilities, safety and loss control, and emergency response. The implementation and enforcement of an effective fire loss control program are dependent on management involvement and support and effective use of property insurance services.

Management Roles

Management can be divided into three echelons, each of which makes important contributions to loss prevention and control: (1) executive management—the board of directors and company officers; (2) middle management—facility managers, department heads, and related staff managers; and (3) line management—the supervisors and team leaders who direct each phase of the operation.

In a relatively small organization, the owner may perform the functions of all three management levels. Although the owner's loss control problems may be fewer, or less complex, than those of the management group in a larger organization, some of the same judgments must be exercised. The owner who tries to be loss control manager may be at a disadvantage, however, because of the lack of specialized training in loss control and the absence of managers with whom to share expertise and creative ideas regarding a sound loss control program. This disadvantage need not pose a major obstacle. Expertise is available from professional loss control consultants, insurance companies, and fire departments.

In today's business environment, facility employees who manage property conservation and or loss prevention may also manage a number of other similar related functions such as safety and health, and security and risk management. To be effective they will need to partner with others within an organization to jointly share goals and objectives while complying with codes and internal programs.

Executive Management. Members of executive management establish company policy, make major financial decisions, de-

termine the product or service to be provided, and establish production levels. Executive management's primary goal is to guide the organization to produce a profit.

Regardless of insurance coverage, losses to plant property by fire, explosion, or other causes can disrupt profitability. On the surface, assets diverted to property protection would appear to be a nonproductive expenditure. However, after a serious loss, the need for an effective loss prevention/control program becomes apparent. For loss control programs to be effective, they must have complete support from executive management. In addition, once a program has been developed and accepted, executive management must insist on regular updates to monitor progress.

Middle Management. Middle management is responsible for the development, implementation, and monitoring of cost-effective loss control programs. The person with primary responsibility for loss control generally has the title of loss control manager. Depending on the organization, titles assigned to individuals vary, and in some cases, the individual may have several other titles when loss control is not a full-time function. To be effective, the assigned individual must have access to decision makers at the executive management level. Direct access would involve reporting to the officer level (e.g., vice presidents of engineering, finance, production, etc.). Indirect access would involve reporting to the director of risk management or other managers with direct access to executive management.

Major responsibilities of the loss control manager include the following:

Overall supervision. Defining loss control program functions, clarifying responsibilities, and ensuring that all procedures are properly carried out

Planning. Anticipating hazards and formulating plans and procedures for fire prevention and overall plant safety

Education and training. Providing employee training in fire prevention; making sure that all production processes and operations are carried out safely, and that contractors follow safe procedures according to company regulations (Figure 12.11.3)

Assignment. Delegating specific maintenance and emergency duties to employees, including guards, caretakers, patrol officers, and night workers

Coordination. Maintaining liaison with the following corporate departments and outside organizations:

- Production and engineering on new processes or materials that can introduce additional fire hazards within the facility
- Plant engineering and maintenance for fire protection installations, impaired protection, maintenance of fire protection equipment, and housekeeping
- The public fire department and insurance company on plant layout, location and type of hazardous processes, coordination of forces, location and type of fire protection equipment, fire doors, fire walls, defense plans, and main defense lines

Review and audit. Periodically checking the efficiency of the entire loss control program; reviewing details of the plan with line management; conducting drills and classes to maintain employee preparedness; auditing

FIGURE 12.11.3 Portable Fire Extinguisher Training—An Important Function for Many Loss Control Departments

and inspecting various facilities for compliance to organization loss prevention policies and plans

In smaller organizations, the facility manager or an appointee must assume these responsibilities.

Line Management. Implementation of a loss control program extends beyond the middle-management level. Unless the members of line management adequately perform their function, the program cannot produce satisfactory results.

Line managers, those with daily personnel contact, should aid in the information collection that middle managers incorporate into loss control programs. Once programs are implemented, line managers are responsible for regular enforcement of company policy.

With regard to employees and work areas under the line manager's supervision, it is the line manager who is responsible for the following:

- Training personnel to carry out individual duties in a loss control program
- Working with the loss control manager and staff in selecting employees for the private fire brigade or other program assignments
- Working with the loss control manager to establish priorities for inspection, testing, and maintenance of fire protection equipment
- Inspiring employees to develop a fire-conscious attitude and respect for the loss control program
- Insisting that access to all protection equipment, as well as all means of egress, be kept open
- Working closely with the loss control manager and staff to ensure that new equipment or processes are adequately protected before startup
- Reporting all occupancy changes that may affect loss control
- Working with the loss control manager and staff to ensure that fire exit drills are held regularly
- Accounting for each employee following facility evacuation
- Supervising emergency action when a fire or other property-related incident occurs in the absence of members of an established emergency organization

Insurance Company Roles

Many property insurance companies focus on recommending management programs that assist facilities to prevent and minimize property damage and business interruption losses. These services are provided to both large industrial sites and small retail operations. When considering the development of a program, management needs to take into consideration the size of the operation, reporting structure within the company, hazards involved, and how the program will be managed and/or directed.

Each insurance program needs to be tailored to address the risk elements that have been identified. Primary management program elements that are typically offered include the following:

- Impairments to fire protection systems
- Smoking regulations
- Maintenance
- Employee training
- New construction
- Preemergency planning
- Hazardous materials evaluation
- Cutting, welding, and other hot work
- Loss prevention inspection
- Handling insurance company recommendations
- Fire protection and security surveillance
- Fire protection equipment inspection
- Hazard identification and evaluation
- Proper housekeeping
- Handling and responding to losses or claims
- Handling inspections from enforcement agencies

Insurance Company Service Options

Today many insurance companies have reduced or eliminated service functions as part of their standard insurance program. In some cases the insurance companies have retained the services but operate with reduced staff and focus on loss prevention activities that support only the insurance underwriting placement. In other cases some property insurance companies have staffed up to sell or offer these services as part of the entire portfolio of insurance products. Some loss prevention services are considered as part of the insurance program but the service has a cost factor attached. The loss control program manager needs to understand what he or she is getting from the insurance companies and clearly understand the scope of the services, cost, and deliverables.

Most insurance policy contracts and loss prevention insurance inspection reports contain a disclaimer that outlines the limitations of the inspection survey or site risk reviews. Before a client spends money on insurance company recommendations compliance, the client needs to determine if the proposed corrective action will impact the insurance program and if the identified recommendation has other more cost-effective options.

Services provided by insurance companies are sometime labeled as "bundled." That is, the insurance policy and loss prevention or risk control services are provided at a fixed cost by one company. Remember that with this approach the loss prevention people work directly for the insurance companies, and the focus of service may be driven from internal insurance company standards or guidelines. In many cases, particularly for small facilities, this approach can serve to fulfill the needs of the risk control client. In other situations, such as a company with many large sites and operations, the client may wish to direct the loss control services to minimize the interruptions to operations in performing the inspections.

With continuing changes in the insurance industry, many more consulting companies now offer high-quality loss prevention and risk control type services, which they call an "unbundled" approach. This approach breaks apart the service elements from the insurance contract. In this method the client purchases the services directly and often separately from insurance coverage.

The following are items that should be included in a service contract with an insurance company:

- Term of agreement
- Duties of both parties—compliance with health, safety, and OSHA standards
- Confidentiality of data security
- Right to work product
- Warranty—limitation of liability
- Indemnity and insurance
- Compensation—upfront payment or schedule
- Termination of contract or agreement
- Miscellaneous rights
- Compliance with jurisdictional codes

These items can also apply to bundled loss prevention service from an insurance company.

Program Monitoring. Based on the approach, unbundled or bundled services, companies need to establish performance requirements in the contracts established for service. It is recommended that the service provider submit a quarterly stewardship report outlining all the activities, cost, and a scorecard measuring the key performance elements of the contract or service agreement.

Facility or company management must routinely audit the insurance services program, thereby providing a means to measure performance of the services delivered. Auditing also provides an effective tool for feedback on the program's strengths and pinpoints deficiencies.

LOSS PREVENTION PROGRAM MOTIVATION AND DEVELOPMENT

Human element factors play a significant role in most fire and explosions. Various statistical studies of loss incidents in a variety of industries have indicated the following general breakdown:

- Human factors (70–85%) (e.g., management program deficiencies, human operator errors)
- Equipment failures (10–20%) (e.g., design or maintenance deficiencies)
- External factors (10–20%) (e.g., earthquake, floods)

It should be noted that some products and equipment are less vulnerable to human error than others, so product or equipment performance can be a factor even though human error is also a factor. It is a mistake to treat the two as mutually exclusive.

To reduce human error leading to fire incidents, many companies are establishing and expanding policies and practices that prioritize the implementation and auditing of loss prevention programs. Integrated into many of these programs are insurance company guidelines, industry recommended practices, regulatory requirements, and NFPA standards.

Insurance Company Guidelines

Traditionally, industrial property insurance companies have focused on recommending management programs that assist in the prevention and minimization of property damage and business interruption losses.

Some of the primary management programs include the following:

- Impairments to fire protection systems
- Smoking regulations
- Maintenance
- Employee training
- New construction
- Pre-emergency planning
- Hazardous materials evaluation
- Cutting, welding, and other hot work
- Loss prevention inspection
- Fire protection and security surveillance
- Fire protection equipment inspection
- Hazard identification and evaluation
- Proper housekeeping

Each major industrial insurance company typically has guidance documents that can be used in conjunction with NFPA standards to implement effective loss management programs.

Modern commercial and industrial programs also include technical reviews of manufacturing equipment and processing hazards and can assist in the risk assessment of many specific manufacturing operations.

U.S. Federal Regulations

The Occupational Safety and Health Administration (OSHA) regulates many aspects of fire prevention and control within commercial and industrial occupancies. Specific regulations include the following:

Part 1910 Subpart E—Exit Routes, Emergency Action Plans, and Fire Prevention Plans
Part 1910 Subpart H—Hazardous Materials
1910.106—Flammable and combustible liquids
1910.107—Spray finishing using flammable and combustible materials
1910.108—Dip tanks containing flammable or combustible liquids
1910.110—Storage and handling of liquefied petroleum gases
1910.119—Process safety management of highly hazardous chemicals
1910.120—Hazardous waste operations and emergency response
Part 1910 Subpart L—Fire Protection
Part 1910 Subpart Q—Welding, Cutting, and Brazing
1910.252—General Requirements

Many of the foregoing OSHA regulations are derived from older versions of NFPA standards and have constituted leading industrial loss control practices for many years. Work is underway to update the references to more current versions of the NFPA standards. Several letters of interpretation issued by OSHA accept the use of more modern versions of the NFPA standards with some limitations.

Many states and local jurisdictions have adopted versions of NFPA standards to serve as the basis for regulatory requirements. The most commonly adopted standards include NFPA 30, *Flammable and Combustible Liquids Code,* to regulate the safety of flammable and combustible liquids, and NFPA 58, *Liquefied Petroleum Gas Code,* to regulate the safety of liquefied petroleum gas operations.

OSHA 1910.119, *Process Safety Management of Highly Hazardous Chemicals,* was introduced in 1992 and focuses on the application of performance-based management programs rather than specific engineering guidelines for the prevention of toxic releases, fires, and explosions on plant sites that use or store hazardous materials that exceed specific volume thresholds. Many of the regulatory requirements arising from this standard represented practices used by leading manufacturing companies for many years.

The following are the major program segments in CFR 1910.119:

- Employee participation
- Process safety information
- Process hazard analysis
- Operating procedures
- Training
- Contractors
- Pre-start-up safety reviews
- Mechanical integrity
- Hot work permits
- Management of change
- Incident investigations
- Emergency planning and response
- Compliance safety audits

In the mid-1990s the Environmental Protection Agency (EPA) promulgated 40 CFR Part 68, *Risk Management Program for Chemical Accident Prevention,* which focuses on the exposure of toxic chemical releases and fire and explosions to the public.

EPA's risk management program (RMP) elements include the following:

- Hazard assessments
- Prevention program
- Emergency response program, including procedures for informing the public and response agencies should an accident occur

EPA's RMP regulation requires development and implementation of management programs at facilities that manufacture, process, use, store, or transport regulated hazardous chemicals in quantities that exceed specified threshold limits as listed in the regulation. EPA's regulation rule adopts the OSHA CFR 1910.119 PSM regulation as the RMP's prevention program segment.

MANAGEMENT LOSS PREVENTION AND CONTROL PROGRAM FRAMEWORK

The details and complexity of program elements for loss prevention and control will vary depending on the type of plant facilities, nature of hazardous operations, complexities of processes, and exposures to plant employees and the public.

Primary management program elements can be categorized as follows:

Process Technology

- Process safety information
- Process hazard analysis
- Pre-start-up safety reviews

Mechanical Integrity Programs

- Process equipment
- Emergency safety devices
- Protection systems

Operating Procedures

- Written operating procedures
- Hot work permits
- Fire system impairments
- Flammable liquid handling and ignition control

Management

- Employee training
- Contractors
- Management of change
- New construction

Incident Management and Investigation

- Disaster/emergency management and pre-incident planning
- Incident investigations

Process Safety Information

For process, storage, and transportation operations involving flammable and hazardous materials, it is important to develop, document, and update process safety information, including information pertaining to the following:

- Hazards of the chemicals
- Process technology
- Equipment

Material hazards documentation provides pertinent hazard data for each chemical involved in a process or operation, including physical and chemical properties such as flammability and thermal stability data, reaction data, and any other property relevant to a particular hazard. Toxicity data are an important part of the package. In many cases, material safety data sheets (MSDSs) will satisfy this requirement, provided they contain the necessary details.

Chemical and flammability data can be extracted from numerous sources including the NFPA *Fire Protection Handbook.* Much of the data available in these publications are at atmospheric temperature and pressure. Experimental data appropriate to process conditions will sometimes be needed. Dust explosion data for explosion-venting calculations are presented in NFPA 68, *Standard on Explosion Protection by Deflagration Venting,* which includes additional references. A considerable amount of dust explosion data can be obtained from various U.S. Bureau of Mines and NFPA publications.

Process Hazard Analysis

Hazard evaluation activities can be accomplished by trained plant personnel working with outside specialists when required. It is the hazard evaluation team's responsibility to study the process operation thoroughly, identify all the potential fire and explosion hazards, and recommend changes or further reviews to eliminate or control the identified hazards. A written report of the evaluation must be developed and should include the following:

- List of participants
- Methodology(s) applied
- List of documents, such as part and identification (P&ID) numbers and issue
- Summary of the findings
- Recommendations

All hazard evaluation reports, recommendation status reports, and follow-up documentation should become part of the process documentation file.

An organized approach is essential to conducting effective and efficient hazard evaluations. Hazard evaluation techniques include the following:

- Safety review
- Checklist analysis
- Relative ranking indexes
- Preliminary hazard analysis
- What-if analysis
- What-if/checklist analysis
- Hazard and operability (HAZOP) analysis
- Failure modes and effects analysis (FMEA)
  - Fault-tree analysis
  - Event-tree analysis
  - Cause-consequence analysis
  - Human reliability analysis

Each technique has specific application benefits, limitations, resource needs (staff, time, budget), and documentation requirements. It would be impossible in this chapter to describe each technique. An excellent reference that addresses those techniques in detail and provides illustrative examples is the Center for Chemical Process Safety's (CCPS) *Guidelines for Hazard Evaluation Procedures with Examples.*[4]

Pre-Start-Up Safety Reviews

A pre-start-up safety review should be performed for new facilities and for modified facilities when there may be changes in process safety information. The pre-start-up safety review should confirm the following:

- Construction is in accordance with design specifications.
- Safety, operating, maintenance, and emergency procedures are in place and adequate.
- Recommendations from insurance reviews and any process hazard analysis are adequately resolved.
- Operating procedures are in place and employees are trained.
- Fire prevention and protection systems are in service.

Mechanical Integrity Programs. A primary fire prevention objective is to prevent the release of flammable and hazardous materials from containment. A quality mechanical integrity program (MIP) is a key element in meeting this objective.

The purpose of an MIP is to ensure the safe operation of process and safety equipment through design, inspection, testing, preventive maintenance, and quality assurance monitoring.

The MIP policies and practices at facilities handling flammable and hazardous materials will have a major influence on the level of failures and accidents experienced. Establishing comprehensive programs is a key ingredient in successful loss prevention and control management and should include the following:

- Identification of all critical equipment requiring inspection, testing, and preventive maintenance
- Procedures and schedules for inspecting process vessels, piping, and associated process equipment and safety and protection systems
- Procedures and schedules for testing critical protective devices, such as pressure-relief valves, detection and alarm interlocks, emergency generators, and fire protection systems
- Quality assurance procedures to ensure corrective maintenance functions, employee qualifications, replacement part specifications, and so on

Systems that protect facilities and personnel from hazardous situations (e.g., toxic releases, fire, explosion) must operate effectively and reliably. Emergency safety devices and protection systems generally remain static for long periods of time and, therefore, need scheduled inspection, maintenance, and testing to ensure that these systems function correctly during an emergency. Testing and maintenance of emergency safety and protection devices are very important and must be covered by a formal system with full documentation. Some examples of equipment and systems include the following:

- Pressure-relief systems, vent systems, and devices
- Process monitoring devices and sensors
- Explosion vents
- Electrical grounding and bonding systems
- Dikes and drainage systems
- Gas and flame detectors
- Emergency alarm and communication systems
- Emergency shutdown devices and system interlocks
- Emergency generators
- Sprinkler and water spray systems
- Fire pumps
- Special suppression systems (e.g., dry chemical, foam)

Testing and inspection policies and procedures should follow applicable codes and standards, such as those published by the American Society of Mechanical Engineers (ASME), the American Petroleum Institute (API), the American Institute of Chemical Engineers (AIChE), the American National Standards Institute (ANSI), the American Society for Testing and Materials (ASTM), and the National Fire Protection Association (NFPA), where they exist, or recognized and generally accepted engineering practices.

Fire Protection Systems. An important mechanical integrity program component is the testing and preventive maintenance of fire protection equipment. Facility management must routinely assess the quality of fire protection equipment testing and maintenance programs. Procedures used to conduct this assessment include code compliance reviews, corrective maintenance tracking, maintenance team qualifications, program monitoring and updating, equipment replacement programs, and compliance with appropriate standards. Examples include the following:

- *Code compliance.* Are documented procedures in place that meet current NFPA standards for the maintenance and testing of fire protection systems? Are procedures being properly applied at the required intervals, and are documented/signed-off testing and maintenance logs being maintained and readily available for review?
- *Corrective maintenance tracking.* Are documented corrective maintenance and testing procedures in place, and is a tracking method showing completion-date status with sign-offs to verify completion readily available for review?
- *Maintenance team qualifications.* Are the people doing testing, maintenance checks, and corrective actions properly qualified and continually trained in conducting proper and efficient maintenance and in recognizing and correcting problem areas?
- *Program monitoring and updating.* Do procedures comply with the manufacturer's suggested maintenance for unique and specific equipment functions, and are procedures updated based on the manufacturer's experience, plant-specific experience, and/or equipment modifications?
- *Equipment replacement program.* Are equipment age, operating environment, and availability of spare parts considered in the updating and modification of maintenance and testing efforts, frequencies, and replacement of systems and system components?
- *Compliance with applicable NFPA standards:*

  NFPA 12, *Standard on Carbon Dioxide Extinguishing Systems*
  NFPA 12A, *Standard on Halon 1301 Fire Extinguishing Systems*
  NFPA 17, *Standard for Dry Chemical Extinguishing Systems*
  NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems*
  NFPA 69, *Standard on Explosion Prevention Systems*
  NFPA 70B, *Recommended Practice for Electrical Equipment Maintenance*
  NFPA 72®, National Fire Alarm Code®
  NFPA 80, *Standard for Fire Doors and Other Opening Protectives*
  NFPA 110, *Standard for Emergency and Standby Power Systems*
  NFPA 780, *Standard for the Installation of Lightning Protection Systems*

NFPA 25 addresses the inspection, testing, and maintenance activities for much of the standard fire protection equipment installed within most facilities, including the following:

- Sprinkler systems
- Standpipe and hose systems
- Private fire service mains
- Fire pumps
- Water storage tanks
- Water-spray fixed systems
- Foam-water systems
- Fire protection valves

Operating Procedures

Written Operating Procedures. It is important to develop and implement written operating procedures that provide clear instructions for safely conducting activities for each process that represents potential hazardous releases, fire, or explosion potential. The written operating procedures should address the following:

Steps for Each Operating Phase

- Initial start-up
- Normal operation
- Temporary operations, as needs arise
- Emergency operations (including shutdown)
- Normal shutdown
- Start-ups following outages

Operating Limits

- Consequences of deviations
- Steps to correct or avoid deviations
- Safety systems and their functions

Safety and Health Considerations

- Properties and hazards of process chemicals
- Exposure precautions, including controls (e.g., engineering, administrative, emergency response)
- Safety procedures for operating equipment
- Control measures in event of exposure
- Any special or unique hazards

Operating procedures should be readily accessible to employees at all times and must be maintained to reflect current requirements.

Flammable Liquid Handling and Ignition Control. The accidental release of flammable liquids or gases from containment and potential ignition present a major loss exposure. An effective management program should address personnel training in the handling of flammable liquids and control of ignition sources. NFPA 30 provides information on this subject. The following highlights some of the management issues, adapted from NFPA's publication, *Understanding Fire Protection for Flammable Liquids:*[5]

- Training of personnel should include the following:
  1. Thorough indoctrination of all employees, including supervisors, in the hazards associated with the storage, transfer, and use of flammable and combustible liquids
  2. Indoctrination of employees in the importance of keeping flammable liquids and vapors confined to closed equipment and containers

3. Indoctrination of employees in the importance of limiting the quantities of liquids in the work area to that amount needed for efficient operations
4. Training of employees in the need for constant attendance during all flammable liquid transfer operations
5. Training of employees in the proper procedure for control and cleanup of leaks and spills

- Control of ignition sources should include the following:
  1. Ensuring electrical equipment and wiring in the area are suitable for the hazard. NFPA 30 and NFPA 70, *National Electrical Code*®, specify the requirements for electrical equipment in hazardous areas.
  2. Not locating any equipment having open flames, hot surfaces, or radiant heat sources in areas where flammable or combustible liquids are used, handled, or stored
  3. Prohibiting the use of friction- and spark-producing equipment in areas where flammable liquids are used
  4. Providing adequate grounding and bonding of all equipment that handles or uses flammable liquids to minimize the accumulation of hazardous static charges. NFPA 77, *Recommended Practice on Static Electricity,* provides the guidelines for grounding and bonding of equipment.
  5. Prohibiting smoking, open-flame torches, and hot work in hazardous areas
  6. Establishing a program to ensure that all vessels, tanks, piping, and process equipment are properly drained and purged of flammable and combustible liquids *prior* to performing maintenance operations

Hot Work Permits. Hot work—that is, work involving burning, welding, or similar operations capable of initiating a fire or explosion—is common in the industrial workplace and is also one of the key element programs covered by OSHA Process Safety standard, 29 CFR 1910.119. Hot work continues to be one of the largest causes of fires in industry.

Hot work is defined in NFPA 51B, *Standard for Fire Prevention During Welding, Cutting, and Other Hot Work,* as any work involving burning, welding, or similar operation that is capable of initiating fires or explosions. Examples of hot work activities include heat treating, grinding, thawing pipe, using powder-driven fasteners, hot riveting, and welding and allied processes (e.g., open-flame soldering, brazing, thermal spraying, oxygen cutting, and arc cutting). Other similar applications, such as grinding, chipping, or abrasive blasting, that produce a spark, a flame, or heat could also be included as hot work. These operations are potentially dangerous, depending on the type of work being performed and the environment in which it is performed. Details regarding the management of a hot work program may be found in Section 9, Chapter 6, "Welding, Cutting, and Other Hot Work."

The centerpiece of an effective hot work program is the hot work permitting process. The three steps to consider for hot work permits are recognition, evaluation, and control. Once the hazard is recognized (in part through the use of the facility-specific checklist on the permit), the extent of the hazard can be evaluated. Based on the severity of the hazard, a control can be developed to minimize or eliminate the hazard, which is then recorded on the permit. The control can include moving the hot work or combustibles, isolating the combustibles, and assigning a fire watch. The hot work permit, which is the start of any good hot work program, is a tool that assists the permit authorizing individual (PAI) to perform all three of these steps in coordination with the person performing the hot work (operator) and the fire watch (see Figure 12.11.4).

FIGURE 12.11.4 Fire Watch Monitoring a Hot Work Area

Precautions for hot work are as follows:

- Hot work should be prohibited in areas where sprinklers are out of service.
- Hot work should not be done in a flammable liquids room unless all liquids are removed.
- Sparks or molten metal should not be permitted to pass through doorways or cracks or holes in walls and floors.
- All exposed combustibles should be moved a minimum of 35 ft (10.7 m) from hot work operations. Noncombustible curtains must be used between the operation and combustible materials when adequate separation cannot be maintained.
- Floors should be swept clean. Wood floors should be wet down or covered with a protective shield, preferably sheet metal.
- Fire extinguishers must always be available at all hot work operations. Any extinguishers that are used should be replaced promptly.
- The immediate area and areas on floors above and below should be inspected for a minimum of 30 minutes after completion of a hot work operation for any sign of smoldering or damage caused by hot slag.
- When oxyacetylene equipment is not in use, the gas should be turned off at the cylinder valve.

Hot work done by an outside contractor should be closely supervised to ensure compliance with the hot work permit system. Approximately one of every three hot work fires reported occurs while outside contractors are engaged in hot work operations.

Fire System Impairment Procedures. Many large fire losses have been directly attributed to impaired fire protection systems or equipment. Major property insurance companies, during routine facility inspections, continue to find fire protection systems of all types out of service. The need for an effective impairment notification program is evident to eliminate the possibility of undetected shutdown of fire protection systems.

A protection system may become impaired for a number of reasons (e.g., maintenance, renovation, construction, equipment failure, or failure to reactivate the system or device). Facility managers and loss control managers should be notified *immediately* of any impairments during normal working hours. During off-hours, depending on the seriousness of the impairment, these same individuals may still want to be notified. This procedure should be addressed in detail in the company policy.

Any impairment program should require the following:

1. Assigning responsibility and authority to control the impairment to one individual. This is normally a plant engineer or fire protection safety supervisor. In an emergency, a shift supervisor or fire brigade chief may have the authority to impair a system, but the overall responsibility for the impairment remains with the loss control manager.
2. Educating plant personnel in basic precautions to be taken when a protection system or equipment is impaired. Precautions include the following:
   - Limiting the number, scope, and duration of impairment
   - Supplementing manual fire protection with extra extinguishers
   - Avoiding hot work operations
   - Shutting down any hazardous processes
   - Completing impairment work in a timely manner
   - Restoring protection system on completion of all work
   - Verifying, by testing, that the protection system is operational

The three forms of impairment are (1) concealed, (2) emergency, and (3) planned.

A concealed impairment is an unknown impairment. It occurs when a fire protection system is left out of service or removed from service by an unauthorized person. Concealed impairments should be discovered during activities conducted as part of a facility's fire protection maintenance and inspection program.

Emergency impairments are caused by unexpected events impairing the normal function of the protection system (e.g., a section of sprinkler piping freezing and bursting). Emergency situations are normally associated with confusion and a sense of urgency. To eliminate much of the confusion, a written procedure should be in a location available to all personnel.

When handling emergency impairments, the following steps need to be performed:

1. Isolate the area where the situation, or condition, is causing the impairment. If possible, the remaining protection system should be kept in service. Doing so may require temporary connections or bypasses.
2. Notify the shift supervisor and fire brigade chief that an impairment has occurred. Institute frequent patrols of the impaired area for fire safety issues.
3. Secure any hazardous production operation in the area where the protection system is impaired.
4. Properly tag out the impaired system or equipment.
5. Start repairs on the impaired system once the area is secured. Work on the impairment should continue until it has been restored to service. Hot work required for the repair should be performed in a protected area.
6. Place additional portable extinguishers and/or charged fire hoses in the impaired area at accessible locations.
7. Notify the public fire department that emergency impairment has occurred and the extent to which the protection system is out of service.
8. Notify the alarm company of the impairment, indicating whether any alarms have been affected.

A planned impairment is a scheduled impairment, typically involving improvement or modification to the present system. Such impairment might involve adding a new section of sprinkler piping or changing old sprinkler heads. When work has been completed, it is important to ensure that fire protection is properly restored. Each of the several steps required should be verified by the individual who authorized the impairment. These steps include the following:

1. Opening all valves that were secured during the impairment and conducting a drain test (Note: If during the test the pressure drops below normal, the system may have a restricted or partially closed valve.)
2. Placing all alarms and/or detection devices back in service

3. Restoring any fire protection equipment to "automatic" that was either secured or placed in "manual"
4. Verifying that portable extinguishers are in place and fully charged and hose lines are returned to racks or reels
5. Notifying plant supervisors (shift supervisors and fire brigade chief) that the fire protection system has been restored
6. Notifying the alarm service or central stations that the fire protection has been restored and that alarms will be verified
7. Notifying the public fire department that the fire protection system has been restored to service and all alarms activated

Self-Inspection. The effectiveness of operating procedures relies heavily on human actions, management oversight, and compliance to established procedures. It is essential that these procedures are audited on a routine basis to evaluate how well they are working and to identify any needs to improvement.

Management must take a positive approach in establishing a program for the periodic auditing of all operating procedures and systems. These audits should be conducted by individuals knowledgeable in the procedures and systems and include a procedure for documenting all findings and reporting them to appropriate levels of management. For those deficiencies that are severe and could be of imminent danger, the facility manager should be notified immediately and should take immediate corrective action. Key areas for self inspections and audits include the following:

Written Operating Procedures

- Check that written procedures are current.
- Ensure that employees are familiar with the content of written procedures.
- Check that the procedures are specific in detailing what should be done during abnormal and emergency situations.

Hot Work Permits

- Decide whether permits are required for all hot work activities.
- Review any facility standards or written procedures governing hot work control.
- View a sample of recently issued work permits for completeness and accuracy.
- Determine whether permit authorized individuals (PAIs) and fire watch personnel are trained.
- Check whether there have been any recent hot work–related fires and whether they were investigated. Determine whether recommendations from the investigation have been implemented.

Fire System Inspections and Impairments

- Review fire equipment inspection records for completeness and timeliness.
- Conduct field inspection of fire systems to ensure conditions match the inspection records.
- Conduct field inspections of fire water control valves and fire water supplies looking for any signs of system impairment.
- Request that facility personnel who are assigned to conduct fire system inspections demonstrate the methods used for their inspections and tests.

Flammable Liquid Handling and Ignition Control

- Check whether employees have a basic knowledge of flammable liquid terminology and hazards.
- Determine if storage of flammable liquid containers is in accordance with NFPA 30.
- Determine whether appropriate safeguards have been taken with open handling of flammable liquids.
- Check that gravity dispensing of flammable liquids uses flame arrestors and self-closing valves.

General Facility Loss Control Conditions

- Check whether poor housekeeping, waste, and combustible materials accumulations exist.
- Determine if careless smoking occurs.
- Check for the presence of oily rag storage in noncombustible containers with lids.
- Determine whether electrical switch gear is blocked and if there is storage of combustible material in electrical rooms.
- Check for improper maintenance of electrical conduits and junction boxes.
- Determine whether there are abnormal amounts of combustible in-process or finished products in areas where fire protection systems have not been adequately designed for this overload.

To simplify facility self-inspections, many property insurance companies and trade associations offer forms with items specific to many different types of occupancies and equipment. Forms should be specific enough to be usable and comprehensive enough so that no element of prevention or protection is overlooked.

Management

Employee Training. Employees should be educated in the hazards involved in the job and in the functions of emergency safety control and fire protection equipment. Employee training should be well documented. This includes initial, refresher, and supplemental training and certification. Initial training requires that all workers involved in a process, as well as newly assigned workers, be trained in the basics of the process, operating procedures, and associated hazards. Refresher and supplemental training should be given at least annually. After training, the employer should certify that workers have received and successfully completed the specified training.

Contractors. Prior to the commencement of work, contractors working at a facility or plant should be informed of the potential hazards of fire, explosion, or toxic releases. Contractors must be trained in the plant's safe work practices, and hot work procedures and be instructed in the provisions of the plant's emergency response plan.

Management of Change. Making design or operational changes that may affect the process hazard level without formal

review and authorization can lead to serious fire or explosion incidents. To reduce this potential, a management of change (MOC) program should be implemented. This program should establish written procedures to manage and document any changes to facilities or to process chemicals, technologies, or equipment, including fire protection equipment. Procedures should address the following:

1. Change of elements
   - Technical basis for the change
   - Impact on safety and health
   - Modifications to operating procedures
   - Necessary time period for the change
   - Authorization requirements for the change
2. Employee training prior to implementation
3. Revision of process safety analysis information
4. Revision of operating procedures

New Construction. Loss control managers should be directly involved in new construction project planning. Responsibilities should include the following:

1. *New construction site evaluation.* The loss control manager should determine if the following conditions exist at the site under consideration:
   - Adequate water supply to meet fire protection requirements
   - Exposure to flood
   - Exposure conditions involving adjacent facilities
   - Acceptable support forces, such as public fire departments, disaster relief, and medical teams
   - Impediments to quick response by support forces (e.g., lift bridges, railroad crossings, or heavily traveled highways)
2. *Facility and protection systems planning.* The following are loss control factors to be considered during the planning stage:
   - Using fire-resistant materials
   - Limiting the size of fire areas by the use of fire walls, fire doors, and so on
   - Segregating unusual concentrations of values (e.g., sensitive equipment and highly hazardous operations)
   - Ensuring emergency exits are adequate in number, size, and location
   - Providing physical protection (e.g., automatic sprinklers, hydrants, and standpipes)
   - Providing access for fire protection vehicles
   - Considering design for earthquake, wind, and heavy snow or rain
3. *Production operations involving new equipment or modifications.* Loss control management should participate in process planning, which may require the following:
   - Segregation to limit exposure from other operations
   - Special protection/suppression systems
   - Limited access or improved security
   - Special exit facilities
4. *Fire protection during facility construction.* Loss control management personnel should participate in the following duties:
   - Advising contractor personnel of loss control management policies (facility personnel must have authority to enforce compliance)
   - Acceptance testing of all fire protection equipment
   - Monitoring construction for compliance with specifications

Incident Management and Investigations

Emergency Planning. NFPA 1600, *Standard on Disaster/Emergency Management and Business Continuity Programs,* and NFPA 1620, *Recommended Practice for Pre-Incident Planning,* provide a very good framework for developing, implementing, and maintaining a facility program to mitigate, prepare for, respond to, and recover from disasters and emergencies.

Key elements of an emergency plan include the following:

- Identification of hazards, the likelihood of their occurrence, and the vulnerability of people, property, and the environment to those hazards. Typical hazards considered include fires, explosions, earthquakes, floods, windstorm (tornado and/or hurricane), water/liquid damage, and flammable/combustible liquid spills.
- Preplanned response scenarios for identified hazards posing high risk
- An emergency organization within the facility capable of directing, controlling, and coordinating response and recovery operations
- Defined relationships and operational procedures between the facility emergency organization and municipal emergency service organizations
- Preferred methods of reporting fires and other emergencies
- Emergency escape procedures and emergency escape route assignments
- Procedures for employees who remain to operate critical plant operations before they evacuate
- Procedures to account for all employees after emergency evacuation has been completed
- Rescue and medical duties for those employees who are to perform them
- Procedures to ensure that critical fire protection systems remain operational, if at all possible
- Plans for business continuity in the event of a major emergency, including consideration for salvage, cleanup, and the use of alternative locations for conducting business
- Frequency and scope of training for employees based on their emergency responsibilities
- Plans for routine exercises and evaluations of the emergency plan

Prefire incident plans should be developed for each building and be organized in a format that is useful to the facility fire brigade and municipal fire service organizations. It should contain, at a minimum, the following information:

- A review of the facility layout and best access and evacuation routes for each area
- A discussion of facility construction features and their probable reaction during a fire incident
- An overview of facility operations, equipment, and associated fire hazards

- A review of available water supplies, fire pumps, sprinkler control valves, fire department connections, detection, alarms, and special suppression equipment
- Expected areas for spill and firewater drainage and runoff, and anticipated exposures created by them
- A description of available communications and preestablished plans with the responding public fire department
- The requirements for manual fire-fighting efforts, including the most appropriate tactics, equipment, and approach to be used by the brigade
- Information on ventilation systems that may cause the spread of smoke or may be utilized to prevent smoke spread
- An evaluation of chemical hazards and methods to handle spills
- The location of flammable liquid and gas system isolation valves and electrical power disconnects

FM Global provides several interactive tools, at no cost, to the Public/Volunteer Fire Service that aid in the development of prefire incident plans for sprinklered commercial and industrial properties.[6]

Incident Investigations. It is important to investigate every incident that results in, or could have reasonably resulted in, a major release, fire, or explosion accident. Most current investigation methods focus on determining the root cause of the incident and basing corrective actions on the root cause. Incident investigation program factors include the following:

- Incident investigations should be initiated promptly. Several U.S. government regulations require investigation of large incidents begin within 48 hours.
- Investigation teams should have plant and process knowledge as well as other specialties, such as fire loss investigation and root cause investigation skills.
- Incident reports should include the following:
  - Date of incident and date the investigation begins
  - Appropriate collection of relevant evidence from the investigation
  - Description of incident, root cause, contributing factors, and resulting recommendations
- Reports should be reviewed with appropriate personnel within the facility and retained in loss incident files.
- Recommendations should be addressed and resolved in a timely manner.
- Management should routinely review the status of open investigation reports and recommendations.

QUALITY GRADING OF MANAGEMENT LOSS CONTROL PROGRAMS

Example Grading System

It is beneficial to develop a quality rating system for loss prevention and control programs to provide a framework for budgeting and monitoring program investments versus program quality. Table 12.11.1 provides an example format for grading some primary loss prevention and control programs. This general framework can be expanded and customized as needed.

Many property insurance companies use other rating systems to evaluate the quality of a risk. Although the methods used are proprietary, each company assesses the intrinsic hazards of a facility to fire, natural disaster, and the specific hazards of the occupancy. Additional adjustments are made to the assessment based on the quality of the fire protection systems, capability of the fire water supply, the quality of other loss control programs, and status of previous recommendations at a given facility. It is important to understand the specific methods used by a facility's insurance company for rating risk, and this understanding should be part of an annual discussion with insurance company representatives.

The example quality scoring in Table 12.11.1 is based on the following four fundamental quality elements:

1. Planning (+40 maximum points)
   - Explicit goals and objectives (+5)
   - Well-defined scope (+5)
   - Clear-cut desired outputs (+5)
   - Consideration of alternative achievement mechanisms (+5)
   - Well-defined inputs and resource requirements (+10)
   - Identification of needed tools and training (+10)
2. Accountability (+40 maximum points)
   - Strong sponsorship (+5)
   - Clear lines of authority (+5)
   - Explicit assignments of roles and responsibilities
   - Formal procedures (+10)
   - Internal coordination and communication (+10)
3. Implementation (at the facility level) (+40 maximum points)
   - Detailed work plans (+10)
   - Specific milestones for accomplishments (+10)
   - Initiating mechanisms (+10)
   - Execution (+10)
4. Monitoring (program effectiveness) (+40 maximum points)
   - Performance standards (+5)
   - Performance measurement and reporting (+5)
   - Internal reviews (+10)
   - Audit mechanisms (+10)
   - Corrective action mechanisms (+10)

The following quality grading score ranges indicate the program level:

Example Program Quality Grading

- 140–160 Excellent-quality program score (i.e., exceeds minimum requirements)
- 120–140 Good-quality program score (i.e., meets expected program requirements)
- 100–120 Fair-quality program score (i.e., marginal, minor improvements needed)
- Less than 100 Poor-quality program score (i.e., major improvements needed)

A description and discussion of the following program factors are presented in *Plant Guidelines for Technical Management of Chemical Process Safety.*[7]

TABLE 12.11.1 Example of Management Loss Prevention and Control Program Quality Grading

PMS Program Safety	*Planning (S1)*	*Accountability (S2)*	*Implementation (S3)*	*Monitoring (S4)*	*Program Score S1 + S2 + S3 + S4*
1. Process safety information	20	20	30	35	105
2. Process hazard analysis					
3. Pre-start-up safety					
4. MIP—process equipment					
5. MIP—emergency safety systems					
6. MIP—protection systems					
7. Operating procedures					
8. Hot work permits					
9. Fire system impairments					
10. Facility self-inspection					
11. Flammable liquid handling and ignition control					
12. Employee training					
13. Contractors					
14. Management of change					
15. New construction					
16. Incident investigation					
17. Emergency planning					

MIP = Mechanical integrity programs. Points are allocated for example only.

Program Monitoring

Two important aspects of program monitoring are (1) auditing and (2) recommendation tracking.

Auditing provides a means to measure the performance of loss prevention and control programs. Audits document program progress and success and also demonstrate the interest of plant management in maintaining a high program performance quality. Effective auditing provides valuable feedback on the program's strength and pinpoints deficiencies in program areas that may need improvement.

A system for tracking recommended corrective actions resulting from the audit should be established. The system should assign responsibilities and provide a follow-up reporting mechanism that tracks progress and completion of action items.

EMERGENCY ORGANIZATIONS AND INDUSTRIAL FIRE BRIGADES

Fire-Fighting Capability Options

One of the most important aspects of emergency organizations is the creation, equipping, and training of private fire brigades, usually referred to as industrial fire brigades. The potential benefits versus the costs of a fire brigade program must be evaluated. Typical questions asked during this evaluation include the following:

- How much is a brigade program going to cost?
- How much time will employees need to spend in training?
- Who will conduct the training and where will it take place?
- How will time be scheduled for training all members on all shifts?
- Will personnel become more aware of fire and its causes and contributing factors, making preventing fires more likely?
- Will fires that are fought by trained industrial fire brigade personnel be fought more safely?
- Will property loss likely be minimized through prompt action by a trained brigade?

OSHA Subpart L and NFPA 600, *Standard on Industrial Fire Brigades,* provide many options to facility management when the level of facility fire-fighting capabilities are determined.

Option 1. *No employee will fight a fire.* This means that on notification of a fire, all employees will evacuate the facility. If

this option is selected, management must provide the means for protecting its assets and production as well as the integrity of the company. This can be provided through fixed fire protection systems and/or by relying on the local fire department. *Note:* Options 2 through 4 deal with incipient fires. An incipient fire is one that is in the initial or beginning stage and can be controlled or extinguished safely with portable fire extinguishers, Class II standpipes, or small hose systems without the need for protective clothing or breathing apparatus.

Option 2. *All employees will be trained (on an annual basis, at minimum) to use fire extinguishers to fight incipient fires.*

Option 3. *Designated employees will fight incipient fires.* This is the same level of training as required in Option 2. However, only specific employees throughout the plant are trained and are expected to respond to incipient fires.

Option 4. *An organized industrial fire brigade will fight incipient fires.* At this level, the management of the plant has written a specific organizational statement regarding the development of a fire brigade. This statement includes a specific leadership structure, procedures, training, and equipment necessary to perform incipient-level tasks. The organizational statement should be part of the site emergency plan. The brigade leaders must have training exceeding that of the regular brigade member. In addition, special hazards should be addressed in training and procedures for all brigade members. Hands-on training is required on an annual basis.

Option 5. *An organized industrial fire brigade will fight fires beyond the incipient stage.* This option incorporates the more sophisticated organization of Option 4 but adds more requirements. These include assessment of physical fitness, use of protective clothing and positive-pressure self-contained breathing apparatus (SCBA), quarterly training with hands-on training required annually, and higher levels of overall training and education. Fire brigades organized to fight fires beyond the incipient stage must meet the applicable requirements of advanced exterior fire fighting and/or interior structural fire fighting contained in NFPA 600. Option 5 is a significantly larger step than Option 4 in terms of training, organization, and equipment.

Based on the needs assessment of a facility (extent of hazard potential, existing fire prevention and automatic fire protection systems in place, and availability and adequacy of public fire department response), management should evaluate its hazards and select the appropriate option. The considerations for Options 1, 2, and 3 involve appropriate documentation in the facility emergency plan, basic training, and availability of basic fire-fighting equipment including fire extinguishers. Due to the complex considerations involved in Options 4 and 5, the remainder of this chapter will be devoted to them.

Often the type of facility that could benefit from an organized industrial fire brigade does not need a brigade organized to fight fires beyond the incipient stage (Option 5) and would probably find it financially difficult to support one. A team of well-trained individuals equipped to attack incipient fires (Option 4) is relatively easy to develop and maintain. In addition, the incipient fire brigade, due to its proximity to potential fires, its vested interest in the property it is protecting, and its level of training, is an excellent loss control resource. However, many large facilities will need a fire brigade organized to fight fires beyond the incipient stage to meet their loss control objectives.

Fire Brigade Organization

Based on the size and needs of the brigade, it is important that adequate organization and leadership be established. Specific roles and skill competencies for each position within a typical fire brigade are provided in NFPA 1081, *Standard for Industrial Fire Brigade Member Professional Qualifications.* Specific titles such as *chief* and *captain* are not important but are useful for discussing roles and responsibilities.

The *fire brigade chief* has overall responsibility for brigade operations. These include training, equipment, procedures, and maintenance of systems and equipment. The fire brigade chief may report to the *plant emergency coordinator* or may have the dual responsibility of chief and coordinator, depending on the size and needs of the plant. The fire brigade chief should possess qualifications commensurate with the responsibilities of the position.

Assistant chiefs of the fire brigade are the senior fire officers on each shift who report to the fire brigade chief. In this capacity, they are the primary brigade leaders or incident commanders for the typical brigade response on any shift. Personnel in this position generally have other full-time responsibilities. Under the direction of the assistant chief, the *captain* directs a fire brigade crew that is performing tasks such as rescue, fire suppression, salvage, and overhaul. In a small brigade, a *leader* may combine the duties of several leadership positions.

Command and control of fire brigade operations is provided by use of an incident management system compliant with NFPA 1561, *Standard on Emergency Services Incident Management System.* As part of the U.S. Department of Homeland Security's National Response Plan, the incident management system has been expanded to become the National Incident Management System (NIMS). A variety of training courses on the newly introduced National Incident Management System (NIMS) are available through the U.S. Department of Homeland Secuity.

Plant personnel who are selected to participate in the fire brigade must have proper physical, mental, and emotional qualifications, in addition to response availability (which is affected by each person's full-time job assignment). The tasks *brigade members* are expected to perform include regular training, fighting fires, rescue, and any other tasks outlined in the plant's brigade organizational statement.

Based on the occupancy and staffing levels of a particular facility, it may be necessary to include fire brigade support personnel who are not directly involved in fire fighting. For example, an *electrician* is responsible for isolation of electrical circuits in an area or control of specific equipment that the incident commander has directed should be shut down. The electrician should also ensure that the electrical service to fire protection systems is not inadvertently shut down.

A *pipe fitter* is an excellent resource for cycling fire protection system valves or operating process control valves that the

incident commander has determined should be closed to isolate specific piping. Maintenance personnel might respond as *fire pump operators* to ensure that the fire pumps have started or to take any manual actions necessary to ensure their operation. In addition, an operator stands by the pumps to monitor their condition or to take actions as directed to shut down the pumps or return them to regular service (standby or automatic start mode).

Staffing

To determine the number of fire brigade members required, it is necessary to define and document what duties the brigade will perform in the brigade's organizational statement. The brigade's primary responsibilities may include controlling and extinguishing the fire, evacuating threatened personnel, minimizing exposures to other areas, and coordinating the efforts of the public fire department.

In order to ensure the safety of brigade members, all fire fighting must be conducted in teams. Since it takes two fire fighters to operate a mobile 1½ in. (38 mm) hose stream of 75 to 100 gpm (300 to 400 L/min), the need for a team concept is further reinforced. A minimum of a five-member brigade fully clothed in their personal protective equipment would be required to provide one 1½ in. (38 mm) hose line: two firefighters to actively fight the fire; two on standby for rescue in the event something happens to the two fighting the fire; and one to act as the incident commander to coordinate the activities and provide communication. Personnel may also be needed to provide additional equipment, operate fire apparatus, set up smoke fans, initiate search and rescue efforts, and so on. In all facilities, minimum staffing levels must also take into consideration vacation schedules, employee absences, and shift schedules. A roster of two to three times the minimum number of responders is usually required to ensure adequate emergency staffing.

Concurrent with the fire-fighting operation, efforts should be made to reduce the damage caused by the fire and the fire-fighting efforts. This is accomplished through salvage and overhaul operations. Obviously, the more responsibilities expected of the brigade through the organizational statement, the greater the number of members that will be required.

Training

No single item is more important to the effectiveness of a fire brigade than a well-organized and well-documented training program. It is too late to develop skills at the time of an emergency. No brigade member should be allowed or expected to perform a duty at an emergency for which he or she has not been fully trained.

NFPA 600 requires that training sessions be held periodically, commensurate with the type of fire fighting expected by the brigade. The actual training frequency for a specific plant will vary depending on the fixed systems provided, the availability and quality of outside fire-fighting help, the frequency of actual fires, the number and experience of brigade personnel involved, the type and level of training provided, and so on. NFPA 1081 specifies a core set of job performance requirements, as well as site-specific requirements for personnel who perform as members of an organized fire brigade.

Training the brigade can be simplified by using contract agencies and groups such as the local fire department, state or county fire academies, colleges with fire programs, and private interests such as training consultants, the National Fire Protection Association, the International Society of Fire Service Instructors, and the International Fire Service Training Association. Public fire department training grounds are often available in the general area of a plant. These are especially helpful since they are usually arranged to emphasize hands-on training with actual fires. To ensure the safety of all training activities involving live fire hands-on training, make sure that the operation is compliant with NFPA 1403, *Standard on Live Fire Training Evolutions.*

As new personnel are added to the brigade, they should receive an orientation that addresses their responsibilities. This orientation should include classroom training that discusses the theory of fire, plant fire hazards, fixed fire detection systems, fixed fire suppression systems, personal protective equipment with special emphasis on self-contained breathing apparatus (for the structural brigade), and manual fire-fighting equipment available to the brigade. Finally, they should receive sufficient practice in actual fire fighting so that some skill is developed. Plant tours are generally needed to show the locations of fire hazards and fire protection equipment.

Fire-fighting training should be made as realistic as possible and should simulate the actual fire conditions expected. Too many brigades rely on stereotyped training that consists only of outside oil-pit fires or scrap-wood fires. This approach seldom prepares the brigade for the typical interior fires that will be encountered. For brigades that will fight fires beyond the incipient stage, practice with SCBA is especially important, since many plant areas have limited capability for ventilation.

An important part of training is conducting fire drills. Unannounced fire drills should be conducted to check the effectiveness of the brigade response and to identify whether the plant prefire plans are viable. It is during these drills that areas that are beyond the reach of hose lines or that are inaccessible because of equipment locations, locked doors, or other obstructions will be identified. The prefire plans should be revised as needed based on the drill critiques. All drill critiques should be documented. Drills should be conducted in a realistic manner using charged hose lines where possible. Brigades responsible for fire fighting beyond the incipient stage should use protective equipment and SCBA during all drills. Appropriate drills will make responses more automatic under the stress of an actual fire emergency.

The use of computer fire models might be considered as an aid in planning drills. These models can be used to predict likely fire-growth and smoke-spread scenarios. With this information, a more realistic assessment of fire conditions can be made and incorporated into drill scenarios. This same information could be adapted for use in prefire plans.

Fire brigade leadership training must be provided to all persons who may direct fire-fighting operations. Their leadership abilities will often determine the success or failure of the fire-fighting effort. This training should emphasize leadership and fire tactics. The brigade leader should possess a working knowl-

edge of the facility layout, fire hazards, existing protection, and plant operations. All brigade members, but especially brigade leaders, should be trained in the use of an incident management system (IMS). NFPA 1561 contains the minimum requirements for an incident management system, and various training courses on the newly introduced National Incident Management System (NIMS) are available through the U.S. Department of Homeland Secuity.

Pre-Incident Plans

NFPA 1620 provides a good framework for evaluating the protection, construction, and operational features of specific occupancies to develop a pre-incident plan that should be used by responding personnel to manage fires and other emergencies in such occupancies using available resources.

Pre-incident plans should be developed for each building and be organized in a format that is useful to the facility fire brigade and municipal fire service organizations. It should contain, at a minimum, the following information:

- A review of the facility layout and best access and evacuation routes for each area
- A discussion of facility construction features and their probable reaction during a fire incident
- An overview of facility operations, equipment, and associated fire hazards
- A review of available water supplies, fire pumps, sprinkler control valves, fire department connections, detection, alarms, and special suppression equipment
- Expected areas for spill and firewater drainage and runoff, and anticipated exposures created by them
- A description of available communications and preestablished plans with the responding public fire department
- The requirements for manual fire-fighting efforts, including the most appropriate tactics, equipment, and approach to be used by the brigade
- Information on ventilation systems that may cause the spread of smoke or may be utilized to prevent smoke spread
- An evaluation of chemical hazards and methods to handle spills
- The location of flammable liquid and gas system isolation valves and electrical power disconnects

FM Global provides several interactive tools, at no cost, to the public/volunteer fire service that aid in the development of pre-fire incident plans for sprinklered commercial and industrial properties.[6]

Fire-Fighting Equipment

The need for fire-fighting equipment varies widely. Equipment should be provided that is commensurate with the duties of the fire brigade and the hazards that it will encounter. When fire-fighting equipment is mentioned, a fire truck is often initially visualized because it is essential to the operation of public fire departments. Many industries, however, have large quantities of water available at a fairly high water pressure for fire-fighting purposes. Since a fire department pumper is used to transport fire fighters and fire equipment and to boost the water pressure, the pumper is seldom needed by the fire brigade. What is needed is a reasonable distribution of yard hydrants and hose houses, even in remote portions of the yard. NFPA 24, *Standard for the Installation of Private Fire Service Mains and Their Appurtenances,* lists equipment required for hose houses.

Inside facility buildings, a well-designed interior standpipe system, installed according to NFPA 14, *Standard for the Installation of Standpipe and Hose Systems,* distributes hose stations throughout large industrial buildings. However, if the fire blocks access to one hose station, others usually will not reach the hazard. In addition, safety dictates that a backup hose line be established for the protection of the primary fire attack team(s). For these reasons, some means of easily transporting fire hose should always be provided within the plant. A vehicle or cart may be useful to carry additional equipment, especially to remote areas of the plant site.

Fire-fighting and supplementary equipment should be distributed throughout the plant with concentrations at convenient brigade access points. Each brigade member who fights fires beyond the incipient stage must be provided with protective equipment, commonly referred to as "turnout" gear, including helmet, coat, boots, trousers, and gloves, as required by NFPA 600.

NFPA 600 also requires the use of protective hoods to protect the head. Fire brigade members' hands receive a high percentage of injuries, indicating the need for gloves specifically designed for use in fire fighting. Foot and eye injuries are also prevalent. Steel-insole fire boots and fire helmets with eye/face shields will reduce these injuries. In addition, goggles and safety glasses have been shown to be effective in reducing eye injuries where SCBA is not needed. NFPA 1971, *Standard on Protective Ensembles for Structural Fire Fighting and Proximity Fire Fighting;* NFPA 1975*, Standard on Station/Work Uniforms for Fire and Emergency Services;* NFPA 1981, *Standard on Open-Circuit Self-Contained Breathing Apparatus for Fire and Emergency Services;* and NFPA 1982, *Standard on Personal Alert Safety Systems (PASS),* cover protective equipment.

Only those familiar with fighting fires inside buildings can appreciate the amount of smoke, heat, and toxic gases generated during a fire. These fire products necessitate the use of positive-pressure SCBA if the fire has developed beyond the incipient stage. The use of protective clothing and SCBA allows fire brigade members to advance safely into a fire area much farther than otherwise would be possible. Because of the limited duration of the air supplied by SCBA during stressful conditions, spare air bottles are necessary.

Specialized equipment may be helpful in conducting fire-fighting operations. Items such as fire-fighting foam concentrate, foam nozzles and eductors, high-expansion foam generators, and handheld infrared heat detectors may be necessary. The need for such special equipment should be identified as a part of the plant fire hazards analysis. Portable communications equipment must be provided if an efficient and safe fire-fighting operation is to be conducted. The brigade leader must have a two-way radio to keep the plant operators and management informed of the situation, to request additional assistance or equipment, and to coordinate the efforts of incoming fire departments. Each fire-fighting team should also be provided with two-way radios to

facilitate communications with the brigade leader. Salvage and overhaul equipment will be needed to minimize water, smoke, and fire damage during and after a fire. Salvage equipment should include such items as ventilation fans (fans will require explosion-proof motors in many manufacturing facilities) and flexible ducts for smoke removal, floor squeegees, water vacuums, and tarps.

All fire-fighting, salvage, and personal protective equipment should be inspected regularly to ensure that it is both available and in good condition. Brigade members should conduct these inspections as part of their routine training program.

Municipal Fire Department Assistance

Regardless of the abilities and resources available to the facility fire brigade, it is a good practice to include the public fire department in pre-incident emergency planning. These personnel may be needed only in the case of a failure of the fixed fire suppression systems or in other unique circumstances, but good emergency planning includes providing for such possibilities. The facility emergency organization should realistically evaluate the local fire department to determine the level of assistance available.

If outside fire departments are to be used, it will be necessary to determine the minimum support they can supply and the response times involved. The number of personnel and response time may vary a great deal in many volunteer departments, depending on the time of day. The number and type of equipment available to respond should also be defined so that pre-incident plans can be developed accordingly.

Another reason for involving the local fire department might be the need for special equipment or capabilities that the facility itself cannot economically provide. These may include the ability to draft water from a static source, such as a pond or river. Departments have this basic capability with their pumpers. However, either the plant or the fire department must provide hard suction hose that may not be needed under normal conditions. The pumper must also be provided with adequate access to the water source. Other equipment, such as ladders, foam generators, and fire hose, should be considered. Compatibility of equipment, such as radio frequencies, SCBA cylinders, and hose threads, should be verified.

Management should not assume that the fire fighters from the local fire department have adequate experience and training in industrial fire fighting. In many cases, local fire department personnel may be most familiar with fighting structure fires with very limited water supplies. Such experience would certainly not provide the average fire fighter with an adequate background for attacking a flammable liquid fire inside a structure. It must be determined what the local fire department is familiar with and the levels of training that are provided for its personnel. The plant may even need to supplement the public fire department's training in the fighting of more typical industrial fires, such as those involving flammable liquids.

It is important to identify the legal relationships involved if the plant is located outside the formal fire department jurisdiction and to develop appropriate mutual assistance agreements. It is equally important to ensure that the incident management systems used by the brigade and municipal fire department are able to be effectively integrated, and determination is made on who will have overall command of an emergency incident (see Figure 12.11.5).

All public fire department personnel should be given periodic familiarization tours of the plant and should be involved in

FIGURE 12.11.5 Fire Brigade Leader Meeting with Municipal Fire Department Representative

pre-incident planning. Pre-incident plans made in conjunction with the public fire department should identify personnel assembly points, general fire attack approaches, equipment needs, and personnel requirements. The pre-incident plan should clearly define who will direct the combined fire-fighting efforts of the industrial fire brigade and the public fire department during an emergency. Plans should include a requirement that outside fire department personnel be escorted by facility personnel, whenever possible, for their safety. Regardless of the amount of time expended by the fire department, they cannot be expected to gain sufficient familiarity with the plant so as to operate safely during an emergency that may generate as much confusion as smoke. Combined drills should be conducted regularly so that the brigade and the fire department can learn to function as a team.

Fire Brigade and Hazardous Materials Response

Since the mid-1980s, there has been a substantial amount of legislation in the United States regarding the handling of hazardous materials and the response to emergencies involving hazardous materials. The most prevalent of these new U.S. federal laws are 29 CFR 1910.120, Hazardous Waste Operations and Emergency Response, and the Emergency Planning and Community Right-to- Know Act, which is Title III of the Superfund Amendments and Reauthorization Act of 1986 (commonly known as SARA Title III).

Under SARA Title III, local emergency planning committees (LEPC) were formed to develop pre-emergency plans. The LEPCs are composed of officials from fire departments, emergency medical services (EMS), law enforcement agencies, community groups, and emergency management organizations, as well as facility representatives from every plant that falls under the hazardous materials reporting requirements of the law.

Each community LEPC should have a comprehensive pre-emergency plan completed for each facility covered under the regulation. These plans should indicate what agencies will handle the response to any facility for which the plans were developed. In some cases, fire brigades may have the responsibility for response to hazardous materials incidents. If this is the case, the brigade must meet the requirements for a hazardous materials (hazmat) response team.

The requirements for a hazmat team include mandatory training, medical surveillance, procurement of necessary equipment, development of standard operating procedures, the use of an incident management system, and others, as required by OSHA 1910.120. Also, specific personnel decontamination procedures must be in place to ensure hazmat team members can safely leave a contaminated area.

The complexity of any plant fire brigade's involvement in hazmat activities will vary according to the chemical hazards encountered, the equipment and training necessary to control expected incidents, and the availability of resources from the community. It will also depend on the level of response expected by the response plans developed by the LEPC and the development of a facility emergency plan compliant with NFPA 1600. This may mean that the industrial fire brigade is not involved at all, is involved only as a first responder agency (which is responsible for recognizing that a hazard exists, calling for trained personnel, and securing the area), or is involved as a hazmat team.

Due to the extensive training time and the cost of equipment, a facility may be financially prohibited from having the fire brigade act as a hazmat team. Management must thoroughly understand and consider the costs and organizational commitment required to maintain a competent hazardous materials response team.

If a fire brigade must function as a hazmat team, management may consider developing a full-time emergency response organization because of the disruption that the additional extensive training and drill time would cause to work schedules. One type of facility where management might consider this decision is a high-hazard facility where outside assistance might be delayed.

Beyond the legislation, NFPA has issued two consensus documents regarding response to hazardous materials emergencies and qualifications for the responders. These are NFPA 471, *Recommended Practice for Responding to Hazardous Materials Incidents,* and NFPA 472, *Standard for Professional Competence of Responders to Hazardous Materials Incidents.* These documents provide excellent support in developing hazmat response programs that will aid in complying with OSHA 1910.120 and SARA Title III.

SUMMARY

Industrial fire risk management responsibilities include identifying and evaluating fire and explosion hazards and risks, developing programs and assigning management responsibilities to manage the identified risks, and establishing emergency organizations to control fire and explosion incidents that do occur.

Fire loss prevention programs, which include written operating procedures, hot work permits, fire system impairment procedures, and self-inspections, are a good investment toward minimizing large fire loss potentials. The loss prevention and control program quality grading example provided in this chapter is a good starting point for assessing the quality of existing programs and areas of improvement. Once good programs are established, continuous monitoring and auditing are essential.

A fire brigade can make many contributions to plant risk management and loss control. Assurance that detection and suppression systems are functional and ready for use is a major contribution that is often overlooked. Quick response by a well-trained and well-organized brigade can minimize loss. The time spent developing the fire brigade and the overall emergency organization will raise the consciousness of the general employee toward fire safety. Moreover, it gives employees the message that management is concerned about fire protection and employee safety and, thus, improves employee morale and the efficiency of facility operations.

Disasters are nothing new. They were a fact of human existence long before recorded history. Humans have lived with them and suffered through them. Many disasters have driven changes in how we live and how society has evolved. The 1666 Great Fire of London, for example, essentially resulted in the destruction of the city but also drove the creation of some of the very first building codes aimed at fostering fire safety. Christopher Wren was charged with rebuilding London and his plans required the use of brick and stone and forbade the use of thatched roofs. Improved sanitation was also a by-product that contributed to a healthier populace.

Natural and man-made disasters over the past four to five years have driven home to many the value of the planning required to handle these catastrophic events. Contributing to an awareness perhaps not seen in recent history were events such as the terrorist attacks of September 11, 2001, and the fear and tension that gripped the nation afterwards. Included in this as well were the anthrax contaminations and other scares, such as hurricanes Katrina, Charlie, Ivan, Francis, Wilma, and Jeanne, and the tsunami in Southeast Asia.

One might imagine that such heightened awareness would mean that almost every entity responsible for disaster operations would have well-thought-out, effective, and proven plans for handling these events. Sadly, that is not yet the case. Consider this: With the publication of this twentieth edition of the *Fire Protection Handbook,* this chapter is the very first devoted solely in this reference book to the subject of disaster preparedness.

For related topics, see Section 1, Chapter 7, "Protecting Against Extreme Events"; Section 1, Chapter 8, "Emergency Management and Business Continuity"; Section 4, Chapter 5, "Strategies for Occupant Evacuation During Emergencies"; Section 5, Chapter 3, "Disaster Preparedness Education"; Section 12, Chapter 17, "Pre-Incident Planning for Industrial and Municipal Emergency Response"; Section 12, Chapter 18, "Pre-Incident Planning for Emergency Response"; and Section 12, Chapter 19, "Community Risk Reduction."

NIMS/ICS APPROACH TO EMERGENCY PREPAREDNESS

National Incident Management System (NIMS) Defined

Pursuant to the U.S. Department of Homeland Security and presidential directives, federal, state and local governments have now been instructed to develop guidelines, standards, and protocols to implement a national incident management system (NIMS). In addition, all state and local governments are strongly encouraged to adopt NIMS as their single approach in order to prevent, prepare for, respond to, and recover from terrorist attacks, major disasters, and other emergencies.

William Van Helden has been in the fire service since 1978 and currently serves as the fire chief and emergency management director for the city of Cape Coral, Florida.

Terry Stewart is city manager of Cape Coral, Florida. He is the former fire chief of the city of Lauderdale Lakes, Florida, and also served as assistant fire chief in Pembroke Pines, Florida.

There have been several approaches to managing large incidents and disasters over the past two decades. Many of those had components similar to those of NIMS, but there was never one unified approach designated by the federal government to be the single all-hazards approach to managing disasters and other related incidents. Typically, the use of NIMS or other forms of incident command models began primarily with the fire service and then began to trickle into other branches of government. NIMS is now the single tool that will be used by all branches of federal, state, and local government, including fire, police, public works, and all other aspects in managing critical incidents.

As NIMS relates to planning, it is essential that every government entity identify who will fill the key roles in the system. Information on NIMS and the specific roles that are incorporated into the system can be found on the U.S. Department of Homeland Security website. On this website is a plethora of information to help local governments plan, including grant opportunities, online training, training via the National Fire Academy and Emergency Management Institute, and other key elements for successful implementation of NIMS. The NIMS incident command structure is based on the following three systems:

1. Incident command system (ICS) (Figure 12.12.1)
2. Multiagency coordination system
3. Public information systems

Core Values and Training

Some of the core values in the use of the NIMS have to do with span of control, unity of command, accountability, resource tracking, and operation of incident action plans. In response to the new NIMS compliance standards, most communities that are striving to be NIMS compliant are facing great challenges in the training aspects. One of the most important things to plan for over the next decade is the initial and recurrent training for all entities that will operate in a disaster setting. The level of training is defined in the NIMS documents from the Department of Homeland Security.

PHASES OF EMERGENCY PREPAREDNESS

Emergency Management Cycle

The four phases in the emergency management cycle are mitigation, preparedness, response, and recovery. As described in the following definitions, these four phases of the cycle make a loop and continually build on one another, with some phases perhaps occurring simultaneously:

1. *Mitigation.* Mitigation involves taking actions to reduce or eliminate risk to people and/or property from future hazards and effects.
2. *Preparedness.* Preparedness may be defined as a balance between the public sector, private sector, and the general populace. Plans are developed with all three of these elements in mind to prepare for, respond to, mitigate, and recover from all hazards.
3. *Response.* The organization responds to the actual emergency event with the goals of saving lives and protecting property by responding with the appropriate resources to care for the public and to begin to restore essential services.
4. *Recovery.* The community and organization begin to implement plans and procedures to attempt to bring normalcy back to that community or organization, while taking into consideration ways to mitigate future events.

These four phases are consistent with NFPA 1600, *Standard on Disaster/Emergency Management and Business Continuity Programs,* which was endorsed by the 9/11 Commission for its relevance to the public and private sectors.

Mitigation

Mitigation can be defined as actions that should be taken or accomplished before an event to prevent it from causing disastrous effects or to reduce its impact, including the protection of life and property and ensuring continuity of operations and continuity of government. Considerations in mitigation should be current code compliance, all applicable standards and laws, and the fiscal impact.

Securing funds from the federal government in a post-disaster scenario for mitigation will often be strongly contingent on relationships and agreements between local governments. Therefore, it is essential that all local governments develop a strategic plan to identify those mitigation efforts based on an all-hazards approach. Many communities refer to this concept as a "local mitigation strategy," whereby the strategy helps communities identify areas that continually suffer damage from hazards, identifies means by which to correct the problems, and develops priority rankings for funding these projects.

An all-hazards approach to a mitigation plan must include all threats via a threat assessment and potential impact to a community. All hazards include natural threats, technological threats, and man-made threats. Public officials must be careful not to develop plans that are so rigid that they lack flexibility and diversity because of what might be considered a single major threat, such as a Gulf Coast storm. The public may spend a lot of time planning for hurricanes at the expense of less probable threats such as domestic security–related issues or health-related concerns such as a pandemic flu.

Preparedness

Preparedness may be defined as those plans, procedures, and tasks that are identified by agencies or local governments to allow them to successfully prepare for disasters in both the response and recovery phases. The preparedness phase is the time in which government and businesses have the most flexibility to assign roles and responsibilities to all facets of both the public and private sectors, in addition to educating the public about the critical elements for a successful response and subsequent recovery from a disaster.

Preparedness can consist of almost any action to ensure and improve the safety and effectiveness of a disaster response. Some of the key elements of preparation should be ensuring homeland security, prevention of and response to terrorist events, protecting and restoring critical infrastructure in accordance with the related disaster, preparation for law enforcement activities related

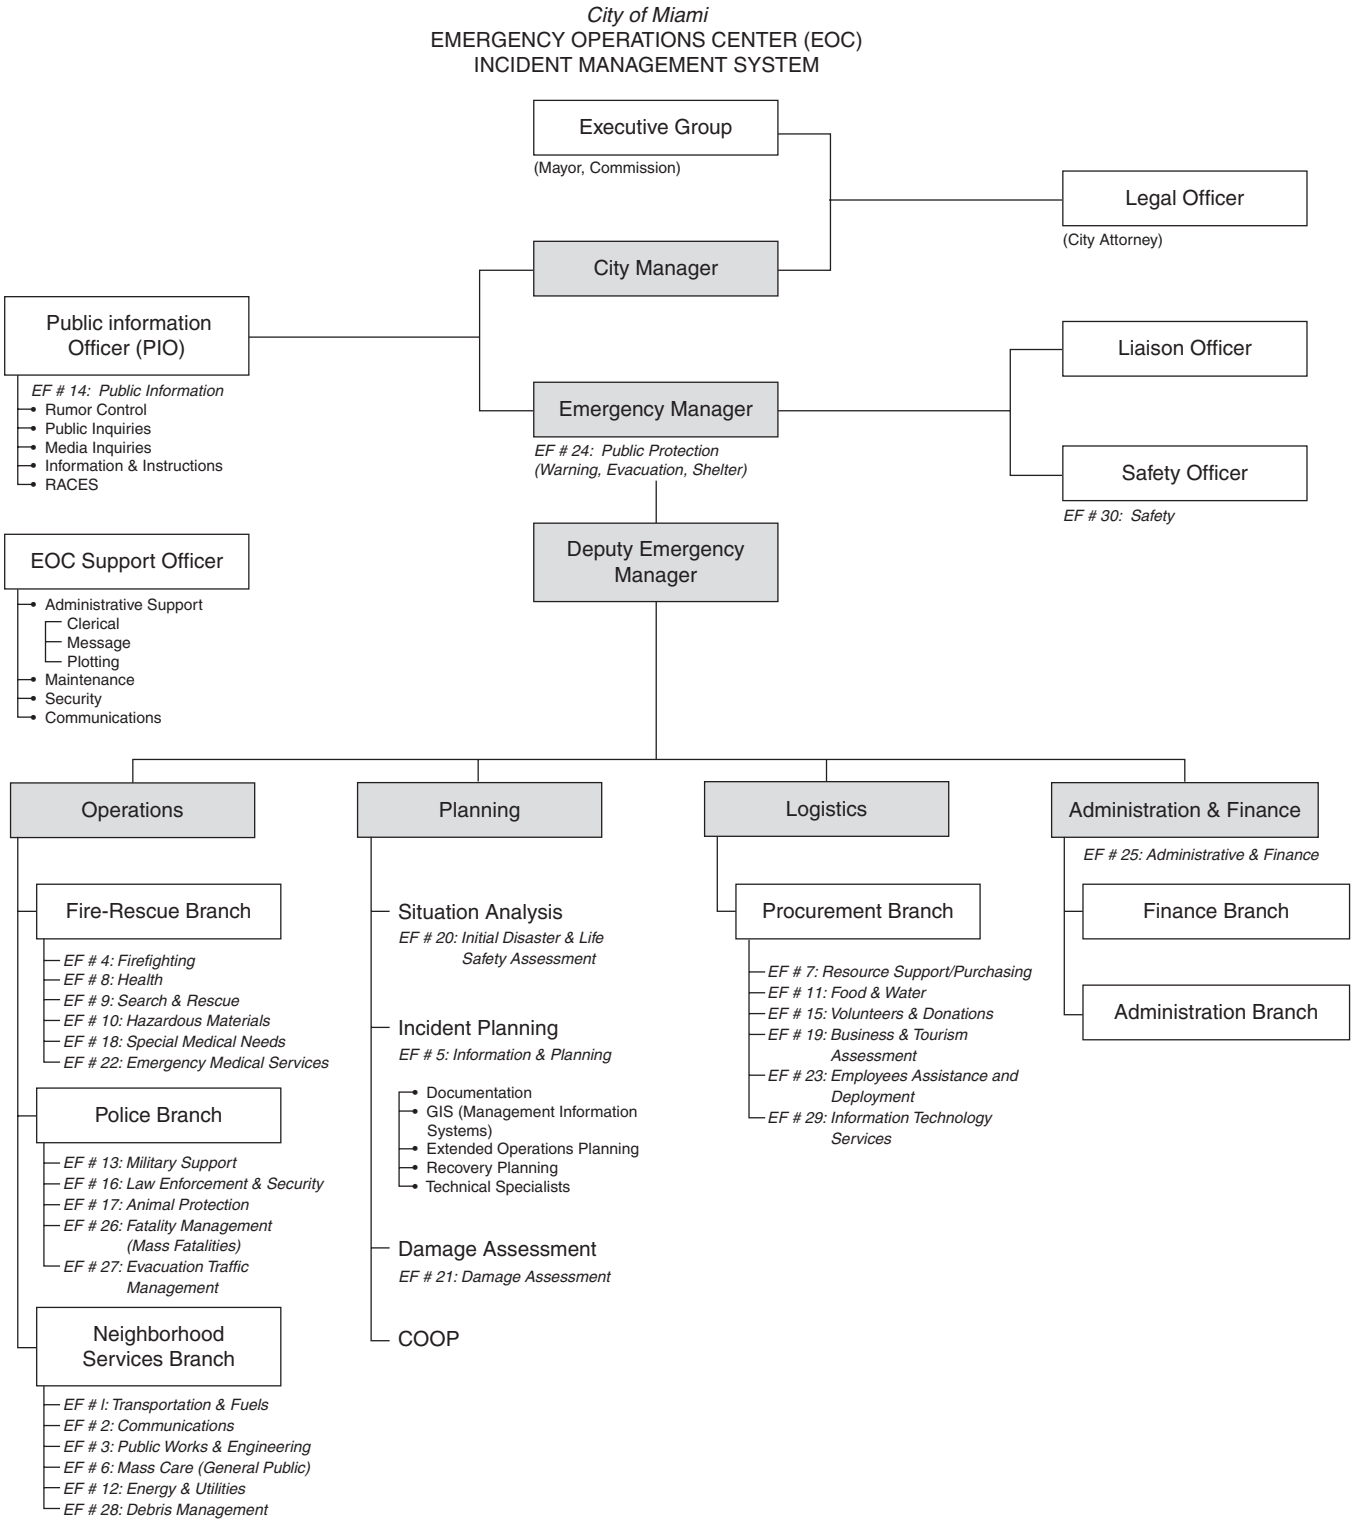

FIGURE 12.12.1 Incident Management System Operations (Courtesy City of Miami Fire Department, Division of Emergency Management)

to an all-hazards approach, and preparedness tasks that will help tie into mitigation efforts and all related recovery issues as noted elsewhere in this chapter. Unfortunately, many preparedness plans designed to be compliant with state and federal guidelines become so comprehensive that they are not practical during a real-time emergency. Therefore, it is strongly recommended that local governments put together a smaller field-operating guide (FOG) or other types of abbreviated versions of their planning

efforts when developing comprehensive emergency management plans (CEMPs).

Emergency plans that define actions to be taken in the field or other areas of government might be further enhanced by plans that present well-defined roles in the emergency operations center setting. The individual organization should clearly define and list roles pertinent to the disaster for which it has planned. Then it should identify potential positions or members of that organization to fill those areas of responsibility, as well as any other associated duties, requirements, and equipment that may be required for that role. All these should be tied into the national incident management system. Plans may be divided into several levels, which would include state plans, regional plans, local plans, and those divided into a specific department or agency. It is essential that all the plans work in concert and build on one another, especially as it relates to the request for additional resources via mutual aid and other agreements. See Section 5.7, Planning, and Section 5.10, Operations and Procedures, in the 2004 edition of NFPA 1600 for additional information about emergency management plans and procedures.

This planning effort should ensure a timely response and a maximum benefit-for-cost recovery in the aftermath of a disaster. As with any plan, if it is never exercised, it will be difficult to determine its potential effectiveness. All plans should have prescribed training exercises to draw those strengths or areas for improvement within the different plans. It is critical that training opportunities include all parties potentially involved and could range from a tabletop exercise to a statewide disaster drill for hazards such as hurricanes, earthquakes, or weapons of mass destruction.

Response

Response may be defined as the use of any and all resources to address the immediate, short-term, and long-term effects of a disaster. The goal of emergency response is to minimize and reduce suffering, loss of life, and property damage and to begin the restoration of essential services to that community. The response phase may be diverse in nature, depending on a variety of different factors, including the hazard itself, available resources, available mutual aid resources, public perception, and support from state and federal governments. Support from state and federal entities is not automatic and may often be contingent on that community's ability to fully and accurately portray the impact. During the response phase, communities must perform an impact assessment.

Impact Assessment. The impact assessment should describe the impact to the community, including the location and number of injuries and deaths, type and extent of damage, and immediate victim needs. The impact assessment should also describe the ability of that community to continue to provide essential services, including medical care, law enforcement, fire rescue, and emergency medical services. Impact to local hospitals and impact to local government infrastructure such as public works and utilities must also be detailed.

During the response phase, the request for mutual aid will be contingent on a community's available resources and needs. The importance of doing early reconnaissance of the community's needs during response cannot be stressed enough. Government officials often underestimate the impact to their local community, thereby delaying the response from state and federal officials. It is of critical importance that first responders and local agencies do not become so focused on the immediate situation that they forget to complete a rapid impact assessment of their community. In a nutshell, information to be reported should consist of the following:

- What has happened
- What is being done about it
- What is needed (specifically)
- What the gap analysis is for the needs of that community

All-Hazards Approach. An all-hazards approach to response may have to include a wide variety of initial first responders. In the event of a natural disaster, such as a hurricane or earthquake, management of debris removal on emergency thoroughfares will be essential to clear roadways for emergency vehicle access. Restoration of essential services such as water, ice, food, and power will also be of critical importance during the response and initial recovery phases (Figure 12.12.2).

An example of an all-hazards approach to hurricane preparedness occurred in many communities in Florida during the 2004 hurricane season, where local emergency responders found many people overcome by carbon monoxide poisoning during the aftermath of various hurricanes. Although emergency responders may be responding to the aftermath of a hurricane (natural hazard), all-hazards planning should include considerations such as carbon monoxide from generators, fuel leaks from overturned vessels in waterways, and other potential hazardous materials incidents that resulted from the hurricane.

However, if the disaster itself takes a different turn, as would be the case from the release of a weapon of mass de-

FIGURE 12.12.2 Distribution of Water and Ice at a Cape Coral, Florida, Point of Distribution (POD) Following Hurricane Wilma, October 2005

struction material, such as smallpox or a pandemic flu outbreak, then the response efforts may be drastically different. Local and state health departments will take key leadership roles in these events. Police and fire fighters may find themselves playing more of a supportive role in the response phase. The key to any response plan and successful operation is flexibility. If communities exercise their plans seriously, they will develop the relationships necessary to carry out a successful response to any disaster. However, if local, state, and federal governments fail to plan, train, and exercise accordingly, local governments' ability to respond to a critical event may be severely hampered.

State of Local Emergency. During either the preparedness phase or the response phase, it is common for local governments to declare a state of local emergency. In the interest of public safety, a state of local emergency is essential for city and county officials to enable them to carry out timely decisions. It is critical to have these states of local emergency and other critical ordinances or laws available and drafted by the local attorney's office in order to enact them in a timely manner.

Critical ordinances should include a state of local emergency, provisions for curfew, price gouging, lines of succession (continuity of government), emergency pay procedures that may already be outlined in a human resources manual, and the activation of local mutual aid agreements.

Recovery

Goals. The purpose of recovery planning is to anticipate what will be needed to restore a community to its full functioning capability. Successful recovery from any disaster is contingent on everyone within that community and the local, state, and federal governments understanding their roles and responsibilities. Recovery from a disaster can last anywhere from days to years, as was witnessed in the aftermath of Hurricane Andrew, which struck southern Florida in 1992.

The overall goals are to maintain leadership and continuity of government, maximize the use of local and regional resources, provide for the coordination of state and federal resources to assist a community in recovery, maintain communication to its citizens before, during, and after an event, provide the maximum support for disaster victims, make maximum use of damage assessment tools for the purpose of recovery planning, promote economic recovery, and bring the community back to some sense of normalcy.

Recovery can be broken down into short-term and long-term phases. Goals of short-term recovery would include restoration of essential services such as utilities; delivery of immediate social, medical, and mental health services; restoration of local government operations; reestablishment of transportation routes; debris management and cleanup; and disaster assistance to the local community, including assistance from both private and public sector organizations such as the Red Cross, FEMA, Small Business Administration, and so on.

The goal of long-term recovery is to restore the community to its predisaster state or an improved condition. Some of the major objectives to long-term recovery would include coordinated delivery of long-term health and social services, long-term housing, improved land use planning, restoration of the economy to predisaster levels, recovery of those dollars expended during the disaster through both public and private sector avenues, and the implementation of any mitigation strategies identified before, during, or after the disaster event.

Recovery Functions. The following is a list of recovery functions that may be utilized during a disaster event; the size and scope of the functions listed are completely dependent on the impact to the community from the disaster:

- Impact assessment (disaster assessment)
- Continuity of government
- Public information
- Human services
- Individual assistance
- Volunteers and donations
- Unmet needs
- Debris management
- Reentry and security
- Health
- Safety
- Repair and restoration of public infrastructure and services
- Building inspections and permits
- Rebuilding construction repairs and restoration
- Housing
- Redevelopment (planning and community development)
- Economic restoration and development
- Environmental concerns
- Mitigation
- Recovery administration and finance
- Mutual aid

Some communities have explored the use of a recovery task force. This task force will consist of key personnel from the public and, potentially, the private sectors who would meet before and after a disaster event to help guide and offer options to local government officials and help expedite recovery from a disaster. Although many communities can survive a minor or major disaster, few are prepared for a catastrophic event. Some of the recovery functions will become critical to the survivability of a community and the timeliness by which it is able to recover from an emergency.

Recovery from minor and major disasters is contingent on local and state response with some federal assistance. However, there must be a well-coordinated effort by federal, state, and local entities for a catastrophic event. How a community plans to recover from a catastrophic event is different from its recovery plans from a minor or major disaster. The initial basic considerations are still the same but the long-term reconstruction, rebuilding, and redevelopment issues can be overwhelming. Nothing will take the place of good planning and exercises that reflect those planning efforts. Finally, excellent relationships must exist between all levels of government in order to be successful in meeting a community's needs immediately after a disaster.

EVACUATION

Evacuations for disasters and catastrophic events can be broken down into two basic categories: pre-event and postevent. Unfortunately, many plans only account for evacuations in the predisaster phase and fail to give equal consideration to the repopulation of a community and/or critical facilities, such as nursing homes and hospitals.

Pre-Event Evacuation

Much consideration has been given in some states for people with special needs and transportation issues. They are two distinct categories. Many people with special needs are those who have a medical encumbrance that requires them to have some medical oversight in their home on a regular basis but does not require the definitive care that hospitalization would provide. Planning for the care of special needs people can be broken down into two categories: those that will require hospitalization due to type of equipment and care they need and those whose care can be satisfied at a special needs shelter (if available) where minimal medical care is rendered. Many communities have worked out interlocal agreements between public safety agencies and local health department officials for providing medical care with some additional support from private sector nursing and paramedics when available.

Some of the population of local communities will require special attention in the area of transportation. This can be one of the greatest challenges for communities with large populations of indigent, low income, and elderly. Communities such as Atlantic City, New Jersey, that are used to moving large volumes of people via mass transit and private busing are used to the concept of timely transportation of people to and from a specific area. This is the exception and not the rule. Many communities do not have enough infrastructure in the form of public transportation to facilitate a timely evacuation of the aforementioned populace.

It is important to have developed procedures and secured contracts with local school board resources, private sector bus companies, and even rail and taxi services. The successful use of this multifaceted approach to obtaining resources for evacuation requires extensive planning and written contracts with an associated cost for securing those services from private industry.

On rare occasions, such as the evacuation of New Orleans in 2005 and the evacuation of critical medical facilities in the Florida Keys, the Department of Defense or the National Guard may be used to supplement the local resources. Although in the past federal resources were typically not deployed until a substantial event occurred, there is a growing consensus that federal involvement must occur earlier and with a much stronger presence than in the past. When addressing such a large need for evacuation, the use of a staging officer is essential for coordination and deployment of resources, fleet maintenance, portable restrooms, and fuel, which are essential to the success of the evacuation.

Most communities lack the transportation infrastructure to handle the evacuation of a significant portion of their visitors and residents from a potential threat. Consideration such as contra flow (one-way traffic) must be put in place prior to the time an evacuation order is given in order to prevent gridlock. Unfortunately, studies have shown that many people make their decisions about evacuation based on local media more than direction from public officials. Therefore, the community should make it essential to pay attention to what the local media is stating about the event and should strive to have the best relationship possible with the local television, radio, and print media.

Postevent

The same consideration that is given to the evacuation of the population before the landfall of a hurricane or the arrival of any threat or potential disaster must be given to the repopulation of those evacuated portions of the communities. Critical to those planning efforts would be the coordination of when essential services are restored to the affected areas and the elimination of the threat and subsequent results from the disaster event.

HAZARD VULNERABILITY ANALYSIS

Information Gathering

A hazard vulnerability analysis is one of the initial steps in implementing a preparedness or mitigation program for a local community. Information gathered in a hazard vulnerability analysis will include FEMA documents, state and local government documents, and firsthand information that can be obtained either from local newspaper archives or interviews from people in the community who were present or participated in previous events. Hazards can be categorized typically either into natural, technological, or man-made events. Hazards can be indigenous to a specific community and they may change from location to location based on geography, population, and other specific elements such as critical or high-profile portions of an area or local government.

Probability Versus Impact

Although there are several models for performing a hazard vulnerability analysis, they all boil down to assessing "probability versus impact." Series of matrixes could be designed that would address the hazard and then the probability, whether it be high, moderate, or low, versus the impact, whether it be high, moderate, or low. From those indices communities can then determine the priority for planning and mitigation efforts for those specific hazards.

Hazards

Different elements or hazards to be considered may include agricultural freezes, air transportation accidents, civil disorder, droughts, floods, hazardous materials incidents, hurricanes, earthquakes, nuclear attacks, power failures, radiological incidents, terrorism, tornados, wildfires, tsunamis, cyber-terrorism, landslides, and heavy snow conditions. Criteria for evaluating the potential vulnerability and associated hazards to a community may be somewhat subjective, but all

communities will have to perform some sort of benefit/cost ratio. Although the threat of terrorism is widespread throughout many nations and large cities, it may be cost prohibitive to invest a large amount of taxpayer dollars into preparing for terrorism in a small rural community. However, that same rural community, depending on its location and hazards, may need to have substantial planning and investment into plans for tornados, earthquakes, hurricanes, or other threats indigenous to that community.

As each organization performs its own hazard vulnerability analysis, it will become readily apparent what the priorities are and where the critical funding should be allocated. A tiered plan or a master plan that would extend planning for those events for 5 or 10 years may be appropriate in order to prioritize the highest threats and eventually address all that could affect that community. See NFPA 730, *Guide for Premises Security,* for additional information on security planning.

IDENTIFICATION OF CRITICAL FACILITIES AND INFRASTRUCTURE

Purpose

The purpose of identifying critical facilities and infrastructure is to prioritize and identify those critical facilities, lifelines, or resources within the community that are essential to protect and ensure limited interruption in services. Usually it is not feasible to identify and perform an analysis on every critical facility in the community, so planners must identify those that are critical for providing essential services to that community and also those that are essential for response and recovery.

Categorization of Critical Facilities

Critical facilities are typically categorized into, but not limited to, the following areas: fire rescue, police, communications, transportation, utilities, government, hospitals, shelters, nursing homes, pump stations, and evacuation routes. When a critical facilities inventory is taken, certain elements of information to be ascertained are very important, and they may include the following: facility type, population and its nature, facility name, owner/operator, location, contact information, address, function, and importance to the community. It is also advisable when identifying these facilities that, in addition to street addresses, the latitude and longitude of the property are determined and maintained in a safe place.

A good example of a critical facility assessment can be found at the National Oceanic and Atmospheric Administration (NOAA) website at http://www.csc.noaa.gov/rvat/criticalEDD.html. Once the critical facilities assessment is completed, it can be used in many of the planning functions described in this chapter. Some of these functions may be given a higher priority depending on the threat. The vulnerability may also rise depending on the threat assessment to that critical facility through both the public and private sector avenues and the implementation of any mitigation strategies identified before, during, or after the disaster event.

RESOURCE TYPING

Purpose

One of the key elements for any successful disaster response is the successful integration of both public and private sector resources into any type of emergency or disaster. Within the national incident management system (NIMS), resource typing is already defined and broken down into different categories such as law enforcement, public works, fire fighting, and the like. Those resources are further defined into kind and type but the overall approach is to make sure all agencies are using one unified approach to categorizing and classifying those resources available in times of an emergency. Some pitfalls experienced by communities in the past have been requesting something as simple as a generator but not specifying the type, the size, or fuel type or not making sure that the generator had the appropriate electrical hookup. Using the principle of resource typing can assure that when a municipality requests a generator to support a specific mission, both the county and the state will understand what the community is asking and can respond in a timely manner.

Mutual Aid Agreements

It should be noted that resource typing is a work in progress and the federal government will continue to further define resource groups and the respective definitive data sets. However, the core elements for resource typing are in place. The specific terms and definitions are listed in the National Mutual Aid Glossary of Terms and Definitions at http://www.fema.gov/preparedness/mutual_aid.shtm#1.

As stated elsewhere in this chapter, all communities should have the appropriate mutual aid agreements in place in addition to contracts with the private sector for the purpose of acquiring resources that a community may not be able to readily provide through its specific governmental entity. Finally, all government entities are encouraged to participate in the Emergency Management Assistance Compact (EMAC), which will allow the timely redistribution of resources across state lines.

CONTINUITY OF GOVERNMENT (COG)

Government infrastructure and the people that work for governments are not immune from the effects of a disaster. Whether it is a disaster that affects a region, such as a hurricane, or one that is more localized, such as a terrorist bombing, infrastructure, personnel, or both will be affected. Since there is no way to predict the level of impact, plans should be made for the most major circumstance.

Although it is often poorly protected or poorly engineered (witness the levee system around New Orleans during Hurricane Katrina in 2005), infrastructure has received the most attention in disaster preparedness. During hurricanes, for example, most communities manage to get buildings boarded up and to bring in supplies in preparation. What is sorely lacking is the preparation needed to ensure continuity of government.

Continuity of Government Defined

Continuity of government is the survival of a constitutional form of government and the continuity of essential functions. Continuity of government is a legal consideration for continuity of leadership in a government organization, whereas continuity of operations is the administrative support for the continuity of government. (See the next section, "Continuity of Operations Plan (COOP)," for more information about continuity of operations.) In general, those functions are viewed as police, fire, and EMS response and also include provisions for public works functions. The broader and more effective the government services available for dealing with recovery, the less devastating will be the disaster.

Emergency Operation Centers (EOCs)

One of the first areas in which continuity planning began to be used was in the development and construction of emergency operations centers (EOCs). A properly designed and constructed EOC provides adequate room and resources to house the logistics and command elements of emergency services. It also ensures a safe location for these elements leading up to, during, and after the impact phase. EOCs have helped to make a significant difference in emergency services' ability to survive intact and continue operations. If the command and logistics structure of emergency services is crippled or destroyed, emergency personnel and their equipment, even if available and ready to serve, would likely not be very effective.

Fire service incident command systems have been a natural fit for dealing with disasters. They demonstrated the value of bringing together and integrating a variety of resources needed to manage an incident. Likewise, operations in EOCs during disasters now include personnel from utilities, transportation, finance, building departments, and so on. Most elements of the governmental structure are now involved and a part of the team, but something is still missing. Assuming that the EOC survives and functions as intended, preserving the command and logistics elements and enabling effective operations into the recovery phase, we could ask ourselves the following questions to help bring into focus why continuity of operations is so vital:

- How long will personnel be able to continue working if computer and data systems are destroyed or inoperable, meaning, among other things, that employees cannot be paid?
- Local governments often find during the recovery phase that certain important decisions must be made. How is that to be accomplished if the elected officials who should make those decisions are not available due to injury, death, or migration?

Continuity Plan Regarding Elected Officials

To ensure continuity of government, the continuity plan regarding elected officials should include the following actions:

- Prepare a plan for the relocation of some or, if necessary, all of the community's elected officials. Determine beforehand who will stay in the community, who will go, and under what circumstances.
- Be sure to enact enabling legislation, especially if the decision process or number of persons required for decisions is different from what it is normally.
- Craft the logistic mechanisms needed to support the distant interaction of the officials, such as telephone, computer, or videoconferencing.
- If the policy calls for elected officials to temporarily leave the community due to a disaster, be sure to preplan for locations in various geographic sites.
- Select alternative locations for your government's public meetings just in case the normal location is damaged, destroyed, or otherwise unavailable. Choose more than one, as an alternative site may be rendered unavailable as well. Citizens want to see that their government is functioning and want to be able to participate as well.
- Be aware that not every community has clear legislation or policy for the ordered succession of power or authority covering its elected officials. Check local legislation and speak with legal counsel to seek guidance on the matter. Do not rely on everyone to "do the right thing" just because a disaster has struck. Egos, alliances, distrust, dislike, and political maneuvering can quickly derail the government's opportunities for successfully handling a disaster. Being in the middle of a disaster and trying to reach resolution on this subject is not an enviable position. Deal with it well ahead of time. Keep in mind that in many communities this is a subject that may require the approval of the voters.

Continuity Plan Regarding Financial Issues

To ensure continuity of government, the continuity plan regarding financial issues should include the following actions:

- In advance, ensure that emergency purchasing mechanisms are established and authorized or enacted.
- Because disasters often severely tax a community's resources, make sure that the chief financial officer works with the CEO (or city manager, mayor, administrator, etc.) to ensure healthy financial reserves, including those specifically designated for major emergencies. Such reserves may serve to offset the cost of less severe emergencies and help to support the overall costs of major emergencies. Remember that federal and state reimbursing agencies do not compensate 100 percent and may refuse to reimburse for certain costs. Adequate reserves will help to bridge any such gap. In addition, those reserves may provide immediate funding availability until commercial paper loans or other bridge-type financing can be accessed.
- Establish and maintain a line of credit such as commercial paper that can function much like a bridge loan. Cleanup after a disaster can cost millions of dollars, money that a community may not otherwise have readily available. Private providers will not do the work for free, and their willingness to continue working in one community versus another community may hinge on the community's ability to pay. The federal government through FEMA and other agencies may provide reimbursement for a good portion of the costs, but be aware of the fact that reimbursement takes time and is not always guaranteed.

- Ensure that the CFO and his or her department have an excellent working knowledge and familiarity with the record-keeping requirements of FEMA and other federal or state reimbursing agencies. Equally as important is the need to properly train and manage the work of personnel who will be doing the record-keeping work in the field. Failure to properly prepare for and manage this function may well mean failure to receive reimbursement. For most communities, that is not an option that will bode well for its future financial health. Any training that is made available by the agencies is an absolute prerequisite.
- Be aware that in the run-up to and immediately after the impact phase of a disaster, it is possible that certain resources may be acquired only with cash. For this reason, it is wise for the CFO to ensure the creation of policies that will allow an adequate amount of cash to be obtained, safely stored, and legitimately accessed. In this case, "safely stored" means the cash is to be kept safe from the effects of the disaster as well as secure from theft or unauthorized access.

CONTINUITY OF OPERATIONS PLAN (COOP)

Objectives of Continuity of Operations Plan

The objective of a continuity of operations plan (COOP) is to ensure that a viable capability exists to continue essential functions across a wide range of potential emergencies, specifically when the primary operating facility is either threatened or inaccessible. The objectives of COOP planning include the following:

- To ensure the continuous performance of essential functions and operations during an emergency
- To protect essential facilities, equipment, records, and other assets
- To reduce or mitigate disruptions to operations
- To reduce loss of life and minimize damage and losses
- To identify and designate principals and support staff to be relocated
- To facilitate decision making for execution of the plan and the subsequent conduct of operations
- To achieve a timely and orderly recovery from the emergency and resumption of full service to all customers

The following are some other considerations that a COOP plan should include:

- Ability to implement the plan with or without warning
- When activated, ability to implement the plan within a 12 hour period
- Capability of maintaining operations for a period of at least 30 days
- Provision for the establishment of alternative facilities
- Provision for alternative means of operating, including telecommunicating (i.e., allowing employees to conduct business from their home or other remote locations via computer)
- Sharing of facilities with other organizations

All COOPs should be tied to continuity of government plans. Other key elements include payroll, accounts payable, and accounts receivable; in order to foster loyalty, employees who are serving the public in the immediate aftermath of a disaster must be taken care of. COOP planning will provide for specifics as to how those employees will be paid in the event that the normal processes in place to pay staff members are no longer possible.

COOP Steps

Steps in conducting a COOP include the following:

1. Identifying the essential functions to that specific organization
2. Identifying which of those functions must continue regardless of the circumstance
3. Prioritizing those functions
4. Establishing staffing and resource requirements in order to carry out those critical functions. Included in this process are succession planning and delegation of authority at least three levels deep for each individual department.
5. Identifying specific systems and/or facilities that must be provided to carry out those functions
6. Identifying any interdependencies among other related functions from that organization and other organizations within the community to carry out those critical elements

Public Works Considerations

As part of COOP, the community should keep in mind public works considerations such as debris management programs, policies to identify participants, and agreements with suppliers.

Debris Management Program. The community should have contracts in place with private providers to accomplish the pickup and disposal of any debris created by the disaster well in advance of any catastrophe. Be sure that the contract provides for specialized handling of certain hazardous or otherwise dangerous materials if needed. It should also have an element that includes provisions for heavy lifting equipment. Such contracts are essential because few, if any, communities have the resources to handle the volume of work to be done. Many communities have what is called a debris management plan in place, which is an all-encompassing plan outlining the procedures for a community to effectively and efficiently manage debris in the aftermath of a large-scale disaster.

The goal of a debris management plan should be to provide a framework for the rapid removal of debris, thereby protecting public health and safety and the business base of a community; ensure that disaster debris is processed in accordance with environmental regulations; minimize the effect on the existing incinerator and landfills in a given area; and maximize federal reimbursement for response and recovery activities.

Even New York City, one of the largest cities in the world, with far greater resources than most communities can imagine, relied on private providers to assist in the cleanup after the 9/11 terrorist attacks. These contracts may enable a community to quickly clear the roadways and allow emergency response as

well as travel routes for other community services. Not the least important of which is that it will also enable a more timely return of the commerce needed to provide resources and support the community's economic health. For a community with rivers, lakes, canals, or ocean access, remember to include those waterways in the cleanup contracts as well, especially where those waterways are navigable.

Establishing Policies That Identify Participants. Establish policies that identify which employees must be available and on what basis. Police, fire, and EMS personnel are accustomed to duty during disasters, but most other employees are not. The changing face of preparedness now recognizes the need for the entire government system to be part of the response. Because these participants are new to this emergency response environment, they may not understand or be comfortable with the demands being placed on them. Inform them ahead of time, adequately train and counsel them, and where possible, provide the support mechanisms to encourage their buy-in. Public works employees are not the only ones who are called on in this response methodology; virtually every government employee will be asked to participate. Personnel involved throughout the process are an indispensable asset for ensuring continuity.

Creating Agreements with Suppliers. Create agreements with fuel suppliers that have resources outside the immediate area. Be sure to include priority clauses in the contracts. Remember to provide for locations and methods to dispense the fuel the community acquires, including power supplies to operate dispensing equipment.

Establish agreements with the local electric utility provider to ensure that the most important facilities receive priority in the return of and maintenance of power. Further explanation of this process can be found in an earlier section, "Identification of Critical Facilities and Infrastructure."

Within purchasing agreements for parts, supplies, materials, and equipment, create clauses to establish how suppliers are expected to interact with other entities during instances of disaster. For example, water and sewer systems often receive significant damage due to uprooted trees, flooding, or other misfortune. The ability to get the systems up and keep them running could hinge on availability of parts and supplies. Do the suppliers normally expect payments within 30 to 90 days? Rather than depending on a supplier's goodwill, it is better to get these matters in writing.

Establish a listing of local heavy equipment resources and persons with the skills to operate them. Various private enterprises may have a variety of such equipment. Knowing who owns the equipment, where it is located, whom to contact, and who can operate it could be most helpful.

Information Technology Systems Considerations

As part of COOP, the community should keep in mind and implement the following information technology systems considerations.

Location of Technology Systems Within EOC. The part of the technology system that directly supports police, fire, and EMS dispatching and record keeping should be located within the EOC. Because an EOC must be designed to withstand and survive extreme natural disasters, it is an ideal location for technology systems. Remember that certain disasters such as radiological incidents or terrorist attacks on the EOC itself will make redundancy essential. A government's technology professionals must plan for redundancy in the system to protect the organization from system failure. Failure of this nature is itself a disaster of sorts. The systems are necessary to keep employee time records and process payroll, to enable accounts payable to process payments for goods and services, and to provide for a myriad of support services and record keeping.

Planning for Redundancy. Establish priorities that determine which systems are to be included in the redundant solution. Decide which elements must remain functional regardless of the circumstances and establish a system hierarchy that will drive the timing of when other elements are to be brought back on line.

Redundancy can be accomplished by contracting with private providers that specialize in this service. It can be done remotely in a different region, or options are available through some providers to bring in systems in completely self-contained semitractor trailers. For small governments with severely limited resources that prevent the acquisition of these services, there is an alternative. It may be possible to identify a similar community in a different region and craft a mutual agreement to provide technology assistance to one another during disasters.

MUTUAL AID AGREEMENTS

Categories of Mutual Aid Agreements

Mutual aid agreements can be divided into three basic categories. The first is the emergency management assistance compact (EMAC). EMAC is an interstate mutual aid agreement that allows states to provide mutual aid to one another through all types of disasters and is managed by the National Emergency Management Association. The next model is the intrastate mutual aid legislation, which is relatively new. This legislation is from the National Emergency Management Association and allows for intrastate mutual aid across different political subdivisions and has been modeled successfully in several states across the country. The third category is a state and county mutual aid agreement. This agreement allows for the deployment of local emergency responders under the auspices of EMAC.

Private Agreements

Private agreements with both the public and private sectors are contracts that can be successfully negotiated prior to a disaster, utilizing the local procurement or purchasing department. Typically, these contracts may have some stipend involved along with a variety of listed performance objectives.

Some communities have taken an all-hazards approach with different private sector models to include debris management, response of emergency generator power, food, comfort stations, rent-a-fence, cell phones, covering structures with tarps, and a

wide range of disaster services. Regardless of where a community is located, the most important aspect is to start building and developing those agreements and relationships needed to be successful in a disaster or emergency scenario.

LEVELS OF DISASTER PREPARATION

As stated in Florida Statutes 252.31 to 252.60:

> *Emergency* means any occurrence, or threat thereof, whether natural, technological, or man-made, in war or in peace, which results or may result in substantial injury or harm to the population or substantial damage to or loss of property.
>
> *Disaster* means any natural, technological, or civil emergency that causes damage of sufficient severity and magnitude to result in a declaration of a state of emergency by a county, the Governor, or the President of the United States.

Levels of disaster can be divided into three basic categories. The first is minor disasters. Minor disasters will necessitate the response capabilities of local government with only minimal need for state or federal assistance. Major disasters are those that will require not only the response of local government but also will necessitate state and federal assistance. Finally, catastrophic disasters are those disasters that require substantial state and federal resources and more than likely will include some support from the military.

Minor Disasters

Minor disasters are those that require the extensive use of local and possibly regional resources to respond to and recover from the specific incident. Critical elements to be considered for minor disasters are local mutual aid agreements, partnerships with both private and public sectors on a local level, coordination with state resources if there are multiple events occurring in the state simultaneously, and creating levels of expectation with both the public and elected officials that response and recovery to this disaster should occur within normal time parameters. Examples of a minor disaster might be multiple wildland fires, a flood, a blizzard, or even a minimal category hurricane.

Major Disasters

Major disasters that exceed local and regional capabilities will necessitate the response from both state and federal agencies. Of course, the type of disaster itself will dictate the type of response from both state and federal officials. There are common considerations for an all-hazards approach to major disasters. They are relationships, relationships, relationships. If local governments have not established the appropriate relationships prior to a disaster event, the success of the response to the event is questionable. Examples of major disasters include hurricanes, major fires, earthquakes, and multiple events of similar magnitude that require the response of local, regional, and state assets.

Local governments must forge relationships with their state and federal counterparts through a variety of different mediums such as drills, meetings, and other affiliations in order to make sure that clear lines of responsibility and communications are defined ahead of time. With recent events in the last decade, it has become readily apparent that communities that lack those relationships are not as successful as those that have forged them in advance. Other key elements in responding to and recovering from a major disaster include interlocal/mutual aid agreements, regional agreements to include multiple states, and a clear understanding of the National Response Plan (NRP) and its capabilities and limitations (Figure 12.12.3).

Typically, one of the chief concerns in major disasters is restoration of infrastructure and essential services. Because of the potential for interruption of these services, it is critical that communities have preplanned for these types of events based on a threat analysis and that they have substantial planning components in place for both continuity of government and continuity of operations.

Catastrophic Disasters

Catastrophic disasters are events that will require substantial state and federal assistance with military involvement. More than likely, catastrophic events will affect a community in a way that will overwhelm both local and state resources at least for a short period. Of great concern in catastrophic events is the loss of infrastructure and local government. Catastrophic events may include major hurricanes, earthquakes, weapons of mass destruction, or even a pandemic incident.

Such considerations as succession planning and relocation of critical facilities are essential and accomplished through COG and COOP planning. From a practical standpoint, if there is time to prepare for a catastrophic event, communities may consider relocating a portion of their resources, both human and material, to other locations that might be out of harm's way. Although relocation would not be practical in a disaster such as an earthquake, it could be a consideration for hurricanes and other events that may lend themselves to time for preparation and planning.

Of great concern to any local government would be a catastrophic event such as a widespread pandemic flu. Such an event would necessitate local governments to plan to operate on their own without the help and assistance of entities such as the state and federal governments. This would require substantial planning for a considerable cutback in essential services to any community. The reason for this change in potential support from other agencies could occur if it was an event that affected the whole country.

It is imperative that in advance of a disaster local government officials communicate to the public clearly and responsibly the officials' ability or their lack thereof to respond in the immediate aftermath of a catastrophic event. The public's personal responsibility cannot be overemphasized in planning for a minor, major, or catastrophic event. The responsibility of government is to give the public as much readily available information as possible in order to allow people to make informed decisions about their own safety.

With each disaster there seems to be a continued reliance on government to perform in a manner that it is not prepared for

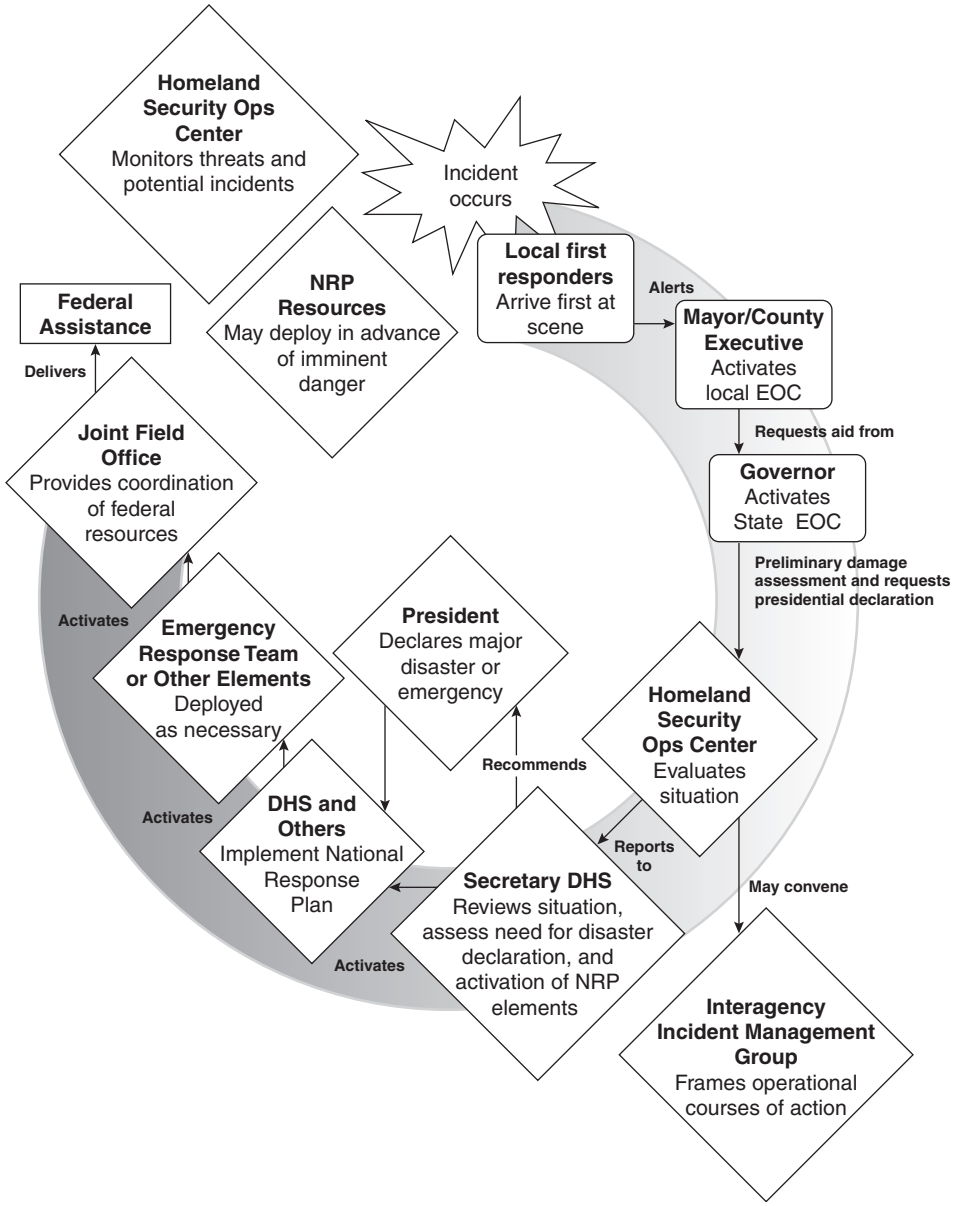

FIGURE 12.12.3 National Response Plan

or may not be equipped to do. In an effort to help mitigate some of these public expectations, it is critical to have a proactive public education program in which local officials are constantly communicating to the public.

GOVERNMENT VERSUS THE PUBLIC'S RESPONSIBILITY

Government organizations in general have become increasingly sophisticated and more efficient and effective in the quality of their responses to disasters. Part of this improvement is a result of constant assessment and refinement of response procedures, some is due to improved training and improved knowledge base of the responders and disaster managers, and another part comes from greater resources to get things done.

Disaster Responsibility in Pre-FEMA Times

In 1964 when the eye of Hurricane Cleo passed over Fort Lauderdale on Florida's east coast, the Federal Emergency Management Agency (FEMA) did not exist. Federal assistance did exist, but it was fractured and divided among many agencies. FEMA was created in 1979 under the administration of President Carter and was brought about by major disasters such as Hurricane Carla in 1962, Hurricane Betsy in 1965, Hurricane Camille in 1969, and Hurricane Agnes in 1972. The Alaskan Earthquake of 1964 and the San Fernando Earthquake in 1971 also tested

the foundations of disaster relief. Presidential disaster declarations were eventually established through the enactment of the Disaster Relief Act in 1974.

The individual citizen in pre-FEMA days did not have the level of resources to rely on that exists today. As a result, the average person understood that he or she had a critical responsibility to properly prepare for the disaster and its aftermath. In recent years, with the increased occurrence of natural and man-made disasters, the resources of local, state, and federal governments have been stretched beyond what officials could have ever anticipated. With so many advances in society today, citizens have grown increasingly accustomed to having their needs fulfilled in very short order.

Government's Responsibility in a Disaster

Although government will continue to strive to provide services at the best possible level, citizens must also remain mindful that their responsibility to take care of themselves and their families does not cease in a time of disaster; in fact, that is when it is more critical than ever that citizens have plans in place and ready to be enacted. An additional responsibility for government to aid in this process is the commitment to continually provide public education tools that will provide guidance to citizens in the development of their personal family emergency plans.

Government must continually shoulder a great responsibility in providing resources for disasters, but that does not relieve each person and each family from the responsibility to do their part in preparing for and surviving such events. Although there is no need to go back to the pre-FEMA days when federal assistance was more meager and fractured, there is clearly a need to regain the greater sense of self-reliance that once existed.

EMERGENCY SUPPORT FUNCTIONS, PUBLIC INFORMATION, AND RESOURCES

Emergency Support Functions (ESFs)

Emergency support functions (ESFs) are those functions that are carried out by federal, state, and local governments in response to a disaster. The initial emergency support function concept was developed by the federal government and contains 10 elements. States have taken the emergency support function concept and have expanded it, and local governments have expanded the concept even further.

The following is a list of the emergency support functions that might be found in a comprehensive emergency management plan (CEMP):

Comprehensive Emergency Management Plan Support Functions

- Transportation
- Communications
- Public works and engineering
- Fire fighting
- Information and planning
- Mass care
- Resource support
- Health
- Search and rescue
- Hazardous materials
- Food and water
- Energy and utilities
- Military support
- Public information
- Volunteers and donations
- Law enforcement and security
- Animal protection
- Special medical needs
- Business and tourism
- Damage assessment
- Public protection to include warning and evacuation
- Administration and finance
- Fatality management
- Debris management
- Safety
- Information technology

To some degree, many of these functions must be accomplished during the preparation, response, and recovery phases. For each function, it is critical that a lead person or organization be designated to carry out the identified tasks. Some functions may be more prominent in the response or recovery phase than others, depending on the threat and the aftermath.

Of significant importance is the ability for incident commanders to ensure that emergency support functions are integrated into a NIMS-compliant plan. There are several models that have successfully integrated these functions. Other communities have NIMS-compliant plans that are less transparent with regard to the emergency support functions. However, all the elements are still incorporated into their response and recovery procedures regardless of nomenclature. The elements described in this section are consistent with successful response and recovery plans.

Public Information

One of the most potentially confusing elements of a disaster occurs in the area of public information. If state and local governments fail to preplan, train, and develop protocol for coordination and communication, they may be creating a recipe for disaster regarding public response and opinion. Under the NIMS plan, a key element for coordination of public information is found in the joint information center (JIC). A JIC, which is an essential point for communication for all local entities involved in disaster response and recovery, is responsible for the overall coordination of public information. This can become essential when disasters cross jurisdictional and geographic boundaries.

Proactive approaches to public information include disaster seminars conducted on potential threats; publications such as an all-hazards brochure that would include all the hazards that may affect a community; and partnerships with local and national media services, which allow for developing and disseminating the multimedia projects a community may develop. Another approach is the use of technology to include interactive websites, DVDs, and other educational tools.

In 2005, for example, the city of Cape Coral, Florida, developed a 30 minute DVD solely dedicated to the process of hurricane planning and preparation as it relates to the unique features and needs of this waterfront community. The DVD has been well received and sought after by residents, businesses, and agencies and is distributed free of charge (Figure 12.12.4). It is also shown on the city's cable access television station regularly throughout hurricane season. Cape Coral's Emergency Management Bureau plans to develop annual updates to the DVD as a continued public education tool for the community.

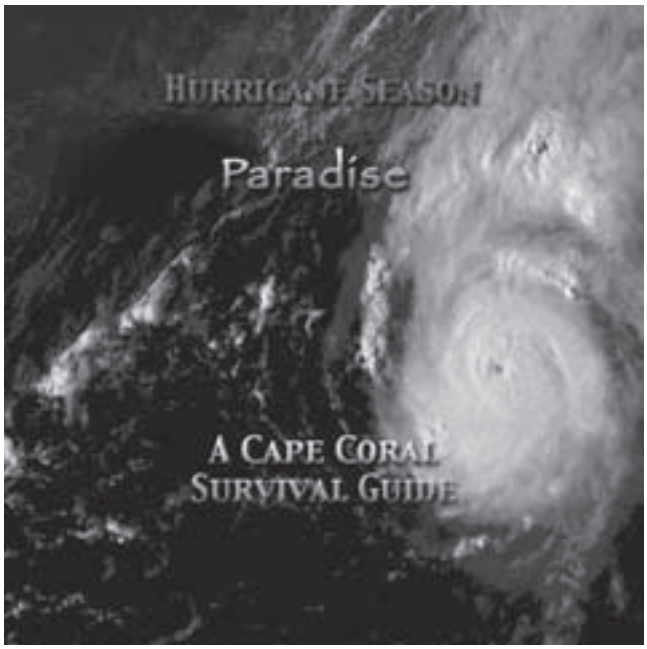

FIGURE 12.12.4 Cover of the Hurricane Preparedness DVD for the City of Cape Coral, Florida

Emergency Planning Resources

The following is a sample of additional resources to help define the context of this chapter and to provide thought processes for emergency planning:

- NFPA 1600, *Standard on Disaster/Emergency Management and Business Continuity Programs*
- National Institute for Occupational Safety and Health (NIOSH), http://www.cdc.gov/niosh/homepage.html
- USFA Training and Education Learning Resource Center, http://www.usfa.dhs.gov/fireservice/training/lrc/
- State and local emergency agencies and plans
- International City/County Management Association (ICMA), http://www.icma.org/main/sc.asp
- Emergency management practices text (e.g., *Emergency Management: Principles and Practice for Local Government,* published by the International City Management Association [ICMA])
- National Incident Management System (NIMS), http://www.fema.gov/emergency/nims/index.shtm

RELATIONSHIPS BETWEEN LEVELS OF GOVERNMENTS AND PUBLIC AND PRIVATE SECTORS

Relationships Among Levels of Government

Depending on which arm of government the reader may represent, his or her perspective may differ regarding which one is of greatest importance. The reality is that each segment of government has its own vital role toward ensuring a successful response to a disaster.

Local Government. Local governments are most often in the trenches for the entire duration of disaster events, including during the preparation, response, and recovery phases. They are perhaps best positioned for the preparation and immediate response role. Who could possibly better understand the local area, its citizens' expectations, its needs, and the status of resources that are available?

Local governments, however, are ill positioned to handle catastrophic events without some form of assistance, whether that assistance is financial or otherwise. It is best for local governments to acknowledge this reality and work to better understand and facilitate their interactions with county, state, and federal agencies. Most local governments would find great benefit in developing solid relationships with their municipal or county emergency management agencies. These agencies serve as an invaluable source of support and information as well as a link to state and federal resources and training opportunities.

State Government. States serve their best role in bringing together resources and in managing regionally centered communications. They serve well in disseminating and controlling vital information and resources. Through the National Guard, states are also able to provide significant human resources and materials following catastrophic disaster events. Certain states such as Florida have stepped up the preparation element of their responsibilities by identifying strategic locations to prestage resources so they can be delivered with as little delay as possible.

Federal Government. When considering relationships on the federal level, a city that has not accessed opportunities to train and learn all it can about the offerings, rules, and regulations of FEMA is doing itself a disservice. For example, failure to properly complete the FEMA forms required for reimbursement could at the very least mean extended delays in recieving reimbursement for disaster-related expenditures. At worst, it could cause reimbursement to be denied. Understanding and working well with this federal agency is imperative. A wealth of information can be found on FEMA's website at http://www.fema.gov.

Relationships Between the Public and Private Sectors

Federal, state, and local disaster response organizations can bring together and effectively apply tremendous resources in the event of a disaster. All of those resources combined would still fall short without the addition of private sector resources. This is perhaps never truer than in the disaster recovery phase. When an earthquake, tornado, or hurricane strikes, millions of tons of debris must be removed and safely discarded. Few, if any, governmental entities have the resources to handle this work, yet the private sector does. Private providers can bring together resources from across the nation to accomplish this work and leave local resources available to handle the more routine daily functions required of a community.

Private sector organizations often feel a sense of obligation to their communities and are willing to contribute labor and resources toward recovery. It's important for the local government to have a close and cordial relationship with the private sector. Local government officials should not wait until after the event to begin building that much-needed rapport. If the stakeholders and the extent of their available resources are known, gaining access to those resources becomes much easier. Knowing who has heavy or specialized tools and equipment, who has expert skills, and who may have an inventory of materials needed to handle a major incident can make a huge difference in how rapidly or how well a community can respond.

Consider developing a list of what resources might be needed under various disaster scenarios, such as a tornado, hurricane, infectious disease pandemic, or terrorist attack. To do this exercise properly, include all elements of the response/recovery organization in the list, not just police and fire personnel. Then set about determining which persons or companies in the private sector might have those resources. Contact them and let them know what you are doing and that you may need to rely on them at some future date. You may be surprised at how eager they will be to assist.

Homeowners and neighborhood associations, fraternal organizations, and various clubs and professional groups are other types of resources that can help make a difference. Maintain a database, including names and contact information for the leadership of those organizations. Developing these relationships and contacts in advance may be more helpful than just accessing resources. Such contact information may help you in getting information out to the community in difficult times.

INTERNAL RELATIONSHIPS

Defined Leadership Roles

Disasters are a time of intense danger with little room for error. The circumstances are critical, the stakes are high, and the consequences of failure are dire. If the leadership roles have not been clearly defined or if the responsible persons fail to perform properly, things can go dreadfully wrong. Remember that leadership abhors a vacuum. Where leadership does not exist or where it does not appear to exist, it is likely that someone will attempt to fill the vacuum. Just imagine that scenario unfolding in the midst a major event.

"The way you practice is the way you play," according to a saying in the world of sports. In other words, the things that you routinely do are exactly those things that you will do when the pressure is on. It is equally true when dealing with disasters. If organizational leadership is weak or ineffective, it will not suddenly heal itself when a disaster arrives. If the organization is fractured and operates with only marginal departmental cooperation at best, then that is exactly what will exist during disaster operations. No matter how thorough the disaster plans, if the organization is not accustomed to operating as a team, then the chances for substantial error are significant.

There must be a role for every element of the organization. Those roles must be clearly defined, well documented, thoroughly trained, routinely practiced, and refined (Figure 12.12.5). They must also be respected by those assigned to every other area of responsibility. As vital as they are in certain phases of disaster operations, police, fire, and EMS are not the only important elements of the team. The importance level of any of those three will lessen when in the recovery phase of a hurricane; for example, when it becomes necessary to manage the removal and safe disposal of millions of tons of debris.

Role of the CEO and the Incident Commander

In local governments, a city or county manager or perhaps a strong mayor is the chief executive officer (CEO), that is, the top person in charge of the organization's day-to-day activities. Such is not always the case in disaster situations. Following the NIMS organizational structure, the event, if large enough, needs an incident commander. Depending on the nature of the event, the incident commander may be the police chief, the fire chief, the health department director, or someone else. Regardless of who it is, everyone must allow that person to do his or her job. Unfortunately, a CEO's need to control things can lead to conflicts and leadership confusion. The way for a CEO to avoid that and at the same time to reinforce the incident commander's role is to let him or her do the job and to visibly be there in support.

The flip side to this scenario is that the incident commander must be confident in his or her role to exercise strong leadership, perhaps in the physical presence of someone who is his or her superior in day-to-day operations. There is little question that this is a fine balance, which requires the incident commander and the CEO to carefully demonstrate through cooperation and support that they are a team. If the CEO is observed sending the right message, then it is simple for everyone else to accept and support the incident commander. The best way to avoid leadership conflict is through good communication, which starts with a clear understanding of the scope of each person's role, is reinforced with practice, and is further fortified through careful attention to the team concept.

FIGURE 12.12.5 Command Staff, Including the Mayor, City Manager, and Public Information Director at the Activation of the Cape Coral, Florida, EOC During Hurricane Wilma, October, 2005

SUMMARY

In the aftermath of events such as 9/11, tsunamis, earthquakes, floods, tornados, pandemics, and hurricanes that have affected the world in recent years, it is apparent that public and private organizations must plan for events that might impact their community. Such plans must be comprehensive yet easy to read and implement during a crisis. Planning must be pertinent, practical, and precise. Plans must include all the critical elements for response and recovery and do so in a systematic format to assure consistency and continuous improvement. Disaster planning is not an option in today's world. Public and private organizations must make every effort to be prepared for natural and man-made disasters, to move communities into a state of readiness, and to forge relationships with each other to respond to these disasters.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on disaster planning and response services discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

Chapter 13

GIS for Fire Station Locations and Response Protocols

Russ Johnson ❑ Mike Price

Chapter Contents

GIS Overview
GIS Analysis
Fire Station Location Planning
Response/Travel Time Standards
Determining Fire Station Locations
Fire Station Site Selection Factors
GIS Response Protocols

Key Terms

deployment, emergency management, emergency medical services, emergency response, fire station, geographic information system (GIS), reflex time, response time

The mission of the fire service is to protect life, property, and natural resources from fire and other emergencies. With increasing demands, the fire service must utilize the best tools, techniques, and training methods to meet public expectations. Risk management, preparedness, and mitigation have taken on new importance in light of the challenges facing fire departments today. One emerging tool that is helping the fire service optimize emergency services delivery is geographic information system (GIS) technology.

GIS supports planning, preparedness, mitigation, response, and incident management. GIS extends the capability of maps—intelligent, interactive maps—with access to all types of information, analysis, and data. When a fire occurs, any delay of responding fire companies can make the difference between the rescue of occupants versus serious injury or death. The critical time between fire containment and flashover can be measured in seconds. From the moment an emergency call is received, through the deployment of tactical resources, GIS helps reduce critical time and increases efficiency. GIS technology brings additional power to fire personnel for hazard evaluation, service demand analysis, and resource deployment. This chapter will examine how GIS technology is helping the fire service meet the needs of the community more efficiently than ever.

For related topics see Section 12, Chapter 14, "Fire Rescue Stations and Fire Service Training Centers"; Section 12, Chapter 15, "Public Emergency Services Alarm, Dispatch, and Communications Systems"; and Section 12, Chapter 16, "Fire Department Apparatus and Equipment."

GIS OVERVIEW

GIS Defined

GIS is a technology that integrates geographic features with tabular data to assess and better understand real-world problems. What is now GIS began around 1960 with the discovery that maps could be programmed using simple code and stored in a computer, allowing for future modification when necessary. This was a tremendous change from the era of cartography when maps had to be painstakingly created by hand; even small changes required the creation of a new map. The earliest version of a GIS was known as computer cartography and involved simple line work to represent land features.

GIS Map Layers

Unlike a flat paper map, a GIS-generated map can present many layers of different information that each provide a unique way of thinking about a geographic space. By linking maps to databases,

Russ Johnson, a public safety industry manager at ESRI, has an AA degree in fire science from San Bernardino Valley Junior College and a BA degree in public administration from the University of Redlands. He has 30 years of service with the federal government in fire management and extensive experience in complex emergency management as national ICS incident management team incident commander.

Mike Price, a public safety GIS analyst at Entrada/San Juan, Inc., has a BS in geology/geophysics from Prescott College (AZ)/Western Washington University. He has over 30 years of experience in municipal fire protection, public safety, and emergency management and an extensive background in GIS mapping, spatial analysis, public safety modeling, and emergency management technology training.

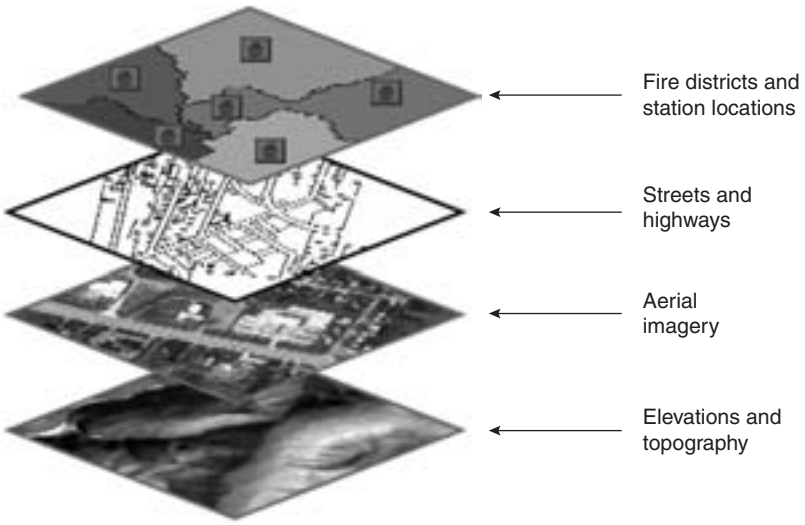

FIGURE 12.13.1 GIS Provision of Data and Information Through Map Layers

GIS enables users to visualize, manipulate, analyze, and display spatial data (Figure 12.13.1). Some GIS map layers that fire departments use include the following:

- Streets
- Parcels
- Fire hydrants
- Utility networks
- Topography
- Lakes and rivers
- Commercial and government buildings
- Fire station locations
- Police station locations
- Hospital locations
- School locations
- Satellite or aerial imagery
- Historical incident or emergency call locations
- Fire districts
- Public occupancies

Map layers can be selected and displayed (overlaid). These layers are linked to data tables that contain detailed information about the geographic features being displayed. The most powerful aspect of GIS is its comprehensive analysis capabilities. GIS analyzes and displays patterns, relationships, and trends through the geographic data layers to help users understand how the world works, make the best choice from among options, or develop plans through what-if scenarios.

GIS ANALYSIS

Incident Analysis

GIS can perform complex incident analysis to display trends, illustrate patterns, and identify areas of high call volume. A GIS display of historical incidents (represented by points or icons on the map where they occurred) includes attribute information for each incident. Attribute information (i.e., descriptive data about a map feature) contained in the underlying database can include the following:

- Incident type
- Incident cause
- Date of incident
- Time of incident report
- Units that responded
- Unit arrival times

Incidents can be queried based on incident type, cause, time, units assigned, or other variables contained in the attribute data (Figure 12.13.2). GIS searches the data tables, gathers data matching the spatial request, and displays the information on the map. Incident trend analysis can be done quickly, displayed

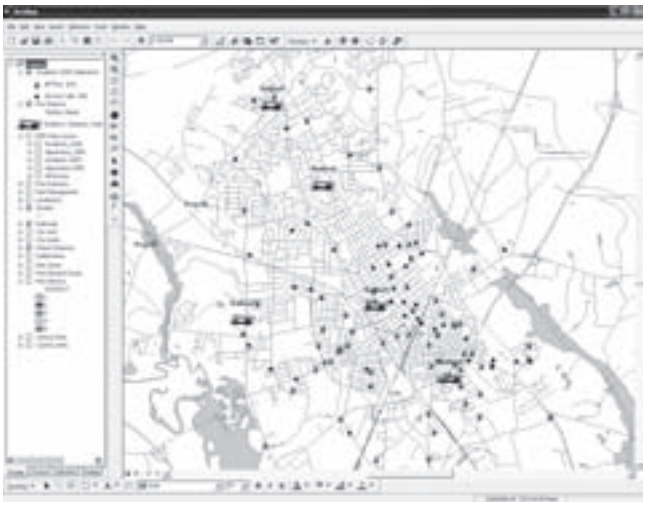

FIGURE 12.13.2 GIS Analysis and Display of Incidents Based on User-Defined Criteria (Time, Location, Cause, Geographic Area, etc.)

logically, and understood easily. For example, a GIS user could request to see arson fires that occurred between the hours of 1:00 a.m. and 5:00 a.m. on Saturdays in Fire Districts 1 and 2. GIS will interrogate the records database and place points on the map that match the request. Such analyses provide decision support for issues related to fire prevention, staffing requirements, and apparatus placement/deployment.

Travel Time Modeling

Using a fire station layer and a street layer, response time analysis can be performed (Figure 12.13.3). A street layer is often represented in GIS as a series of lines that intersect on the map, creating a GIS street network. Each street line segment between intersections contains attribute information such as road type, distance, and travel speeds (miles or kilometers per hour). This allows users to identify a station location, specify a travel time, and run a network analysis. The result will be displayed by an irregular polygon around the station that illustrates where the fire apparatus could travel in any direction for the specified time. This type of analysis can be performed on a single station or simultaneously on all stations to analyze gaps in coverage, establish run orders, and more.

FIRE STATION LOCATION PLANNING

The primary responsibility of a fire department is the delivery of fire and rescue services, normally originating from fire stations located throughout the area to be protected. To provide effective service, crews must respond in the minimum time possible after the incident has been reported and with sufficient resources to initiate fire, rescue, or emergency medical activities. Fire station location planning must take into account a number of variables, including the following:

- Importance of response time
- Flashover
- Fire department total reflex time sequence
- Emergency medical services

FIGURE 12.13.3 GIS Analysis and Display of Travel Times from a Station, Based on Information Contained in Street Centerline File

Importance of Response Time

Time is the critical element when an emergency is reported. Fire growth can expand at a rate of many times its volume per minute. Time is the critical factor for the rescue of occupants and the application of extinguishing agents to minimize loss.

The time segment between fire ignition and the start of fire suppression has a direct relationship to fire loss. The delivery of emergency medical services is also time critical. Survival rates for some types of medical emergencies depend on rapid intervention by trained emergency medical personnel. In most cases, the sooner trained fire or emergency medical rescue personnel arrive, the greater the chance for survival and conservation of property.

Flashover

Regardless of the speed of growth or length of burn time, all fires go through the same stages of growth. One particular stage, called *flashover,* is significant because it marks a critical change in conditions. Depending on room size, contents of the room, and available oxygen, flashover can occur in less than 2 or more than 10 minutes. Flashover occurs most frequently between 4 and 10 minutes. Measuring the time to flashover is a function of time and temperature. Fire growth occurs exponentially; that is, fire doubles itself for every second of free burn that is allowed. This can be plotted on what is known as the time and temperature curve (Figure 12.13.4).

A number of factors determine when flashover may occur. These include the type and arrangement of the fuels in the room, room size, and so on. Because these factors vary, the exact time to flashover cannot be predicted. Flashover can typically occur from less than 4 to beyond 10 minutes after free burning starts. A postflashover fire burns hotter and moves faster, compounding the search and rescue problems in the remainder of the structure at the same time that more fire fighters are needed for fire attack.

There are a number of critical time frames that the fire department can manage, as well as some it cannot, that affect success. The time from ignition to discovery to reporting of a fire is indirectly manageable. This time period can be managed through requirement of automatic detection and/or suppression systems and automatic reporting to the public safety answering point (PSAP). In a perfect world, all structures would be equipped with automatic detection and/or suppression systems. One factor that has helped to manage this segment of time is the increasing use of automatic smoke detectors in residential

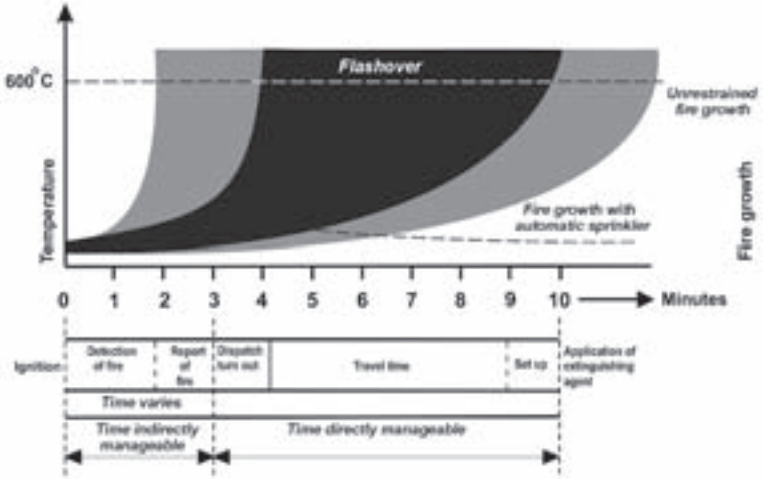

FIGURE 12.13.4 Fire Growth over Time and Sequence of Events That May Occur from Ignition to Suppression

occupancies. What is lacking, however, is automatic reporting to the public safety answering point.

Fire Department Total Reflex Time Sequence

The following are five steps in the fire department total reflex time sequence after receipt of an alarm:

1. Dispatch time
2. Turnout time
3. Response time
4. Access time
5. Setup time

Dispatch Time. Dispatch time is the amount of time that it takes to receive and process an emergency call. This includes the following:

1. Receiving the call
2. Determining the type of emergency
3. Verifying the location of the emergency
4. Determining the resources required to handle the call
5. Notifying the units that are to respond

Dispatch time is manageable by the way that alarms are received and the way that dispatch systems and activities are handled. Enhanced 9-1-1 (E9-1-1) and computer-aided dispatch (CAD) systems can minimize the time required to receive and process alarms.

Turnout Time. Turnout time is the period beginning when units acknowledge notification of the emergency to the initial point of response time. Turnout time may be managed to some degree by improving the method of communications between the dispatch center and the fire station to reduce the time processing the alarm information.

Response Time. Response time is the period beginning when units are en route to the emergency incident and ending when units arrive on the scene (wheel start to wheel stop). Response time is one of the most manageable segments of time in the entire sequence. Travel time can be managed by selecting strategic fire station locations based on the amount of time that it takes to travel from the fire station along the most efficient travel route to the incident scene.

Access Time. Access time is the time required for the crew to move from where the apparatus stops to the emergency. This can include moving to the interior or upper stories of a large building and dealing with any barriers along the way. Access time can be managed through a good prefire planning process that familiarizes the fire fighters with access points, automatic system controls, annunciator panel locations, and travel routes through the building. Key boxes can facilitate getting doors unlocked. Working with security forces at larger facilities to expedite access can also reduce access time.

Setup Time. Setup time is the time required for fire department units to set up, connect hose lines, position ladders, and otherwise prepare to extinguish the fire. Setup time includes disembarking the fire apparatus, pulling and placing hose lines, charging hose lines, donning self-contained breathing apparatus, making entry into the building, and beginning to apply water. The opportunity for saving time during setup is minimal, even for trained personnel.

Emergency Medical Services

The delivery of emergency medical services (EMS) by first responders is also time critical for many types of injuries and events. If a person has a heart attack and cardiopulmonary resuscitation (CPR) is started within four minutes, the victim's chances of leaving the hospital alive are almost four times greater than if the victim does not receive CPR until after four minutes. Figure 12.13.5 shows the survival rate for heart attack victims when CPR is available, and Figure 12.13.6 shows

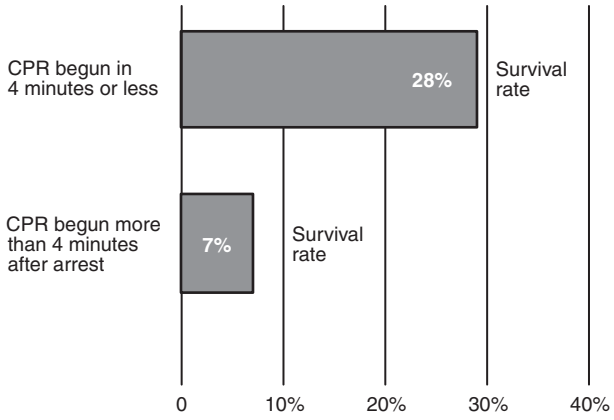

FIGURE 12.13. 5 Survival Rate of Heart Attack Victims When CPR Is Available (Source: Heartsaver Manual, American Heart Association)

the outcome for heart attack victims based on when CPR is provided

For both fire and medical emergencies, the basis for the placement of fire stations should be the amount of time that it takes to deliver adequate emergency resources to the point of demand from each fire station or combination of fire stations.

Reducing Response Times

The most effective way to improve outcomes for both fire and medical emergency response is to reduce response time. By understanding the objectives of each step in the response sequence, a fire department can measure its current performance against these objectives. That information provides the necessary framework for assessing the cost of reducing response time during any of these steps. The rest of this section will describe how GIS can be used to apply a rational decision-making process for reducing overall emergency response time.

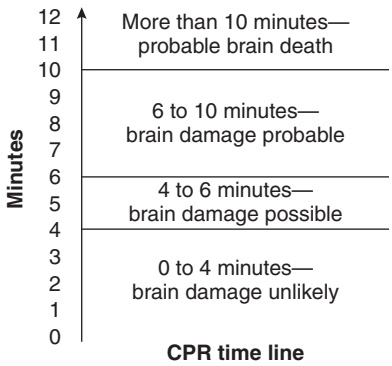

FIGURE 12.13.6 Outcome for Heart Attack Victims Based on When CPR Is Provided (Source: Data from http://www.firstaid.com)

Essentially, each community must decide its desired response and travel times. There are a number of factors that influence the selection of a specific response/travel time. All applicable factors must be considered when making a decision on a specific response/travel time for a community. Factors that should be considered include types of fire department services, reasonable travel time, size of area and type and amount of resources, and acceptable level of risk.

Types of Services. What types of services are delivered by the fire department? Does the department deliver both fire and emergency medical services or fire service only? The delivery of emergency medical services is an important factor in selecting a response/travel time because of the need to provide initial service as rapidly as possible.

Reasonable Travel Time. What is a reasonable travel time for the community? The selection of a response/travel time must be practical. A short response/travel time will enable a department to deliver services within a short period of time but will require more stations. Is there prescription for travel times based on the type of risk, hazard, or demand? Certain hazards or occupancy types may require a faster response time. Response time standards for the community may have to reflect a variation based on these types of considerations. The time or times selected must provide a balance between service expectations and the financial ability of the community to provide the necessary stations and resources.

Area Size and Resources. What is the size of the area being served and the type and amount of available resources? Large rural regions normally have longer response/travel times and fewer resources than urban or suburban areas. For example, a countywide fire response and emergency medical service operated by volunteer personnel will most likely have longer response/travel times than an urban or suburban area staffed by full-time career personnel. The demographics of the area being served and traffic patterns during peak periods, as well as past fire and EMS activity, must be considered.

Acceptable Risk Level. What level of risk is the community willing to accept? When a community selects a longer travel time, it must be willing to accept a larger level of risk. Accepting a larger level of risk may be based on past experience; for example, areas that take longer to reach may be known to have a significantly lower number of incidents.

The selection of a response/travel time for a community should be made after all factors are examined. In many cases, this decision should be made after the analysis has started and decision makers are able to review the results of the analysis.

There are several ways that a community can establish a response/travel time standard. Some of these are (1) the use of historical fire and EMS response data, (2) demand for service, (3) the level of care that the community wants to provide, and (4) the level of care that the community is able to afford. In some cases, the analysis will assist in establishing the standard after a number of scenarios are examined.

RESPONSE/TRAVEL TIME STANDARDS

National Standards

Three National Fire Protection Association (NFPA) standards contain time requirements that influence the delivery of fire and emergency medical services, as follows:

- NFPA 1710, *Standard for the Organization and Deployment of Fire Suppression Operations, Emergency Medical Operations, and Special Operations to the Public by Career Fire Departments*
- NFPA 1720, *Standard for the Organization and Deployment of Fire Suppression Operations, Emergency Medical Operations, and Special Operations to the Public by Volunteer Fire Departments*
- NFPA 1221, *Standard for the Installation, Maintenance, and Use of Emergency Services Communications Systems*

NFPA 1710, *Standard for the Organization and Deployment of Fire Suppression Operations, Emergency Medical Operations, and Special Operations to the Public by Career Fire Departments.* NFPA 1710 contains time objectives that must be established by career fire departments as follows:

- Turnout time: One minute (60 seconds) for turnout time
- Fire response time: Four minutes (240 seconds) or less for the arrival of the first arriving engine company at a fire suppression incident and/or eight minutes (480 seconds) or less for the deployment of a full first alarm assignment at a fire suppression incident
- First responder or higher emergency medical response time: Four minutes (240 seconds) or less for the arrival of a unit with first responder or higher-level capability at an emergency medical incident
- Advanced life support response time: Eight minutes (480 seconds) or less for the arrival of an advanced life support unit at an emergency medical incident, for incidents in which the service is provided by the fire department

The standard states that the fire department must establish a performance objective of not less than 90 percent for the achievement of each response time objective. NFPA 1710 does contain a time objective for dispatch time in the following requirement: "All communications facilities, equipment, staffing, and operating procedures shall comply with NFPA 1221."

For the purposes of NFPA 1710, the following definitions apply:

> *Dispatch Time.* The point of receipt of the emergency alarm at the public safety answering point to the point where sufficient information is known to the dispatcher and applicable units are notified of the emergency
>
> *Turnout Time.* The time that begins when units acknowledge notification of the emergency to the beginning point of response time
>
> *Response Time.* The time that begins when units are en route to the emergency incident and ends when units arrive at the scene

NFPA 1720, *Standard for the Organization and Deployment of Fire Suppression Operations, Emergency Medical Operations, and Special Operations to the Public by Volunteer Fire Departments.* NFPA 1720 contains a time objective for dispatch time that requires "All communications facilities, equipment, staffing, and operating procedures shall comply with NFPA 1221." NFPA 1720 contains requirements for response times related to area population density.

NFPA 1221, *Standard for the Installation, Maintenance, and Use of Emergency Services Communications Systems.* NFPA 1221 requires that 95 percent of alarms must be answered within 15 seconds, 99 percent of alarms must be answered in 40 seconds, and the dispatch of the emergency response agency must be completed within 60 seconds at least 95 percent of the time. The time lines for dispatching shown in Figure 12.13.7 and Figure 12.13.8 are taken from NFPA 1221.

Standards of Response Coverage

Other guidelines for the deployment of emergency resources is the Commission on Fire Accreditation International's standards of response coverage. The standards of response coverage process has the following nine parts:

1. Existing deployment
2. Community outcome expectations
3. Community risk assessment
4. Distribution study
5. Concentration study
6. Historical reliability
7. Historical response effectiveness study
8. Prevention and mitigation
9. Overall evaluation

Existing Deployment. Existing deployment is an assessment of the department's current deployment configuration and capability. Included in the assessment is a review of the historical decision-making process of the agency. Is there a reason stations are in their present locations? What equipment has been purchased and why? Can these past decisions be changed?

Community Outcome Expectations. What are the current community expectations for fire protection and emergency service delivery? Included in this process is a review of response anticipated for the variety of fire risks in the community as well as man-made and natural disasters; it also includes EMS, heavy rescue, hazardous materials, aircraft and airport, and water and shipboard incidents.

Community Risk Assessment. What assets within the community are at risk? For example, structure fire risk might be assessed using fire and life safety factors such as fire flow and code compliance for life safety to determine a risk classification. Risk classes might include low, moderate, and maximum risk. Many communities may identify the majority of areas composed of dwelling units as moderate or typical risks. In addition, different responses may be provided to

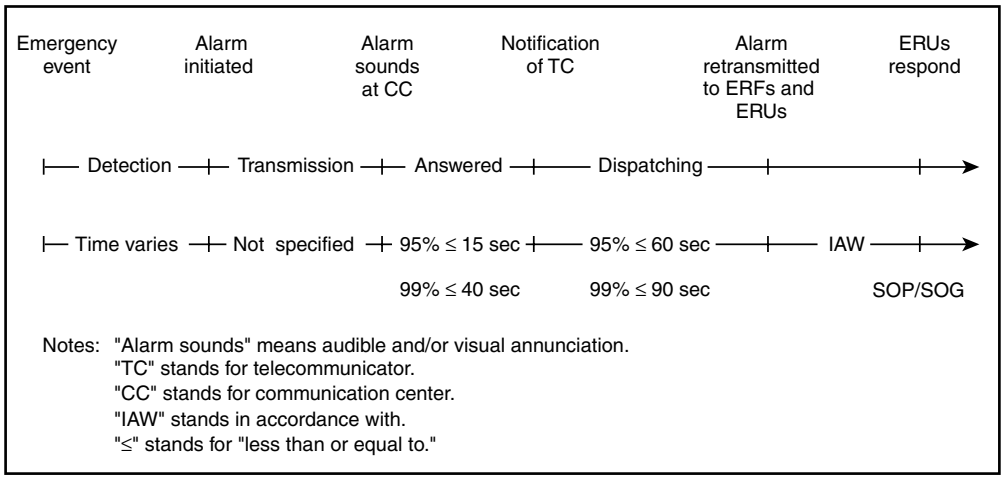

FIGURE 12.13.7 Alarm Time Line Where Primary PSAP Is Communications Center (Source: NFPA 1221, 2007 ed., Figure A.7.4.1[a])

urban, suburban, rural, or remote areas as defined using census terminology.

Distribution Study. Where are the locations of first-due resources?

Concentration Study. Where are incidents concentrated and what is the adequacy of the first alarm assignment or effective response force?

Historical Reliability. Is there a multiple-call frequency issue such as call stacking, or simultaneous calls within a specific area or areas?

Historical Response Effectiveness Studies. What percentage of compliance does the existing system deliver based on current performance goals?

Prevention and Mitigation. Are there tactics that can strategically affect the outcome of events that do occur? The United Kingdom released *The National Plan* in 2004, which replaced earlier standards of coverage documents. The new report found that without prevention and mitigation, the level of safety for responders and the public would reach a plateau. Using analysis of risk and looking at possible strategic actions may not only prevent the incident in some cases, but may also minimize the severity of an incident that does occur.

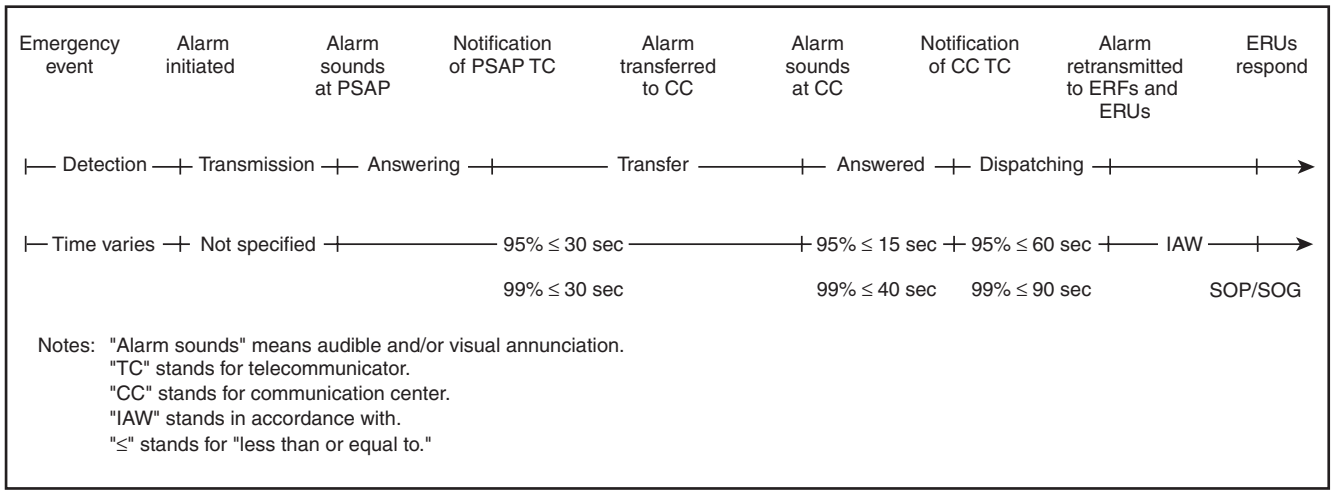

FIGURE 12.13.8 Alarm Time Line Where Primary PSAP Is Not the Communications Center (Source: NFPA 1221, 2007 ed., Figure A.7.4.1[b])

Overall Evaluation. Overall evaluation consists of proposing standards of response coverage statements by risk type, as in the following example:

> In 90 percent of all incidents, the first-due unit shall arrive within 4 minutes' travel or 6 minutes' total reflex time. The first-due unit shall be capable of advancing the first line for fire control or starting rescue or providing basic life support for medical incidents. In a moderate risk area, an initial effective response force shall arrive within 8 minutes' travel or 10 minutes' total reflex time, 90 percent of the time, and be able to provide 1,500 gallons per minute for fire fighting, or be able to handle a five-patient emergency medical incident.[1]

Risks Versus Response Time Standards

Some communities may elect to adopt several response time standards for various levels of risk in the community, or they may adopt one single response time standard for all risks. Here, a *risk* refers to a response location and the potential fire, occupant, and exposure problems that will be encountered. Providing several response/travel times based on the level of risk means that some areas will be reached in a shorter period of time than other areas. A single response time standard for the community or area served will provide approximately the same level of initial response to all areas of the community. Some of the risks that may be considered for various response/travel times follow:

- *Sprinklered versus nonsprinklered.* The fully sprinklered property is theoretically at less risk than the nonsprinklered property. The community may elect to place fire stations closer to the nonsprinklered property because of the ability of sprinklers to automatically put water on a fire.
- *Commercial versus residential.* The community must decide, in this case, where the greater risk is located. Is there a greater risk with the commercial property? At what time of day is the risk greater? Is the risk greater in residential occupancies at night?
- *Multifamily versus single-family residential.* Is the risk greater in multifamily residential areas than in single-family residential areas? Fire station location should be influenced by population factors.

The risk questions should address the following:

- High life hazard (i.e., loss potential) or high dollar value
- High incident rate areas versus low incident rate areas
- High rate of incidents that require a high level of resources versus low rate

The community that chooses to provide various levels of service to different areas, based on the level of risk, will require a much more complex fire station location study.

It should be noted that most of the information provided addresses career fire departments with stations staffed around the clock. For call and volunteer fire departments, turnout time typically will be greater. This is significant and must be considered in overall response time.

DETERMINING FIRE STATION LOCATIONS

Adopting a Response/Travel Time Standard

The first step in determining where a fire station should be located is the adoption of a response time standard or standards for the community based on the items discussed previously. Once the response time standard has been developed, it should be divided into specific time intervals for each of the components that make up total reflex time: dispatch time, turnout time, response time, access time, and setup time.

For most incidents, the dispatch time and turnout time can be established by using historical data. Setup time depends on the type and complexity of the incident. A single-family dwelling fire will generally require less time than a major fire in a high-rise building or an industrial complex. A thorough analysis will examine setup times and incident frequencies for several types of incidents. For larger incidents, the standard may be stated in terms of response time for the last of several units required for the total operation. Relevant times by type of incident can be established through training or historical experience.

Response time minus the cumulative time for dispatch, turnout, access, and setup yields the allotment for travel time. Once the response time standard has been established and a travel time standard selected, the process of determining or planning fire station locations can begin. Even though response time and travel time standards are selected prior to the beginning of the study, this does not mean that other times cannot be examined and used in the analysis. The final response/travel time may be selected after a number of scenarios are examined.

Using GIS for Fire Station Placement

Accuracy of Data. With the advent of modern software and computer technology, the selection of best fire station locations can be determined with a greater degree of accuracy using geography information system (GIS) technology. Unlike previous methods that employed grid and concentric circle analysis, GIS simulates the real road network of the area being analyzed. A high degree of accuracy is ensured by using actual travel distances, vehicle speeds, and time delays for roadway conditions (e.g., congestion, turning radius, weather, hills); accounting for one-way or unusable roadways; and implementing user-defined risk factors.

Additional data that may be used to ensure accuracy are historical response and travel times. This can be data taken from the computer-aided dispatch data or recorded manually. Data may include response/travel time, turnout time, time of day, and day of the week. All of this data can be analyzed to determine if there are specific traffic patterns that affect response times. If so, the base map can be adjusted to reflect alternate response routes or apparatus. In some instances, an alternate fire company may arrive more quickly due to heavy traffic at peak travel hours.

GIS Analysis Results. The results of GIS computer studies are a series of color maps of the street/roadway network that are easy to comprehend. These maps can show a variety of information, such as the street segments that can be reached from all stations for a specified target travel time, the overlap between stations,

the response area for each station, and other information, depending on the capability of the software program being used.

GIS analysis can effectively illustrate problem areas as well as proposed solutions. GIS can show various data for simulated responses to specific locations including apparatus and personnel on a time-arrival sequence, multiple alarms, and travel time to each street segment in the system. This will provide accurate information for critical decision making by an incident commander, including the ability to predict the time needed to assign resources for various emergency operations.

The response area for each fire station, based on the travel time specified, can be calculated and displayed. Each station's response area can be shown as different colors on the map. GIS analysis produces color maps that show the overlap between stations for a specified travel time. The color maps show the areas where there are two or more stations whose first-due response areas overlap, with the overlap colors different from the station response area colors. These maps can be used to determine multiple-company response to an area or to show where stations are placed ineffectively. Areas that receive no coverage or deficient coverage are also displayed.

Mutual-Aid Station Analysis. The response from mutual-aid stations can also be analyzed as part of the overall study, to show the arrival of additional resources. This is particularly useful to show the response of special apparatus and teams such as hazardous materials teams, advanced rescue teams, or other special teams. Given limited resources, a whole region can be analyzed using the entire resources of the region.

Examination of Alternative and Future Station Locations. Alternative and future station locations can be examined through the use of what-if scenarios, using various fire station locations and travel times. The information from these programs can be integrated with the data from local and regional planning groups to show where new stations and/or roadways may be needed to best serve existing and growing communities.

Comprehensive GIS Study. A comprehensive GIS-based fire station location study can be the central component of a master plan for fire station locations. This plan can show both the efficiencies and deficiencies of current fire station coverage for a specified travel time and provide a model for future fire station coverage using the specified or other travel time standards. Figures 12.13.9 through 12.13.17 illustrate maps from a GIS analysis that assess existing station locations as well as alternative station locations and additions.

Resource Allocation

Once the locations for fire stations have been selected, the program can be used to allocate resources to most efficiently cover the identified risks. A comprehensive GIS-based fire station location analysis provides the foundation for effective resource allocation that is critical to fire department and community master planning.

The colored maps and data are very useful when making presentations to citizens and elected officials. The computer programs take complex response scenarios, which may include many interrelated factors, and greatly simplifies them by producing color map images. Most of the maps and data are easily understood and provide factual data on the response of emergency equipment to specific locations.

All fire department planning that involves the allocation of resources requires a fire station location study. A proper study will show how the effective deployment of resources through proper station locations can improve emergency service to the community while minimizing both capital and recurring costs.

FIRE STATION SITE SELECTION FACTORS

Terrain

Once a location for a fire station has been determined, there may still be multiple choices for the precise site. One of the general items that should be considered when selecting a site should be the terrain and the susceptibility to flooding or other conditions due to weather. GIS can provide very detailed information regarding terrain features and optimum site location. GIS can analyze and display soil types, earthquake faults, elevations and slope, flood-prone locations, and other features important to station location placement. The size of the structure, the number of personnel assigned, and the provision of a training area will dictate the size of the site that is required.

Traffic Patterns

Another important consideration is the relationship to the adjacent streets and highways. An analysis of traffic patterns in the surrounding area will aid in determining whether the site is suitable for a fire station. The station must be located so that responding apparatus can enter streets and highways as safely as possible and return to the station without disrupting traffic and placing personnel at risk. It may be more desirable to locate a station on a side street rather than on a heavily traveled street.

Traffic pattern requirements for a specific site will differ for volunteer and career personnel. The major reason is that volunteers must respond to the station before responding to an emergency. Therefore, the site must allow easy access for volunteers responding to calls. There may be situations where apparatus is leaving the station and, at the same time, volunteers are still arriving. This is more complex than an all-career station, where all personnel are at the station and respond immediately to a call.

Response Time Standards

A primary responsibility of fire departments is to deliver fire and rescue services. Fire can grow at a rate many times its volume per minute; time, therefore, becomes a critical element when crews respond to an emergency. The timely delivery of services depends to a great extent on the location of the fire stations. Thus, when planning where fire stations should be located, the community needs to develop its response time standards. These standards are based on an analysis of the types of services to be delivered, what a reasonable travel time is, the size of the area to be serviced, the resources available, and the level of acceptable risk. Once the response time standards have been established, GIS can be used to determine fire station placement with a greater degree of accuracy.

GIS RESPONSE PROTOCOLS

GIS technology is being deployed in a number of other emergency response areas to increase efficiency, reduce response time, and provide higher-quality decision support information and data. This includes dispatch, mobile operations, and emergency management.

Computer-Aided Dispatch

Dispatchers have the important responsibility of processing emergency calls and sending the appropriate public safety resources to the emergency location based on the type and urgency of the incident. GIS is an important component of the dispatch system. Dispatch or CAD systems typically contain a file called the Master Street Address Guide (MSAG). This file contains street address information and service areas for the jurisdiction that the dispatch center services. As emergency calls are received, they may be accompanied with address information from the telephone company's emergency phone record database. This address is entered or electronically transferred to the CAD system, which compares it to MSAG. When the address is matched, the specific service area is also identified with the specific units that should be dispatched to the emergency. If the telephone company does not provide a digital address with the call, dispatchers must obtain it from the caller and type it into the system. Many computer-aided dispatch systems have begun to integrate GIS technology. GIS takes the address and automatically geocodes (places a point on the map) the incident and displays it on a map.

There are several benefits of having the incident displayed on a GIS map. New calls reporting the emergency may have different addresses but are reporting the same incident previously recorded. The GIS map display will illustrate that a different address making a call may be in close proximity to the original call location. Other benefits are shown in the following sections.

Global Positioning System (GPS). Many public safety agencies are equipping response units with global positioning system (GPS) devices, which provide the dispatcher (and perhaps other appropriate public safety managers) the ability to locate units through a GIS display and track them to the incident when dispatched. This is important during heavy call volume or for mobile vehicles such as police units and emergency medical units, because it provides dispatchers with a virtual, near real-time view of incident locations and emergency response units to activate an appropriate dispatch based on emergency unit availability.

Routing. GIS can quickly analyze and display a route from a station or GPS location to the emergency call. This route (depending on the sophistication of the street file) may be the shortest path (distance) or the quickest path (depending on time of day and traffic patterns). This information can be displayed to the dispatcher as well as on a mobile computer screen in the response vehicle. Vehicles equipped with mobile computers and GIS can also benefit by providing first responders with access to preplans, hazardous materials locations, photographs, and other location-based documents linked to actual specific locations through the GIS map display.

Move Up and Cover. During periods of high volume and simultaneous calls or a complex emergency, GIS can display areas of high risk that are left substantially uncovered. GIS can provide recommendations for reallocating available resources for better response coverage.

Emergency Wireless Calls. Wireless and cellular telephone technology have added to the necessity of GIS. Wireless phone–reported emergencies are not associated with an address, and the caller may not know his or her address or street location. GPS-enabled cell phones can provide latitude and longitude coordinates during an emergency call. Other technologies are available that triangulate the call location between cell towers or measure strength of signal to provide approximate location information. These coordinates are relatively meaningless to a dispatcher, but GIS can quickly process and display a latitude/longitude or other coordinate location. This enables the dispatcher to see the incident location or general area and the closest or quickest response units on the GIS display.

Records Management System. Dispatch systems often have a database to capture, store, and archive incidents. This database may be called a records management system or a CAD records system. The records stored in this database concerning emergency calls usually contain location information. GIS can link to and geocode (place a point on the map) the location that represents this event. These events can be analyzed and assessed by any field in the records database (time, incident type, etc.). GIS provides a powerful capability to see, understand, and assess a department's volume of business, developing trends, and response performance. The information within a records management system can be leveraged for additional purposes when geospatially enabled.

Mobile Operations

As wireless broadband networks expand, GIS support for tactical operations becomes more powerful. Mobile PCs, computer tablets, and handheld devices with GPS and wireless advances allow first responders to send and receive geographic information and incident updates. As shown in Figure 12.13.18, GIS mobile applications can provide the tactical map interface to information and data important to first responders. Information such as preplans, floor plans, and other documents are linked to building facility addresses and are easily displayed by clicking or touching the map. As fire and emergency medical services expand, the importance of GIS is becoming widely recognized. First responders must get to and size up the emergency and then deploy. The first responder's mission is to save lives and protect property and natural resources. GIS information support to the first responder mission can include the following:

- Incident location
- Quickest route
- Hydrant locations
- Preplans
- Photographs
- Floor plans
- Hazardous materials locations
- Utility control panels

The incident commander requires additional information to perform the command mission. Depending on the complexity and size of the incident, the information and data requirements may include information on the following:

- What exposures or other facilities are threatened by this incident
- Where incoming units should be positioned and assigned
- If a staging area or an incident command post is required, where parking lots, schools, churches, malls, or other suitable facilities are located
- If helicopter evacuation of victims is required, where suitable landing sites are located
- If medical triage or decontamination is required, where it can be implemented
- If hazardous materials are involved or a chemical plume is being generated, in what direction it is traveling, whom does it threaten, and what actions are required to protect and evacuate the public
- If an explosion is possible, who needs to be evacuated and where an immediate evacuation facility is located

All these decisions require maps and a variety of information from different sources. Having access to GIS data, imagery, school locations, parking lots, adjacent exposures, and hydrant locations provides an accurate picture of the event and supports critical command decisions.

Much of the information first responders require has already been collected but resides in a variety of formats and in numerous locations. GIS can integrate the information and provide it graphically to first responders through maps. GIS provides intelligent maps and allows the user to acquire other critical information. GIS can model explosions, plumes, and other potential emergencies. Instead of guessing or estimating evacuation requirements, transportation network problems, and other infrastructure threats, GIS will provide a more accurate prediction of the event and display potential consequences.

Emergency Management

During an emergency or crisis, maps play a critical role in response, search and rescue, mitigating further damage, and understanding the extent of the impacts. GIS is an appropriate platform for organizing the extensive amount of spatial data both generated and utilized during an emergency. A properly designed and implemented GIS will allow managers and

FIGURE 12.13.18 Sample GIS Mobile Application Providing Tactical Map Interface to Information and Data Important to First Responders (Courtesy of Chief Don Oliver, Wilson Fire Department, Wilson, North Carolina)

responders to access critical location data in a timely manner so that lives and property can be protected and restored.

Fire departments are the front line of defense for emergencies of all types. Large-scale emergencies range from natural disasters (e.g., earthquakes, floods, hurricanes, ice storms, etc.) to industrial or technological emergencies (e.g., train car derailments, petroleum fires, hazardous material spills, etc.) to terrorist attacks. Large-scale emergencies often involve multiple casualties, critical infrastructure damage, and evacuations; also, the emergency can last for several days or months.

Managing large-scale emergencies is complex and can involve search and rescue operations; displaced citizens; loss of utility services; and coordination among many departments, agencies, levels of government, and the private sector. One of the most complex challenges of emergency management is determining where damage is most extensive, where lives are most threatened, and where to assign limited emergency response personnel and equipment. During a major search operation for a lost or overdue hiker, GIS can accurately determine which sectors have been searched adequately and which sectors need to be revisited.

GIS provides a primary capability to organize, display, and analyze information for sound decision making. Integrating GIS data layers and imagery of the affected area or areas

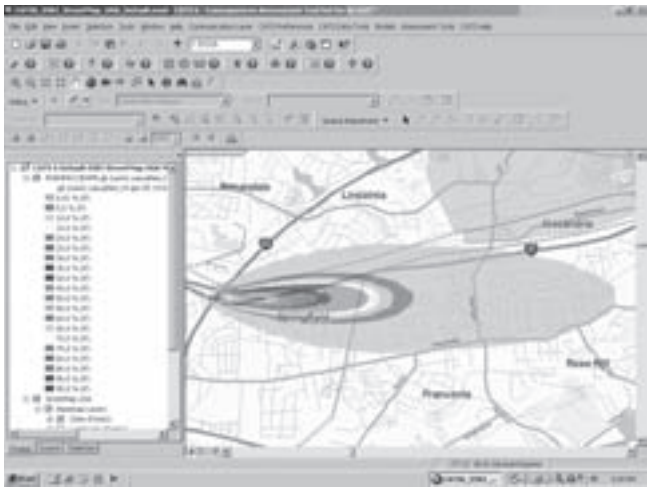

FIGURE 12.13.19 Sample GIS Model Illustrating How an Emergency Event (Plume, Explosion, etc.) May Impact the Area in Which It Occurs (Source: ESRI)

provides incident commanders with a comprehensive view of the emergency. GIS provides a primary capability to create a "common operating picture" for the incident. Emergencies are very dynamic and, as circumstances change, GIS can reflect these changes. GIS can incorporate temporal information (e.g., weather, hazardous materials locations, and emergency personnel locations) and model how an emergency might continue to evolve or what type of damage may be expected. These models could include the following:

- Chemical plume dispersion
- Blast models
- Hurricane tracks and effects
- Flood damage
- Earthquake damage
- Wildfire spread

GIS models illustrate how an emergency event (plume, explosion, etc.) may impact an area (Figure 12.13.19). In addition, GIS will analyze and display population effects, road closure requirements, best evacuation routes, potential shelters, and facilities out of the danger area that may support incident management.

Models provide incident commanders with a relative understanding of where evacuations may be necessary, potential damage to critical infrastructure, transportation network disruption, and so forth. Maps can be printed with the appropriate symbology to illustrate work assignments and incident facilities (e.g., incident command post helispots, staging areas, hot zones, etc.) and quickly dispersed to emergency personnel as part of the incident action plan. Areas with catastrophic damage are often confusing and disorienting to emergency personnel. GIS provides a view of the area before the damage occurred, including underground infrastructure, control points, potential hazardous materials locations, and other information to support emergency response actions.

SUMMARY

The fire service mission is to assist the public in the protection of life and property by minimizing the impact of fire, medical emergencies, and potential disasters or events that affect communities and the environment. Defending communities from natural or man-made emergencies through planning, preparedness, incident response, public education, and code enforcement is best accomplished through accurate information sharing. GIS is one of the most effective tools to analyze, define, clarify, and visualize community issues and problems to deliver emergency services to all.

Chapter 14

Fire Rescue Stations and Fire Service Training Centers

Revised by
David J. Acomb ❑ Roger M. LeBoeuf

Chapter Contents

Fire Rescue Station Design
Fire Service Training Center Design

Key Terms

fire rescue station, fire service training, live fire training, master plan

Fire stations and fire training centers can range from basic to complex. An adequate fire station could be a single bay with a desk at the back or it could be a multiple-company station that houses engines, ladders, ambulances, and a complete administrative function. Similarly, a training center could consist of just a small training tower or it could be a large campus that offers both classroom and practical education to hundreds of students at one time. Because there is no "one size fits all" solution, it is important to follow a planning and design process that creates the right facility for the community's protection and the department's training needs.

This chapter provides a general overview of the steps necessary to develop fire stations and fire training centers. The steps should be taken with the assistance of knowledgeable architects/engineers (A/Es) and should include the following:

1. Needs assessment
2. Planning
3. Design
4. Construction

This chapter provides ideas and insight for configurations, building options, and training props without providing an exhaustive list of possibilities. For related topics, see Section 12, Chapter 10, "Training Programs for Fire and Emergency Service Personnel"; Section, 12, Chapter 13, "GIS for Fire Station Locations and Response Protocols"; and Section 12, Chapter 16, "Fire Department Apparatus and Equipment."

FIRE RESCUE STATION DESIGN

Fire stations exist in virtually every city and town in the world, and there is a variety of functions that the fire stations have to serve. A fire station may be simply a garage to store a truck; others, in addition to housing trucks, provide housing for a complex hierarchy of offices for managing delivery of safety services. There are, however, many elements of fire stations that need to be present without regard to what is housed in the building. The design professional must be aware of these elements.

One of the most important elements of a fire station is whether or not it represents a safe and efficient place for people to use. A careful analysis of the proposed building and the functions it is

David J. Acomb, AIA, LEED, is the executive vice-president and partner of Rick Swisher Architect, Inc., a Florida- and Ohio-based corporation. With more than 25 years of professional experience, he has developed a nationally recognized expertise in the planning and design of fire rescue and emergency facilities. He has pioneered the concept of incorporating training into fire stations and many of his innovations can be found in stations around the country. His expertise has afforded him the opportunity to speak nationally and author numerous articles on public safety design.

Roger M. LeBoeuf, P.E., specializes in planning and designing fire training centers. He is president of Elliott, LeBoeuf & McElwain in Springfield, Virginia, and has worked on over 140 fire training center projects in 27 states plus Egypt. He serves on the NFPA Technical Committee on Fire Service Training.

expected to serve is required. There are obvious program elements consistent for all stations, such as security, fire protection, weatherproofing, and structural stability. The building where the fire equipment is to be housed must be designed to withstand the forces of man and nature. Other necessary design elements are lighting, heating or cooling, storage facilities, and emergency backup power.

It is very important when designing a fire station that a clear understanding between the design professional and the fire department be established in the conceptual design phase of the project. It is also necessary that the design professional have a clear understanding of the development costs of program elements to keep the total costs within the budget.

The fire station design must address the needs of its users. Even if it is a single-bay station without any other space required, consideration must still be given to the people who are going to use the station. If it is a complex that is planned for housing a mix of civilians and fire rescue personnel, the building must be functional for both the civilian and the fire rescue personnel. If the design professional is not familiar with the necessary elements of a fire station, then the project will be difficult to bring to a successful conclusion. The design professional cannot and should not depend on the fire chief to be aware of all of the elements necessary for a fire station, particularly architectural elements, that need to be considered in the design of the building.

Needs Assessment

Preparedness and planning are inherently important for the success of all public safety providers, particularly those in the fire and emergency services. Similarly in the design of a new station, the preparation and planning begin with a thorough needs assessment. This first step is critical and should be completed prior to any land acquisition. Ideally, determine the required station square footage and operational needs before beginning the assessment of potential sites. It is desirable to formalize this process with a design consultant and key staff. A common approach is to form a building committee to discuss the station issues and make decisions. Do not overlook comments and suggestions made by interested parties and end users, particularly members of the community who may have use of the building. If the future station will have shared or joint use, such as a police substation, be sure to include their representatives.

Another way to think of the needs assessment is comprehensive information gathering. The committee and design team want to know everything that will impact the design and operations of the planned station. This information will be generated from the following three-step assessment:

1. *Existing conditions.* Document existing spaces, room sizes (square footage), staff, equipment, apparatus, and so on.
2. *Current needs.* Determine what program spaces and sizes are currently required for the safe and efficient operation of the station. Consider what services and apparatus are required at this station.
3. *Future needs.* As best as possible, assess the future growth and development of the site's needs at least 20 years into the future. Many guidelines even suggest predicting 50 years out but may not be practical.

Room-by-Room Approach

The best way to approach the gathering of these data is with a room-by-room assessment. Consider who and how many persons will occupy the space and what functions will be supported. Provide the design team with a list of equipment and furniture for each space and note any special requirements such as additional phone/data outlets or storage needs.

Questions to anticipate during the needs assessment process include the following:

- How large will the staff be—current and future?
- What size and type of offices are required—private and shared?
- What type and size of apparatus will be used—current and future?
- Will the public have access to and use of this station?
- Will there be drive-through bays?
- What is the predicted future expansion of this station?
- Is there a current station prototype to follow?
- Where is protective gear cleaned and stored?
- How are hoses cleaned, dried, and stored?
- How will gender issues be addressed?
- What are the present and future storage needs?

Planning

Site Selection. The site for the building must be selected before the structural system can be determined. The site is usually determined by the analysis of many factors, including ISO evaluations and sometimes it is determined by a single factor. In any case, the selection of a building site is a task that requires some knowledge of fire department operations and goals. To properly site a fire station, an analysis of the department's response goals must be undertaken. If it is the goal of the department, for example, to respond to any incident within 4 minutes, the site location will be different than if the goal is a 9 minute response time. The analysis of response time must include a traffic study, addressing potential intersection delays, travel times, and access to travel routes. Response time for volunteers to the station should be part of the analysis, taking into consideration where they will be responding from.

Often a fire station is located in response to past growth; site selection, however, should be preemptive instead of reactive. Future growth projections, including the location and types of land uses, must be considered. The design team must project ahead 50 years to attempt to determine the growth patterns for the area and, thus, develop a site that serves the needs of the fire department.

Often fire stations are located on major travel routes based on the thinking that the response time is the most efficient. This approach has some validity, but it also removes what may be very expensive real estate from the tax base. An alternative approach is to locate the station on a secondary route, just off the major route, and utilize a signalized intersection to allow safe access to the major route. This plan improves emergency egress

and access to the station and reduces the risk for vehicular accidents and traffic stacking. With the recently developed technology to allow intersection signal control from fire apparatus, this method of secondary route location is becoming more popular, and the property on the secondary route is often not taxed at the same high rate as the property on the major route.

Once the site has been tentatively selected, it is necessary to consider improvements that must be made to construct the fire station. It is also necessary to consider such areas as parking for both fire fighters and apparatus, keeping in mind that the apparatus must have room to back in and sufficient turning radii, as well as visitor parking; drainage and runoff from storms; and security. A rule of thumb is two parking spaces for each member on a shift to allow for the shift change plus spaces for additional staff and a few spaces for the public.

Site Acquisition/Assessment. (See also sections on site selection and design for training centers.) Some rules of thumb for acquiring a desirable site include the following:

- Avoid congested thoroughfares, which increase the risk for accidents and traffic stacking, particularly during peak hours.
- Locate egress curb cut a minimum of 100 ft (30.4 m) from an intersection.
- Allow for a minimum 60 ft (18.2 m) apparatus apron measured from the street right-of-way to the apparatus bay doors.
- Avoid locating the station at the bottom of a hill.
- Avoid permanent barriers such as railroad tracks, one-way streets, or bridges prone to high-water risk.
- Avoid close proximity to schools or entertainment venues with heavy pedestrian and vehicular traffic.
- Allow 2 percent maximum slope of apparatus apron.
- Ensure minimum road width of 24 ft (7.315 m).
- Ensure good visibility and clear site lines for both approaching and exiting vehicles.

Site Due Diligence. A comprehensive site evaluation requires a thorough due diligence process and failure to do so may result in unexpected project costs or future complications. Potential building sites may have above- and below-ground issues that may create limitations or derail plans for that particular site all together. Some recommended due diligence steps include the following:

- *Environmental investigation.* A minimum Phase I is recommended; however, if the site had previous use for industrial, manufacturing, or filling station purposes, a Phase II investigation is recommended. Contaminated soil mitigation costs can be expensive.
- *Geotechnical investigation.* Many state building codes now define fire stations as essential facilities and require soil investigation as part of the permitting process. Poor soil-bearing capacity will impact the structural design, systems design, and pavement design of the station.
- *Archeological investigation.* For a nominal fee, an archeologist can access records for a Phase I archeological assessment of the site. This initial expense is minimal compared to the generally excessive financial and time constraints incurred when artifacts are discovered during construction.
- *Hazardous material investigation.* Prior to the demolition of any existing structures, certification that the station has been investigated for hazardous materials is required. Asbestos is generally the concern and abatement is normally expensive. The EPA will require certification of hazardous material abatement prior to demolition or construction.
- *Traffic studies.* If traffic is remotely a concern, consider a traffic study for current and future patterns. Peak hour congestion and projected rate increases will negatively impact response time and safety.
- *Future road improvements.* Check agencies with jurisdiction of thoroughfares bordering the potential site. Investigate future road widening or development plans.
- *Utilities.* Investigate existing and proposed utilities for the potential site. Relocation or connection costs and tap fees may be prohibitive. Because some station equipment may require three-phase service, check to see what service is available.
- *Storm water.* The Clean Water Act requires responsibility for the storm water generated from the station site. Consider how the storm water will be removed or detained on the property as it may require additional land or storm water utility upgrades.
- *Community concerns.* Try to gauge the potential negative impact of placing or removing a fire station in an existing neighborhood.

Establishing a Budget. Despite the best planning efforts, at the end of the day most decision makers naturally want to have some idea of the anticipated expenses. In some cases the budget alone will have the greatest impact on the station design and amenities. As such, it is wise to get a handle on the budget at the earliest possible convenience, so that educated decisions can be made before the design team has ventured far into the process. Additionally, the planning process may include determining what funding source or strategy is required and the potential for success. In establishing a budget a total project cost must be estimated. Total project cost is simply the sum of the *construction costs* (hard costs) and project *soft costs.*

Construction costs—often referred to as the bricks and mortar of a project—is the bid submitted by the contractors for material and labor and typically includes contractor overhead and profit, construction contingencies or allowances, and required construction inspections.

Soft costs are often overlooked in the budgeting and design process but are essential to the project. Though all the soft costs may not be known in the early planning phases, it is important to include some estimated amount. Experienced design consultants and vendors can provide valuable assistance. The following are a few of the anticipated soft costs to consider:

- Land acquisition expenses
- Site surveys
- Environmental assessments, studies, and abatement
- Hazardous material assessments and abatement
- Archeological assessment

- Geotechnical testing—soil borings
- Consultant fees
- Infrastructure and utility tap fees
- Permit fees
- FF&E—fixtures, furniture, and equipment
- Moving and storage costs
- Temporary facility costs
- Telephone/data/dispatch/cable
- Demolition expenses
- Audiovisual equipment
- Severe weather siren
- Building signage (beyond that required by code)
- Legal advertising—for consultants and contractors
- Ribbon cutting/grand opening ceremony expenses

Planning for Building Functions. The designer and the fire department personnel must work closely together on the development of the building plan and the relationship of the spaces to each other. The building must function properly for each type of use. If the building contains one or two bays for fire apparatus, it is not difficult to design the building efficiently. If the building will also function as an office, residence, and community center, then careful analysis of the relationship of the different spaces is necessary. One method of evaluating the spaces is to have the fire department personnel fill out a spreadsheet on each proposed room and its relevance to the other rooms in both importance and travel distance.

There are also other items to consider, such as the effect of the apparatus starting, leaving, and returning, on the other operations in the building. The noise and vibration caused by apparatus movement can be a distraction for other building uses. Fortunately, several methods of removing exhaust gases have been perfected and, with the proper installation of one of these systems, the effect of exhaust can be eliminated. However, the method selected for exhaust gas removal must be carefully considered. Some designers have simply opted to totally change the air in the apparatus bay when the apparatus is started or is returning. This method may not be desirable in areas where the air is conditioned either by heating or cooling and where a total change of air will result in the necessity of conditioning entirely new air in a relatively large space. The newer systems either filter the existing air or connect to the exhaust pipe of the vehicle and direct the exhaust completely outside the building.

The proximity of personnel to fire apparatus when a response is required must be considered when laying out a fire station. Because the key time for fire suppression and emergency medical operations is the time spent getting equipment out of the door, the building design should minimize the travel time of the personnel to the vehicles. Several spaces need to be in close proximity to the apparatus floor. They can include staff sleeping area, medical supply rooms, and equipment storage for fire trucks such as hose and spare self-contained breathing apparatus (SCBA) bottles. Locating these spaces next to the apparatus floor limits the travel necessary to replace supplies on the apparatus and increases efficiency.

Single Story Versus Two Story. It is design practice today to attempt to construct a single-story building within the allowable limits of the site. Because of concern over injuries, sliding poles in fire stations are a rapidly diminishing tradition but are still desired by some departments. It is far safer to design and construct a stairway for personnel to use. When a single-story building is not reasonable, care must be taken to properly design the building to limit the amount of travel from the first floor to other levels. One approach is to locate administrative functions on the second level and maintain, as much as possible, response functions, including sleeping accommodations, on the first floor. One-story stations are typically less expensive than two stories, primarily due to the fact that two-story stations will require an elevator and vertical circulation.

When the program for the building has been completed and a conceptual layout for the building has been created, it is necessary to begin to develop designs for structural stability, sewer, water, heating, cooling, ventilation, electrical, and fire protection. Each of these tasks is important to the functionality of the building. The structure of the building must be such that it supports all the operations of the building.

The structure must withstand the forces of nature, including snow, wind, rain, and earthquake. A fire station cannot withstand even the slightest failure of a structural component and, thus, must have a stronger frame than most buildings. The structural engineer must ensure that the building will not fail by using extra bracing and stronger components than normal for a comparable building size. All fire stations, regardless of size, should have a backup power supply in case of emergency. Adequate response time and sufficient power are critical (see FEMA 454 and 543).

Gender Separation. With both men and women in the fire and rescue service, many new issues have developed. Separate shower and bathroom facilities must be provided. Many of the existing fire stations were designed to accommodate only men. Therefore, they had one large "bunk room" where the entire company slept and one shower/bathroom facility. To avoid potential problems, men and women need separate showers and bathrooms. There are three ways to approach gender separation in fire station design, and each will impact the building's layout, construction cost, and departmental policies. The most common areas impacted by gender are sleeping quarters, locker, shower, and restroom facilities. The following are the three approaches:

1. *Separate but equal.* Separate but equally sized spaces and facilities for both male and female fire fighters
2. *Separate but unequal.* Separate but different sized spaces and facilities for both male and female fire fighters; typically larger facilities for male occupants
3. *Gender neutral.* Often referred to as unisex, spaces and facilities that can be equally shared by both. Individual bunk rooms fall into this category. Unisex shower rooms and toilet rooms are also common, and this option tends to be the most flexible and cost-effective.

ADA

The Americans with Disabilities Act (ADA) is a civil rights law that is enforced at the federal level by the United States Department of Justice. A citizen who believes there may be an

ADA violation may file a complaint with this agency. Contrary to some beliefs and actions, local government interpretations and waivers are not recognized in a court of law. As fire stations are public facilities (ADA category Type II), they will need to comply with these accessibility standards. Many states have adopted accessibility standards into their local building codes. Multistory stations are required to have elevators by this federal law. Familiarity and conformance with this law and guidelines in the station design process are required.

Sustainable Design

Sustainable design or green building design is a movement gaining acceptance at all levels of society. These principles stress responsibility for the impact of development and construction on the environment and resources through the promotion of energy conservation and alternative energy sources, sustainable site development, adaptive reuse, recycling, and so on. This entire process has been formalized into a certification process called the LEED (Leadership in Energy and Environmental Design) rating system, which provides standards and requirements for the different levels of certification. Additional information and resources on LEED and sustainable design can be obtained from the U.S. Green Building Council.

Typical Fire Station Space

For a majority of fire stations, the programmed spaces tend to fall into the following four categories:

1. Apparatus and vehicular storage
2. Administration
3. Residential and living areas
4. Operation and support

The following are some of the typical spaces that are programmed into fire stations. Not all of these spaces must be in every building, but this list is a guide to assist in the development of a program for a fire station.

Apparatus and Vehicular Storage. The fire trucks, rescue trucks, ambulances, and other support vehicles are housed in an *apparatus bay* (Figure 12.14.1). Design considerations must address the fact that heavily loaded trucks may sit day after day on the floor and that the trucks are loaded when they enter and leave the building. The trucks will be the full height and width allowed by law, and the station doors (recommended 14 ft × 14 ft [4.26 m × 4.26 m]) should be oversized to reflect this fact. Station bay width (minimum 16 ft [4.8 m] wide) for the trucks should be wider than in a normal garage because the trucks should and do receive some maintenance in place, and there needs to be space to open doors and tilt hoods without forcing the personnel to crawl over or under the trucks. Provide 5 ft (1.5 m) minimum clearance between the station bay doors and the front of the apparatus (see Figure 12.14.1). The bay should also have enough space to store minor repair items, perhaps on some shelves. The bay should be equipped with a system to vent exhaust gases from the trucks and be well lighted and heated. Most floor drains are installed under the trucks with sloping floors to collect drippings from the trucks. If floor drains are incorporated, then an oil/water separator must be used to limit pollution.

FIGURE 12.14.1 Large, Well-Thought-Out Apparatus Bay

Administration. Several types of *offices* are found in fire stations. Each subset of administration may require a different type of office. The minimum size of each office type does not vary much, but the equipment found in the offices is vastly different and will determine the required size. Shared office space for two or more individuals and open office areas with systems furniture can provide some economy of scale.

A chief's office is similar to that of the CEO of a corporation. The office requires space for the chief to work, as well as a space for meeting with other people. A fire prevention officer's office is essentially an engineering office and requires space for plans review as well as other office functions. The plans review space may be a drafting table or an oversized desk but should accommodate oversized plans sets. A secretarial office must contain space for the secretary to work and for a file cabinet, fax machine, copy machine, and other equipment often found in a modern office. A training office, which is basically a teacher's office, should be located next to a training space or seminar room so that training materials do not need to be carried great distances.

There are other types of tasks that may be required by fire administration such as receivables and payables, and these office types should be structured the same as any other business. In all cases, it is advisable to ascertain early on what personnel require private offices and what furniture and equipment are associated with each.

If the station serves an administrative function, then there should be space in the building for people to wait. This may be a small separate room or it may be a space near the offices, but it should not be a few chairs set up in a corridor. If conference rooms are desired, they are best designed large enough for multiple functions. Consider what activities will take place in each conference room and consider locations for white boards, audiovisual presentations, and storage. This room can serve as a place where administrative personnel can meet with individuals or small groups, for example, the fire prevention officer meeting

with a group of prospective developers or builders in a relatively private setting.

If a separate space for *training rooms* is desired, then it should be set up as a classroom (Figure 12.14.2). The room should be spacious, provide desks for the personnel to use, contain blackboards, allow space for slide and overhead projectors, provide adequate space for the display of training materials, and contain equipment for multimedia presentations and interactive training. The training room should also contain a lecture table for the instructor. The training room dimensions and proportions determine what type of audio can be used effectively.

The *watch room,* which has a variety of names (e.g., alarm room, station office), is essentially the office for the apparatus floor. This space can range from a minimum of 120 ft^2 (11 m^2), generally containing a desk, a chair or two, a phone, a map, and usually a radio, to a space for up to six or more people. The typical watch room serves as the place where paperwork for the apparatus, the log-in of calls, and station-to-apparatus communications are handled. The space is generally located adjacent to the apparatus floor to facilitate operations and has visual access to the bays and front apron. Often this is the place where visitors to the fire station first enter without going directly onto the apparatus floor.

A recent addition to fire station design is a small *exam room* near the front entrance of the station. The room can be set up similar to an exam room found at a physician's office. An increase in the number of walk-up emergency cases at fire stations has facilitated the need for this space to accommodate uninsured persons looking to the fire service for emergency care. These rooms serve as a location for blood pressure screening, and in areas prone to natural disasters they can become triage locations.

Residential and Living Areas. In fire stations where personnel are on duty at all times, *sleeping accommodations* commonly called the "bunk room" are provided for sleeping. Traditionally, bunk beds (two beds, one on top of another) were provided to save space. For a more "homelike" feel, many new sleeping areas are now being designed like dormitory rooms, which can vary from very simple (bed and lockers only) to more elaborate accommodations that include desk areas with computer and cable connections.

FIGURE 12.14.2 Training Room with Interactive Whiteboard

A growing trend in the volunteer fire and rescue service is to require or encourage volunteers to perform a "duty night" where they staff the stations at night. In many cases, this can reduce response time to emergencies by 4 minutes or more. To support these efforts, many amenities are being added for such volunteers.

Access from this area to the apparatus bays should be as direct as possible. The best case is to have this room on the same level of the station as the apparatus bays, because injuries have occurred when personnel traveled from the sleeping area to the bays using poles or stairs and because response time is faster. Although stairs are safer than poles, both have caused serious injuries and should be avoided. Some of these sleeping spaces have walls of soundproof materials of partial height, and some are full height.

In a large "bunk room" area, men and women can and do share sleeping facilities with few problems. This type of traditional arrangement helps to ensure that each member feels part of the company. Fire fighting is a team activity and every effort should be made to support the team concept. One problem that needs to be specifically dealt with is the clothing that is acceptable in these situations. Acceptable sleepwear could be an issued item from the fire department.

Some departments have provided separate sleeping facilities for women, which can have some negative consequences. Women may feel alienated by feeling that they are not part of the company. Also, from a practical point of view, it is not known how many men or women will be sleeping at the station on any given night. There may be a whole crew of women (as reported in one large West Coast fire department) or there may be none on duty. Designs that can double the amount of space and furniture needed for sleeping accommodations may result.

Having men and women sleeping in two-person, "dorm-type" rooms should not be allowed. A rule should be enforced that stipulates either all men or all women in each room. Also, using one-half or three-fourths height separation walls will provide privacy without sacrificing the company feeling that is so important to a well-functioning team of fire fighters.

Another trend occurred after fire departments started providing ambulance service. Separate sleeping rooms have been provided so that the EMS crew can be alerted for a call without disturbing other fire crews, which has many of the disadvantages noted in our previous discussion of women in the fire service. If this arrangement is a problem, some other type of alerting should be considered. Designating certain beds for the EMS crew and providing a separate telephone have been successful in some cases.

Adequate clothing storage should be provided for personnel to keep several sets of clean uniforms and other clothing. Many departments provide clothing storage areas for each person assigned to the station (Figure 12.14.3), which can mean up to three or four storage areas for each on-duty person. Volunteer departments that commit to having on-duty companies for immediate response may also need several clothing storage areas

FIGURE 12.14.3 Sleeping Room with Desk and Space for Clothing

for each person on duty. Several designs use a separate room for clothing storage with metal lockers and wooden benches similar to a dressing area of a sports facility.

For a staffed station, the *kitchen* quickly becomes an essential part of the building. The kitchen is where the fire fighters take their meals and their breaks. The eating area of the kitchen can also be used for training. The cooking area should be of commercial quality, due to the almost constant use of the kitchen (Figure 12.14.4). In a station with two or three full companies and a chief, the kitchen can be called on to serve upwards of 60 meals every day. If the kitchen is used in conjunction with a community room or other similar space that is, or may become, accessible to the public, then even more meals can be expected to be served in an emergency situation. Part of the kitchen must be reserved for storage of food, and each shift expected to use the station should have a separate space or pantry for food. The kitchen should also be equipped with at least one dishwasher but two are more desirable to ensure that, even if the station has a busy day, there will be clean, sanitized dishes for meals. The same is true of microwaves, which have an equal amount of heavy use. The kitchen should be designed to be similar in size to a commercial kitchen, and the dining area also should be designed based on the number of expected diners. The dining and kitchen areas need to be separated from the apparatus bay to prevent diesel contamination.

FIGURE 12.14.4 Kitchen Space in a Multiple-Company Station

Lounge or living room areas resemble the typical family room in many homes, except they are larger. A TV and videotape recorder will be found that can be used during training sessions or for relaxation between alarms. Several couches and chairs to accommodate the normal number of personnel in the station will be provided. Many departments prefer reclining chairs, which will require a larger space. The furniture is normally commercial grade to hold up under constant use. The area should provide a homelike environment for the comfort of the fire and rescue personnel.

Most fire departments have recognized the health and safety benefit derived from implementing a fitness or wellness program. If the program is not mandatory, *fitness/wellness rooms* are provided for the voluntary benefit of the staff. In designing this space, it is best to determine the type, sizes, and quantity of desired equipment first. The room size is a function of this information and the required clearances. Allow for a minimum 3 ft (0.914 m) corridor for quick access out of the room. The ceiling height should be established by the highest vertical equipment dimension and clearances. When laying out the room, consider such features as full length mirrors, wall-mounted fans or televisions, drinking fountains, and rubber flooring. Perimeter walls should be stabilized with plywood behind the finished gypsum wallboard and insulation for soundproofing.

Operations and Support. Regardless of whether or not the personnel are medical or hazardous materials responders, it is reasonable to assume that they will at some time encounter a contamination problem, either a biohazard or other type, that will require complete clothing removal. A *decontamination room or space* must be available where personnel can be decontaminated, beginning with the removal of the outer layer of clothes, and cleansing their skin without contaminating the rest of the station or its personnel. A room, or more likely rooms, with equipment to allow contaminated personnel to enter without touching anything, to remove and properly dispose of clothing, to clean themselves, and to don new noncontaminated clothing with some degree of dignity and privacy is required. The equipment involved includes foot-activated hampers, motion- or foot-operated wash basins and soap dispensers, automatic showers, automatic doors, and linen rooms for spare clothes and towels. Locating this room with a direct exterior entrance allows contaminated personnel to avoid spreading the contamination to other areas. Additionally, it is advisable to provide a toilet room adjacent to the decontamination room for similar reasons. As emergency medical services by the fire service become more common, the appropriate supplies for the service become more important. The supplies stored in an *emergency medical supply room* include narcotics, which require a large

degree of security. Other medical supplies have shelf lives that require frequent rotation. The diversity of the medical equipment needed to provide effective emergency medical services is increasing at a rapid rate. These items and the need to keep them clean and secure establish the need to have a room dedicated to the storage of medical supplies. This medical supply room should be located near the emergency medical vehicle(s) and must have a lock. It should be of such size that the equipment can be stored in a neat and orderly fashion. The room should be equipped with shelves and small cabinets, as well as a locked cabinet for narcotics and other regulated equipment. A double sink is also handy in this space. A room 10 ft by 12 ft (3.1 m by 3.7 m) generally will serve this purpose.

As with decontamination of personnel, protective clothing also needs to be cleaned. *Laundry rooms* are becoming a popular feature in fire stations. Turnout gear and other personnel clothing worn on the job need to be cleaned. It is not reasonable to expect personnel to take this equipment home to wash, and few commercial laundries will wash turnout gear. A commercial washer and dryer, as well as adequate venting, are necessary for this space. This space may best be incorporated into an area near where the fire personnel hang their protective gear during off-duty time (Figure 12.14.5). Separate and smaller residential-style laundries can be provided near the dormitory area for washing station laundry and sheets.

FIGURE 12.14.5 Lockers Providing Ventilation to Dry Equipment

A fire station layout must provide space for personnel to wash. Separate or unisex *bathing facilities and toilets* for men and women should include sinks, toilets, showers, and lockers, as well as closets for linen. These spaces should be of tile or some other type of construction to withstand constant use with very little care. The equipment in the space should be of such quality as to give an adequate time of use before renovation. The space allocated for these rooms can be based on the expected number of users. In addition to the space for personnel, space should be allocated in the building design for toilet facilities for other personnel or visitors to the station.

Construction

Construction materials, techniques, and types for fire stations are generally indigenous to the respective regions. Design professionals and engineers are normally well versed in the options and associated costs for construction and will have these discussions early in the planning and design phases. For each material specified and technique used, consider the following:

- Structural capacity
- Durability and degradation—how well the material will hold up to internal and external elements
- Maintenance requirements and costs
- Life cycle and replacement costs
- Energy efficiency

FIRE SERVICE TRAINING CENTER DESIGN

Fire training center design and construction are unique fields that require specialized expertise. Fire training centers can incorporate several types of building functions, such as the following:

- Classrooms
- Offices
- Apparatus bays
- Equipment storage and maintenance areas
- Auditoriums
- Break rooms (or cafeterias)
- Exercise facilities
- Working fire stations
- Emergency operations centers
- 9-1-1 call centers
- Television studios
- Living quarters

As complex as these combinations can be, it is the specialty, hands-on fire training props that make fire training center design especially challenging.

To succeed in designing and constructing a fire training center, the fire department needs to assign personnel who will be highly involved in all stages of the process, from planning through design and construction. This will provide the designers with needed expertise relating to fire training operations and current fire-fighting tactics that need to be taught. It will also ensure that the fire department's needs are heard and implemented.

The fire department should look ahead, beyond design and construction, to make sure that adequate funding and personnel will be in place to operate and maintain the training center once it is built. The basic process for planning, designing, and constructing a fire training center follows, along with types of features, buildings, and props that could be incorporated into the facility.

Needs Assessment

Many fire departments fall into the trap of trying to design the training center as the first step. Although it may be enjoyable to dream about different types of training props and to lay them out on a site plan, it is important to step back to the true starting point—assessing the need for the fire training center. Questions that need to be answered include the following:

- Why do you need a training center?
- Whom do you need to teach?
- What do you need to teach?
- What training resources do you already have?
- Do the existing resources provide effective training for a reasonable cost?
- At what rate is the community growing and will growth affect future training needs?

To answer these and related questions, a valuable resource is a working group representing the entities that might use the training center (see section headed "Identification of Potential Users" that follows). Tools available to the working group include meetings to exchange information plus written surveys to be filled out by potential users, either online or in paper format. It is important to gather data that help evaluate the need, such as the following:

- How many potential students exist?
- What is the geographical distribution of the potential students?
- What are the annual training requirements (curriculum and hours)?
- Where is training currently conducted and at what cost?
- What training requirements are not being met?
- If a new fire training center were built, who would use it?
- What classes and facilities at the new fire training center would be in highest demand?
- Would potential users be willing to pay fees to train at the training center?

These data, if properly gathered and interpreted, should provide enough information for the working group to know if the training center is really needed and, if so, what preliminary resources exist to help build, operate, and maintain it.

Architect/Engineer (A/E) Selection

Selecting an architect/engineer (A/E) should be one of the first steps. The A/E team typically includes an architect, civil engineer, electrical engineer, mechanical engineer, structural engineer, and a fire training center design consultant, if the A/E does not already have this expertise. It might be necessary to add a geotechnical (soils) engineer, environmental engineer, or other specialists to the team.

The role of the A/E is multifaceted. The A/E could participate in the needs assessment or should, at least, validate it. The A/E should perform all of the following:

- Determine training objectives (what skills need to be taught at the training center).
- Determine what buildings and training props are needed to facilitate the training objectives (prepare the program).
- Estimate how much land is required.
- Help find a suitable site.
- Estimate project budget.
- Assist with marketing the project to the city council, grant agencies, potential contributors, or the public at large.
- Prepare the master plan, which includes a site drawing that shows buildings, training props, roads, parking areas, utilities, and other features.
- Design the training center.
- Assist with bidding the project out to contractors who would construct the training center.
- Provide construction administration to help oversee and facilitate the project as it is being built.
- Provide postconstruction assistance with evaluations and maintenance.

While selecting the A/E, the fire department should look for the best combination of qualifications and those qualities that make the department believe it could work well with the A/E for the next several years. Most publicly funded projects require qualifications-based selection (QBS), as opposed to low-price selection, to ensure that the A/E is properly qualified to plan and design this specialized facility. A/Es with no fire training center experience should team with specialty consultants because designing K through 12 schools or fire stations does not provide the necessary expertise to design live fire training structures and other specialty training props (Figure 12.14.6). Vendors that sell training props, equipment, tools, or other items for fire training centers should not be hired as "consultants" for planning and design efforts because of potential conflicts of interest. Fire departments should seek independent advice about all of the options, not just those of one vendor. Be certain that companies that represent themselves as consultants do not also act as sales representatives for vendors.

Identification of Potential Users

Many fire training centers are intended for use only by the local fire department. Others are to be regional facilities used by career and volunteer fire departments from the extended region surrounding the facility.

If many departments and communities are involved, a regional consortium could be formed to pool resources (land, money, and personnel). There are several factors to be evaluated for a consortium. For example, which locality will provide the site? Which will operate and maintain the facility? How will the nonhosting consortium members support construction, operations, maintenance, and other costs? Will there be usage fees for rental and consumables? Will there be an annual contribution from each member of the consortium?

FIGURE 12.14.6 Live Fire Training Structure

Other agencies besides fire departments could be users of the training center. For example, law enforcement, EMS, emergency management, emergency operations center, 9-1-1 call center, and communications center departments are potential partners in a training center. If community resources are limited to the point that having separate facilities for these departments is not feasible, sharing certain facilities at one training center is an option. For example, classrooms, auditorium, physical fitness rooms, conference rooms, driver training course, and a training tower could be shared by the fire department and law enforcement agencies (police and sheriff) to maximize cost-effectiveness. Other critical training functions, however, could be kept separate, so that the fire department live fire training structure (burn building) and drafting pit are separate from the law enforcement shooting range and bomb disposal training area.

Identification of Operation and Maintenance Personnel

Before designing the training center, key personnel and budget decisions should be considered. Will there be full-time administrative staff, full-time instructional staff, and full-time maintenance staff? The answers to these questions will have a significant impact on the operations and maintenance budget once the training center is built.

Even though design has not begun, now is the time to start estimating operations and maintenance budgets. When requesting funding for construction, the department should also request operations and maintenance funds for the years immediately following construction to ensure that the proper budget is in place once the facility is built.

Identification of Funding Sources

Funding a new fire training center can be a tremendous challenge. Municipal capital outlay budgets and bond funds are the most common funding sources, but many departments need to supplement these funds. Other potential funding sources include the following:

- Construction grants
- Federal or state grants
- Local industry
- Donors
- Regional participants
- Other participating municipal or state agencies

Historically, federal grant funds could not be used for building construction, though federal grant rules should be explored for current opportunities before ruling out these funds for construction. Even if federal grants cannot be used for construction, they might be available for funding equipment, mobile training props, and training programs, allowing more of the local resources to be used for the construction of fixed buildings.

It is never too early to start marketing funding sources to gain support for the project. Some departments have needed years to obtain adequate financial support. Some departments have raised funds simultaneously with land acquisition and design phases, shortening the waiting period for construction to begin. Adequate funding ("seed money") for A/E fees for the initial programming, master planning, and perhaps land development submission will be necessary up front. This seed money will result in a well-developed master plan and budget, which could be used to help market funding sources for the full project cost.

Master Plan

Master planning initiates the design process. The key steps in creating the master plan include the following:

- Determine the training objectives.
- Write the program for training facilities needed to support the training objectives, including space requirements (space within buildings and space around training props). This program is the foundation for a successful project and should be established through significant interaction between the A/E and the fire department. Should it be necessary, the program could be adjusted during later stages of planning and design.
- Evaluate current and future needs.
- Create a conceptual site plan (Figure 12.14.7). This task should be coordinated with the "Site Selection and Design"

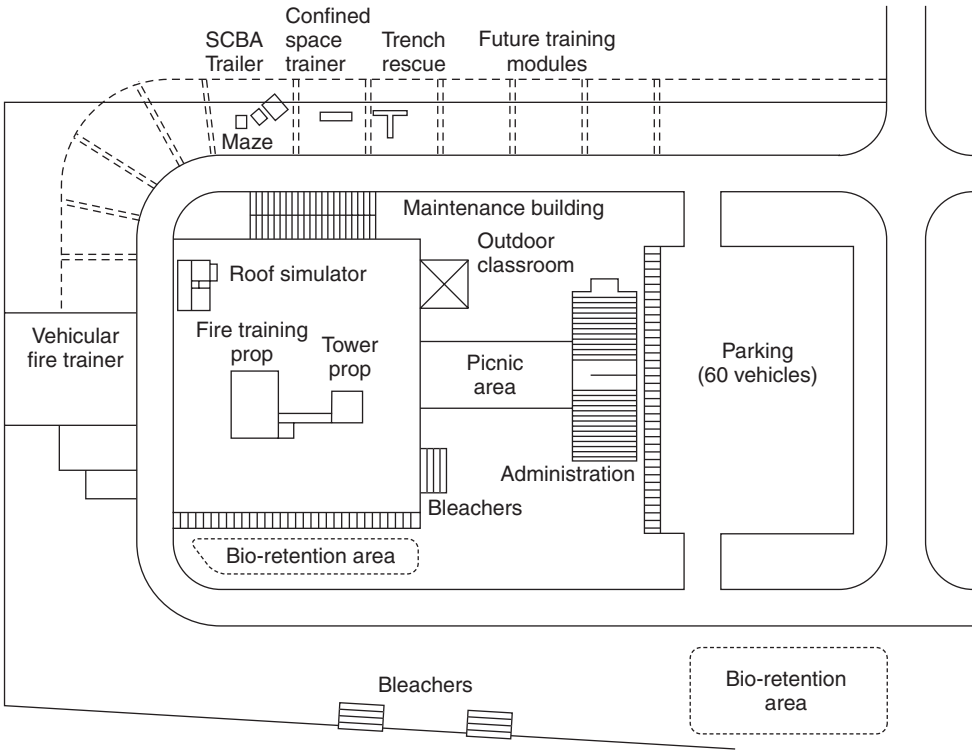

FIGURE 12.14.7 Sample Master Plan

tasks described later. The first draft of the conceptual site plan could be a simple "bubble diagram," showing approximate areas where buildings, props, and site features could be placed on the site. Eventually, the conceptual site plan will be more detailed, showing all features including their approximate shapes and sizes.

- Create conceptual plans of primary buildings and training props (Figure 12.14.8).

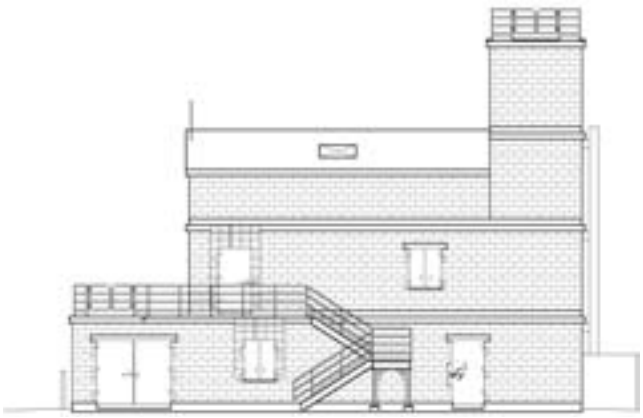

FIGURE 12.14.8 Conceptual Burn Building Elevation to Be Included in Master Plan

- Establish the budget for land acquisition, construction costs, furnishings, equipment, apparatus, and soft costs. Soft costs include fees (design, legal, and permitting), inflation, and contingency.

The site needs to be laid out to allow for future expansion. Training needs should be expected to change in the future, and the training center will need to adapt. Fifty years ago, training centers often did not need classroom spaces, and those classrooms were not designed for the technology demands of modern classrooms. After September 11, 2001, training for mass casualty incidents, building collapses, and multiagency concurrent training have been in higher demand. Many existing training centers do not have enough remaining space to accommodate these new needs. What new training will be needed 10 or 20 years from now? No one can predict, making future expansion capacity a critical component to the master plan. The master plan should consider the site issues listed next under "Site Selection and Design."

Site Selection and Design

Finding a suitable site can be difficult and requires perseverance. The process should coincide with preparation of the master plan because (a) the programming and space requirements of the master planning effort must be known in order to establish the selection criteria needed for the site search; and (b) on the other hand, the site must be selected before the master plan can be finalized.

Evaluating potential sites often involves filling out a criteria matrix that resembles a scorecard. There are many different features to evaluate for each site, as further described later. Scoring each of the needed features on a scale of 1 to 10 helps quantify which potential site is best suited. Some criteria can be weighted more heavily if they are more important. For example, a good score for environmental sensitivity might be more important than a good score for ease of obtaining a permit, especially if the latter could be overcome with a little extra time and effort on the part of the A/E. All potential sites should be scored, even if some appear at first glance to be unworthy of consideration, to validate the process and to confirm that the most suitable site is selected.

Resources for finding potential sites include local knowledge of the municipality and fire department, geographic information systems (GIS), local or state planners, tax maps, real estate companies, U.S. Geological Survey quad sheets, and other regional maps. The list of potential sites, and the evaluation of those potential sites, should look into the following criteria, at a minimum. These criteria will also impact the design.

Zoning. The area master plan, or similar document, should provide information about how potential sites are zoned. Industrial zoning or other suitable classifications are desirable, so that the training center is not located in a residential or commercial area.

Acreage. There seems to be no such thing as too much land at a training center. First, there needs to be adequate setback from neighboring properties, even if the neighbors are industrial in nature. Visible distractions (unsightly appearance of props, lights during night training, visible flames, and fire department activity), noise, and smoke have a negative impact on any neighbor. Creating adequate setback and visual buffering, through use of land berms, vegetation, fences, and buildings, has proven an effective method of minimizing complaints from neighbors.

Second, there needs to be ample space between the training props, so that crews working at the different props do not interfere with each other. If it becomes necessary to overlap working spaces around adjacent props in order to conserve land area, then those two props might not be usable simultaneously, requiring careful scheduling.

Third, there needs to be adequate distance between the training props and the conventional buildings (classrooms, offices, maintenance buildings, etc.). Smoke, noise, and lights interfere with the activities of these buildings and separating the props from the buildings is desirable.

Fourth, room for future expansion of the training center is desirable to be able to accommodate more students in the future plus different types of training that might not be known today but could be critical in the future.

There are many factors that can reduce the land that could be developed at a site. A 15 acre (6.1 hectare) site might have only 7 acres (2.8 hectares) that can be developed, once setbacks, wetlands, easements, or other restrictions are considered. Evaluate the developable acreage in addition to the overall acreage when selecting a site.

Location. On the one hand, it is desirable to have the training center close to the students to reduce travel time to the site. On the other hand, it is desirable to have the training center far from the population base to minimize its impact on the heavily developed portions of the community. A balance must be reached, including thoughts about potential community growth over the next 20 to 50 years. Many training centers that were built in remote, rural parts of a county found themselves surrounded by residential suburbs 10 to 15 years later.

Regardless of the site location, some students inevitably have a significant travel distance to the training center. In some cases, that is not a problem. In other cases, it affects cost (overtime requirements) and community protection (if a company that is training has to remain in service). Possible solutions for these issues include the following:

- Locate the site in a central location to balance the travel time of the students.
- Schedule other companies to backfill a station when that company is training.
- Provide sleeping facilities (dorms) at the training center, so that students attending weekend or longer programs do not have to travel long distances every day. Keep in mind that this solution is less common due to construction and operational costs.
- Provide satellite training centers, so that distant students can accomplish basic training closer to home and travel to the primary training center for specialized training.
- Provide mobile training props to take some of the basic training opportunities to the students rather than the other way around. This solution has been effective for training centers that serve large regions or entire states. Due to their size, it is difficult for mobile props to adequately simulate buildings, but several skills can be taught effectively with mobile props, including fire behavior demonstration, mask confidence (maze), aircraft fire fighting, and confined space skills.

Infrastructure. The site needs to have suitable infrastructure to support buildings, apparatus, and training operations. Site selection and design should consider the following:

- *Water supply.* Is potable water available? It will be required for drinking water, emergency eye washes and showers, restrooms, dining facilities, laundry operations, and similar functions. Potential sources include municipal water and wells. Water for training operations and irrigation could be potable or it could be supplied by tankers, ponds, or drafting pits. Recycling training water should be considered, and the A/E should look into methods for collecting training water and holding it for reuse. The recycling system could have a pumping station to charge hydrants around the site, or the system could include a series of dry hydrants. Water loss due to evaporation and conversion to steam should be considered when designing a recycling system, for the lost water will need to be replaced periodically by the fire department if precipitation is not adequate.
- *Sewer.* Is the site supported by municipal sewers or will a septic tank be required? Runoff from training operations usually does not need to go to sanitary or septic receptacles.

- *Storm water management.* Is a municipal storm sewer available to the site or will storm water be controlled on site through means of ponds, holding tanks, or other devices?
- *Power.* Is power readily available to the site? If not, the construction cost will increase.
- *Soils.* Are the soils suitable for supporting buildings, training structures, and roads used by apparatus? If there are loose fills, expansive clays, or rock on the site, there could be a significant cost impact.
- *Access roads.* Is the road network leading to the site suitable for supporting apparatus loads that will travel to and from the site?
- *Topography.* If the site is too hilly or too flat, the development costs could increase because soil might have to be added or removed. At some point in the site selection or site design process, a topographical survey will be required. This survey should also map the features of the existing site (buildings, areas of major vegetation, utilities, roads, and property lines).

Environmental and Other Restrictions. Due to the industrial nature of a fire training center, finding a site that meets environmental and other developmental restrictions is critical. Here is a sample list of items to evaluate for potential sites:

- Smoke plume and prevailing winds
- Water runoff that could include contaminants (soot, unburned Class A or Class B fuels, fire-fighting chemicals)
- Wetlands
- Endangered species habitats
- Protected vegetation
- Flood plain
- Landfill or hazardous materials
- Historical preservation
- Adjacency to airport or other facility that could impose restrictions on use and airspace above or around site

Public Access. Because there will be times when the public will need to access the site, it is best to design the site so that the public access areas, such as administration building, auditorium, and visitor parking, are near the road and main entrance. In most cases, this also puts the most attractive buildings near the road and main entrance, which is good for public relations.

Security. There are areas where public access should be denied, including training grounds and storage buildings. Fencing should be considered to separate the public access points, such as the visitor parking lot, from the rest of the site. Similarly, receptionists controlling locked doors could separate public areas in the administration building from offices, classrooms, and the rear doors that exit to the training grounds. Other security measures, such as cameras, manned gates at access points into the training grounds, and combination locks into storage rooms that contain harmful chemicals (or weapons if the facility is used by law enforcement), could be considered depending on the security needs.

Caution with Donated Land. Fire departments are sometimes offered land donations for the training center. The donation of an old landfill is a common example. Before accepting such a donation, the land should be evaluated for all of the environmental and other developmental restrictions that could make it expensive to develop, as listed earlier. It should also be evaluated for the infrastructure needs that are listed previously. In some cases, the department might not be able to afford the donation.

Design

Once the site is obtained, the master plan is in place, and the funding is available, it is time to design the facility. If hiring the A/E has been delayed until now, there is a good chance that the budget, land, and expectations could be off target. The A/E would need to validate all the work performed to date before commencing design efforts. Ideally, the A/E would have been retained during needs assessment to avoid potential delays.

The design process for a fire training center is similar to that of a fire station or any other conventional building. First, it is important to follow the applicable codes, standards, and guides. Some documents that relate to fire training center design include the following:

- State and local building codes, interpreted carefully for the training props
- NFPA 54, *National Fuel Gas Code*
- NFPA 58, *Liquefied Petroleum Gas Code*
- NFPA 86, *Standard for Ovens and Furnaces*
- NFPA 1001, *Standard for Fire Fighter Professional Qualifications*
- NFPA 1002, *Standard for Fire Apparatus Driver/Operator Professional Qualifications*
- NFPA 1402, *Guide to Building Fire Service Training Centers*
- NFPA 1403, *Standard on Live Fire Training Evolutions*
- IFSTA, *Essentials of Fire Fighting*
- U.S. Department of Homeland Security, Office for Domestic Preparedness, *WMD Training Program*
- State training guidelines, if any
- OSHA standards

The design process usually follows the standard steps of schematic design (15%), design development (35%), and construction documents (60%, 95%, and final).

The fire department should have constant opportunities to interact with the A/E, including chances to review the drawings at each stage and provide feedback. It is important to be vocal. A/Es require the fire department's input in order to provide a good design, starting with master planning through each step of design. If A/Es do not seem to listen, they should be confronted so that they can provide better service.

Four key design issues include (1) safety, (2) training effectiveness, (3) durability, and (4) ease of maintenance. Be sure the A/E explains at each stage how these issues are being met with the design.

Construction

Once the design is finished, the project will likely be bid to contractors (builders). The bidding process usually follows the

state and local procurement laws, especially if public funds are being used. For the most common form of bidding, the project is advertised, contractors give price bids based on information shown on the A/E's drawings and specifications, and the contract is awarded to the lowest responsible bidder.

The fire department should remain heavily involved during construction, including regular visits to the site and attendance at the construction progress meetings. Should anything look unexpected, the fire department should call the A/E. Occasionally, the fire department might want to make a design change during construction, which is feasible but usually requires paying a change order (extra charge) to the contractor, especially if the change alters something that has already been built. In most cases, it is better for design changes to be completed during the design phase.

During construction, the A/E's role includes the following:

- Run routine progress meetings.
- Make periodic site visits to observe construction.
- Review shop drawings.
- Answer questions from the field.
- Answer fire department's questions.
- Design modifications if the fire department requests design revisions or if unforeseen conditions require it.
- Process the payment applications.
- Communicate between the contractor(s) and fire department's representatives.

Postconstruction

When the dedication ceremony is over, there is a need for an operations and maintenance (O&M) budget, starting in the first year. Ideally, this funding would have been placed into the municipal budget during the planning phase. Budget items required for O&M include the following:

- Staff salaries and benefits
- Building maintenance (cleaning, lightbulbs, trash removal, and painting)
- Grounds maintenance (landscaping, roads, parking lots, and snow removal)
- Equipment maintenance (vehicles, gear, mannequins, and SCBAs)
- Utilities (water, electricity, gas, sewer, telephone, and Internet)
- Training fuel costs
- Noise, smoke, and runoff abatement costs, if any
- Training structure and training prop maintenance, including routine structural engineering evaluations of the live fire training structure (burn building), per NFPA 1403

Buildings at Fire Training Centers

The two most common buildings at fire training centers are classroom/administration buildings and support buildings. Other buildings could be included, such as fire stations, dormitories, and vehicle maintenance facilities, but the two primary building types are described next.

Classroom/Administration Building. The classroom/administration building could be a single portable classroom in a trailer or a large, multistory, multifunctional building (Figure 12.14.9).

Classrooms should accommodate the typical anticipated class size but have moveable partitions that could allow for larger or smaller classes within adjoining spaces. The classroom space should be multifunctional. One day it might be used for a classroom lecture, using the latest audiovisual and computer equipment. The next day it might be used to demonstrate SCBA equipment or to teach CPR on mannequins. As a result, it is beneficial to have tables and chairs that could be easily reconfigured or moved out of the way altogether. It is also beneficial to have durable finishes, for even if dirty gear will not be brought into the classrooms, the finishes will see ample wear and tear.

Classrooms could also be equipped to record sessions (video and audio), so that the sessions could be played again later at stations or other regional departments for distance learning opportunities.

Other functions to be considered in a classroom/administration building include the following:

- Dirty classrooms accessible from the outside drill area, so that students could enter in gear for classroom sessions relating to the hands-on training exercises being conducted; this function could also be out on the training grounds, in the form of outdoor classrooms
- Breakout rooms—small meeting rooms that allow for small group activities; a breakout room could also be used as a conference room or room for instructors to create curriculum and prepare for classes
- Offices for permanent staff
- Office for temporary staff and temporary instructors
- Formal conference room; could also serve as a breakout room for classroom sessions
- Work rooms, including printing, copying, and other functions
- Break room/kitchenette; for large fire training centers, there could also be a need for a full kitchen and cafeteria
- Library
- Auditorium for uses including large lectures and graduation ceremonies; tiered seating is problematic for comput-

FIGURE 12.14.9 Classroom/Administration Building

erized testing techniques, so a traditional auditorium might not be functional for examinations
- Audio/video functions, such as recording studio, editing rooms, and storage
- Physical fitness room; could be located in a support building instead
- Locker rooms and showers; not all training centers need these facilities. The training center could support the physical fitness room. If there is no physical fitness room, this function could be located in a support building closer to the training grounds. If this function remains in the classroom/administration building, it should have an exterior entrance from the training grounds, so that students in dirty gear do not pass through the clean portions of the building.
- Restrooms
- Heritage hall
- Storage areas for office supplies, training props, classroom equipment, training records, recordings of classroom sessions, cleaning supplies, break room supplies, and other equipment stored at the facility
- Parking, which should be sufficient to accommodate permanent staff, students, and visitors; if graduation ceremonies or other heavily attended public events are anticipated, the parking areas should be designed accordingly, or overflow parking areas should be identified on the site

Support Building. The support building serves the classroom/administration building as well as the training grounds (Figure 12.14.10). Functions in this building include the following:

- Vehicle storage and minor maintenance
- SCBA storage, refilling, and maintenance
- Locker rooms and showers; this function could be in the classroom/administration building instead
- Physical fitness room; this function could be in the classroom/administration building instead
- Restrooms
- First aid
- Storage for training props, equipment, and gear

FIGURE 12.14.10 Support Building

- CPAT course; a candidate physical ability test course could be set up in the apparatus bays, if the bays are large enough, in order to control the environment during the test

Training Structures and Props

The following is representative of training structures and props commonly found at fire training centers.

Live Fire Training Structure ("Burn Building"). A burn building is usually the first training structure provided at a training center. Its function is vital in teaching skills required by NFPA 1001, especially those requiring live fire training scenarios.

Burn buildings are exposed to harsh conditions and could deteriorate quickly if not designed correctly. There are three primary causes for damage. The first is heat, which could reach as high as 2000°F (1093°C) in areas of direct flame impingement, such as ceilings directly above training fires. The second is thermal shock, which is created when heated surfaces are sprayed with cold water. The third is abuse that is inherent in live fire training, such as impact from direct hose streams and impact from tools and gear carried by personnel.

No building materials are immune to damage from these conditions. Masonry cracks and gradually deteriorates. Steel warps and corrodes. Concrete cracks and spalls, a condition that occurs when pieces of concrete fall out of slabs or walls. Careful design and construction are required to eliminate the potential for damage to structural components.

When designing a burn building, the first step is to determine which type of fuel is required to meet the training objectives. The two primary options are Class A fuels and gas-fired props, which burn either LP or natural gas. The benefits of Class A fuels are the drawbacks of gas props, and vice versa. Some training centers have burn buildings that can accommodate both fuel options to achieve the benefits of both.

The structural elements of the burn building need to be protected with thermal linings. There are several options. For ceilings, the options tend to be proprietary ones. The options currently on the market are not equal products, in that different materials are installed in different ways from one vendor to the next. In choosing a thermal lining, the qualities to be evaluated include initial cost, long-term cost (including maintenance costs), verifiable evidence of durability and insulating capability, and references. Thermal linings for walls and floors could include the proprietary options but could also include more conventional options, such as fire bricks and masonry blocks. Steel is not an insulator, plus it tends to warp when exposed to heat. If steel is used as a thermal lining, it will need to be supplemented with additional insulation or ventilated air spaces, though these might not eliminate warping and the need for periodic steel replacement. Refractory concrete (calcium aluminate concrete) should not be used for structural components in burn buildings, given its track record of severe damage in burn buildings.

Two types of burn buildings are most often constructed. The first is a combination of concrete and masonry (Figures 12.14.11, 12.14.12, and 12.14.13). The second is preengineered steel. Each option has advantages and disadvantages and should

FIGURE 12.14.11 Two-Story Burn Building

FIGURE 12.14.12 Three-Story Burn Building with Attached Four-Story Tower

FIGURE 12.14.13 Five-Story Burn Building with Tower

be considered. Determining factors should include long-term cost, durability, and ability to provide realistic floor plans that simulate occupancies found in the community. The A/E should guide the discussions on options for building types, fuels, and thermal linings, as well as design the burn building and features.

Details should be designed for function as well as safety, durability, and ease of maintenance. For example, various roof pitches, roof ventilation cutout areas, durable doors and shutters that can expand and contract when exposed to heat while still blocking out light and keeping in smoke, and drainage scuppers should all be detailed by the A/E to ensure proper function and durability. Other potential features include forced entry doors, breach wall simulators, standpipes, temperature monitoring systems, rappelling anchors, and mock utility meters.

Around the exterior, it is best for the burn building to be accessible from all sides. Realistic challenges, such as curbs, street signs, and simulated overhead power lines (Figure 12.14.14), could be incorporated at one or more sides at low cost. Paving near the structure needs to be nonslip for ladders and durable for apparatus loads. Consider seasonal conditions as well, for asphalt could soften during hot summer days, making it susceptible to damage from apparatus loads and ladder bases.

In many cases, it is desirable for the burn building to be lockable at all accessible doors and windows, especially if the training grounds are not secured with a fence.

Training Tower. Training towers vary in floor plan and range in height from 3 to 10 stories, though 4 to 6 stories is the most common range (Figures 12.14.15 and 12.14.16). The construction of training towers is typically either wood or concrete, although steel towers have been used. Preengineered steel training towers are also available, usually combined with preengineered burn buildings. Other types of towers can be combined with burn buildings as well.

The following training functions are often performed at training towers and should be considered:

- Ground ladders to windows (could be various size windows), flat roof deck, pitched roof, or balconies
- Aerials; tower height should accommodate tallest aerial that is anticipated to be used in the community in the next 10 to 20 years
- Stair drills, both interior stairwells and exterior fire escapes
- Rappelling from roof, windows, and perhaps other locations unique to the community
- Standpipe connections and charging standpipe at fire department connection
- Search and rescue drills using artificial smoke or smoke from small Class A burns in a barrel, though soot from these fires could damage ropes
- Elevator shaft drills
- SCBA confidence maze (which could alternatively be in a shipping container on the site)
- Forced entry doors
- Technical rescue drills, including tripod over aligned manholes, high angle rescue, and building-to-building rescue

FIGURE 12.14.14 Simulated Power Lines and Other Obstacles Near Training Structure

FIGURE 12.14.15 Small Training Tower

Some towers have small floor areas and are used for basic ladder, stair, and rappelling drills. Other towers have larger floor areas in order to simulate various occupancies that exist in the community. Floor plan options should be considered in light of the search and rescue and other cold training opportunities already provided by the burn building.

In some cases, it is advantageous to combine the burn building and tower together, especially if site space is limited and if mid-rise evolutions need to be combined with live fire training. On the other hand, it could be more advantageous to separate the burn building from the tower, so that live fire training and tower drills could be conducted simultaneously by different classes. Furthermore, separating the two structures allows all four sides of the structures to be used for their intended purpose. If combined into one structure, the D side of the burn building and the B side of the tower, for example, would be eliminated from training possibilities.

Around the exterior, it is best for the training tower to be accessible from all sides, preferably with enough clearance for aerials to be utilized on all sides. Realistic challenges, such as curbs, street signs, and simulated overhead power lines, could be incorporated at one or more sides at low cost. Paving near the structure needs to be nonslip for ladders and durable for apparatus loads. Consider seasonal conditions as well, for asphalt

FIGURE 12.14.16 Large Training Tower

could soften during hot summer days, making it susceptible to damage from apparatus loads and ladder bases.

For hotter environments, consider a canopy roof over the roof, so that rappelling instructors and students can have shade during long training days. Like the burn building, it is often desirable for the training tower to be lockable at all accessible doors and windows.

Exterior Fire Training Props. Exterior fire training props are typically gas fired (LP in most cases because natural gas flames are difficult to see in daylight) and come in many configurations. Vendors offer props configured to simulate car fires, fuel spill fires, tank fires, dumpster fires, railcar fires, aircraft fires, shipboard fires, broken pipe/flange fires, outdoor grill fires, industrial fires, and other simulations. Many fire training centers have utilized the local gas company to design and build these training props as a lower-cost option to vendor-provided props. It is important to follow the gas code and all applicable NFPA documents, including the requirements of NFPA 1402 and 1403, when designing such props. Most A/Es do not have the expertise to design these props.

Mobile gas-fired props are being utilized more frequently, especially for statewide training and regional training. Rather than bringing students to a centralized fire training center, the mobile gas-fired props can be taken to the students. Mobile gas-fired props include trailers to simulate structure fires (though these props cannot provide the proportions of a burn building), car fires, aircraft fires, and tanker truck fires.

Exterior props could utilize Class A fuels instead of LP. For example, Class A materials could be burned in a junked car for training purposes. To conduct such burns, all closed containers, such as tanks, bumpers, pistons, shock absorbers, and some steering columns, must be removed from the car to prevent bursting. Any item that could have hazardous emissions, such as upholstery and plastics, should also be removed. In many cases, the car needs to be stripped to bare metal frame before being used for fire training.

Flammable liquid pits are becoming less common due to concerns about groundwater contamination and black smoke emissions. Should such a pit be utilized at a training center, the proper environmental containment is essential, as is setback from neighbors and other buildings/props at the training center for smoke dissipation.

Vehicle Extrication Training. Although some training centers have utilized gravel areas, most vehicle extrication training areas consist of a concrete pad that can accommodate several vehicles at one time for cutting and extrication exercises. Fluids should be removed from the vehicles before training but the concrete pad should be designed to ensure that any spilled fluids will be contained. Obstacles, such as precast concrete "Jersey barriers," could be added so that vehicles could be placed against the obstacles in order to make the training more challenging.

The vehicle extrication area could also be used for hazmat training by enlarging the pad to hold tanker trucks that could be used to simulate leaks and spills. The paved area provides space to practice containing hazmat spills.

Drafting and Pump Testing Area. When teaching the basics of pumping and drafting, it is necessary to have an area where the pumper can recirculate the water it flows rather than wasting resources and wetting down the training grounds. The two most common options are a pond, which could double as a storm water management device for the site, or a drafting pit, which is an underground concrete tank. For either case, there should be access to the water source for a suction hard sleeve and one or more dry hydrants, depending on the pump sizes. For the drafting pit, there should also be a horn-type steel tube or some other collection device to return the flow into the tank (Figure 12.14.17). The drafting pit should have a minimum capacity of 20,000 gallons (75,700 L). There should be a concrete pad, measuring approximately 50 ft × 25 ft (15.3 m × 7.7 m) adjacent to the pond or drafting pit for the pumper to be parked during operations.

Emergency Vehicle Operations Course (EVOC). An EVOC could include a large driver-training track that consumes more than 50 acres (20.2 hectares) of land, to simulate urban grids and highway interchanges. In most cases, however, a 1.5- to 2-acre (0.6- to 0.8-hectare) paved area is sufficient to teach the basic skills required by NFPA 1002. In many cases, the road network around the training structures and props can be utilized for driver training rather than building a dedicated driver training pad.

Outdoor Classrooms. Outdoor classrooms are typically open pavilion structures, with a wall on one side to hold a white board for use by an instructor. The pavilion offers students a place to sit on benches in the shade in dirty gear, to take in water and be cooled by fans (or warmed by heaters) while listening to instructors brief/debrief training evolutions. These structures also serve as shelters during sudden inclement weather. Outdoor classrooms could be equipped with restrooms, water fountains, emergency showers and eyewashes, first aid equipment, vending areas, and storage. It is good practice to provide several outdoor classrooms strategically located on the training grounds near clusters of training structures and props.

FIGURE 12.14.17 Drafting Pit

Other Training Props. There are numerous other training props that could be utilized, such as the following examples:

- Fire behavior lab, also known as a "flashover simulator," which consists of two shipping containers placed side by side and offset vertically, in order to demonstrate fire behavior
- Confined space prop, which could consist of any combination of connected vertical and horizontal pipes, manholes, tanks, and shipping containers with mazes inside. It is considered safe practice to keep as much of this prop above grade as possible, providing walkout access for all below-grade components.
- Trench rescue prop, which could consist of parallel concrete retaining walls holding back a hillside. Soil is placed between the walls, so that bracing is placed against the concrete walls during excavation. Should mistakes be made, the concrete retaining walls will ensure that a real trench collapse could not occur. The trench could be configured as a straight run, T-shape, or L-shape and should have a walkout condition for safety (Figure 12.14.18).
- Roof ventilation prop, consisting of a sloped, wood-framed structure built on the ground to allow roof ladder cutting exercises with no risk off falling of the roof of an actual building
- Rapid Intervention Team (RIT) prop, also known as FAST prop or RIC prop. This prop is a small, wood-framed structure that simulates conditions where fire fighters could get trapped, requiring rescue.
- Collapse rescue props, which could consist of basic concrete cutting props, basic balancing props, partially collapsed buildings with rubble on the floors, and rubble piles simulating fully collapsed buildings

SUMMARY

When developing a fire station or training center project, many issues must be considered. Because these factors will vary depending on the needs of the community, designers should adapt the application of the information presented in this chapter to suit local conditions and regulations.

The process of needs assessment, A/E selection, master planning, site selection, and design is consistent for both types of facilities, regardless of project scope and budget. Typical fire station spaces include an apparatus bay, sleeping accommodations, a watch room, a kitchen, a lounge or living room area, a decontamination room or space, and other functions. Fire training centers include a classroom/administration building, support building, burn building (live fire training structure), training tower, and various training props, such as drafting pits, exterior fire props, trench rescue props, confined space props, vehicle extrication areas, and others.

In all cases, the primary design issues are safety, functionality, durability, and ease of maintenance.

FIGURE 12.14.18 Trench Rescue Prop

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on fire rescue stations and training centers. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

Consolidation of Communication Centers
Reporting an Emergency
Processing Communications Within the Communication Center

Key Terms

alarm box, communication center, communications system, computer-aided dispatch, dispatch, emergency medical service, enhanced 9-1-1, Federal Communications Commission, fire alarm reporting system, hazardous material, joint powers authority (JPA), public safety telecommunicator, radio communication, radio frequency, repeater, transmitter

The goal of this chapter is to provide the *Fire Protection Handbook* user with an overview of public emergency services communication systems. It addresses issues related to the design, installation, operation, maintenance, and management of such systems and the facilities that house and support them.

In previous editions, this chapter addressed fire department communication systems. However, the widespread adoption of universal emergency number (9-1-1) service, coupled with requirements for formal training and certification of personnel and flexibility in resource allocation, has resulted in many jurisdictions combining central communication functions for all emergency services (fire, police, emergency medical services, etc.) into a single public safety answering point (PSAP) or communication center. Therefore, it has become increasingly difficult to address the emergency communication needs of the fire service without also addressing other emergency services.

NFPA recognized this trend when it changed the title and scope of NFPA 1221, *Standard for the Installation, Maintenance, and Use of Public Fire Service Communication Systems,* to NFPA 1221, *Standard for the Installation, Maintenance, and Use of Emergency Services Communications Systems,* commencing with the 1999 edition.

No two communities are exactly alike. Whether planning a new emergency communication system or evaluating an existing system, it is important to conduct an individualized needs assessment of the service area and then use it to analyze the emergency communication services provided and planned. In all cases, the requirements of NFPA 1221 should be followed.

For related topics, see the following: Section 12, Chapter 4, "Managing Fire-Rescue Departments"; Section 12, Chapter 13, "GIS for Fire Station Locations and Response Protocols"; Section 12, Chapter 16, "Fire Department Apparatus and Equipment"; Section 13, Chapter 9, "Emergency Medical Services and the Fire Department"; Section 14, Chapter 1, "Fire Alarm Systems"; and Section 14, Chapter 4, "Fire Alarm System Interconnections."

COMMUNICATION CENTERS

In creating any communication network, one must first establish a center point (communication center) through which all related process and control functions will be directed (Figure 12.15.1). A communication center may serve a single agency or area, multiple agencies under the control of a single political subdivision, several similar agencies from adjacent political subdivisions, an entire county, or any other large political jurisdiction. Combining fire, police, and emergency medical communications within a specific political jurisdiction (and for several adjacent jurisdictions) has

John M. Merklinger is director of the Monroe County 9-1-1 Communications Center in Rochester, New York. He has been a member of the Gates Fire Department since 1991 and is a past fire chief. He has been a member of Gates Volunteer Ambulance for 27 years.

FIGURE 12.15.1 Communication Center (Photo courtesy of Paul Ramirez, Phoenix Fire Department)

become an increasingly common management concept. If properly planned, such consolidations can provide positive results.

The communication center is where requests for emergency assistance are received and translated into an appropriate response. The communication center should be structured to provide logistical support to the responding units until the situation is under control. Accordingly, as an operating entity, the communication center must ensure that the equipment, personnel, and established procedures are adequate to satisfactorily perform in emergencies.

The communication center is a critical component of the jurisdiction's comprehensive emergency management plan. It is particularly important that communication center and emergency services communication systems be able to survive and continue to function during and after natural disasters such as floods, earthquakes, blizzards, hurricanes, and tornadoes. Such disasters may cause public utilities such as water, gas, and electricity to be unavailable to the communication center for extended periods of time. Lessons learned from past events and the probability of future events must be carefully considered and the communication center designed and equipped accordingly. One example is the resupply of fuel to emergency generators. A large-scale disaster could cut off normal sources of resupply, necessitating greater on-site storage than is required by code. There are resources that specifically address disaster management in the communications center. Resources to address these needs can be found at the National Emergency Number Association (NENA) website at http://www.nena.org or the Association of Public Safety Communication Officials (APCO) at http://www.apco911.org. In addition, the Commission on Accreditation of Law Enforcement Agencies (CALEA) at http://www.calea.org offers a Public Safety Communications Accreditation that specifically addresses disaster as well as all facets of communications. You do not need to be a police agency to use this resource. Finally, many statewide sheriff and chief of police associations offer free information on communication centers and disaster management for the communication center. Much of the free information offered applies to communications for the fire service as well.

Design Considerations

The following are some of the items that should be considered in the development of a communication center:

- Location
- Seismic stability
- Security (building layout and cameras)
- Emergency electrical power
- Wiring access (computer floor)
- Lighting (indirect lighting to prevent screen glare)
- Air conditioning (computers, dispatch, and personal environments)
- Air-conditioning backup
- Workstation layout (per Occupational Safety and Health Administration [OSHA] and Americans with Disabilities Act [ADA] regulations)
- Console arrangement (always consider ergonomics in your design for long-term employee health)
- Acoustics (background noise suppression)
- Restroom facilities
- Kitchen facilities
- Interior design
- Rest areas (lounges)
- Dormitories (sleeping quarters)
- Emergency rations
- Alternate locations
- Building storage areas
- Loading dock access or some type of access for future upgrades and deliveries
- Fire suppression systems

The communication center should be designed and constructed so the probability of interruption to operations due to fire or other causes will be minimized. Security concerns have changed significantly in the last few years. Today most communication centers have sophisticated security systems with features like key card access, security bollards, bullet-resistant or explosion-resistant glass, and much more. Simple things like restricted access to the communication center have become more critical today. When a separate building is not feasible and the communication center must be housed with other operations, such as city hall offices or in a fire station, the communication center should be properly separated from the remainder of the building by vertical and horizontal separations with a fire resistance rating of at least 2 hours and preferably with entrance only from the outside. Protection should be provided against fire exposures and unauthorized entry.

Alternate Communication Facility

An alternate communication facility that, when fully staffed, is capable of performing the emergency functions normally performed at the communication center should be provided. For example, a bomb threat or fire in the center requires both an alternate facility and a plan to evacuate the communication center. This alternate location should be totally removed from the primary location and should have all the necessary requirements for long-term usage. In the event of fire in the center, provi-

sions should be made to continue operations long enough to transfer operations to the alternate facility. In smaller facilities and jurisdictions that cannot afford an off-site backup, the communication center should make arrangements with neighboring jurisdictions for backup services. Many times reciprocal agreements of this nature can benefit both jurisdictions.

Communication Center Protection

Because of the types of activities conducted and the records maintained in any modern communication center, building and systems protection must be provided. Security begins at the entrance to the communication center and can be as simple as a dead-bolt lock or as complex as a computerized entry control system. Only authorized personnel should be allowed access to the center. The center should be protected against damage due to vandalism, sabotage, and civil disturbances. The lowest floor should be above the 100-year flood plain. Entrances into the center directly from the exterior, if provided, should be protected by a security vestibule. Windows, if provided, should be bullet resistant if they face an area accessible to the public. The communication center should be located in a fully sprinklered, fire-resistive, or noncombustible building. Alarms and supervisory signals from the building sprinkler system(s) should be monitored in the operations room. The center and the spaces adjoining the center should be provided with an automatic fire detection system that is monitored in the operations room. Evacuation signals should be designed to avoid interference with communications operations. Portable fire extinguishers should be provided throughout.

Heating, ventilating, and air-conditioning (HVAC) systems serving the center should be independent of the main building HVAC systems to avoid the possibility of smoke contamination from a fire elsewhere in the building. Fresh-air intakes should be located to minimize the possibility of drawing in smoke from a fire inside or outside the building. Consideration should be given to providing operator-controlled smoke-control modes for the center HVAC system. Interior finishes in the center should be noncombustible. Records must be properly safeguarded. Access to records should be limited to authorized personnel only. Off-premises storage of backup records, software, and so on is essential. This backup information should be updated on a regular basis. Cyber-security or computer security is becoming a critical component of communication center operations. It must be part of all plans for protecting the facilities.

Power

The communication center must be able to operate normally in the event of a power failure. Two sources of power need to be provided. Any loss of data can have a severe impact on the communication center, so an uninterruptible power supply (UPS) system is critical. In most cases, the primary source of power will be the commercial electrical distribution network with the secondary source being one or more on-site engine-driven generators. However, in some cases the primary power source may be one or more on-site engine-driven generators with the secondary source being other on-site engine-driven generators. Automatic transfer to standby power on failure of primary power should be provided. During this transfer process, the UPS system should automatically kick in to maintain adequate power while the generators start and come up to full power.

Engine-Driven Generators. Engine-driven generator installations should conform to NFPA 37, *Standard for the Installation and Use of Stationary Combustion Engines and Gas Turbines,* and NFPA 110, *Standard for Emergency and Standby Power Systems.* The generators should be located in secured areas. Fuel should be stored on-site to permit a minimum of 24 hours of operation at full load without resupply, or in some cases a connection to a natural gas supply line should be established. Where the potential exists for longer interruption of primary power caused by natural disasters such as hurricanes and earthquakes, on-site fuel storage should be increased accordingly. Equipment essential to the operation of the generator, such as fuel transfer pumps and cooling systems, must be supplied with backup power from the generator. Generators should not depend on the public water supply (which might fail during a disaster) for engine cooling. Generators should be tested for at least 1 hour each week under load. This can be done by transferring the communication center's load to the generator or by loading the generator through other means such as an electric-resistant grid "load box."

In determining the capacity of the generator, essential loads in addition to those of the communication systems, such as HVAC systems, adequate lighting to permit personnel to perform their duties, fire protection and security systems, water supply and sanitary facilities operation, and so on need to be considered. In many cases your local utility company will provide an energy audit free of charge.

Uninterrupted Power Supplies and Battery Systems. Under worst-case scenarios, engine-driven generators can fail. Therefore, in addition to standby generators, communication centers should be equipped with stored emergency power supply systems (SEPSS) conforming to NFPA 111, *Standard on Stored Electrical Energy Emergency and Standby Power Systems,* to power essential electronic equipment. An SEPSS is defined by NFPA 111 as a system consisting of an uninterrupted power supply (UPS), a central battery system, or a motor-generator set powered by a stored electrical energy source, together with a transfer switch designed to monitor the preferred and alternate power sources and provide desired switching of the load, plus all necessary control equipment to make the system functional.

Electronic equipment, such as a computer-aided dispatch (CAD) system, is sensitive to momentary power interruptions during transfer from primary to standby power, as well as to voltage fluctuations normally associated with commercial power distribution systems. A momentary power outage or surge can cause systems to go off-line or damage sensitive circuits. Where such equipment is present and essential to operation of the communication center or network, it should be powered through a UPS conforming to NFPA 111. A UPS is a system consisting of a battery source, a converter, an inverter, and control equipment designed to provide clean, conditioned power for a finite period of time.

RADIO COMMUNICATIONS SYSTEMS

Radio System Selection

Considerable thought should be given to selecting the proper radio system, and professional personnel should be used to ensure the proper functioning of each system. For new systems, every entity should consider building an APCO Project 25 (P25) compliant radio system. A P25 radio system allows for multiple manufacturers' radios to work on the same system. Some older models are proprietary and can not work on other manufacturers' systems. For more information on P25 radio systems, you can go to the APCO website at http://www.apco911.org. Two other major considerations when upgrading or replacing your radio systems are FCC order 01-092 on narrow banding for UHF and VHF systems and FCC order 04-168 on rebanding for the 800-MHz spectrum. You can find further information on both of these critical subjects at http://www.fcc.gov.

An analysis of the service area and system configuration will help determine the number of base station transmitters, receivers, and repeaters needed and the number of radio channels (frequencies) required to support current usage and allow for future expansion. Small agencies may be able to operate with just a few frequencies. However, if a communication center serves multiple agencies, or if individual agencies consider the need for tactical on-scene frequencies, mutual-aid/interagency frequencies, disaster management, and the like, it is obvious why careful planning is necessary. Coverage overlays will need to be considered along with the topography of your area. Engineering will likely have to be done by the equipment manufacturer or an independent third party. The most important aspect will be the completion of a propagation study of the area. It is also critical that all aspects of the radio system meet recommended grounding standards as set forth by the radio's manufacturer.

Radio Frequency Selection

Several bands of radio frequencies are available to the public emergency services. These bands are VHF low band, VHF high band, UHF 450 MHz, and 700, 800 and 900 MHz. Each band of frequencies has its advantages and disadvantages, and the selection of a particular band will depend on factors such as frequency availability, area to be covered, type of terrain, number of radio units required, frequencies used by bordering fire districts, mutual-aid agreements, type of operation, and use of emergency medical radios.

Due to the finite number of available frequencies, it may be necessary for emergency response agencies to share radio frequencies. For small agencies, sharing radio channels with neighboring agencies having similar missions could be advantageous.

Type of Radio System Operation

The several types of radio systems available are as follows.

Simplex. This system utilizes a single radio frequency for both transmitting and receiving in all radios for each channel. With a simplex system, only one radio can transmit at any time and all others must receive.

Two-Frequency Half Duplex. This system utilizes separate frequencies for transmitting and receiving. As in the simplex system, half duplex allows only one radio to transmit at any one time.

Two-Frequency Full Duplex. The two-frequency, full-duplex system utilizes separate transmitting and receiving frequencies and permits simultaneous conversations in two directions.

Two-Frequency Repeater System. With this system, a high-powered base station repeater is centrally located at a favorable site overlooking the area to be covered, preferably on a mountaintop, a tall building, or a tower. The repeater receives a transmission from any radio in the system on one radio frequency and instantly retransmits or repeats the message on a second frequency that is received by all other radios in the system. A repeater system greatly increases the range of all of the radios in the system. It is especially useful in hilly or mountainous terrain where it might be impossible to talk directly from unit to unit. Repeater systems are two-frequency, half-duplex systems as described earlier.

Trunked Systems. The trunked system uses a group of radio frequencies. The system is controlled by a computer at the communication center or at the base station transmitter site. When a transmitter is keyed, it transmits its unique identity code to the computer. The computer instantaneously selects an available communications frequency and automatically directs the transmitting radio to use that frequency for the transmission. The advantage of this type of system is that it uses a group of available frequencies more efficiently by utilizing the capabilities of the computer to manage the radio traffic on each frequency. Thus, more radio traffic can be handled on the available frequencies without causing congestion and interference. The computer can prioritize traffic from competing transmitters based on their individual identity codes. For example, a request for a clear frequency transmitted by a fire department radio can receive a higher priority than a request from a nonemergency agency's radio. Provisions should be included to keep the system operational in the event of failure of the computer controlling the system.

In the interest of personnel safety, trunked radio system talk groups should not be used to fulfill the requirement for the provision of a simplex radio channel for on-scene tactical communications. A simplex radio channel is required because it enables emergency messages to be transmitted to and from on-scene command without reliance on communication equipment at another location.

Tone-Coded Squelch. In a tone-coded squelch system, each radio transmits a subaudible tone along with the voice signal. This audio tone is used to turn on the receiver so the conversation will be heard. Only the proper tone will activate the receiver, which eliminates the reception of radio interference.

Radio Paging Systems. Contacting emergency response personnel who do not normally monitor voice radio traffic can be easily accomplished with a radio paging system. A paging sys-

tem includes a paging encoder, which is located in the communication center, and individual pagers. Pagers that receive voice messages, alphanumeric text messages, or both are available. With voice messages, a signal from the communication center activates an alerting device (typically a beeping tone or vibrator) in the pager and turns on the receiver audio. The wearer can then hear the dispatch message. With alphanumeric text pagers, the wearer is alerted in a similar manner and the dispatch message is displayed on a text screen on the pager. In some cases with alphanumeric paging a two-way alphanumeric communication can be established aiding in the dispatch of calls. Systems typically have the capability of alerting an individual pager, a group of pagers, and all pagers associated with the system.

Commercial paging service is available in most areas. Although suitable for administrative paging, its use for emergency dispatching is not permitted by NFPA 1221, since the commercial system is not under the control of the authority having jurisdiction. The volume of traffic in a commercial system may significantly delay transmission of emergency messages. In addition, the authority having jurisdiction cannot ensure that commercial facilities not under its control comply with the requirements of the standard for communication centers and dispatching systems.

Use of Multiple Radio Channels

The size and complexity of each agency will determine the number of radio channels necessary for adequate communications. Very small agencies may require only one radio channel for their exclusive use, whereas agencies in large metropolitan areas will require many. A separate frequency exclusively for on-scene tactical communications is required for each agency (or multiple agencies sharing the same dispatch channel). In addition, all agencies having similar missions adjacent to one another should share a common mutual-aid radio channel. This is provided for by the Federal Communications Commission (FCC) and is usually managed on a statewide basis.

Transmitter and Repeater Locations

Care should be taken in selecting the main transmitter and repeater locations for the radio system. Each radio coverage area is unique and must be dealt with on an individual basis. A high, central location, such as a mountaintop or large hill overlooking the area to be covered, a tall building, or similar structure is generally the ideal site. (This depends on coverage requirements, frequency availability, and requirements for channel sharing.) Again it is critical that proper system engineering and propagation studies are done to provide for adequate coverage. Where none of the foregoing locations is present, a high antenna tower can be utilized. Towers are required, even on mountaintops, to ensure proper antenna system operation.

The availability of commercial power and telephone access is also desirable when locating a transmitter site. Standby power supplied by a generator and backup battery system or UPS must be provided to ensure the site remains "on the air" in the event of a commercial power outage.

In some locations, where commercial power is unavailable, solar power (solar panels), batteries, or generators may be used as the primary source of power for the site. If the base station or repeater location is remote and unattended, provisions should be made to secure the area against unauthorized entry and vandalism. Intrusion alarms should be monitored at the communication center. A chain-link fence should surround the area, and all radio equipment should be located inside a building, out of sight, and protected from the weather. Security, fire protection, standby power, and circuit protection considerations are similar to those of the communication center. Remote camera access from the communication center to monitor the radio sites is an excellent idea.

Alternate Transmitter

An alternate transmitter, preferably at a separate location, should be provided to maintain communications in the event of failure of the primary transmitter. The alternate transmitter should have the same operational capabilities as the primary transmitter. A high central location is also desirable for this site. Primary and backup power, circuit protection, security, and fire protection requirements are the same as those for the primary transmitter site.

The communication center should have the capability of selecting either the main or alternate transmitter. To ensure its readiness, the alternate transmitter should be used at least twice daily.

Radio Site Antenna Configuration

When more than one radio is installed at a single site, an antenna system may be required. It may be impractical for each radio to have its own separate antenna because considerable interference could be generated using separate antennas. When several compatible radios are used, it is customary to provide one or more transmitting antenna systems and a separate receiving antenna system. A base station repeater using a single antenna requires a duplexer in order to transmit and receive simultaneously. Several transmitters can be connected to a single antenna by use of an antenna combiner; several receivers can be connected to a single antenna through the use of a multicoupler. Keep in mind that some output degradation can occur when sharing antennas, so this method may not be the preferred method. Professional assistance should be utilized to design the antenna system for all radio sites.

The antenna design should provide maximum radio frequency (RF) isolation between transmitting and receiving antennas, which is usually accomplished by mounting them one above the other on the antenna structure. Coaxial cables should be used for connections between radios and antennas. These cables should be high quality and low loss, with length as short as practical. Good grounding of the antenna system is required to prevent damage due to lightning.

Access from Communication Center to Radio Site

If base station radio transmitters are located at the communication center, individual wires ("house cables") can be used to connect the operators' consoles to the proper base station. If the

base station radios are located remotely from the communication center, they can be connected by dedicated leased telephone lines, a microwave radio system, fiber-optics connectivity, or a point-to-point radio. Redundant links should be provided so that failure of a single link will not prevent operation of the remote transmitter site from the communication center. Adequate circuit protection should be provided at the communication center and at the remote site. Always meet or exceed the manufacturer's recommendations for circuit protection.

Mobile Radios

Mobile radios have high RF power output (typically 20–100 W) and, therefore, have considerable transmitting range. However, because they are vehicle mounted, they cannot provide on-scene communication once personnel leave the vehicle. Each emergency response vehicle should be equipped with a multichannel, two-way mobile radio that is capable of (1) communicating with the communication center over the assigned dispatch channel(s) and (2) communicating with other units on the assigned tactical channel(s). In addition, emergency vehicles that are assigned to respond to airfield emergencies should be equipped with mobile radios capable of operating on the aircraft ground control emergency channel(s). Each mobile radio should be equipped with a visual "transmit" indicator and a carrier control timer that disables the transmitter after a predetermined time as established by the authority having jurisdiction to prevent a malfunctioning radio from tying up a channel indefinitely. Mobile radios equipped with scanning receivers should have an automatic priority feature that causes the radio to revert to its priority channel automatically when that channel is being used. Consider P25 compliant radios. Spare radios should be kept on hand for exchange with malfunctioning radios. The minimum required by NFPA 1221 is one spare radio for each 20 radios or fraction thereof in service and not less than one unit for each (noninterchangeable) radio model in use.

Portable Radios

Each emergency response vehicle should carry at least one multichannel, two-way portable radio capable of operating on the assigned dispatch and tactical channels. Consider P25-compliant radios. Many agencies issue portable radios to each emergency responder on duty for both personnel safety and ease in dispatching. Radio discipline becomes crucial with that many portable units in use. Portable radios have the advantage that they can be carried (worn) by emergency response personnel. However, they have a much lower RF power output than mobile radios and, therefore, have a considerably shorter operating range.

Portable radios should be manufactured for the environment in which they will be used. For example, most portable radios need to withstand exposure to precipitation, rough handling, and ambient temperature fluctuations. Radios used in fire fighting must withstand repeated exposure to very rough handling, water, and high heat and humidity. Radios used where explosive vapors might be present also must be labeled as intrinsically safe. Portable radios should be designed to allow channels to be changed while the user is wearing gloves. Radios that are equipped with keypads should have a means for the user to disable the keypad to prevent inadvertent use. Each portable radio should be equipped with a "transmit" indicator and a carrier control timer that disables the transmitter after a predetermined time. Radios equipped with scanning receivers should have an automatic priority feature that causes the radio to revert to its priority channel automatically when that channel is being used. Battery chargers and stocks of charged spare batteries should be maintained on hand in quantities sufficient to provide for continuous use of portable radios during long-duration incidents. Spare radios (at least one spare for each 10 radios or fraction thereof in service) should be kept on hand for exchange with malfunctioning radios. For personnel who work in very noisy environments, provision of sound-attenuating headsets should be considered.

Diversity Receiver-Voter System. Because portable radios have a very low RF power output, this low power creates problems for communications over large areas. Portables can normally receive the high-power base station, but they do not always have sufficient power to transmit back to the main radio site. This problem can be eliminated by a diversity receiver-voter system in which radio receivers are installed in a uniform manner at various locations throughout the coverage area. This solution provides a receiver for each subarea in the system. In this manner, a portable radio should not be more than a mile or two from one of the receivers in its subarea.

The signal from each of these receivers is fed to the communication center. The voter is capable of switching from receiver to receiver in midsyllable so, as the RF signal rises and fades at each receiver, the dispatcher hears only the best signal received. A diversity receiver-voter system can also be incorporated into a repeater system to greatly exceed portable-to-portable communications. A block diagram of a simple diversity (subarea) receiver-voter system is shown in Figure 12.15.2.

Mobile Data Terminals. Mobile data terminals (MDTs) sometimes also called mobile computer terminals (MCTs) are small computer terminals that may be connected to a radio system, allowing that unit to access another mobile terminal, base station terminal, or computer. These units generally consist of a microcomputer that converts digital information into a signal

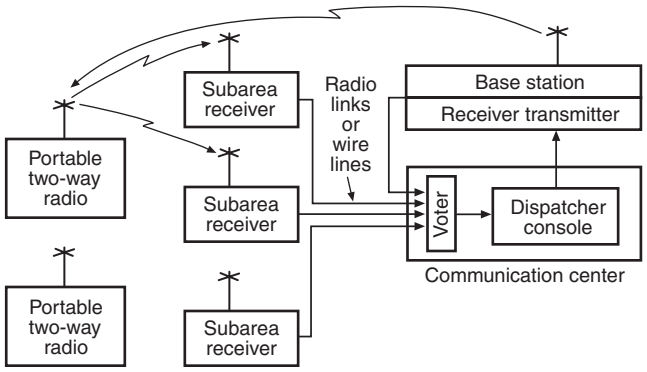

FIGURE 12.15.2 A Simple Diversity (Subarea) Receiver-Voter System

that a radio can transmit or receive. These units may have preprogrammed display capabilities where, by pressing one key, a canned message, such as unit status, condition, operator name, or even the time of day, can be sent. These units can be so reduced in size they can be handheld (including the radio).

Screen formats vary from simple light indicators to complex visual images including text and graphic characters. Some systems even have city maps or building drawings showing specific items relative to access, hydrant location, standpipes, and hazardous materials storage. Some today even have aerial photography for use by the field responders. One major consideration, however, is that these units may require dedicated, conventional radio channels. There are many options for having these computers be able to talk back to the communication center. It can be accomplished via an RF platform that is privately owned by the public safety entity. Some use cellular systems and still others use a hybrid system of RF and wireless hot spots. Consult with the manufacturer on the best system to serve your needs.

Emergency Response Facility Dispatch Notification. There are three items that should be included as part of a dispatch/alerting system: (1) a voice announcement or public address system to alert the company to an emergency response requirement, (2) a remote control for station lights annunciator, and (3) dedicated communication paths to ensure the reliable sending of the dispatch message. For agencies receiving more than 730 alarms per year, at least two means of alerting stations are required. Vehicles may even be included in this alerting process by the use of digital decoders or other suitable audible alarms. You can also consider having remote MDTs in each station connected to the CAD system, thus allowing for the computer event/incident to display in the station prior to response and allowing for a rip-and-tear function, so that the responding units can take the information with them for response. In addition some agencies now provide MDTs in their apparatus as well.

Emergency Medical Service Communications

In many communities, the communication center is involved in dispatching emergency medical services (EMS), both basic and advanced life support, to the citizens they serve (see Section 13, Chapter 9, "Emergency Medical Services and the Fire Department"). Each state has an EMS communications plan on file with the FCC, and these plans identify how the EMS communications system will be implemented in that state. The EMS system differs from the normal fire communications system in the approach the FCC has taken to frequency allocation. The FCC has set aside UHF frequency pairs for communications between field EMS personnel and base hospital personnel. These channels are shared and used in all 50 states. Therefore, to ensure quality, noninterfering communications on these channels during critical life-threatening incidents, it is imperative that local coordination prevail.

Hazardous Materials Team Communications

The development of hazardous materials (hazmat) response teams in the fire service has resulted in new communications requirements for safety. These new requirements are in two major areas: (1) hazardous materials information and (2) hazmat team communications from within encapsulating suits.

A major element in the successful outcome of hazardous materials incidents is the ability to rapidly obtain information about the material(s) involved. This generally involves contacting outside agencies for a variety of information. Mobile radio telephone patch(es) may be considered, but this usually ties up the only available radio channel. Cellular telephones should be carried on the hazardous materials team apparatus to facilitate obtaining needed information. This approach also allows a printer to be installed along with the telephone so that one of the hazardous materials computerized information services can be used for on-scene, rapidly printed information.

Cellular telephones also allow the hazardous materials team member's direct access to hazmat information services, reducing the potential for errors. The medical component of the hazmat team should be equipped with a medical radio for medical control and to obtain toxicological information from base hospitals.

Many hazardous materials team members must work inside encapsulating suits. They require special communications systems designed to meet their requirements for operational safety. Two-way wireless communications, preferably hands free, should be considered. A variety of radio systems that use bone, ear, or throat microphones for voice transmission are available to meet these needs. These radio systems come in simplex, half duplex, or full duplex. They use push-to-talk or voice-actuated circuits to transmit, and mobile repeaters may be integrated into them. An agency should thoroughly examine its needs and the experience of similar agencies in this area prior to purchase.

PERSONNEL

No matter how well designed, installed, and maintained, no system is better than the people who operate it. Communications systems should be supervised by responsible and competent people whose duties include directing, testing, and inspection programs. Public safety telecommunicators should be temperamentally suited to the position and be able to efficiently handle assigned duties. They should have the ability to remain calm, take decisive action during emergencies, remain alert during periods of inactivity and while carrying out normal repetitive operations, and work harmoniously with other people. They should also be familiar with operations.

Work schedules should be structured to provide for maximum efficiency. Stress and high activity lead to operator fatigue. Therefore, operators should be provided with a place to take work breaks in the communication center but outside the operations room.

Training

Communications personnel should not become isolated from the agencies they serve. Their structured training should be directed toward maintaining and improving their call-taking and dispatching skills, but it must also include a full understanding of all agency operations. Standard operating procedures should be provided in writing to ensure standard performance. Continual in-service training is a must to help maintain proficiency,

familiarize personnel with new equipment and new technologies, and to prepare employees for the next level.

The authority having jurisdiction should require call takers and dispatchers to be certified as meeting the requirements of NFPA 1061, *Standard for Professional Qualifications for Public Safety Telecommunicator.* Telecommunicators should be familiar with the geographic area they serve, including the locations of streets, landmarks, important and high-hazard structures, and locations of congested areas. Their training should include maintaining their call-taking and dispatching skills and understanding the needs and operating procedures of the agencies for which they take calls and for which they dispatch. It is important to note that many states have now set minimum training standards for telecommunicators. You should check with your state to see what training requirements apply.

Operating Procedures

Standard operating procedures for the telecommunicators should be provided in writing to ensure uniform performance in accordance with the requirements of the authority having jurisdiction in charge of the communication center. The authority having jurisdiction should develop standard operating procedures in conjunction with each emergency response agency served by the communication center to establish when a telecommunicator shall be assigned exclusively to an emergency incident in progress.

Staffing

The authority having jurisdiction should ensure that an adequate number of qualified telecommunicators are on duty at all times to promptly receive and process emergency calls (alarms). With very limited exception, at least one qualified telecommunicator should be on duty in the communication center at all times. Again, many states now require a minimum of two telecommunicators on duty. As the number of alarms increases, the staffing level should increase to ensure prompt receipt and processing of alarms, which may require varying staffing levels at different times based on anticipated call load established from historical data, weather forecasts, large public events, and so on. Where telecommunicators provide emergency medical instructions to callers prior to arrival of emergency response personnel, at least two telecommunicators should be on duty at all times, since giving emergency medical instructions can occupy one telecommunicator full time for several minutes. In addition to the telecommunicators, at least one supervisor should be on duty when more than two telecommunicators are on duty. The supervisor should be assigned to the operations room when more than three telecommunicators are on duty. Also keep in mind that with new federal requirements, the use of the National Incident Management System (NIMS) should be applied in any communications center. Keep in mind that an effective span of control under NIMS is five to seven people per supervisor in the communication center.

In jurisdictions receiving fewer than 730 alarms per year (average of 2 alarms per 24 hour day), a dedicated telecommunicator may not be required to be on duty at all times, where an alternate means approved by the authority having jurisdiction can effect the prompt receipt and processing of alarms as required by NFPA 1221. However, with the trend toward multiple jurisdictions and multiple agencies sharing communication center services, instances where this limited exception to NFPA 1221's requirement for full-time telecommunicators exists are becoming increasingly rare. For additional information on staffing requirements, consult the latest edition of NFPA 1221.

You may also want to consider that some states have now set minimum training and staffing standards for communication center employees. Review those requirements if there are any in your state. The two 9-1-1 organizations, the National Emergency Number Association (NENA) and the Association of Public Safety Communication Officials (APCO), both have recommended staffing standards as set forth by their advisory boards and staff. In some states the regulating authority has recommended adoption of either the NENA or APCO standard as the minimum staffing standard. Further information is available on their websites at http://www.nena.org and http://www.apco911.org.

CONSOLIDATION OF COMMUNICATION CENTERS

Consolidation of Functions

Many small-to-medium-sized jurisdictions have found that by consolidating communications functions with other jurisdictions, they can provide a higher level of service to their citizens at a lower overall cost. One of the major benefits of consolidation for these agencies is the ability to provide highly trained telecommunicators who are on duty 24 hours a day. A larger communication center will also have adequate backup to handle multiple, simultaneous incoming alarms, whereas the smaller center may not have the personnel to cope with them. The major benefit of consolidation is to provide an increased level of service at reduced costs.

Methods of consolidating communication centers vary, but the two most popular are forming (1) a joint powers authority (JPA) to provide this service as an independent agency or (2) one or more jurisdictions contracting with another jurisdiction to provide this service. Either system can work well and provide the same benefits to the participants.

Joint Powers Authority (JPA)

A joint powers authority (JPA) is an independent government entity established to provide specific services. There are several benefits of a JPA arrangement for combined communications versus other arrangements, but the major benefit is shared administration. With a JPA operating with an independent board of directors, no agency or jurisdiction that might set policy unacceptable to another agency or jurisdiction is in control. In this way, each participant has equal representation and equal responsibility to make the operation a success.

REPORTING AN EMERGENCY

Reports of fires and other emergencies originate from three principal sources: (1) the general public, (2) the business community (industrial, institutional, commercial, and mercantile), and (3) other public service/safety agencies. The reporting process may utilize any of the following means, individually or in combination: (1) telephones, (2) public alarm reporting systems, (3) two-way radio communications systems, and (4) intelligent transportation systems.

Telephones

The most common method is the conventional public switched telephone network (PSTN). Increasingly, however, communication agencies are seeing calls placed from wireless cellular customers and most recently from Voice over Internet protocol (VoIP) providers. Currently, almost all interface at some point to the public switched telephone network. However, there are a few VoIP providers that bypass the public switched telephone network and connect directly to the communication center.

Universal emergency number 9-1-1 service, where adopted, provides a universal, easily remembered telephone number for use by the public to summon emergency services. Enhanced 9-1-1 service provides both the calling number and the location of the related telephone instrument directly to the dispatcher. This indication is presented visually on a display screen at the call taker's workstation and can be automatically recorded if the communication center includes computer-aided dispatch (CAD) or computerized logging support systems.

With the relatively new nature of VoIP telephones, 9-1-1 access can be sporadic or nonexistent in some cases. Some VoIP providers are actually answering 9-1-1 type calls in private call centers not staffed by trained 9-1-1 professionals. Any automatic number or automatic location information for VoIP telephones should be considered suspect and possibly not correct. The good news is that many of the VoIP providers realize the critical nature of 9-1-1 and are working with 9-1-1 professionals to resolve these issues. To further complicate matters in many cases, if power goes out, VoIP telephones will have no 9-1-1 access of any kind. The Federal Communications Commission (FCC) has asked all VoIP providers to provide 9-1-1 access.

The increasing use of personal cellular telephones is both a blessing and a challenge to emergency response agencies. On the positive side, many lives have been saved by the ability of a victim or a bystander to dial 9-1-1 from nearly any location and swiftly summon help. However, high-visibility incidents, such as vehicle accidents on a major highway, can generate dozens or hundreds of calls for the same incident, overwhelming call takers and even the 9-1-1 system itself, thereby delaying receipt of calls for other emergencies. Also, use of a cellular phone negates the automatic location information features of the enhanced 9-1-1 system. If the caller is unable to accurately identify his or her location, the telecommunicator cannot determine where to send help. Over the last several years many wireless providers have installed technology to provide the callers cell site location and the latitude and longitude (x, y) coordinates of an actual cellular telephone. Many of the communication centers across the country have installed the technology to receive this information, but some have not. When taking incoming calls, it is necessary to be able to accept this technology and convert the coordinates into a street address. In urban areas, there may be hundreds of buildings and thousands of people within range of that cell site. There are still some issues with the technology, but its accuracy is improving daily. Actually, finding the victim may be much more difficult than if he or she were calling from a conventional, wired telephone.

Where 9-1-1 service is provided, telephone directory listings for emergency response agencies should indicate that 9-1-1 is the number to call for emergencies. Where 9-1-1 service is not provided, a specific telephone number should be assigned for emergency calls and should be publicized as such. Separate business numbers should be assigned for nonemergency use. Emergency telephone numbers should appear on the inside front cover or page facing the front cover of the telephone directory. They should also appear in the body of the directory under the name of the jurisdiction, under the headings "Police," "Fire," and "Ambulance."

Although there are some disadvantages to total dependency on a utility owned, operated, and maintained communications network, specifically with regard to emergency reporting during natural disasters, telephones are often the only means of communication available. Where present, outdoor pay phones increase the availability of telephones for emergency reporting. In general, the public telephone system, widely used for reporting fires and other emergencies, provides a very viable function.

Public Alarm Reporting Systems

From the perspective of the operator receiving an alarm, use of a public alarm reporting station (alarm box) eliminates the difficulty of determining the location from which the alarm is being transmitted. When actuated, an alarm box transmits a distinct code to the communication center, which enables the operator to pinpoint the exact location of the box.

Removal of public alarm reporting systems began to take place in many major metropolitan centers in the mid-1970s. This trend has since spread to smaller communities. System maintenance costs, vandalism, malicious false alarms, and the nearly universal availability of telephones for alarm reporting all contributed to the elimination of public alarm reporting systems in many communities.

Although not an alarm system, the expanding implementation of universal emergency number 9-1-1 service has further reduced the need for public alarm reporting systems. This is especially true where enhanced 9-1-1 service provides the alarm operator with the exact location of the caller.

Recently, however, some jurisdictions have shown an increased interest in the use of public emergency reporting systems. In poverty-stricken areas, many households may not have working telephones, and vandalism and other criminal activity have caused the removal of many public pay phones. Also, public emergency reporting systems have been shown to provide reliable alarm reporting during natural disasters, such as hurricanes, earthquakes, tornadoes, and blizzards, when the public switched telephone network becomes jammed with traffic or is physically damaged.

A typical public alarm reporting system consists of a mix of publicly accessible manual alarm boxes ("street boxes") and "master boxes" that can be actuated both manually and automatically by a connection from a protected premises alarm system. "Auxiliary boxes" that are activated by the protected premises alarm system but lack the ability for manual activation by the public are also sometimes used. In many cases, the operating jurisdictions reduce their legal liability by accepting auxiliarized connections from government buildings only and referring all others to private supervising station alarm companies. Requirements for installation, maintenance, and use of public fire alarm reporting systems are contained in Chapter 6 of *NFPA 72®*, *National Fire Alarm Code®*.

A public fire alarm reporting system may be used for the transmission of other emergency signals or calls, provided such transmission does not interfere with the proper handling of fire alarms. For example, systems employing voice communications between the street alarm box and communication center can be used to transmit alarms of nonfire emergency nature. Fire alarm boxes in a radio-type system can be provided with push buttons for calling the police department, the emergency medical service, or other emergency services, and signals can be transmitted directly to the service called. With parallel-type telephone systems (each box served by a separate circuit), the telecommunicator can cross connect to the proper emergency service, such as the police department, or systems can be arranged so authorized callers, such as law enforcement personnel, can be connected directly to their own agencies. For additional information on public fire alarm reporting systems, refer to Section 14, Chapter 1, "Fire Alarm Systems."

Another form of the public emergency reporting system is the motorist-aid call box system, installed on some limited-access highways. These systems typically take one of two forms. First, coded radio transmitters may be mounted on pedestals, similar to (or incorporated with) radio fire alarm transmitters, typically with multiple, publicly actuated messages such as requests for fire, police, emergency medical services, and motorist aid (towing) services. These may be battery powered, with solar panels providing battery charging during daylight hours, or user powered. Second, cellular-type telephones (in weatherproof enclosures) may be mounted on pedestals, which are arranged to dial only a preprogrammed telephone number when the handset is lifted or a button is pressed. These are typically battery powered with solar panels providing battery charging during daylight hours. In either case, when actuated, the call box sends a distinct identity code to the receiver so that the location of the actuated box can be readily determined.

Intelligent Transportation Systems

With increasing density in population centers and increased prosperity, vehicular traffic is increasing. This increase funneled into a fixed highway network in turn results in more incidents requiring emergency response. Increasingly, jurisdictions are using technology, including wayside and in-pavement sensors and video cameras, to enable them to monitor traffic on hundreds of miles of highways from a central control center. When an incident occurs, the operators at the central control center can take actions, such as notifying emergency response agencies, redirecting traffic using remote control of traffic signals and/or electronic message boards, and making public announcements via commercial radio and television stations. Mass transit systems and railroads have similar centralized control centers. How these control centers interface and exchange information with traditional emergency communication centers for police, fire, and EMS agencies is not currently addressed in detail in NFPA 1221. The standard may, however, be used voluntarily as a guide for construction and operation of such centers.

Vehicle manufacturers are equipping some of their models with emergency communication devices (based on land-based cellular telephone and/or earth-orbiting satellite systems), which enable the driver to initiate a distress call in an emergency. These messages are answered by telecommunicators at private communication centers, which may be hundreds or thousands of miles away from the incident site. The technology also exists to automatically send a distress message whenever a vehicle is involved in a crash. This message could include information such as the attitude of the vehicle (upright or otherwise), the number of occupants, the negative acceleration forces experienced, whether seat belts were in use, and whether the air bags deployed. These systems are in their commercial infancy, but their use can be expected to grow significantly. They are not currently addressed by an NFPA standard.

Public Alerting Systems

Public alerting systems can be used for the mass alerting of the public to both natural and man-made events (e.g., tornadoes, hurricanes, floods, hazardous materials release) that can be expected to result in the loss of life, health, or property. Public alerting systems utilizing outdoor audible devices such as sirens have been established on a limited basis, usually for specific target hazards (such as nuclear power plants and chemical plants), and their use is likely to grow. A logical control point for such a system is the jurisdiction's emergency communication center. Technology also exists to permit the deployment of personal/in-home alerting devices in conjunction with such systems. Public alerting systems, as such, are not addressed by an NFPA standard as of this writing; however, their inclusion in the 2007 edition of NFPA 1221 has been proposed.

Two-Way Radio Communications Systems

A commonly overlooked alarm/emergency notification source is the two-way radio networks of public safety agencies. Notification of incidents in watershed areas is typically reported by mobile patrols. Similarly, requests for supplemental dispatches to multiple-alarm fires usually originate from units in the field.

Communications between agencies in adjacent jurisdictions, as well as between agencies of a single jurisdiction, may often be expedited by using two-way radios.

PROCESSING COMMUNICATIONS WITHIN THE COMMUNICATION CENTER

Regardless of the method by which an alarm is received, the location of the emergency is the minimum information required

to respond to an emergency. The nature of the incident being reported is also obviously essential. However, bear in mind that thousands of responses to nonvoice notifications are made each year.

Data Collection Systems

To efficiently operate a communication center, reliable data must be available. To be useful, these data must be both accurate and readily available. The data may take a wide variety of forms, from card indexes to sophisticated computer files, and may include such categories as the status of vehicles, the availability of resources, geographic information, and personnel information. The following categories outline the various types and uses of data that can be collected and maintained by a communication center.

Incident-Related Data. It is important (and often a legal requirement) to keep accurate records of emergency incidents to which emergency response agencies respond. The types of data worth collecting include the following:

- Time of alarm
- Time of telecommunicator's initial response to alarm
- Time of dispatch
- Address
- Identifications and times of responding units
- Arrival times at the scene
- Departure times from the scene
- Radio traffic voice recordings
- Telephone voice recordings
- Times of significant events at the scene

Operational-Related Data. These data consist of information that must be rapidly available at all times to maintain efficient operation of the communication center. The data include the following:

- Geographic data
- Equipment data
- Response order data
- Occupancy/hazard information
- Additional resource data

Reports. Many types of reports are necessary for overall fire department management. Some of these reports will be required at regular intervals, whereas others will be required on demand to fill a specific departmental information need. A list of probable reports includes the following:

- Response time reports
- Emergency activity reports
- Occupancy activity reports
- Specific incident reports
- Reports for outside agencies
- Fire loss/injury reports
- Equipment-related reports

These reports can be used to project future needs of the agencies, such as location of new stations, hiring of additional personnel, and relocation of existing equipment.

Receipt of Alarms

Most alarms are received by telephone over the public switched telephone network. Automatic recording devices should be interconnected to all types of voice-reporting circuits, including radio systems.

Correct telephone numbers are the only means of positively identifying the location of an informant. Enhanced 9-1-1 service is designed to provide the call taker with an immediate reference to the number of the telephone in use and its specific location. The data are usually displayed on a CRT screen. The data input is formulated for electronic data processing (EDP) usage and can be fed concurrently to a departmental CAD system.

All public emergency reporting systems (e.g., municipal fire alarm systems) provide an individual code for each box installed, and the proper code is transmitted when the box is activated. All incoming coded signals are permanently recorded on printers integral to the specific systems and, in some cases, are also displayed on direct readout (LED, CRT, etc.) devices.

The translation of the numerically coded data into a usable address is performed with the aid of a running-card file or CAD system, which is necessary for processing of alarms.

Voice Recording and Reproducing Systems

The voice recording and reproducing system should consist of a multichannel recording device that provides a permanent, time-referable, unalterable, and court-admissible recording of all emergency-related telephonic/radio communications within the communication center.

The communication center supervisor(s) and at least one of the operators on duty should be totally familiar with the operation and maintenance of the multichannel recording device. Familiarizing other personnel is advisable, but responsibility should lie with no more than two individuals per watch or shift.

A multichannel recording system can provide the following:

- Verification of emergency messages
- A log of all emergency communications within the communication center
- Protection against false or exaggerated complaints
- Substantiation or negation of claims against the agency
- Added protection to the civilian population
- A training tool for telecommunicators
- Validation of response times

The importance of these various benefits will differ from agency to agency.

Running-Card Files

A running-card file contains a dispatch plan for every area of the jurisdiction served. The number of running cards in a given file depends on the size of the jurisdiction and the manner in which it has been indexed for responses. The most common method of indexing is to assign numeric designations to all intersections or to grids superimposed on a map of the jurisdiction. There is a specific running card to each intersection or grid. Public emergency reporting stations (alarm boxes) are normally assigned an

identity code corresponding to the intersection or grid closest to their physical location.

When an alarm is received, the telecommunicator utilizes the addresses and/or intersection data obtained from the informant to find the correct running card, which is referenced to determine the appropriate units to be dispatched.

Status-Keeping Systems

The ability to maintain an accurate record of the current status of all emergency units in the system is essential to a successful dispatch system and will aid in (1) minimizing response times, (2) ensuring appropriate response, and (3) collecting nonemergency unit activity information.

Status-keeping systems may involve the tracking of various pieces of information, such as the following:

- Availability of the unit for emergency response
- Service capabilities of the unit (e.g., paramedic service, extrication equipment, all-terrain capability)
- Location of the unit
- Means of contacting the unit (e.g., radio, phone)
- Miscellaneous items based on the particular agency's operating philosophy

The mechanism of a status-keeping system will vary, depending on the number of units on which status must be kept and the actual dispatch process utilized by a communication center. A small agency might utilize a manual system with a small manual status display board; a large agency may require a computer.

Dispatch Circuits and Equipment

A dispatch circuit is the means by which an alarm operator notifies units to respond to an alarm. In general, two separate dispatch circuits must be provided, but only one is required when fewer than 730 alarms per year are received.

The primary dispatch circuit should consist of one or a combination of the following:

- Dedicated wired circuit monitored for integrity
- Voice radio channel with duplicate base station transmitters, repeaters, microphones, encoders, control circuitry, and antennas (system must alert telecommunicator in the event of failure of signal transmission)
- Microwave carrier channel monitored for integrity
- Polling or self-interrogating digital data radio channel (if primary transmitter fails on operation, switchover to the second transmitter should be automatic, accompanied by alerting of the telecommunicator)
- Approved, dedicated telephone circuit that is monitored for integrity
- Fiber-optic connection that is monitored for integrity.

When they detect a circuit fault, systems for monitoring circuit integrity should provide both visual and audible notification to the telecommunicator.

The secondary dispatch circuit need not be monitored for integrity and should consist of one of the following:

- Dedicated wired circuit
- Voice radio channel (duplicate base station transmitters, antennas, etc. are not required for the secondary dispatch circuit)
- Approved dedicated telephone circuit or fiber-optic connection

A telephone connection through a public switched telephone network via regular dial-up mode or nondedicated telephone lines is not considered acceptable as an approved circuit. Where a telephone circuit is used as the primary dispatch circuit, a telephone circuit should *not* also be used as the secondary circuit. When radio channels are used for both the primary and secondary circuits, each circuit should consist of a separate radio system operating on a separate frequency with separate receivers at each emergency response facility.

Radio circuits can be used for voice and/or data transmission and are commonly used for dispatching. They have the advantage of transmitting alarms simultaneously to all units, regardless of whether they are in quarters or out in the field. Also, they are not dependent on wired circuits, unless the transmitter is connected by wired circuit to the communication center.

Wired circuits can be used for data and/or voice transmission. They are limited to transmission to fixed locations. Units in the field must still be contacted by radio.

A telegraph circuit is one example of a wired circuit. Once more commonly used, telegraph circuits are still in use in some jurisdictions. Telegraph systems transmit coded signals to emergency response facilities, where they are received on a variety of instruments, including gongs and punch or printing registers that register the coded signal with holes or marks on a paper tape. The location of the alarm is then decoded manually or electronically in a manner similar to that previously discussed. Other uses of wired circuits include voice, teletype, and computer data transmission.

Computer-Aided Dispatch (CAD)

Computer-aided dispatch (CAD) systems have become increasingly commonplace. NFPA 1221 categorizes CAD systems as Class 1, 2, or 3. The Class 1 system is the most sophisticated, utilizing computers to automatically track the status of all units and to select and recommend the appropriate available units for dispatch. On approval of the dispatch telecommunicator, signals and data are then transmitted by the CAD system to the appropriate emergency response facilities, personnel, or units. A Class 1 CAD system requires complete redundancy and, in the event of a computer failure, must automatically switch over to an online backup computer.

A Class 2 CAD system uses computers to support dispatching operations and transmit and receive data transmissions to and from emergency response facilities, personnel, or units. Redundancy is required; however, manual switchover to the backup computer is permitted.

A Class 3 CAD system uses desktop personal computer (PC) technology to support the dispatching telecommunicator. Typically, data (such as changes in unit status) are manually entered through keyboard operation by the telecommunicator. Class 3 CAD systems may be used to keep track of unit sta-

tus and to retrieve information regarding appropriate units to dispatch, occupancy hazards, pre-incident plans, and the like. Computer redundancy is not required by NFPA 1221 for Class 3 CAD systems.

Class 3 CAD systems typically utilize off-the-shelf hardware and software. Care must be used to select hardware that fully supports the software. Class 1 and 2 systems are more complex and are typically professionally designed or configured for a specific jurisdiction based on the user's requirements.

In all classes of CAD systems, a manual backup dispatching method must be maintained and available for use in the event of failure of the CAD system. Telecommunicators should periodically practice using the manual backup method so that they are familiar with its use. There should also be a hard-copy file of the information stored in the CAD system readily available on the premises to support manual dispatch should the CAD system fail.

CAD systems should be capable of exchanging data with the 9-1-1 system, other CAD systems, central stations (refer to Section 14 of this handbook), and intelligent transportation systems. CAD system computers should not be used for administrative applications; they should be kept free of time-consuming processes to allow rapid retrieval of dispatch information. It should be understood that CAD is a *method* of dispatching, not a dispatch *circuit.* Therefore, the presence or absence of a CAD system does not negate the requirement for two dispatch circuits.

Other Alerting Facilities

Radio alerting receivers in volunteer residences or places of business and radio pagers (i.e., portable receivers carried on the person) are frequently used for dispatching volunteer and off-duty personnel. Many agencies today also use some form of digital paging for administrative notifications and as a secondary means of notification in addition to voice systems. Many volunteer emergency response agencies have traditionally used outside sirens, air horns, whistles, or bells to alert volunteers when an alarm has been received. Although such devices remain in use in many areas, they do not comply with the requirements of NFPA 1221 as a method of dispatching and are considered supplemental to the required method(s).

Supervision and Testing Facilities

The communication center is where trouble signals from public emergency reporting systems are received and testing facilities are generally provided. In a leased telephone system, some test facilities are located in telephone buildings. In the event of trouble, both an audible and a visual signal should be provided. An audible signal may be silenced, but it should be designed to operate again in the event of trouble in any of the other circuits connected to the same supervisory device.

SUMMARY

Effective and reliable emergency communication systems play an essential part in the delivery of emergency services. In most cases, at least two independent communication paths or circuits should be provided for essential functions. These should be diversely arranged so that an event that damages one circuit is not likely to damage the other. Wire circuits (both metallic and fiber-optic) that are essential to the operation of a communication system should be monitored for integrity. Essential systems must be able to operate during power failures; therefore, backup power sources of adequate duration should be provided both at communication centers and at remote sites.

The communication center is the operational nerve center of the emergency service delivery system. It must be designed to prevent disruption of operations by fire, natural disaster, and criminal activity. An alternate communication center should be provided that, when fully staffed, is capable of performing the essential functions of the primary center. When a public safety answering point (the place where calls for help are first received) is not located within the communication center, it should meet the requirements for a communication center.

Whether serving one political jurisdiction or several, one response agency or many, the communication center needs to be adequately staffed around the clock to process emergency calls. Call takers and dispatchers, collectively called *telecommunicators,* provide human interface between a person calling for help and the emergency service delivery system. They need to be properly trained and familiar with the geographic area and agencies they serve. They need the ability to remain alert during periods of low call activity and calm during periods of high stress.

Two-way radio is an essential part of emergency services communication. Radio systems must be carefully designed to provide complete coverage of the service area. A sufficient number of frequencies should be provided to handle anticipated peak radio traffic. Separate tactical frequencies should be provided for uninterrupted on-scene communication. Where radio is the primary means of dispatching, duplicate radio base station transmitters should be provided. When used as a means of emergency dispatching, wireless paging systems should be under the direct control of the authority having jurisdiction.

Rapid technological and social changes, including proliferation of cellular telephones, increased emergency call volumes, increased demand for separate channels in a finite radio frequency spectrum, and expansion of intelligent transportation systems will continue to challenge the managers of emergency communication systems for many years to come.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on public emergency services alarm, dispatch, and communications systems discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 37, *Standard for the Installation and Use of Stationary Combustion Engines and Gas Turbines*
NFPA 70, *National Electrical Code®*
NFPA 72®, *National Fire Alarm Code®*
NFPA 110, *Standard for Emergency and Standby Power Systems*

NFPA 1061, *Standard for Professional Qualifications for Public Safety Telecommunicator*
NFPA 1221, *Standard for the Installation, Maintenance, and Use of Emergency Services Communications Systems*

Chapter 16

Fire Department Apparatus and Equipment

Robert Tutterow

Chapter Contents

Apparatus
Roadability
Equipment Carried on Apparatus
Apparatus Procurement Policies
Inspection, Maintenance, Testing, and Retirement of Apparatus and Equipment
Ground Ladders
Hose, Couplings, and Nozzles

Key Terms

acceptance test, aerial ladder, aircraft rescue and fire-fighting vehicle, elevating platform, fire apparatus, fireboat, fire fighter safety, fire-fighting foam, fire hose, ground ladder, mobile water supply apparatus, nozzle (solid-stream), nozzle (spray), pumper, quad, quint, rescue vehicle, service test, squad vehicle, utility vehicle

Fire apparatus and the equipment they carry are essential to fire departments for providing fire suppression and emergency services. Without the proper tools and the knowledge of how to use those tools correctly, a fire department cannot do its job effectively. This chapter contains information on the standards used and procurement policies that should be followed in specifying and acquiring apparatus and equipment. In addition, there are many other items described that fire departments should consider in the design of their apparatus.

For related topics, see Section 12, Chapter 9, "Fire and Emergency Services Protective Clothing and Protective Equipment"; Section 15, Chapter 7, "Fire Pump Controllers and Power Supply Arrangements for Motor-Driven Fire Pumps"; and Section 16, Chapter 10, "Standpipe and Hose Systems."

APPARATUS

The basic fire apparatus in North America is a diesel or gasoline engine-driven vehicle that carries an extensive assortment of tools and equipment for fighting fires. Such equipment may include a pump, hose, water tank, aerial ladder or elevated platform, ground ladders, and various portable tools and appliances. The amount and capacities of the various fire-fighting components carried vary in accordance with the intended service of the particular vehicle.

For pumping operations and fire attack, the size of the pump and the amount of water, hose, and equipment carried will vary with the type of service the fire department provides and the nature of the community it protects, which can be predominantly urban, suburban, rural, or a combination of any of the three. The fire apparatus standards set 250 gpm (950 L/min) as the smallest fire pump, but pumps of 750, 1000, 1250, 1500, and 2000 gpm (2850, 3785, 4732, 5678, and 7570 L/min) capacities are popular for general municipal service. NFPA has promulgated two standards for the design of fire apparatus. They are NFPA 1901, *Standard for Automotive Fire Apparatus,* and NFPA 1906, *Standard for Wildland Fire Apparatus.* It is important to note that the Insurance Services Office (ISO) requires that pumpers meet the general criteria of NFPA 1901, that is, 750 gpm (2850 L/min).

Fire departments can supplement units equipped primarily for pumping and fire attack with other vehicles that provide a large variety of tools and equipment for support functions. These tools include ground ladders, forcible-entry tools, generators, lights, and rescue equipment. Such units are variously termed *rescue, squad,* or *utility vehicles.*

Equipment for Rescue Work

About one-third of the work at an average fire involves the use of tools and equipment in duties classed as rescue or ladder-company work. Apparatus suitably equipped for such service should be

Robert Tutterow is the health and safety officer of the Charlotte Fire Department. He has held this position for over 20 years. He is a member of the NFPA Technical Committee on Fire Department Apparatus and chairs its Safety Task Group. Prior to joining the Charlotte Fire Department, he had over 10 years' experience as a volunteer fire fighter. He was also co-founder and is a board member of F.I.E.R.O. (Fire Industry Equipment Research Organization).

available at all structural fires and at major emergencies, such as significant highway accidents. Although pumping engines may carry considerable equipment, the larger aerial ladder and elevating-platform apparatus commonly transport additional equipment for forcible entry, cutting, and extrication. This type of apparatus provides effective elevated stream service and vehicle-supported, power-operated equipment for access to areas above the normal reach of ground ladders. Some fire departments go a step further and use aerial ladder *tenders* to carry support equipment. The tender does not have an aerial device, nor does it carry water or fire hose. Departmental procedures determine which apparatus respond to an incident.

In rural districts and in the outlying districts of cities where hydrant distribution is not complete, supplemental water-transport apparatus, defined as *mobile water-supply apparatus,* is common. Such apparatus has large water tanks with quick-fill and -dump connections. It may have a permanently installed pump. In most of the United States, they are referred to as "tankers."

A wide combination of fire-fighting equipment is often provided on a single fire apparatus. Besides combinations of water pump, hose, and water tank, commonly termed a *triple combination,* it is not uncommon to provide a booster pump and small-stream equipment on aerial ladder or elevating-platform apparatus or a water tower on a pumping engine. When fire apparatus is equipped with long ground ladders and other usual ladder-company equipment, in addition to the usual pumping engine equipment, the apparatus is referred to as a *quadruple combination,* or *quad.* If a power-operated aerial ladder or elevating platform is added, such apparatus is termed a *quint.*

The trend is toward apparatus designed to improve functional performance. Initial fire-attack capability for pumpers may include not only a variety of preconnected hose lines but also preconnected master stream capability or elevated-stream equipment. Pumpers are built with considerable compartment space for emergency medical service and rescue equipment. Combination fire-fighting rescue/pumpers can now be found in many fire departments.

NFPA 1901 deals with the design, performance, functions, and components of most fire apparatus. The current standard is broken down into chapters that address the requirements for different types of fire apparatus as well as requirements for many of the components installed on those apparatus.

Pumpers. Vehicles designed for sustained pumping operations during structural fire fighting and for supporting associated fire department operations are known as pumpers (Figure 12.16.1). NFPA 1901 requires a pump of at least 750 gpm (2850 L/min) capacity, a water tank of at least 300 gal (1135 L), storage for both supply hose and preconnected attack hose lines, and miscellaneous equipment.

Mini-Pumpers. Initial attack fire apparatus are defined as vehicles designed for making the initial fire suppression attack on structural, vehicular, or vegetation fires and for supporting associated fire department operations. Initial attack apparatus require a pump of at least 250 gpm (950 L/min) capacity, a water tank of at least 200 gal (757 L), and lesser requirements for hose and equipment than a pumper. Another term for initial attack apparatus is *mini-pumper.* This type of vehicle became popular in the early eighties, and then its popularity diminished. Today, mini-pumpers are slowly reemerging in municipal fire departments for use at parking garage fires. The mini-pumper is also now being used by a few departments as a first responder vehicle for emergency medical service.

FIGURE 12.16.1 Modern Pumper (Courtesy of Plano, Texas, Fire Department)

Mobile Water Supply Apparatus. Vehicles designed to transport water to the scene of an emergency where the water is applied by other apparatus or pumping equipment are defined as mobile water supply apparatus. NFPA 1901 requires these vehicles to have a water tank of at least 1000 gal (3785 L) with quick-fill and -dump capability, as well as limited hose and equipment to support the pickup and dumping of the water. Mobile water supply apparatus have a higher rate of rollovers per mile driven than any other type of apparatus. As a result, they also have a higher rate of fire fighter line-of-duty deaths from apparatus accidents than any other type of apparatus. In their design specifications, fire departments should pay particular attention to the center of gravity, braking capabilities, and handling characteristics of these types of vehicles.

Tank baffling is very important to the stability of mobile water supply apparatus. NFPA establishes tank baffling requirements. Fire departments should avoid used trucks with tanks that were used for non–fire service applications such as fuel or milk delivery. Typically, these trucks have little or no baffling.

Elevating-Platform Apparatus. Aerial ladder or elevating-platform fire apparatus are defined as vehicles designed to provide elevated fire-fighting and rescue capability. NFPA 1901 requires that these vehicles have a power-operated, self-supporting aerial device capable of attaining an elevation of at least 50 ft (15.3 m). Aerial ladders are required to support at least 250 lb (113.4 kg) at the tip in any position in which they can be placed. The elevated platform must be able to support at least

750 lb (340 kg) in any position in which it can be placed without water in the water delivery system. NFPA 1901 provides minimum requirements if a pump is installed. From 1997 to 1999, municipal fire departments reported 6300 aerial or ladder apparatus in use.[1]

Quints. Apparatus with a pump, water tank, hose storage area, an aerial or elevating platform with a waterway, ground ladders, and complement of equipment are known as quints. Quints have become popular in many fire departments. However, operating efficiency and capability tend to decrease if too many functions are to be performed by one piece of apparatus. The ability to position a quint on the fire ground for multiple purposes can occasionally be cumbersome. Fire departments must understand the staffing requirements of a multifunctional piece of apparatus. Moreover, if one feature of the apparatus requires repair, the entire apparatus must be taken out of service.

Special Service Vehicles. Apparatus that is multipurpose and that primarily provides support services at emergency scenes is known as a special service vehicle. These services could be rescue, command, hazardous material containment, air supply, electrical generation and floodlighting, or transportation of support equipment and personnel. The systems and components installed on these vehicles will vary with the support they are designed to provide and can range from no fixed systems to elaborate power generation or breathing-air compressor systems.

Mobile Foam Apparatus. Mobile foam fire apparatus is similar to a pumper except it may not carry any water but must have at least a 500 gal (1900 L) foam concentrate tank and foam proportioning capability. This apparatus is generally used in industrial environments for the control and extinguishment of flammable and combustible liquid fires in storage tanks and other flammable liquid spills. For information on foam systems used on other vehicles, see the section on foam and foam proportioning equipment later in this chapter.

Wildland Fire Fighting Apparatus. NFPA 1906 deals with the design, performance, functions, and components of wildland fire-fighting vehicles, defined as vehicles equipped with a pump, water tank, limited hose, and equipment. The vehicle must be capable of supporting pump-and-roll operations. Generally, these are smaller vehicles, frequently equipped with all-wheel drive; a small water tank; forestry hose; a small-volume, high-pressure pump; a number of portable water extinguishers; and various hand tools for fighting wildland fires. Larger vehicles may have up to a 500 gpm (1900 L/min) front-mounted or power takeoff (PTO) pump and a 500 gal (1900 L) or larger water tank to support wildland fire fighting as well as to provide exposure protection when structures or other properties are threatened.

Performance Requirements

NFPA 1906 includes requirements for auxiliary systems that are often installed on wildland fire apparatus. These may include a foam system or compressed air foam system, winches, and vehicle protection systems.

Both NFPA 1901 and NFPA 1906 define performance requirements for the apparatus and define tests to measure this performance. In the annex of each document, there are explanations of the requirements and details, as well as work sheets, to assist in the purchase of the apparatus. A separate annex in the standards provides a form that will guide purchasers through the process of determining and stating their needs in a fire apparatus, a valuable step in the specification process. Also, there is a separate annex outlining the criteria for retiring apparatus.

Persons buying the apparatus must specify the options that make it suitable for local needs. For example, requirements for fighting large brush fires in southern California are quite different from those for fighting fires in below-zero weather in northern Minnesota. Fire departments in the northern regions are well advised to specify snow and ice chain systems for their apparatus. Systems are available that engage the chains with the activation of a switch. NFPA 1901 and NFPA 1906 provide for standardization of many items for which uniform performance, measurable by tests, is desirable, but they allow the necessary flexibility to meet local needs that could not be supplied by one assembly-line production. Such differences include rated pump capacity, water-tank capacity, length of aerial ladders, height of elevating platforms, and many other important design features.

Besides the functional characteristics of a piece of fire apparatus, considerable thought should be given to personnel safety and operations. The design of the vehicle's driving compartment and riding spaces and the location of various components should be studied carefully. Only fully enclosed driving and crew compartments with sufficient seating for all fire fighters who are expected to ride on the apparatus should be specified. Fire fighters should never be allowed to ride standing up or in exposed positions on the rear or sides of the apparatus. The use of seat belts is mandatory in all cases. All of the equipment carried in the crew compartment area should be restrained in mechanical holding devices or placed in compartments. This minimizes the possibility of injury to fire fighters by flying objects in the event of a sudden stop or an accident.

The pump operator's panel may be positioned to the side, to the rear, or in a top amidships position. The position of valve controls and other control equipment will affect the overall efficient and safe operation of the apparatus. The better the operator's view, the more effective he or she can be.

ROADABILITY

Engines, Braking Systems, Weight, and Stability

Engines. Engines may be either diesel or gasoline types, but there are few gasoline engines capable of supplying sufficient power for modern apparatus. Consequently, diesel engines comprise almost all engines in apparatus manufactured. Fire departments must understand that the diesel exhaust is a carcinogen and provisions must be made to remove diesel exhaust from fire stations. This can be accomplished in one of three ways:

1. Source capture (hose connected to the exhaust pipe)

2. Air handling/filtration unit installed in the apparatus bay
3. On-board system contained within the apparatus

The engine size and horsepower must be chosen to correspond with the conditions of service and apparatus design. Apparatus must have enough power to move it over the road network on which it is expected to operate. Road tests are conducted with apparatus fully loaded with hose, water, ground ladders, the applicable personnel weight, and an equipment allowance weight. From a standing start, the vehicle must attain a true speed of 35 mph (56 km/h) within 25 seconds. The vehicle must maintain a minimum top speed of 50 mph (80 kph) on level ground. The vehicle must be able to maintain a speed of at least 20 mph (32 kph) on any grade up to 6 percent. This demonstrates that the vehicle has the necessary power to operate safely and efficiently in traffic. Although these tests demonstrate the power needed to negotiate the grades found in most communities, any special requirements that the apparatus climb very steep grades should be specified, and the finished apparatus should be tested to those requirements.

Braking Systems. A braking performance test is required. The vehicle must come to a complete stop within 35 ft (10.7 m) after attaining a speed of 20 mph (32 km/h). This test is required in NFPA 1901 and NFPA 1906 and Title 49, Code of Federal Regulations, Part 571, Subpart B, "Federal Motor Vehicle Safety Standards." This test is required to be performed only one time, not repeatedly, which is not realistic for emergency vehicles. Many agencies require secondary braking systems to be installed on their apparatus to enhance braking performance. NFPA 1901 requires that secondary braking systems be installed on vehicles weighing over 36,000 lb (16,330 kg) and recommends a system if the vehicle weighs over 31,000 lb (14,062 kg). There are four types of secondary braking systems:

1. Hydraulic retarder
2. Exhaust brake
3. Engine brake
4. Drive line

Agencies should match their driving conditions to the type of secondary brake desired. Secondary braking systems provide an extra margin of safety as well as extend the life of the primary braking system.

The set or parking brake provided is required to hold the vehicle on grades up to 20 percent. This may not be adequate for every fire department, so the agency needs to specify its particular requirements. Some states require parking brakes to hold on any grade.

Weight. Carrying capacity is one of the most important but least understood features of a vehicle. The gross axle weight rating (GAWR) and gross vehicle weight rating (GVWR) of the apparatus must be adequate to carry the weight of the fully equipped and staffed vehicle. This includes 200 lb (76 kg) per person personnel weight, a full water tank, the specified hose load, ground ladders, and a miscellaneous equipment allowance.

Extra care should be taken when determining the miscellaneous equipment allowance. Too many fire departments seriously overload apparatus by adding more equipment than the vehicle was designed to carry. NFPA 1901 specifies minimum equipment allowances of 2000 lb (907 kg) for pumpers and mobile foam fire apparatus, up to 2000 lb (907 kg) for initial attack vehicles depending on their size, 1000 lb (454 kg) for mobile water supply apparatus, and 2500 lb (1136 kg) for aerial ladder fire apparatus, elevating-platform fire apparatus, and quints. The equipment allowance for special service units varies by chassis gross vehicle weight rating from 2000 lb (907 kg) for smaller units to 3000 lb (1360 kg) for the largest units. NFPA 1906 specifies the equipment allowance for wildland fire apparatus, which also varies by chassis gross vehicle weight rating from a low of 300 lb (136 kg) to a high of 2000 lb (907 kg). Probably one of the most important things a fire department can do in developing specification for a fire apparatus is to realistically evaluate the weight of the equipment that the apparatus will carry and be sure the chassis will not be overloaded when that equipment is added to the vehicle.

One of the critical factors is the size of the water tank. Water weighs about 8⅓ lb per U.S. gal (1 kg/L). A value of 10 lb (4.54 kg) per gallon (to include the weight of the tank) is often used when estimating the weight of a full water tank, making a full 500 gal (1893 L) tank 2½ tons (2.27 metric tons). Larger tanks mean heavier vehicles, which may have limited mobility on rural roads and bridges. The efficiency of mobile water supply apparatus when transporting water to a fire depends on the vehicle's over-the-road mobility. Any apparatus that weighs too much for local operating conditions severely limits the capabilities of the fire department.

GAWR is the value specified by the vehicle manufacturer as the loaded weight on a single-axle system, and gross combination weight rating (GCWR) is the value specified by the manufacturer as the loaded weight of a combination vehicle, such as a tractor-trailer unit. GVWR is the value specified by the manufacturer as the loaded weight of a single vehicle, and it is the sum of the weights of the chassis, body, cab, equipment, water, fuel, crew, and all other loads. A number of components affect the GVWR, such as the springs or suspension system, the rated axle capacity, the rated tire loading, and the weight distribution between the front and rear axles. All chassis are designed with a "rated GVWR" or maximum total weight that should not be exceeded, whether by the manufacturer when building the apparatus or by the fire department after the vehicle has been placed in service.

Stability. The improper distribution of weight between the front and rear wheels can make a vehicle difficult to control and may require tires of different sizes to carry the load. Overloading of the vehicle not only affects the handling characteristics but also will result in increased maintenance problems with transmissions, clutches, drive train, and brakes, as well as suspension systems and tires. Many states exempt fire apparatus from meeting weight limitations; however, it is never a good practice to overload the vehicle. In the event the vehicle is involved in an accident, the overloading issue may be used against the department in litigation. Considerable attention is now being given to technology that enables vehicle stability. Most of the technology is electronics based and tied to the braking system. Sensors warn

the driver when the vehicle is in a potential rollover situation. Data from these systems can also be part of the information captured in a "black box." These systems are common in Europe and rapidly becoming available in the United States. Fire departments will be wise to learn about these systems and consider them in their design specifications.

Compliance with Government Standards

National governments promulgate motor vehicle safety standards that are applicable to all vehicles, including fire apparatus. In the United States, the Department of Transportation (DOT) enforces this legislation. It is unlawful to sell a vehicle that is not in compliance with the current federal standards. It is unlawful for manufacturers to build fire apparatus that do not conform to these standards. Because fire apparatus are complex and often require considerable lead time between the signing of a contract and delivery, the federal regulations provide that the standards in effect at the time the contract is signed must be those complied with, provided the apparatus is delivered within 2 years.

Additional requirements are placed on the apparatus and engine manufacturers in the United States by the Clean Air Act, which is enforced by the Environmental Protection Agency (EPA). Engines cannot be modified once approved by the EPA. These standards have caused some downgrading in engine performance, often resulting in the need to use larger engines than previously employed to obtain the same performance. Likewise, more frequent maintenance checks may be required due to mandated pollution-control devices.

Safety in Apparatus Design

Fire departments must consider safety as the primary concern when writing specifications and purchasing apparatus. Throughout history, fire fighters have been killed and seriously injured while driving, riding, and operating around fire apparatus (Figure 12.16.2). In a typical year, over one-quarter of all on-duty fire fighter deaths and thousands of on-duty fire fighter injuries have occurred during response or return.[2] In 2003, more fire fighters were killed responding or returning from incidents than killed at incident scenes.

FIGURE 12.16.2 Damaged Fire Apparatus (Courtesy of Charlotte, North Carolina, Fire Department)

The attention to apparatus safety was identified in the February 2004 National Fallen Firefighters Foundation's national summit on fire fighter safety. From this summit, 16 fire fighter life safety initiatives were identified. One of the initiatives was "Safety must be a primary consideration in the design of apparatus and equipment." In addition to apparatus design, there are two other areas of emphasis for safe apparatus that cannot be overlooked. These are driver training and apparatus maintenance. All three areas depend on each other. Failure to adhere to recognized safety standards jeopardizes the safety of fire fighters. Moreover, it puts the community at risk and creates a high risk of potential liability problems.

Fire departments must include an extensive apparatus driver/operator training program as part of their service delivery. Fire apparatus are big, heavy, complicated vehicles, and many drivers have never operated heavy vehicles prior to joining the fire department. It is imperative that no one operates a fire apparatus until he or she has been thoroughly trained. The fire department driver training program should be based on NFPA 1002, *Standard for Fire Apparatus Driver/Operator Professional Qualifications.*

Apparatus maintenance (discussed later in this chapter) has become more critical as apparatus have become more complicated. It is difficult to find qualified technicians to work on today's apparatus.

There are several areas of focus in apparatus design that impact fire fighter safety. These include audible and visible warning devices, steps and surfaces, mounting of equipment, cab ergonomics, and pump-panel layout.

Audible and Visible Warning Devices. The siren and air horn are the predominant audible warning devices for fire apparatus. These devices must be located as low and as forward of the cab as possible so the noise level will not cause hearing loss to fire fighters in the cab. NFPA 1901 states that the maximum noise level in cabs is 90 db while the vehicle is traveling at 45 mph (72 km/h). It must be understood that sirens are not as effective as they used to be, because any external sound is less audible to the occupants of today's road vehicles. Reasons include increased sound insulation in today's vehicles, use of high-volume sound systems, and use of cell phones. Visible warning devices, when specified to NFPA 1901 requirements, are the most effective warning devices.

Visible warning devices should be installed in a manner that portrays an outline of the vehicle. There are requirements for devices installed for the upper portion of the vehicle as well as the lower portion. Each portion must be divided into four warning zone quadrants (front, rear, and the two sides). The upper-portion devices are for warning traffic at a distance; the lower-portion devices are for warning traffic in close proximity to the vehicle. There should be two modes of operation for visible warning devices. One mode is for responding (calling for right-of-way) and the other mode is for blocking the right-of-way. The color of warning lights depends on local laws.

Amber, if permitted, has proven to be very effective at the rear of apparatus.

Fire departments should be careful not to use too many warning lights. Too many brilliant flashing lights can create serious risks, including blinding other motorists, attracting impaired motorists (whether through alcohol, drugs, or drowsiness) directly into the lights, and putting emphasis on the apparatus rather than personnel working at the incident. Purchasers must be aware of the electrical load requirements of audible and visible warning devices. In addition to electrical devices, all apparatus must have at least a 4 in. (100 mm) reflective stripe on at least 50 percent of the cab and body length and the rear and 25 percent on the front. The reflective striping adds an additional margin of safety to the warning lights and provides visibility to motorists in the event of warning light failure.

Steps and Surfaces. Fire departments must remember that many personnel operating on or around apparatus will be wearing personnel protective equipment (PPE), including self-contained breathing apparatus (SCBA), which is considerably more cumbersome than street clothes. In addition, they are often operating in a less than pristine environment, including wet, icy, oily, and nighttime conditions. It is important that all steps, standing surfaces, and walking surfaces be designed and constructed with fire fighter safety in mind. NFPA 1901 has many requirements addressing this issue. All steps must have at least a minimum surface area of 35 $in.^2$ (22,580 mm^2) and be able to support a minimum static load of 500 lb (227 kg). The first step leading onto an apparatus cannot be over 24 in. (610 mm) in height, and each succeeding step cannot be over 18 in. (457 mm) in height. All exterior surfaces that are designated by the purchaser as a step, a walking surface, or a standing surface must be slip resistant. NFPA 1901 provides an option of two tests that can be used to determine the coefficient of friction. Handrails must be placed at the entrance of cabs or anywhere else steps are located. The handrails must be slip resistant and between 1 in. (25 mm) and 1⅝ in. (41 mm) in diameter. Ground illumination is required anywhere fire fighters will climb on an apparatus, including beneath the cab.

Mounting of Equipment. Purchasers should review their need to mount equipment in the cab of apparatus and avoid doing so if at all possible. Loose equipment or equipment that can become loose in the case of an accident or sudden deceleration can be lethal. NFPA 1901 requires that, with exception of SCBA, all equipment carried in the cab must be enclosed in a latched compartment capable of withstanding a longitudinal 9-g force and a 3-g force in any other direction. SCBA must be stored in a bracket with a positive mechanical means of holding the SCBA in the event of a 9-g force in any direction.

Cab Ergonomics. Fire departments should consider the ergonomics of the cab from several aspects. The cab should be free of sharp edges and the doors should be free of any handles or latches that can snag clothing. All foot and hand controls should be within convenient reach of the driver. Frequently used controls should be placed so the driver can reach them without diverting attention from the road. Mirrors should be designed and placed so that adjustment is easy from the driver's seat, either through direct contact or remote control. This is also true for de-icing and defogging. The windshield should be large enough so that the driver has excellent visibility to the areas in close proximity to the vehicle. Seats should have a minimum width of 18 in. (457 mm), and headroom should be a minimum of 37 in. (940 mm). More headroom is recommended for apparatus with suspension seats. It is not recommended that helmets be worn inside cabs as they are not crash helmets; wearing them can actually be a contributing factor to an injury. Most importantly, the driver of the fire apparatus should never move the apparatus unless all occupants are seated and belted.

Pump Panel Layout. Fire departments should specify the layout of their pump operator's panel rather than leaving it up to the discretion of the manufacturer. The layout should be as simple and easy to understand as possible. Controls and indicators should be grouped according to their function. All pressure or flow-indicating devices must be located within 6 in. (150 mm) of the control. Ideally, there should be no intakes or discharges at the operator's panel because serious injuries and some deaths have occurred to pump operators as a result of hose rupture near the apparatus. NFPA 1901 prohibits any discharge larger than 2½ in. (65 mm) on the pump operator's panel. Pump and engine controls must be no higher than 72 in. (1829 mm). All controls and gauges must be properly labeled and illuminated.

Roadway Scene Safety. Increasingly, more emergency responders are being struck by motorists while working roadway incidents. In addition to roadway incident standard operating procedures (SOPs), fire departments should design and equip their apparatus to maximize fire fighter safety for such incidents. Consideration should be given to the following:

- Advance warning devices for motorists (such as directional signals and other signage)
- Traffic cones
- Safety vests
- Reflective and fluorescent striping

Chevron pattern reflective striping on the rear of the apparatus is proven to be an effective way to minimize the chances of an apparatus being struck from the rear. Particular attention should be given to the emergency warning lights. Excessive lights can have a detrimental impact, especially during darkness.

Black Boxes. Advances in vehicle electronics have led to the emergence of event date recorders or "black boxes" for fire apparatus. These recorders can capture information such as date, time, hard braking, speed, g-forces, and seat belt usage. They can also be linked to video and audio capturing equipment. Black boxes are very useful in helping with accident investigation. Also, by their nature, they aid in accident prevention as drivers know their actions may be reviewed.

Electrical Power for Apparatus

Electrical power needs for fire apparatus far exceed those of other commercial trucks. Sufficient electrical capacity for the

vehicle and its components is a major requirement for fire apparatus. Electricity is essential to start the apparatus reliably under all temperature and weather conditions. Emergency warning lights and sirens impose a heavy electrical demand with vehicle lighting and communication equipment as an added load. Electric rewind hose reels, pump controls, scene lighting, and electrically operated tools can all impose additional loads. Much of the equipment must perform when the apparatus is idling at a fire or other emergency, and the engine is not producing maximum output from the alternator. Electrical system performance tests are required for new apparatus by NFPA 1901.

Batteries, which are an integral part of the electrical system, must be a minimum of 1000 high-cycle, cold-cranking amps (CCA). However, the batteries should not be expected to carry the electrical load when the engine is idling; many of the electronic components on modern apparatus will not function properly if the voltage drops by 10 percent or more. It is also critical to provide a means for keeping the batteries charged while the apparatus is in the station. This can be done with an onboard battery conditioner or charger or with a polarized plug for connection to an external charger.

NFPA 1901 requires a load management system for the electrical components on the vehicle if the total connected electrical load exceeds the alternator output at idle. The load management system will shut off electrical loads if the alternator and batteries cannot keep up with the demand. The fire department should work with the manufacturer to determine which electrical components to shut down. These items should be ones that are less critical to the mission of the apparatus.

Documentation of a vehicle's electrical performance tests is required by NFPA 1901. A written electrical load analysis must include nameplate rating of the alternator, alternator rating at idle, minimum continuous load rating, total connected load, and individual intermittent load.

Fire departments should do considerable research to understand electrical systems before writing specifications and making a purchase. Special attention must be given to the maintenance of the electrical system after the apparatus is placed in service. A vehicle electrical system that needs frequent or major repairs is no asset and no bargain, whatever its purchase price and design capabilities may have been.

A department, when specifying apparatus, should require an electrical audit. The department or manufacturer could perform the audit. The audit determines the amperage required to power all electrical accessories so a determination can be made if the alternator supplied is large enough for the load. With more engine and transmission combinations becoming computer controlled, it is imperative that batteries be maintained properly.

Pumps for Fire Apparatus

A fire pump is defined as a pump of at least 250 gpm (950 L/min) at 150 psi (1035 kPa) net pump pressure. It must be capable of pumping 70 percent of its capacity at 200 psi (1380 kPa) net pump pressure and 50 percent of its capacity at 250 psi (1725 kPa) net pump pressure. The largest rated pump available is 3000 gpm (11,356 L/min). These large pumps are typically used in industrial settings such as refineries. Fire departments most commonly use pumps of 2000 gpm (7570 L/min) or less.

Certification. When new, fire pumps of 750 gpm (2850 L/min) or greater on fire apparatus are certified by tests witnessed by an independent third party. The certification test includes, among other things, a test at draft during which the pump must deliver its rated capacity for 2 hours at 150 psi (1035 kPa) net pump pressure, followed by two half-hour test periods during which 70 percent of rated capacity is delivered at 200 psi (1380 kPa) net pump pressure and 50 percent of rated capacity at 250 psi (1725 kPa) net pump pressure. The apparatus must also perform a 10-minute overload test, discharging rated pump capacity at 165 psi (1138 kPa) net pump pressure to demonstrate reserve engine power.

Pressure. The pump on initial attack fire apparatus is typically a pump of at least 250 gpm (950 L/min) but not more than 700 gpm (2650 L/min) at 150 psi (1035 kPa) net pump pressure. Like fire pumps, they must be capable of pumping 70 percent of their capacity at 200 psi (1380 kPa) net pump pressure, and 50 percent of their capacity is delivered at 250 psi (1725 kPa) net pump pressure. Pumps on initial attack fire apparatus may not be designed for long-duration pumping, although they must meet a 50-minute pump test and can be designed for longer operation.

The design requirements for fire pumps include the ability to develop 22 in. (55.88 cm) of mercury vacuum at 2000 ft (610 m) of elevation and the ability to deliver rated capacity while lifting water up to 10 ft (3.1 m) through 20 ft (6.1 m) of suction hose. Where a pump on a piece of apparatus is expected to perform at an altitude above 2000 ft (610 m), the purchaser must advise the apparatus manufacturer both of the altitude and whether a 10 ft (3.1 m) lift-suction capability is required, so that the proper engine and pump can be provided.

The pump and the attached piping and valves are designed for 500 psi (3448 kPa) hydrostatic pressure. Depending on the size of the pump, one or two large suction intakes and at least one auxiliary gated suction intake are required. This auxiliary intake is normally a 2½ in. (64 mm) intake and is provided so an additional water supply line can be taken into the pump without shutting down. It is also a means of connecting a supply line in mutual-aid operations if hose connections for the large intake are not compatible. As the large suction intake provides the least restriction, normal supply to the pump should be through that intake, whether directly or through a suction siamese.

Discharge Outlets. Discharge piping from the pump feeds a variety of outlets and, in some cases, may feed a master stream device directly. Fire pumps 750 gpm (2850 L/min) or larger are required to have two 2½ in. (64 mm) discharge outlets and enough additional outlets to allow the capacity of the pump to be discharged. If the apparatus is equipped with an aerial device with a prepiped waterway, the pump must be piped directly to the waterway.

To control the development of water hammer in the pump and hose lines, any 3 in. (76 mm) or larger valve should be designed to restrict changing the position of the flow-regulating

element from full close to full open, or vice versa, in less than 3 seconds. The pump should be further protected by a permanently installed intake pressure-relief system that is 2½ in. (64 mm) or larger and discharges directly to the atmosphere. The surplus-water-discharge location should be away from the pump operator's position and may terminate in a male fitting so hose can be attached to carry any water away from the apparatus.

The pressure on the discharge side of the pump must also be controlled, either through an automatic relief valve or a pressure control device that controls the excessive discharge pressure. The device is required to limit the pressure rise on activation to a maximum of 30 psi (207 kPa) and be capable of operating over a range of 90- to 300-psi (620- to 2070-kPa) discharge gauge pressure.

Midship Mounting. For the past few decades, the midship-mounted pump has been the standard configuration. It is powered by the vehicle engine through a pump transmission that redirects power from the rear wheels to the pump itself. Power is transferred with the vehicle in a stationary position and only after the parking brake has been set. An interlock should be provided to ensure that the engine speed cannot be advanced until the parking brake is set, the transfer is complete, and the chassis transmission is either in neutral or in the correct gear for pumping. Otherwise, the apparatus may move when the engine speed is advanced. New automatic transmission designs allow the use of a power takeoff (PTO) to transmit power to a large pump. They should be limited to no more than 1250 gpm (4732 L/min), due to horsepower requirements through the PTO. The PTO feature has led to a steady rise (20% per year) in rear-mounted pumps in the U.S. market. (Over 99% of the European market uses rear-mounted pumps.) There are many benefits of a rear-mounted pump, including increased compartment space, a cleaner pump panel, a better pump operator position (270 degree visibility), weight reduction of between 400 lb (181 kg) and 1000 lb (454 kg), and decreased service time. If a fire department chooses a rear-mounted pump, it should also consider a reinforced rear bumper to protect the pump during minor collisions.

On smaller pumps, the power is often transferred to the pump through a PTO device. In some designs, the pump is mounted at the front of the chassis where it is driven through a clutch arrangement from the front of the engine.

Auxiliary Capacity. Some fire apparatus will have auxiliary pumping capability as either a separate pump for small-volume/high-pressure operation or as a third stage in the main pump to develop higher pressures. Typically, auxiliary pumps have a capacity of 100 gpm (379 L/min) or less and may be capable of providing discharge pressures up to 600 psi (4137 kPa) or more. If an auxiliary pump is provided and is interconnected with a fire pump, suitable valving and controls should be provided to preclude the introduction of higher pressures into piping and fire hoses not designed for the pressure. Auxiliary pumps are often used to supply pressurized hose reels of small-diameter hose that can be used in extinguishing rubbish fires, grass fires, and other small fires.

Transfer Pump. Another type of pump, designated as a transfer pump, is used to assist in filling or dumping water tanks on fire apparatus. These pumps have a minimum rated capacity of 250 gpm (946 L/min) at 50 psi (345 kPa) and are typically used with mobile water supply apparatus to draft water from a static source to fill a water tank or to move water from the tank to a folding tank or other tank arrangement on the fire ground.

Wildland Pumps. There is a variety of pump products used on wildland fire apparatus. NFPA 1906 defines four ratings for wildland pumps. Low-pressure pumps are rated at 100 psi (690 kPa), medium-pressure pumps are rated at 150 psi (1035 kPa), high-pressure pumps are rated at 300 psi (2070 kPa), and extra-high-pressure pumps are rated at 400 psi (2760 kPa). All of these pumps are available in a variety of discharge capacities. NFPA 1906 also requires that the pumps be capable of pump-and-roll operation (i.e., pumping while the apparatus is in motion). This is accomplished by either driving the pump through a PTO arrangement or using a separate engine to drive the pump. The use of skid-mounted, self-contained fire-fighting packages, complete with pump and engine, water tank, hose, and equipment, are popular in the wildland fire-fighting arena.

Hose-Carrying Capability

The amount of hose carried should be sufficient to support the function of the apparatus. Operations involving pumpers typically need the most hose. NFPA 1901 requires a minimum of 800 ft (244 m) of 2½ in. (65 mm) or larger hose and 400 ft (122 m) of 1½ in. (38 mm), 1¾ in. (44 mm), or 2 in. (51 mm) hose. However, most fire department pumpers carry a minimum of 1200 ft (366 m) of 2½ in. (65 mm) or larger hose and 400 ft (122 m) of 1½ in. (38 mm), 1¾ in. (44 mm), or 2 in. (51 mm) hose. Some fire departments carry 2000 ft (610 m) or more of 2½ in. (65 mm) or larger hose, and 800 to 1000 ft (244 to 305 m) of 1½ in. (38 mm), 1¾ in. (44 mm), or 2 in. (51 mm) hose on their pumpers to permit more versatile use of the apparatus.

Predominantly, fire departments use hose diameters at least 2½ in. (65 mm) in size for supplying water from a hydrant or in a relay operation. Through comparative analysis, many fire departments have determined that 5 in. (125 mm) is the most efficient and economical size to supply pumpers.

NFPA 1901 requires a minimum of 30 ft^3 (0.85 m^3) of hose storage on a pumper although most pumpers have at least 55 ft^3 (1.56 m^3) of space. A larger hose storage area will likely be needed for large-diameter hose. Even if large-diameter hose is not used, a larger hose bed may be required to carry the hose necessary to flow the capacity of the pump. Often the hose bed space is designed to provide a split hose load. By splitting a hose load into two bed sections, either one long lay or a shorter double hose line can be made quickly, saving considerably on the time and personnel needed to establish flows approaching the capacity of the pumper. A convenient way to relate needed hose capacity to pumper discharge capability is based on the relative water-carrying capacity of various sizes of hose at normal operating pressures, as follows: 250 gpm (946 L/min) for 2½ in. (65 mm) hose; 350 gpm (1325 L/min) for 3 in. (76 mm) hose; 500 gpm (1893 L/min) for 3½ in. (89 mm) hose; 750 gpm

(2839 L/min) for 4 in. (100 mm) hose; and 1300 gpm (4921 L/min) for 5 in. (125 mm) hose. Thus, moving 500 gpm (1893 L/min) 1000 ft (305 m) requires 2000 ft (610 m) of 2½ in. (65 mm) hose or 1000 ft (305 m) of 3½ in. (89 mm) hose. In short lines, some increases in flow may be obtained by higher discharge pressures, but in longer hose lines, increased flow will be minimal.

Fire departments should pay close attention to the accessibility of hose storage areas in developing their specifications. Hose should be stored in a manner that fire fighters can easily deploy without having to climb on the apparatus. The same is also true when repacking hose. There are many places and many ways hose can be stored on an apparatus. It is very common (and advisable) for fire attack lines to be preconnected. Preconnected lines can be deployed from the rear, front, and sides of an apparatus. Some fire departments use slide-out hose trays to facilitate repacking of hose.

In 2005, NFPA issued a requirement that all hose be secured in a manner to prevent accidental deployment. The requirement was prompted by the death of a child who was struck by a hose being dragged by an apparatus. In addition, there were numerous incidents of accidental hose deployment causing property damage. The standard does not specify how hose must be secured. That is left up to the manufacturer and the fire department.

Water Tanks

The majority of fire apparatus equipped with pumps are also equipped with water tanks. The tank supplies water to the pump for initial hose streams before water from hydrants or suction sources is available. NFPA 1901 requires that initial attack vehicles must have a minimum 200 gal (757 L) water tank; pumpers and quints must have a minimum 300 gal (1136 L) water tank; and mobile water supply apparatus must have a minimum 1000 gal (3785 L) water tank. NFPA 1906 requires that wildland apparatus carry a minimum of 125 gal (473 L). Most pumpers in municipal settings have at least a 500 gal (1900 L) water tank; pumpers in rural settings often have 750 gal (2850 L) to 1000 gal (3785 L) water tanks.

All water tanks should be constructed of noncorrosive material or materials that are protected against corrosion and deterioration. Tanks being used today are typically constructed of plastic material. Almost all water tanks, regardless of material, carry a standard lifetime warranty. Water tanks should be equipped with a water-level indicator visible at the pump operator's position. One or more sumps with a 3 in. (76 mm) or larger removable pipe plug should be provided so that debris in the tank can be cleaned out.

All tanks must have baffles to minimize water movement when the vehicle is in motion. The dimension of any spaces in the tank, either transverse or longitudinal, should not exceed 48 in. (1220 mm) or be less than 23 in. (584 mm). The baffle arrangement should allow an adequate flow rate from the tank to the pump, which is typically tested to 80 percent of the tank capacity.

The tank fill opening should be at least 20 $in.^2$ (12,900 mm^2) and vents/overflows at least 12 $in.^2$ (7742 mm^2). The venting must be matched to the maximum fill and discharge rate so as not to overpressure the tank. The overflow outlet should direct any water behind the rear axle so as not to interfere with rear-tire traction.

NFPA 1901 requires that tanks on mobile water supply apparatus have a single outlet capable of allowing water to be dumped from the tank at an average rate of 1000 gpm (3785 L/min). Likewise, a single external fill connection is required that permits a minimum-filling rate of 1000 gpm (3785 L/min) from sources outside to the unit. Even if the apparatus is not designed specifically to be a mobile water supply apparatus, it is good practice to have this rapid-fill and -dump capability, if the water tank holds more than 1000 gal (3785 L).

Fire departments that use apparatus with water tanks in excess of 1000 gal (3785 L) should pay close attention to the center of gravity and overall stability of the vehicle in order to avoid rollover accidents. Furthermore, these types of apparatus are heavier and require that drivers receive additional training to become familiar with the handling characteristics.

Aerial Ladders

Aerial ladders have been used by fire departments for more than a century to gain access to the upper floors and roofs of buildings (Figure 12.16.3). Aerials can be laborsaving devices if they can be strategically positioned. One fire fighter can set an aerial device, whereas three fire fighters are required to raise a 35 ft (10.668 m) extension ladder. The first aerials were manually operated before spring-assist and air-assist hoists were introduced. Current aerial ladders are steel or aluminum truss construction with hydraulic hoists and ladder controls. All aerial ladders are mounted on a turntable that must be capable of rotating a full 360 degrees in either direction.

Mount and Stabilization. All aerial ladders must have stabilizers and outriggers to keep the units from tipping over during operation. There are many interlocks in an aerial ladder to keep one function from causing problems with another function and causing harm to fire fighters and the apparatus. Fire departments

FIGURE 12.16.3 Aerial Ladders (Courtesy of Charlotte, North Carolina, Fire Department)

must fully understand interlocks and thoroughly train personnel on their function.

Aerial ladders can be mounted on a straight chassis or a tractor-drawn chassis (tillers). The advantage of the tractor-drawn units, which are not as popular as they once were, is improved maneuverability in narrow streets. However, improved designs in straight chassis have provided fire departments the opportunity to purchase highly maneuverable units. In addition, many aerial units built today also have a pump, water tank, and hose bed. These features are not common on tractor-drawn units. Moreover, it takes two fire fighters to drive a tractor-drawn aerial.

Size and Capacity. Common sizes of aerial ladders range from 75 ft (22.8 m) to 135 ft (41.1m). The rated height of an aerial is measured by a plumb line from the top ladder rung to the ground with the ladder fully extended at its maximum elevation. A locking mechanism is required to hold an aerial in its desired extended position. A locking mechanism is also required to hold the aerial in the nested position. The rear-mount aerial ladder has become common. This arrangement places the turntable over the rear wheels, with the ladder extending forward when bedded, which results in shorter overall vehicle lengths. In some cases, a shorter aerial ladder mounted on a pumper chassis provides a useful combination of devices for fire attack. A mid-mount aerial generally provides fire departments a vehicle with lower overall height when the aerial is in the nested position. This is crucial for older fire stations with low door openings and in jurisdictions with low overpasses.

Aerial ladders must have a minimum rated capacity of 250 lb (114 kg). Many departments choose to use a heavier rated capacity. Aerial ladders rated above the minimum are rated in 250 lb (114 kg) increments.

Aerial ladders must have a minimum width of 18 in. (457 mm) at the narrowest point of the ladder. Rungs must be spaced 14 in. (356 mm) on center, and the top rails along the sides must be at least 12 in. (305 mm) high. The ladder must support 250 lb (114 kg) at the tip of the fly section with the ladder fully extended in a horizontal position without water in any permanently piped water system. It must support the same weight at the tip of the fly section with the ladder at 45 degrees with water flowing.

Fixed Waterway. Aerial ladders may be equipped with a fixed waterway to the tip of the fly section or some other section. Where such a waterway is provided, it should be capable of flowing 1000 gpm (3785 L/min) at 100 psi (690 kPa) nozzle pressure through a 45-degree, side-to-side range of motions and through an arc of 135 degrees from a line parallel to the ladder and downward. Often the monitor and nozzle on these systems are controlled remotely by electric wires or radio control. The friction loss in the water system between the base of the swivel and the monitor outlet should not exceed 100 psi (690 kPa) with 1000 gpm (3785 L/min) flowing and the water system at full extension.

When the aerial ladder is not equipped with a prepiped waterway, a detachable ladder pipe provides elevated fire-stream service. When supplied by 3 in. (76 mm) hose up the ladder, 600 gpm (2271 L/min) is the practical maximum that can be supplied in normal fireground operations. The ladder pipe is normally provided with 1¼-, 1⅜-, and 1½-in. (32-, 35-, and 38-mm) smooth bore tips and with a 500 gpm (1893 L/min) spray nozzle.

Stability. The aerial ladder must be stable when a load 1½ times the rated capacity is suspended from its tip while the aerial ladder is in its least stable position and the vehicle on which the ladder is mounted is on a firm, level surface with the stabilizers extended to a firm footing. The aerial ladder must also be stable when a load 1⅓ times the rated capacity is suspended from its tip when the vehicle on which it is mounted is placed on a firm surface that slopes downward at 5 degrees in the direction most likely to cause it to overturn. Again, the stabilizers are extended to a firm footing. The stability of the apparatus is checked during the certification tests, and the vehicle cannot show any signs of instability during these tests. Innovations in aerial devices have led to the development of several nontraditional aerial devices. Elevated piercing nozzles are being installed on airport crash-vehicle apparatus. One manufacturer has teamed with a construction equipment company to develop an elevated device for multiple purposes such as ventilation, breaching concrete walls, removing debris, and an elevated stream.

Elevating Platforms

Elevating platforms are of three principal designs. In the first, the platform is mounted on an articulated boom that travels in the arc desired by the operator. In the second, the platform is mounted on an extendable or telescopic boom, in much the same fashion as an aerial ladder. In the third design, the platform is mounted on booms that are both articulated and telescopic.

Protection Features. For fire fighter safety, an elevating platform is clearly the best choice for aerial devices. By description, the platform provides a more user-friendly work area for fire fighters when in an elevated position. It provides a level of protection not available on straight ladders if fire fighter(s) unexpectedly become enveloped in the products of combustion. It provides a safe working area during rescue operations for both fire fighting and technical rescue incidents. In addition, the platform provides space for tools, hose, and other needed equipment. Finally, the platform is uniquely functional during the rescue of persons with limited physical abilities. This is becoming more important for two emerging reasons: (1) baby boomers are becoming senior citizens and, therefore, the population of persons with limited mobility is rising at a faster rate; and (2) high-rise residential buildings are becoming more numerous in urban areas.

Fire departments are advised to consider the cycle time to raise and lower an elevating platform if there is no ladder from the turntable to the platform. Platforms on extendable ladders provide the best of both worlds when rescuing victims from elevated positions (Figure 12.16.4).

All elevating platforms must have a stabilizer system to keep the units from tipping over during operation. There are many interlocks in an elevating platform to keep one function

FIGURE 12.16.4 Elevating Platform

from causing problems with another function and causing harm to fire fighters and the apparatus. Fire departments must fully understand interlocks and thoroughly train personnel on their function.

Characteristics. Platforms are available with booms designed for elevations from approximately 75 ft to more than 200 ft (23 m to 61 m). The rated height of an elevating platform is measured by a plumb line from the top rail of the platform to the ground, with the platform raised to its maximum elevation. In selecting an elevating platform, it is important to know its reach and elevation capabilities under all operating conditions. The articulated-boom design provides its maximum horizontal reach at approximately half of its maximum elevation. The extendable telescopic boom of the same nominal length generally permits somewhat greater horizontal reach at higher and lower elevations. The telescopic boom often has an extending ladder attached to it, which provides access to and from the platform while it is elevated.

The platform itself must be a minimum of 14 ft^2 (1.3 m^2). There must be a continuous guardrail around the platform. The distance from the top of the guardrail to the floor of the platform must be between 42 in. (1069 mm) and 44 in. (1118 mm). There cannot be an opening below the top of the guardrail that is greater than 24 in. (610 mm) in any direction. A heat reflective shield must be included on the front, sides, and bottom of the platform to protect fire fighters. In addition, a water curtain spray assembly must be installed under the platform for additional protection. The water curtain must flow at least 75 gpm (284 L/min). The surface of the platform must be skid resistant and include holes to drain any water that might accumulate.

All designs provide stable platforms with controls located both on the platform and at ground level. The ground-level controls must be able to override the platform controls so an operator on the ground can move the platform away from danger if the platform operator is in trouble.

An elevating platform should be able to carry a load of at least 750 lb (340 kg) in all operating positions without the water system charged. Units of 110 ft (34 m) or less should be able to reach their maximum elevation and extension and to rotate 90 degrees within 150 seconds. An advantage of an elevating platform in operation is that the platform can be moved quickly from window to window for fire-fighting or rescue purposes.

Platforms are designed to provide elevated fire streams. The platform turret or turrets must be able to rotate through at least 45 degrees up, down, and to each side. The mobility of the platform permits the operator to change the turret location quickly, as desired. The apparatus must be designed so that, regardless of the position of the platform and the direction of the stream, the equipment can be operated safely while it discharges 1000 gpm (3785 L/min) at 100 psi (690 kPa) nozzle pressure. The friction loss in the water system between the base of the swivel and the monitor outlet should not exceed 100 psi (690 kPa) with 1000 gpm (3785 L/min) flowing and the water system at full extension.

The stability requirements described earlier for aerial ladders also apply to elevating platforms. In addition, there are requirements in NFPA 1901 for the hydraulic system, for the structure, and for quality control during manufacture that apply to both aerial ladders and elevating platforms.

Water Towers

The success of elevating platforms on the fireground during the 1960s was a prelude to the use of hydraulically operated water towers designed to apply large flows on a fire from effective heights and positions. Such water towers have proved very useful and have been widely accepted in both large and small communities as an important addition to the attack capabilities of a pumper.

Water towers are designed to discharge 1000 gpm (3785 L/min) or more at 100 psi (690 kPa) nozzle pressure in either a straight stream or a spray pattern and to move the boom and the nozzle both horizontally and vertically under the control of the operator for the best application of water on the fire.

Like elevating platforms, water towers may be of either articulated or telescopic boom design. Heights typically range from 50 to 75 ft (15.2 to 22.9 m). The tower is mounted on a turntable or pedestal to permit it to rotate 360 degrees in either direction and rotate with the nozzle operating at rated capacity. The telescopic type may be equipped with a ladder extending the full length of the boom. In such cases, the ladder should meet the same requirements as those of an aerial ladder.

Water towers are typically installed on pumpers with the controls grouped at the pump operator's position so the operator has full control of the pressure, volume, and stream pattern and position. The stability requirements described for aerial ladders apply for water towers as well. NFPA 1901 also provides requirements for the hydraulic system, the structure, and quality control during manufacture.

Foam-Proportioning Equipment

Where the potential for encountering serious flammable liquid fires is present, fire departments can provide, on the apparatus, various types of foam-making equipment or other agents that are more effective than plain water. NFPA 1901 specifies minimum requirements for foam systems. There are several methods of mixing foam concentrate with water to form the foam that

is delivered through a fire stream. Eductors that siphon foam concentrate through a pickup tube that is inserted in a foam concentrate container can be installed in the hose line at the pump discharge. The foam concentrate can also be premixed with water in a tank before it is pumped through a hose line. An around-the-pump proportioning system, consisting of an eductor mounted between the pump's discharge and intake, can be used. Balanced-pressure systems use water pressure between the bladder inside a pressure tank that contains foam concentrate and the walls of the tank to force foam concentrate into a water stream. Another method is to use a concentrate pump to directly inject foam into the pump's discharge. Regardless of the method used, all controls and indicating devices for foam systems must be located at the pump operator's panel.

Foams used for flammable liquid fires (Class B) typically form a film over the surface of the liquid that is on fire, thus removing the oxygen supply. Increasingly, fire departments are using foam for Class A fires such as wildland fires and structure fires. Class A fires typically reduce the surface tension of water, causing it to penetrate burning material and increase the cooling effect of the water. Special foams are also available for certain types of polar solvent/alcohol and unusual liquid fires.

Some departments also use compressed air mixed with water and Class A foam for suppression. This hardware is referred to as compressed air foam systems (CAFS) and was originally developed for wildland fire suppression application, although compressed air foam is now showing strong growth in urban and suburban fire departments for structural fire fighting. The rule of thumb for the ratio of water and air is 1 gallon of water per 1 cfm of air. CAFS systems provide the fire fighter with a lighter weight, charged hose line, and the capability to see exactly where the foam solution has been applied. The use of Class A foam and CAFS is currently gaining widespread acceptance by fire departments.

Portable Pumps

In selecting portable pumps, fire departments should be careful to choose models that will give the needed flow characteristics at a safe, continuous engine speed. Portable pumps for fire department service are usually centrifugal type. They are grouped in categories based on the pressure-volume characteristics that make them suitable for various classes of work. Low-volume streams at high pressure are intended mainly for grass and brush fire operations. Pumps delivering relatively large volumes at low pressures can be used to supply pumps on fire apparatus or to refill water tanks where a static water supply is beyond the reach of suction hose on fire apparatus. These pumps may also be used for dewatering operations. NFPA does not have a standard on portable pumps.

Communications Equipment

Effective communication is essential for any fire department operation. Every fire department vehicle should be equipped with a two-way radio that operates on all frequencies used for dispatch and fireground communication. Providing a radio speaker and microphone at the apparatus operator's position so messages can be heard above the usual noise on the fireground is highly desirable. In addition, each vehicle, including the chief officer's vehicle, should carry portable radios for effective fireground communications.

Vehicles may also be equipped to send and receive hard-copy messages or to receive visual displays of information, including maps and fire hazard data that may be transmitted from the communication center. These can be referred to as mobile data terminals (MDTs) or mobile status terminals (MSTs) depending on the type of data being transmitted. Also, laptop computers, usually in hardened cases, are becoming commonplace in many apparatus. Automatic vehicle locating (AVL) systems are now used in most larger jurisdictions. Cellular phones are also gaining popularity in fire apparatus and chiefs' vehicles. They can be used on the fireground or at hazardous materials incidents. They are especially beneficial in providing added value to the emphasis on customer service in today's fire and EMS service.

Fire departments must consider their communications equipment needs when they purchase the apparatus. The rapid growth of mobile information technology is as applicable to fire apparatus and equipment as to any other sector of society. Typically, communications equipment is installed after the purchaser receives the vehicle from the manufacturer. Considerations include mounting, grounding, visibility, wire chases, antenna, and shielding from outside wave interference.

Specialized Apparatus

There is a wide diversity of fire apparatus designed for special types of service. These units, which should be designed with the rigors of fire duty in mind, should conform to the general requirements outlined in NFPA 1901.

Many fire departments operate a vehicle to support rescue services, carrying equipment that deals with everything from emergency medical service to vehicle extrication to building collapse. The larger of these vehicles are typically equipped with a large 120/240 V electric generator, hydraulic rescue tools, and a wide variety of hand tools, power tools, and devices for jacking, shoring, cutting, and breaching. This emergency equipment typically supplements that carried on pumpers and ladder trucks. Many rescue vehicles have fully enclosed bodies to provide places for personnel to ride, to provide shelter for emergency medical treatment, and to provide an environment for incident scene rehabilitation during inclement weather.

Fire departments are equipping vehicles to support operations dealing with the spill or release of hazardous materials (Figure 12.16.5). The size and amount of equipment on these vehicles will vary with the role that the fire department sees for itself in such operations. Typically, these vehicles carry a library of materials to assist in identifying a hazardous material, tools and equipment for shutting valves or stopping leaks, materials for diking or absorbing spills, and special drums for recovering leaking drums. They also carry specialized clothing to protect the fire fighters while they are working in the contaminated area.

Fire departments can use a dedicated SCBA service unit to field-service SCBA and recharge depleted air cylinders on the fireground. These vehicles may carry numerous spare SCBA

FIGURE 12.16.5 Vehicle That Supports Operations Dealing with Hazardous Materials

cylinders for exchanging depleted cylinders, several large air cylinders arranged to allow for refilling of SCBA cylinders in the field, or both large cylinders and a high-pressure air compressor for filling SCBA cylinders in the field. Small fire departments may not need a separate vehicle, but every fire department should be able to provide full SCBA cylinders in the field.

Some fire departments find it advantageous to have separate vehicles with large generators to provide 120/240 V electricity. These units may have a generator of 15,000 W or larger. The generator may be driven by its own engine or hydraulically, with the hydraulic pump driven by the vehicle engine or directly from a PTO on the vehicle's transmission. These units typically carry floodlights, electrical cord and adapters, and various power tools.

Electrical wiring or equipment on an emergency vehicle must be properly installed and grounded. This equipment is typically used under conditions of extreme wetness, where failure to properly install and maintain the electrical integrity of the wiring and equipment will result in injury or death to persons using the equipment.

Larger departments also have units dedicated as "command" vehicles. These self-contained vehicles typically carry an array of communications equipment as well as provide an environmentally controlled area for command officers to plan and direct emergency operations. Since the September 11, 2001, attacks and several natural disasters, many fire departments have been active in planning and training for possible similar mass destruction events. Considerable federal and state grant monies have been made available to help departments purchase equipment for these types of incidents. Large recreational vehicles (RVs) have been modified into command-type vehicles. Heavy-duty step vans have also been outfitted as command vehicles.

There has been an increase of tractor-drawn units to transport the vast amounts of equipment necessary for large disasters. In addition, there has been a rapid increase in the number of trailers towed by pickup trucks or SUVs. Departments must fully understand the training and state licensing requirements to operate these vehicles.

Chief Officers' Vehicles

Fire departments often provide vehicles for use of staff and command officers. In larger fire departments, sizable fleets of vehicles are maintained. Vehicle transportation is necessary for chief officers, fire prevention officers and inspectors, training officers, communications officers, fire investigators, and others. Some fire departments pay a mileage allowance for the use of private cars. This may not be a good arrangement, especially where response to emergencies may be involved, as private vehicles are generally not properly equipped with warning lights and sirens or otherwise properly marked. They may also not be properly insured for that type of service.

All fire department vehicles that respond to fires and emergencies must be equipped with warning lights, sirens, and radio communication equipment that can operate not only on local emergency networks but also on the mutual-aid frequencies the department shares. The vehicles should be clearly identified as fire department vehicles. They should carry protective clothing and equipment for the officers and their staff aides, as well as portable fire extinguishers, first-aid equipment, and hand lights. If command officers are using the vehicle, it should also carry directories containing prefire plans on properties in the area served, water distribution plans, and reference books on hazardous materials.

Fire departments can provide their command officers with sports utility vehicles (SUVs) or other vehicles with large interiors in which the necessary equipment and materials are mounted or provided for ready access. The SUV has been the vehicle of choice for chief command officers. However, crew cab pickup trucks are proving to be a popular alternative to SUVs. The comfort and space of the cab are similar to that of SUVs, with the improved benefit of isolating stored equipment away from the cab area. This minimizes cab debris, offensive odors from used fire equipment such as personal protective equipment, as well as noise from equipment vibration. With the general public's increasing use of SUVs, vans, minivans, pickup trucks, and crossover vehicles, fire departments should consider the safety and visibility of the chief officer's vehicle. Sedans are usually very low profile and are difficult for other drivers to see. Moreover, chief officers are not able to see other drivers as well if they are in a sedan.

Fireboats

Fireboats are available in various sizes and types, in accordance with local needs, and vary from large tugs to fast, jet-propelled fire and rescue craft. Fire departments or port authorities may operate them. U.S. Navy and Coast Guard vessels are also equipped to provide fire-fighting services. As rescue has evolved into a fire service function, airboats, hover craft, "john" boats, inflatable rafts, and other waterborne craft are now found in many fire departments.

NFPA 1925, *Standard on Marine Fire-Fighting Vessels,* provides the minimum requirements for the construction of new fireboats or the conversion of existing boats to fireboats. The

standard designates three classifications based on length, pumping capacity, and other criteria.

Fireboats are principally used to protect vessels in a harbor; protect piers, pier sheds, and cargoes along the waterfront; protect yachts and houseboats in basins and marinas; assist in marine rescue from all types of water accidents; and serve as pumping stations to provide large flows at fires within reach of hose lines supplied by the boats. Fireboats may also provide a valuable emergency source of water for fire protection, should an earthquake or other accident interrupt the normal supply. Some fire departments operate hose trucks, or "fireboat tenders," that carry large-diameter hose to allow fireboat-pumping capacity to be used at shore fires along the waterfront.

The size, type, pumping capacity, and equipment carried by fireboats will depend on the type of service expected of the vessels. Fireboats must carry much of the same equipment as pumpers, ladder trucks, and rescue vehicles on land. They need foam-making equipment and may carry quantities of special extinguishing agents. Fireboats need radar as well as radio communication for safe operation under all weather conditions and, at times, in heavy smoke. SCBA is essential for fireboat crews.

Pumping capacity for individual fireboats varies from 500 gpm (1893 L/min) for very small craft to 10,000 gpm (37,854 L/min) or more for larger vessels. Pumping capacity is rated at 150 psi (1035 kPa) discharge pressure, as with pumpers. Some small jet-powered fireboats rely on their jet pumps to supply water for fire fighting. These pumps may develop substantial volumes at pressures adequate to supply turret nozzles attached to the pump, but it may be difficult to provide the necessary pressure to supply the hose streams to fight ship fires or fires ashore, unless additional pumps are provided to meet standard pressure requirements.

Large pumping capacity boats are not as popular as they used to be because they are slow and cumbersome. Smaller, faster, and more nimble boats capable of working in shallow water are becoming popular. Smaller fireboats are now designed to have a pumping capacity of 2000 gpm (7570 L/min). These boats can also be transported on trailers across land and placed in the water as needed.

Fire departments' decision making on fireboats should be based on the expected responses. If rescue is a function of the boat, then the boat should have a stable platform large enough to accommodate a victim. Sufficient lighting must be available for the work platforms. Another consideration is the ease with which rescue personnel can get a victim out of the water and onto the boat.

For the safety of personnel, fireboats should not be operated by only one person. They should be equipped with enough personal protective equipment for all persons on the boat.

Airport Crash Trucks

Specialized apparatus is required for aircraft rescue and fire-fighting service at airports. In many cities, such equipment is part of the municipal fire department. In others, it is maintained and operated by an airport authority. NFPA 414, *Standard for Aircraft Rescue and Fire-Fighting Vehicles,* covers the design and performance requirements for aircraft rescue and fire-fighting vehicles equipped for rescuing occupants and combating fires in aircraft at or near an airport. The size, number, and type of airport crash trucks needed are determined by Federal Aviation Administration (FAA) regulations. Airports are given an index number based on the number of flights and passengers. The index number determines the number and type of airport crash trucks required.

NFPA 414 covers three types of vehicles: (1) major fire-fighting vehicles, (2) rapid intervention vehicles (RIVs), and (3) combined-agent vehicles. RIVs are intended to reach the emergency site quickly so rescue operations can be started before the major vehicles arrive. Airport crash apparatus should include a small rescue vehicle, which can also serve as a command vehicle, and a "nurse" tanker carrying additional water and extinguishing agents where needed. Crash trucks can be modified to fight fires in hangars and other airport structures, but this use should not detract from the primary function of these vehicles.

Because of off-highway performance needs, the vehicle weight of crash trucks should be distributed equally over all wheels. These vehicles need greater axle and chassis clearances than standard fire apparatus, as well as high-acceleration characteristics. Positive drive to each wheel is required to negotiate soft ground, snow, and ice. The positive drive can be provided by torque proportioning, by no-spin differentials, or by other automatic devices that ensure that each wheel, rather than the axle, is driven independently.

EQUIPMENT CARRIED ON APPARATUS

Apparatus must be equipped with the tools necessary to accomplish fireground operations. The NFPA fire apparatus standards include listings of equipment and appliances needed with various types of fire apparatus. When developing specifications for fire apparatus, the fire department must evaluate its operation and determine how the apparatus will be used and what equipment will be necessary to support its operation.

Most fire apparatus carry hose. Pumpers typically carry the most hose, as the operational purpose of a pumper is to establish a continuous water supply and apply water to the fire. Use of larger-diameter supply hose (4 in. [100 mm] and 5 in. [125 mm]) for supplying water to pumping apparatus is common, with 5 in. (125 mm) providing the most efficiency. The length to be carried will depend on such things as hydrant spacing and distances to water supply points. Attack hose in 1½, 1¾, or 2 in. (38, 44, or 51 mm, respectively) diameters is common for hand-held hose lines for interior attack, and 2½-in. (65-mm) diameter hose lines are common when larger flows are required during exterior attack or to protect exposures. A variety of nozzles that will produce both spray and straight streams are carried for the various sizes of hose.

Besides hose, nozzles, and ground ladders, fire fighters need a wide variety of other equipment to perform their jobs. This includes SCBA, cutting tools for forcing entry and ventilating smoke from a building, positive-pressure fans and/or smoke ejectors for ventilation, salvage covers for protecting unburned contents, and a variety of fittings and adapters for use with hose lines, generators, portable lights, thermal imaging cameras, and electrical cord. The complement of equipment

carried will vary from department to department, based on the needs and operations of the companies. Career and combination departments typically must transport their structural personal protective clothing when responding to nonfire events, which historically is stored in the cab. However, consideration should be given to specifying a dedicated compartment for this use. This is particularly true for the driver/operator. In addition, fire departments that perform emergency medical and rescue operations must carry an array of equipment and supplies for delivery of that service.

Fire departments should list all of the equipment that will be carried on the apparatus and determine its weight and storage space requirements. It is critical that sufficient space and carrying weight be allotted for the equipment when the apparatus is designed so the equipment does not cause the apparatus to become overloaded. A well-designed apparatus will maximize the space available for equipment by including pull-out trays, drawers, and other means of organizing the storage. Equipment should be stowed in a manner that is secure and easily identifiable. A missing piece of equipment should leave a conspicuous void space. Heavy pieces of equipment should be stored as low to the ground as possible. In determining space and weight needs, fire departments should anticipate their future needs and understand that they will likely encounter unforeseen needs. The apparatus cab should not be a place to store equipment. Only equipment used during the response should be stored in the cab. The tendency to store equipment in cabs for convenience or quick action upon scene arrival should not override the hazards of having equipment come loose during an apparatus accident. For equipment used during the response that is carried in the cab, it must be positively secured to withstand the g-forces of an impact as described in NFPA 1901.

APPARATUS PROCUREMENT POLICIES

Procurement Process

The responsibility for procurement of fire apparatus and equipment should rest with the agency operating the fire department, whether a municipality, fire district, or private industry. In some cases, procurement is a cooperative measure in which a larger unit of government contributes to the cost of providing fire apparatus for fire departments serving its territory. In a few cases, state governments contribute to local fire apparatus costs. In some areas, several fire departments have banded together to generate standard apparatus specifications to buy apparatus in quantity and realize significant cost savings. Various fire department groups also cooperate in volume purchases of hose and other equipment.

When the fire department is an agency of municipal government, it is the responsibility of the latter to provide for all public fire-fighting equipment. Providing the necessary funds is the responsibility of the appropriate fiscal authorities, but the actual selection of the equipment should be the responsibility of the fire department management. The chief administrative officer of the fire department, aided by a staff of technical specialists, should keep the municipal administrator informed of the age and condition of department equipment and should prepare specifications consistent with applicable national standards for items that need to be replaced. The technical specialists should include at least the following: master mechanic, safety officer, driver/operator, training officer, and fire fighter. In autonomous volunteer fire departments, a purchasing committee may be appointed to procure apparatus. In municipalities, the city purchasing department usually purchases the apparatus. The purchasing department should not try to tell the fire department what type of fire apparatus it should use but should see that required procurement procedures, such as open competitive bidding, are followed.

The annexes of NFPA 1901 and NFPA 1906 contain helpful suggestions covering the purchase of fire apparatus, including developing specifications, reviewing proposals, dealing with manufacturers, and accepting completed apparatus.

In general, the purchase and replacement costs of fire apparatus should be a regular item of the fire department capital budget. In most cases, except for accidents, the requirements can be planned and funded on a long-range basis. Systematic apparatus replacement provides the fire department with reliable apparatus at all times. Improvements in fire apparatus design can be introduced, maintenance costs become more favorable, operating efficiency increases, and equipment remains reliable.

The apparatus procurement process, if performed properly, will take several months. The experience can be rewarding as well as frustrating. The process involves gathering information and learning as much about apparatus as possible. Information can come from several sources. Among the best sources are educational seminars, trade shows, and other fire departments. Once the information is gathered, specifications must be developed. Dividing the specifications into a format consisting of general requirements, construction specifications, and a bid evaluation sheet will facilitate the procurement. An alternative to construction specifications is performance specifications.

Another method of procurement that has gained in popularity in recent years is the request for proposals (RFP). This process allows bidders to be more competitive and it encourages innovation. In some cases, purchasers require bidders to submit their pricing separately. This allows for the evaluation of the technical merits of the bid without the bias of the cost factor. It is always a good idea to have a prebid conference with potential bidders to allow for all questions to be asked and answered in a consistent manner and provide for an equitable base of knowledge about the purchaser's expectations.

Once a bid is awarded, the fire department should have a preconstruction conference with the successful bidder, thus allowing the purchaser and apparatus builder to focus on the construction process. The purchaser should require drawings for approval and should have an understanding of how any change orders will be handled. Throughout the process, it must be clear to both the builder and purchaser how many factory inspection visits are needed and who will pay for them. Many fire departments require three factory visits: a preconstruction visit to understand how the manufacturer builds its apparatus, an intermediate visit to inspect basic components that are not readily visible after final assembly, and the final inspection. Factory visits allow for a quality control inspection by the purchaser as well as an opportunity to identify any unforeseen changes that

may be required. The visits assure that the purchaser is getting exactly what is being paid for. They should be conducted thoroughly and professionally.

An often overlooked part of the procurement process is the training and maintenance requirements for the apparatus. The complexity of fire apparatus requires that the user be trained. The purchaser must state up front what the training expectations are from the manufacturer.

Lease or Lease/Purchase

Lease or lease/purchase of fire apparatus can be an alternative to outright purchase. Income tax benefits and depreciation accrue to the actual, commercial owner of the apparatus; and the fire department, which is tax exempt, realizes savings in overall life-cycle cost. In addition, the department does not have to expend a large purchase price at one time but can spread the cost of apparatus over several years. Furthermore, there is no capital tied up in the event the department wishes to trade, exchange, or dispose of the apparatus. Closed and open-ended leases are available, and the finance department of the municipality should evaluate these alternatives carefully. In a smaller or volunteer department, a local banker can advise the purchasers of the advantages of a lease versus a purchase arrangement.

Any lease or lease/purchase contract should clearly spell out who is responsible for maintenance, repairs, and liability. Likewise, the contract should clearly state the conditions under which either party may terminate the arrangement.

As stated earlier in this chapter, there is an annex in both NFPA 1901 and 1906 that provides guidance on the retirement of apparatus. The annex explains how technological and safety advancements should be a primary consideration in the retirement of apparatus. This is especially applicable to apparatus that are not subjected to heavy use. Some departments have determined that rotating its fleet before the apparatus is worn out reduces maintenance costs and provides a much higher return on resale of the apparatus. This method provides for a modern fleet and a more equitable distribution of resources for both fire fighters and the public. A few larger departments have started to implement "total care" arrangements through lease agreements. The apparatus is leased, maintained, tested, and replaced by the supplier in accordance with the contract.

All fire departments should have a fleet replacement plan that averages the costs over several years for ease in budget development and justification. For larger departments, this can be as simple as a certain percentage of apparatus a year. For smaller departments, it could mean allocating and investing appropriate amounts of funds for capital improvements.

Acceptance Tests

Acceptance tests are designed to demonstrate that apparatus will perform as specified in the purchase contract. Tests should be performed within 10 days of delivery and before the apparatus is accepted. The tests should be conducted by the manufacturer's representative and in the presence of persons whom the purchaser may have designated in the delivery requirements. Normally, the fire chief or a designated representative is the acceptance authority. Third-party acceptance is gaining in popularity and should be considered by the agency. Costs for third-party testing are generally associated with the purchase price of the vehicle.

The acceptance-test requirements for fire apparatus and its various components should be detailed in the purchase specifications and should be based on the manufacturer's certification tests and any additional tests the fire department desires to ensure that the apparatus performs to specification. The acceptance tests should always be conducted in the community, so that any problems that developed during the delivery of the apparatus will be detected.

If the apparatus is equipped with a pump, a test plate is required at the pump operator's position that gives the rated discharge and pressures, together with engine speed determined by the manufacturer's certification test for the unit. The no-load governed speed of the engine, as stated on a certified brake horsepower curve, is also given. Tests are conducted to see that the water tank can flow the specified rate to the pump.

Documentation of electrical system performance tests must be supplied with the apparatus. These tests include reserve capacity test, alternator performance test at idle, alternator performance test at full load, and low-voltage alarm test.

Aerial devices are inspected and tested in accordance with the requirements in NFPA 1911, *Standard for Service Tests of Fire Pump Systems on Fire Apparatus,* as part of the certification tests. In addition, the stability of the aerial device is tested with the aerial device on a level surface and then on a firm surface sloping downward at 5 degrees in the direction most likely to cause it to overturn. The vehicle cannot show any signs of instability during these tests. These stability tests should not be conducted other than at the manufacturer's facility.

If the aerial device is equipped with a prepiped waterway, the system is flow tested to determine whether the water system can flow 1000 gpm (3785 L/min) at 100 psi (690 kPa) nozzle pressure with the aerial device fully elevated and extended. If there is a fire pump on the vehicle, the test is conducted using that fire pump, and the intake pressure to the fire pump cannot exceed 20 psi (138 kPa).

Other components and systems on the apparatus such as foam systems, line voltage electrical systems, and air systems should also be tested to be sure they have been installed properly and are working as designed.

INSPECTION, MAINTENANCE, TESTING, AND RETIREMENT OF APPARATUS AND EQUIPMENT

Program Setup

Equally important to the procurement of proper fire apparatus and equipment is their inspection, maintenance, testing, and retirement. Because apparatus are vital to life safety, they must be in top-notch condition. A regular inspection, maintenance, testing, and retirement program should be set up to ensure that all apparatus and equipment are serviced and tested in accordance with the manufacturer's recommendations and NFPA standards. The program should define the roles and responsibilities for the personnel and outside agencies involved. Fire apparatus are

becoming increasingly more complex, and attention to such a program cannot be neglected.

Based on concerns expressed by the National Transportation Safety Board (NTSB) in a 1991 report about the quality and type of maintenance on fire apparatus, the NFPA issued a preventive maintenance standard in 2000. In 2007, the NFPA issued a combined standard to include maintenance as well as testing. The new standard is NFPA 1911, *Standard for Service Tests of Fire Pump Systems on Fire Apparatus.* The old pump testing standard and aerial testing standards were merged into this document. NFPA 1911 should be the guiding document for fleet maintenance for all departments. It is a very user-friendly standard with several useful charts and checklists that any department can use. The standard defines the minimum requirements for fire departments to establish a preventive maintenance program. The standard is comprehensive and covers chassis, cab, body, low-voltage pumps, foam systems, aerials, CAFS, line voltage, air systems, winches, and breathing-air systems.

Apparatus safety should be the primary objective of a fire department's fleet management program. In fact, NFPA 1911 states that safety is the primary consideration in the decision to retire apparatus. The program should be in a written format and should include criteria for taking apparatus out of service. A thorough inspection program that covers the various systems of the apparatus should drive the program. Any preventive maintenance program should be conducted in accordance with the manufacturer's requirements.

Only qualified personnel should conduct the fire department's preventive maintenance program. NFPA 1071, *Standard for Emergency Vehicle Technician Professional Qualifications,* defines the minimum job performance requirements for an emergency vehicle technician. The standard prescribes two levels of competency. The EVT Certification Commission (EVTCC) offers a certification program for emergency vehicle technicians. The program recognizes mechanics as having demonstrated a working knowledge and skill required for emergency vehicles. Fire departments should insist that their mechanics become certified. Because of the complex systems associated with fire apparatus, an emergency vehicle technician must have knowledge and training that exceed that of typical automotive mechanics. The emergency vehicle mechanic must be able to inspect, diagnose, maintain, repair, and test the functions of the apparatus. It is the responsibility of the fire department to assure that its vehicles are maintained by qualified mechanics in accordance with their competencies. There are several state and regional fire mechanics associations that offer excellent training and networking opportunities for emergency vehicle technicians.

Retirement of Apparatus

The topic of when to retire a piece of apparatus has been debated for decades. Larger fire departments with high-volume responses typically replace their apparatus based on maintenance costs and general wear and tear. However, most fire departments do not have the call volume to justify maintenance costs or wear and tear as sufficient substantiation to replace apparatus.

NFPA has addressed this situation by calling attention to the technological advances in apparatus, particularly in regards to safety. Annex D of NFPA 1901 references previous editions of the NFPA 1901 as benchmarks for replacement. There are at least two dozen clearly identifiable safety features found on today's apparatus that were not required or available in the seventies or eighties. Safety and technological advances will definitely continue, as will the need to consider apparatus replacement on these criteria.

Service Tests of Pumps. All pumps should undergo service tests at least annually and after any major repairs. These tests demonstrate that the pump/engine combination is capable of meeting the performance requirements of the original certification or acceptance tests. Records of service tests are important evidence of proper apparatus maintenance.

NFPA 1911 outlines the procedures for the service test. The test should cover the following items:

- A test pumping from draft for 20 minutes at 100 percent of rated capacity at 150 psi (1039 kPa) net pump pressure; 10 minutes at 70 percent of rated capacity at 200 psi (1380 kPa) net pump pressure; and 10 minutes at 50 percent of rated capacity at 250 psi (1725 kPa) net pump pressure
- An engine speed test to determine if the engine is capable of reaching its no-load governed speed
- A vacuum test to ensure that the pump and the attached piping are still tight
- A pressure control test to ensure that the pressure control device can control the discharge within the specified limits
- A check of the accuracy of the gauges and flow meters

The purpose of the test is to ensure that the pump is generally in good condition, that the pump casing and various fittings are tight, and that the transfer valve is operating properly, if the pump is a series parallel type. If rated capacity cannot be obtained at 150 psi (1035 kPa) and the pump is not cavitating, or it appears that the pump, engine, pump accessories, or other parts of the power train and pumping equipment are not in good condition, the apparatus manufacturer, an authorized representative, or a competent mechanic should be contacted for advice so the condition can be corrected. Personnel conducting the pump service tests should take safety precautions, including working on a slip-resistant surface and putting guards around pressurized hose lines.

Service Tests of Aerial Devices. Aerial devices also need to be service tested periodically. These devices develop problems not only from use at fires but also from responding to and returning from alarms. NFPA 1911 requires a yearly inspection of the aerial device and of the prepiped water system, if so equipped, and a test of their operation. NFPA 1911 requires additional nondestructive tests, at intervals not exceeding 5 years, that check structural components for hardness, welds for cracks or discontinuities, and bolts and pins for wear or internal flaws. The full testing should be done any time the aerial device has had major repairs or if the department has reason to believe that it has exceeded the manufacturer's design criteria to ensure that it can be returned to service.

A qualified fire department mechanic can normally conduct the annual inspection and testing. The more complex,

nondestructive tests require expertise that may be beyond the abilities of fire department personnel. The qualifications of the inspection personnel and the test protocols used are outlined in NFPA 1911. Only personnel meeting those qualifications and having the proper equipment should do nondestructive testing.

Refurbishing Apparatus. Fire departments may wish to consider refurbishing an apparatus rather than purchasing a new one. NFPA 1912, *Standard for Fire Apparatus Refurbishing,* provides the minimum requirements for refurbishing an apparatus. The standard provides for two levels of refurbishment. In a Level I refurbishment, the vehicle receives at least a new chassis frame, cab, front axle, steering, and suspension components. The new items must comply with the latest revision of NFPA 1901. In a Level II refurbishment, the vehicle receives an upgrade of major components or systems but these upgraded components only need to comply with NFPA standards in effect at the time the apparatus was manufactured. The standard provides an excellent specification form in the appendix or annex for purchasers to use. All refurbishments must be performed in accordance with Title 49, Code of Federal Regulations, Part 571, Subpart B, "Federal Motor Vehicle Safety Standards." As with the purchase of new apparatus, a refurbishment process must make safety a primary concern.

The decision to refurbish must be evaluated very carefully. It must be noted that the number of apparatus being refurbished has steadily declined over the past 10 years. Though refurbishments are less expensive than new apparatus, they are still very expensive. A careful cost analysis will aid fire departments in this decision. The analysis should include the age of the vehicle (depreciation), the anticipated remaining life of the vehicle, resale value of the vehicle, proposed cost of refurbishment, and time out of service during refurbishment. The result needs to be related to the cost of a new vehicle. A refurbishment program should not be initiated for the sole purpose of improving the cosmetic appearance of the vehicle.

The refurbishing process is as detailed as purchasing a new apparatus. Detailed specifications should be written as part of an overall procurement process. It is critical that both the purchaser and the manufacturer understand each other's expectations and have them in writing. Refurbishments typically expose unforeseen areas that need to be upgraded or repaired. For this reason, fire departments should establish a contingency fund.

GROUND LADDERS

Ground Ladder Characteristics

Most apparatus carry ground ladders designed for rescuing persons and gaining access to buildings for fire-fighting purposes. Ladders may be constructed of wood, aluminum, fiberglass, or a combination of aluminum and fiberglass. Aluminum is by far the most common material used. All ground ladders used in the fire service should be designed and built to conform to NFPA 1931, *Standard for Manufacturer's Design of Fire Department Ground Ladders.* The NFPA 1901 standard allows fire departments flexibility in determining the appropriate ladder lengths for their needs. There are varying length requirements for pumpers, attack vehicles, quints, and aerial devices.

Loads that fire ladders are designed to support vary according to the type of ladder. Extension ladders, single ladders, and roof ladders built since 1984 are designed for 750 lb (340 kg) maximum load; folding and pompier ladders are designed for 300 lb (136 kg) maximum load. Load limitations are based on the use of the ladder supported at the top end against a building and set at a 75½ degree angle. This angle is measured from the horizontal with the ladder in the raised position. At smaller angles, the ladder may be unable to support the design load.

Although the NFPA apparatus standards list the minimum requirements for ground ladders on each type of vehicle, careful consideration should be given to the ladder needs of the area served. Manually raised extension ladders more than 40 ft (12 m) long are generally not required because aerial ladders and elevating platforms provide adequate emergency access to upper floors and roofs. If congested conditions prohibit the placement of aerial apparatus to provide effective aerial service, however, additional or longer ground ladders should be provided. It must be recognized that additional personnel are required to raise longer ladders and that the space available for ladders on some vehicles is limited.

Ground Ladder Service Testing

NFPA 1932, *Standard on Use, Maintenance, and Service Testing of In-Service Fire Department Ground Ladders,* calls for service testing all ladders at least annually and at any time the ladder is suspected of being unsafe. The tests are designed to show that the ladder is safe for continued use under the conditions for which it was originally designed. The service-test procedures must be carefully observed to ensure that the ladder is not damaged. Ladders also should be inspected visually, as outlined in NFPA 1932, to detect loose rungs, loose bolts and rivets, weld defects, cracks, splintering, breaks, discoloration, and other signs of possible weakness that might warrant testing to determine whether the ladder is safe to use or needs repair.

There is a misconception that the procedures used to test ground ladders are destructive. It is true that the load test may appear to be damaging, but a safe ground ladder will pass the annual load tests for many years.

HOSE, COUPLINGS, AND NOZZLES

Fire hose is the vital link between the water supply and the nozzles used to project streams on a fire. Fire hose failure can put fire fighters at great risk. Hose must be rugged, dependable, and capable of carrying water under substantial pressures, yet flexible and sufficiently easy to handle. Fire department management should be concerned with selecting the proper grades and types of hose and with maintenance to ensure maximum useful life. These two factors are covered in detail in NFPA 1961, *Standard on Fire Hose,* and NFPA 1962, *Standard for the Inspection, Care, and Use of Fire Hose, Couplings, and Nozzles and the Service Testing of Fire Hose.* Aside from unavoidable mechanical injury at fires, a hose's dependability and length of life rest on three factors: (1) the quality and suitability of the

hose purchased, (2) the care with which it is handled at fires, and (3) the maintenance and care the hose receives.

Types of Fire Hose

Fire hose is manufactured for at least four uses:

1. *Attack hose.* Fire attack by fire department personnel
2. *Large-diameter supply hose.* Relaying water through large-diameter hose from a source to the fire
3. *Occupant use hose.* Occupant use in buildings from standpipe systems
4. *Forestry hose.* Fire department use at wildland fires

Each of these types has minimum requirements for strength. Attack hose is designed for a minimum service-test pressure of 300 psi (2069 kPa) to meet a normal highest operating pressure of 275 psi (1896 kPa). If a higher working or operating pressure is needed, the purchaser needs to specify a higher service-test pressure. The most common size of interior attack hose is 1¾ in. (44.45 mm). For larger fires, 2½ in. (63.50 mm) is often used.

Large-diameter supply hose has a minimum size of 3½ in. (89 mm) and a minimum design service-test pressure of 200 psi (1380 kPa) to meet a 185-psi (1276-kPa) normal highest operating pressure. Large-diameter hose is typically used as supply hose or hose to supply ground placed master stream appliances. The most common size is 5 in. (127 mm).

Occupant use hose has a minimum size of 1½ in. (38 mm) and a minimum design service-test pressure of 150 psi (1035 kPa) to meet a 135-psi (931-kPa) normal highest operating pressure.

Forestry hose is only available in 1 in. (25 mm) and 1½ in. (38 mm) sizes and has a minimum design service-test pressure of 300 psi (2069 kPa) to meet a 250-psi (1725-kPa) normal highest operating pressure.

All hose must meet a proof-test pressure—formerly an acceptance-test pressure—of twice its service-test pressure, a burst-test pressure of three times its service-test pressure, and a kink-test pressure of one-and-a-half times the service-test pressure.

NFPA 1961 provides requirements for the hose jacket, the lining and the lining adhesion, any covering and its adhesion, the tensile strength of the hose, the ultimate elongation of the hose, and the cold resistance of the hose. Tests are outlined to verify these requirements. Another section in NFPA 1961 defines how the hose must be marked.

Care, Maintenance, and Testing of Fire Hose

Fire hose should be properly maintained to ensure its reliability. Burst hose at a fire may seriously injure fire fighters and other persons and may mean a loss of time in bringing a fire under control. NFPA 1962 and the manufacturer's instructions should form the basis of a hose care and maintenance program.

Hose carried on fire apparatus should be loaded to reduce edge wear and loaded so that air can circulate around it. The hose storage areas should be protected by waterproof covers to keep the hose dry and to protect it from ultraviolet rays and from debris.

Hose installed at yard hydrants at industrial plants should be kept in well-ventilated hose houses in such a way that air can circulate and excessive heat can be avoided.

To prevent damage and permanent set to the rubber tube, hose should be removed from the apparatus or hose house at least quarterly and reloaded so the folds are in a different position. If hose jackets are of cotton or synthetic construction, the hose should be cleaned and dried after use to remove possible abrasive or contaminating material and to protect the hose compartment of the apparatus against rust or water damage.

When used for fighting fires, fire hose is subject to severe strains, pressure surges, burning embers, and abrasion. Care should be taken to lay hose so that damage will not result from contact with sharp or rough objects. Vehicles should not be driven over hose lines. Where it is necessary for fire department vehicles to cross, hose bridges should be used if possible. When it is necessary to hoist hose lines, hose rollers can make the task easier and prevent mechanical injury. A hose extended up a ladder should be supported by a hose-rope tool to minimize the strain on hose couplings.

Pressure surges are a principal cause of damage to fire hose. Shutoff nozzles should be opened and closed slowly because sudden closure of nozzles can cause severe pressure surges, or water hammer, that can be extremely damaging to both hose and pumping apparatus. Pressure-relief devices on pumping engines should always be used to control unexpected, sudden increases in pressure.

In cold climates, care should be taken to prevent water from freezing in the fire hose. Once a hose line has been charged, a small amount of water should be left running through the hose because moving water does not freeze readily. Sharp bends should be avoided in any frozen hose. Care must be used in chopping hose free from ice after a fire so as not to cut the hose. The ice should then be allowed to melt off the hose, and any hose that has been frozen should be service tested before being placed back in service.

Care must also be taken to avoid burning the hose at forest and grass fires. As fire is knocked down and the nozzle is advanced, the hose may come in contact with hot spots or embers. When hose has been returned to the fire station, it should be laid out where it can be inspected, swept, and washed as needed to remove dirt and contaminants.

Good hose record keeping is necessary for accurate data on hose performance. Records for hose on racks, on reels, or in hose houses or similar enclosures may be kept at the hose location or at a central location on the premises where the hose is located. Fire department records should include a complete record of all hose. Upon delivery and acceptance, each length of hose should be given an identification number to be used throughout its service life. The ongoing record of the hose should include all testing and repairs and, ultimately, the reason it was condemned and removed from service.

All fire hose, except occupant use hose, should be tested at least annually and after repairs, or at any time it has had hard usage and its condition is suspect. NFPA 1962 includes required service-test procedures and a typical annual hose-test record form. The standard also specifies service-test pressures for hose manufactured before July 1987. Hose manufactured after that date has the service-test pressure stenciled on it.

Fire departments should avoid using the fire pump of an apparatus to test fire hose if at all possible. Apparatus fire pumps are not intended for hose-testing applications. Using smaller, low-volume, high-pressure pumps will minimize the unnecessary wear on a fire pump. Personnel conducting hose tests should take precautions against being in close proximity to charged hose lines.

Occupant use hose (normally stored on a rack or reel) should be examined carefully at least once a year. This annual physical inspection should consist of a visual examination to see that the hose has not been vandalized, that the couplings and nozzle are attached and free of debris, and that there is no evidence of mildew, rot, chemicals, vermin, or abrasion. Racked hose should be reracked with the folds in a different location. Five years after the date of purchase and every three years thereafter, the hose should be service tested, as it should be any time the condition of the hose is questionable.

Fire Hose Connections

The need for standard fire service connections is most apparent during mutual-aid operations. When hose couplings, nozzles, and other equipment do not conform to standards, it becomes necessary to use adapters, thus complicating fire-fighting operations.

NFPA 1963, *Standard for Fire Hose Connections,* applies to connections on fire-hose couplings, suction-hose couplings, relay supply-hose couplings, fire pump suction, discharge valves, fire hydrants, nozzles, adapters, reducers, caps, plugs, wyes, siamese connections, standpipe connections, sprinkler connections, and all other hose fittings, connections, and appliances that connect to fire pumps, hose, and hydrants.

The standard defines requirements and tests to verify the design and performance of couplings on fire hose. These include issues of minimum waterway size, internal strength, connect and disconnect capability, retention, and performance after rough usage, high-temperature conditions, and low-temperature conditions. There are also requirements for the gasket material used with the couplings.

For threaded connections in the 10 sizes from ¾ to 6 in. (19 to 152 mm) used in fire protection, the standard gives the dimensions for the American National Fire Hose Connection Screw Thread, abbreviated throughout as NH but also known as NST and NS. It also gives the dimensions for gauges, gaskets, and gasket seats associated with threaded connections. These threaded connections are defined by specifying, in sequence, the nominal size of the connection, the number of threads per inch, and the thread symbol. The 10 standard sizes of threaded connections are designated in Table 12.16.1.

To accommodate the increased use of nonthreaded connections on large-diameter hose, the machining dimensions for nonthreaded connections in 4 in. (100 mm) and 5 in. (125 mm) sizes are defined to ensure interchangeability as well as to prevent accidental disengagement of the couplings. Finally, the standard defines when the different thread sizes should be used on hose connections, nozzles and shutoffs, and both the initial connection and subsequent connections on large-stream devices.

TABLE 12.16.1 Standard Sizes of Threaded Connections

0.75–8 NH	3.5–6 NH
1–8 NH	4–4 NH
1.5–9 NH	4.5–4 NH
2.5–7.5 NH	5–4 NH
3–6 NH	6–4 NH

Nozzles

Nozzles used in the fire service are of either the spray or solid-stream design. A spray nozzle can produce a straight stream with similar characteristics as a stream from a solid-bore nozzle. Nozzles for 1, 1½, 1¾, and 2 in. (25, 38, 44, and 51 mm) hose are typically spray nozzles. Nozzles for 2½ in. (65 mm) hand lines and for master stream devices may be of the spray or solid-stream design. All hand line nozzles should be equipped with shutoff valves, either as an integral part of the nozzle or as an attached item.

Fire department nozzles for 1½ in. (38 mm) hose normally are designed to discharge approximately 95 to 125 gpm (360 to 473 L/min). Nozzles for 1¾ and 2 in. (44 and 51 mm) hose normally are designed to discharge approximately 125 to 200 gpm (473 to 757 L/min). Nozzles for 1 in. (25 mm) hose generally discharge in the 20 to 30 gpm (76 to 114 L/min) range. A standard hose stream from a 2½ in. (65 mm) hose with a 1⅛-in. (29-mm) smooth bore tip is 250 gpm (946 L/min) at 50 psi (345 kPa) nozzle pressure.

Solid-bore nozzles have a straight open tip that generally is attached to some type of stream shaper. These nozzles are designed to hold the solid stream together as water is thrown a considerable distance. The design of the nozzles provides a gentle taper from the diameter of the inside of the hose to the diameter of the tip to reduce the turbulence that causes a stream to break up.

Requirements for spray nozzles are covered in NFPA 1964, *Standard for Spray Nozzles.* There are three general types of spray nozzles: (1) the basic spray nozzle, (2) the constant-gallonage spray nozzle, and (3) the constant-pressure (automatic) spray nozzle.

The basic spray nozzle is an adjustable-pattern spray nozzle in which the rated flow is delivered at a designated nozzle pressure and nozzle setting. Due to its basic design, the flow (gpm [L/min]) will vary as the pattern is changed from a straight stream through a wide-spray pattern. This is caused by the orifice size changing to affect pattern adjustment.

The constant-gallonage spray nozzle is an adjustable-pattern spray nozzle in which the flow is delivered at a designated nozzle pressure. At the rated pressure, the nozzle will deliver a constant gallonage from straight-stream through a wide-spray pattern by maintaining a constant orifice size during flow-pattern adjustment. These nozzles are popular because the friction-loss characteristics in the hose and the nozzle pressures remain constant regardless of the selected orifice setting.

A constant-pressure (automatic) spray nozzle is an adjustable-pattern nozzle in which the pressure remains con-

stant through a range of flows. The constant pressure provides the velocity for an effective stream reach at various flow rates, which is accomplished by means of a pressure-activated, self-adjusting orifice baffle. These nozzles can produce streams whose discharge varies considerably but whose visual characteristics and stream reach remain the same. The user should not be misled by a good-looking stream that lacks the adequate flow for proper fire attack. However, these are very effective nozzles if the fire department understands the principles behind the automatic nozzle—namely, that the volume of water, not the pressure alone, extinguishes fire.

There are other nozzles available for special purposes. For decades, fire fighters have argued over the effectiveness of spray nozzles versus smooth bore tips. The argument usually is more emotional than logical. One key difference is that a spray nozzle can be placed in the "straight-stream" mode for basically the same effect as a smooth bore tip. However, a smooth bore tip cannot be converted to a spray pattern. These include nozzles used in the aspiration and delivery of foaming agents, very high-pressure spray nozzles that are designed to deliver small flows at pressures in the 400 to 800 psi (2756 to 5516 kPa) range, and spray nozzles used on standpipe hose for first-aid fire protection.

SUMMARY

The selection and purchase of fire department apparatus and equipment are obviously an important part of any fire department's business. For volunteer fire departments, the largest portion of their budget is dedicated to vehicles and equipment. In career and combination departments, it is usually second to salaries and benefits. Foremost, the selection and purchase process must be based on community needs. Careful research and planning are crucial to meeting these needs. Fire vehicles and equipment are very specialized and technical in their nature. They cannot be purchased at the local car dealership, corner hardware store, or megadiscount store.

Fire departments must be knowledgeable about all applicable standards and laws that impact the design, performance, use, and maintenance of the equipment. The selection and purchase of apparatus and equipment must take into account several factors. The foremost factor is the safety of the fire fighters and the public. As stated earlier in this chapter, one of the 16 Firefighter Life Safety Initiatives of the National Fallen Firefighters Foundation states: "Safety must be a primary consideration in the design of apparatus and equipment." Another factor is how the vehicle or equipment fits in with previous purchases. In addition, the fire department must provide training on the proper use of all the vehicles and equipment and must provide maintenance for the items purchased as described by the manufacturer.

Chapter 17

Pre-Incident Planning for Industrial and Municipal Emergency Response

Michael J. Serapiglia

Chapter Contents

Pre-Incident Planning Defined
Planning Process
Data Components

Key Terms

building construction, industrial fire brigade, occupancy classification, pre-incident planning, public fire department

A pre-incident plan is one of the most valuable tools available for aiding the fire department and the on-site fire brigade if available, in effectively controlling a fire or other emergency incident. The plan can be used by responding personnel to help them effectively manage emergencies with available resources. Planning for fires in industrial and commercial facilities increases the confidence and ability of fire service personnel to deal with most emergency situations. More importantly, it increases the potential for saving lives and property. This chapter will discuss the pre-incident planning process, who needs to be involved in this process, and the type of information industrial and commercial facilities need to gather.

For related topics, see the following chapters in Section 12: Chapter 1, "Planning for Public Fire-Rescue Protection"; Chapter 11, "Industrial Fire Loss Prevention"; and Chapter 18, "Pre-Incident Planning for Emergency Response."

PRE-INCIDENT PLANNING DEFINED

Pre-incident planning can be defined as a written document resulting from the gathering of general and detailed information/data to be used by public emergency response agencies and private industry for determining the response to reasonably anticipated emergency incidents at a specific facility.

In simple terms, pre-incident planning is ensuring that responding emergency personnel know as much as they can about a facility's construction, occupancy, and fire protection systems *before* an incident occurs. With this knowledge, the fire department can compare a potential incident at the facility with its available resources and plan the department's response accordingly. Pre-incident planning is not restricted to building components. It includes other factors and conditions that may be relevant to an emergency at a particular site.

Pre-incident planning is not easy. It takes considerable effort by the fire department to get a pre-incident planning program up and running. As growing demand for an expanding scope of services collides with limited budgets and other resources, fire departments are faced with much competition for staff time and money.

This means that pre-incident planning is more important than ever, not just for the traditional reasons of greater effectiveness and safety, but also for greater efficiency in resource utilization. No matter what effort it takes, fire departments today literally cannot afford *not* to pre-incident plan. The more information available, the better the opportunity for an incident commander to manage the incident successfully. Advance knowledge of the facility could mean the difference in managing the incident properly.

Proper training is also critical to pre-incident planning success. The individuals doing the pre-incident surveys and preparing the resulting documentation (Figure 12.17.1) must have the proper

Michael J. Serapiglia is a health, safety, and environmental coordinator for Saint-Gobain, High Performance Materials, Research and Development Center in Northborough, Massachusetts. He is a professional member of SFPE, ASSE, and former chairman of the NFPA Technical Committee on Pre-Incident Planning.

FIGURE 12.17.1 Pre-Incident Planning Session

level of training. Conducting the survey requires much more than walking through the building. It requires asking the right questions about construction features, storage arrangements, water supply adequacy, and sprinkler system components and design. This information must then be converted into a usable format for both fire department training and an actual incident.

The burden for successful pre-incident planning does not rest with the fire service alone. Pre-incident planning requires three-way open communication among facility management, the fire service, and the property insurance industry. Other agencies might also be able to provide valuable input during the development of the pre-incident plan. Such agencies include police, security, public utilities, environmental agencies, and contractors.

Facility management must take a coordinating role in pre-incident planning and be willing to host a joint meeting of all three entities. At this meeting, management must be willing to share information that its property insurance carrier has most likely already gathered about the hazards within the facility and the level of protection that is available. Most highly protected risk (HPR) insurance carriers are willing to provide this information, if they have the consent of facility management. The fire department must then take this information and incorporate it into its response plan for the facility.

When pre-incident planning is successful, everyone benefits. The fire department manages its response effectively, which results in a safer response and minimized property loss. A minimized property loss keeps the facility in business, which maintains the tax base for the fire department's budget. And the loss cost is kept low for the property insurance carrier.

Conducting pre-incident planning is not the same as inspecting for code violations. When pre-incident planning, the fire department representative takes the facility "as is" and develops a response strategy around existing conditions. Conducting pre-incident planning is not an attempt to improve fire prevention or identify code violations at the facility. Its sole purpose is to prepare for an incident at the facility under existing conditions. Pre-incident planning assumes an incident will occur. It makes no special effort to prevent a fire or eliminate a hazard, but rather it is preparation for an incident, regardless of the likelihood.

Assume for a moment that a facility in the community is known to have several automatic sprinkler system code deficiencies. Also assume that the facility's management has agreed to correct the situation within 90 days. What happens if a fire occurs the day after tomorrow? Just because the code violations have been documented does not mean a pre-incident plan is not needed. Code inspections and pre-incident planning are two distinct functions with two different purposes.

The fire department that is responsible for both code inspections and pre-incident planning needs to handle these types of situations with tact and diplomacy. When conducting code inspections, it is easy to stand behind the delegated authority of the position. But the fire department will never get the cooperation it needs for effective pre-incident planning if an authoritative approach is taken. The difference between each function must be understood by the fire department and communicated effectively to facility management.

Pre-incident planning is continuous. Many major fire incidents can be traced back to a change—often seemingly

minor—that took place at a facility. Perhaps the packaging of the products stored in the warehouse was changed from cardboard to plastic. Or maybe some renovations took place that left concealed spaces unprotected by automatic sprinklers. Maybe the on-site suction tank for the fire pump is going to be drained and repainted over the next several weeks and it is the only adequate water supply for the facility.

If a pre-incident plan is prepared once and never updated, these changes could go unnoticed until it is too late. Keeping up with changes in a facility requires a high level of commitment, communication, and cooperation among the pre-incident partners. For example, depending on total area and intended use, installation of modular office buildings at an existing property may not trigger code requirements for sprinkler protection, but egress issues may be impacted and should be thoroughly evaluated.

Determining the best frequency for updating pre-incident plans depends on the facility. Updating once per year may be fine at some locations but could be woefully inadequate at other locations.

Pre-incident planning requires a willingness by facility management to bring the fire department in and tell them what they need to know (e.g., "The sprinkler system in the warehouse is not currently adequate to protect what we're storing there"). It requires the fire department to know what questions to ask and to react positively when they get the truthful answers to those questions. And it requires the property insurer to act as an information link between the two.

PLANNING PROCESS

From the fire department perspective, once a facility has been selected, the owner/operator should be contacted. The needs and benefits of pre-incident planning might have to be explained in detail. The fire department should explain the nature of the information required, because the facility might have to arrange to have certain specialized employees available when the visit is made.

Situations may arise in which the selected property encompasses building areas in more than one municipality. In such cases, it is important that all fire service agencies involved be included in the planning process. The cooperation of multiple agencies in the planning phase will help assure smooth operations during the emergency incident phase.

When selecting a property, do not limit the choices to the largest facilities. Consider medium and small locations in which on-site emergency response resources and protection features may be limited. Locations such as commercial storage facilities for swimming pool supplies and municipal or private golf courses should not be overlooked. A number of challenging fires involving pool treatment chemicals have been documented over the past 10 years in large bulk retail stores. Although the quantities may be different, similar hazards are presented. When was pre-incident planning last conducted at your local golf course? Large clubhouses, battery charging and storage areas for electric carts, flammable or combustible liquid storage for maintenance vehicles, and significant quantities of pesticides and fertilizer are commonly found at such locations.

The pre-incident planning process can be shown as a flowchart (Figure 12.17.2). Obviously, much time and effort will be needed with the collection of data. This will involve consulting with the facility's staff and other individuals as necessary. The site will need to be visited to get an overview of the layout, construction, occupancy, and fire protection features.

Most major industrial and commercial facilities have developed an emergency operations or crisis plan in which the actions to be taken in the event of an emergency have been specified. A review of the emergency operations plan by the fire department can provide valuable insight into the actions to be coordinated by both facility personnel and the fire department. Incorporating the emergency operations plan into the fire department pre-incident plan is beneficial in case the facility personnel are assigned certain responsibilities but circumstances during the emergency prevent them from performing these duties.

A number of commercially available software programs may be utilized to assist in the recording of data. These programs are also useful in developing building drawings and a general layout of the facility.

Once the data are collected, decisions will need to be made about what data to keep and how the data should be stored, retrieved, and presented. The method of presentation is best left up to the discretion of each fire department, but it should be based on the fire department's incident management system.

Many fire departments keep certain parts of the plan in the dispatch center for reference. The dispatcher may transmit a facsimile of pertinent sections of the plan or the entire plan to a fire station prior to apparatus responding to an incident. This same information may also be sent directly from the dispatcher to the incident commander on scene. Others use computers in apparatus to store and retrieve information. Other departments may keep hard copies of the pre-incident plan in the individual fire stations or the apparatus itself. A sample pre-incident planning data form is shown in Figure 12.17.3.

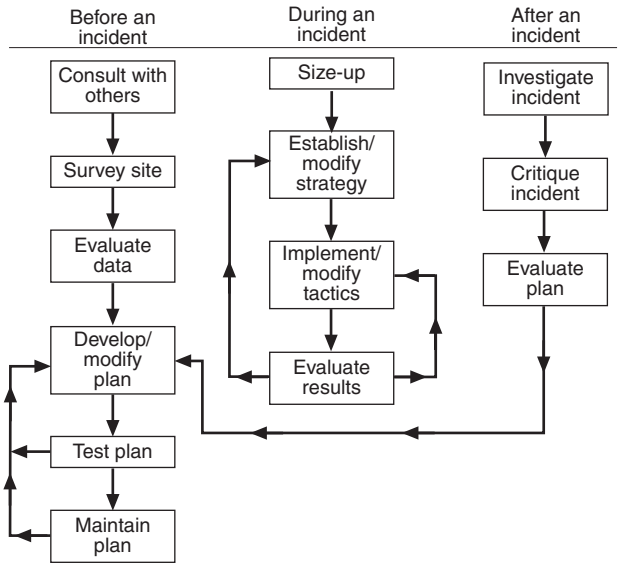

FIGURE 12.17.2 Pre-Incident Planning Process Flowchart

Pre-Incident Planning Data Gathering Form

Date: 7/24/93 Number of employees: 43

Location: 20511 Hicks Rd. Phone number: 708-634-3035

Sport Fashions

(Name of company and address)

Owner name/operator name: Fashion Apparel USA/Fred Jones Mfg.

Access to site: Streets— 1000-ft private drive with many large potholes to main west of Hicks Rd.

Lockbox: Outside of office door on left side

Annunciator panel—location:

Outside of office door on right side

Fire department connections—location:

1. Front of Guard House at Hicks Rd. entrance; 2. W. corner fenced yard, accessible from Ridge Rd.

Door locations/forcible entry notes:

1. Office-use lockbox key; 2. Dock office, center, E. side, 24-hr occy. ex. weekends;
3. Pump house—lockbox key at main office.

Storage configuration hazards:

Clothing warehouses; stock in cardboard boxes on back-to-back double row racks 23 ft high; 8-ft-wide aisles, ordinary wood pallets; no solid shelves

Construction: Width (side facing fronting street): 345 ft

No. stories: Depth: 200 ft

Height: 1 story = 27 ft

Wall construction: Insulated metal

Roof construction: Support structure — Steel joists on unprotected steel beams and columns

Roof covering — Built-up layers w/tar and gravel

Location of vertical and horizontal cutoffs (space separation—fire walls):

Type of fire doors: 12-in. HCB w/parapet at offices

Utilities:				
Gas	Unit heaters	Cutoff points	100 ft w/guard house
Electrical		Cutoff points	1. 200 ft
Oil pumps	None	Cutoff points	2. Ridge Rd. side
Propane tank	None	Cutoff points	

Critical exposures: Side 1: Open Side 2: Automatic sprinkler whse 90 ft

Side 3: Open Side 4: Open

Protection (on site): Public water: 1650 gpm

Residual pressure: 51 psi Normal static at site: 65 psi Test date: 6/14/2007

Sprinkler design: 1380 gpm 57 psi

FIGURE 12.17.3 Pre-Incident Planning Data Form

In-rack sprinklers provided: [x] Yes [ ] No

(#) Booster pump 1500 gpm 40 psi Driver type Elec.

(#) Fire pump 2000 gpm 75 psi Driver type Diesel

Hose stream supply: On site: Pond Public: 16-in. main—Hicks Rd.

Hose length to reach: Hydrant—200 ft; Pond—600 ft

Water demand: for AS: 1610 for hose streams: 500 gpm

Venting: Manual hatches: [ ] Yes [x] No

Automatic: _____ Powered: _____

Power switch locations: _____

_____

Special conditions:

Employee head count location: Guard house—Main Hicks Rd. entrance

Contact person: Days—Mgr. Fred Jones; Nights—Shift Foreman

Special units needed: 2nd ladder truck on 1st alarm from Ft. Mudge FD. Shift commander must request dispatch to TX.

Other: _____

Sketch details:

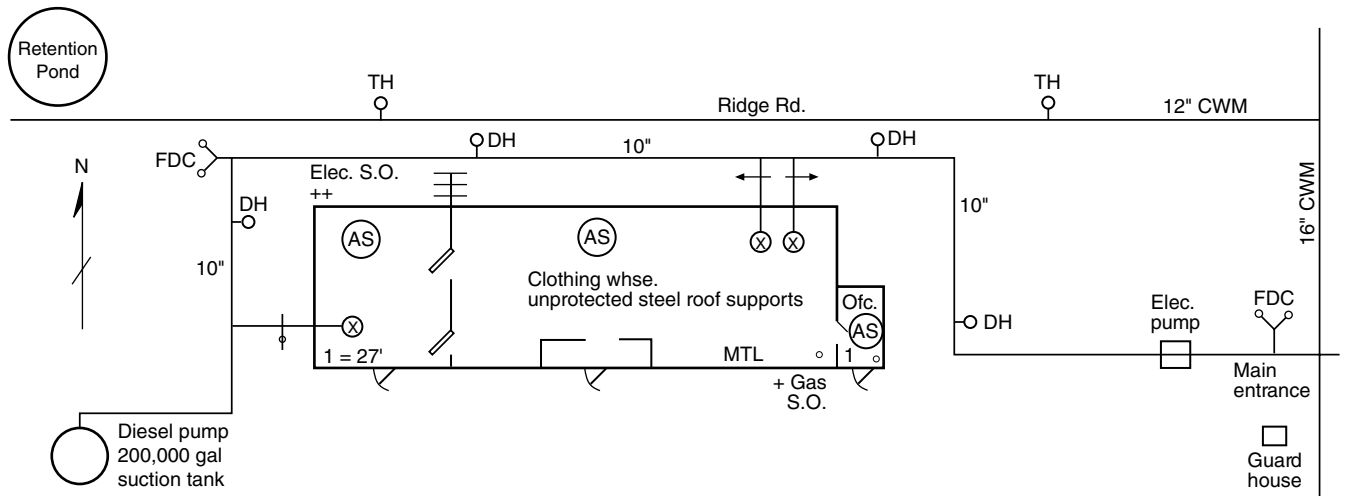

FIGURE 12.17.3 Continued

Testing and practicing the pre-incident plan will provide an opportunity to fine-tune the data and to revise and update the plan.

During the incident, the pre-incident plan should become the foundation for operations. It will provide important data that will assist the incident commander in developing appropriate strategy and tactics for managing the incident. Changes in conditions might dictate a revised strategy, including adjustments to responses and tactics. Throughout the incident, consulting the pre-incident plan will keep the incident commander informed about factors that might affect the success of any given strategic or tactical adjustment.

Each incident provides an opportunity for improvement. Assumptions, predictions, and accuracy of the pre-incident plan should be evaluated in light of the actual results during the incident. Modifications to the pre-incident plan should be made as necessary, and the plan should be retested, especially if the modifications are extensive.

DATA COMPONENTS

Building Construction

Construction features, such as structural framing systems, building materials, and the interior and exterior finishes, can be key factors in the rate and extent of fire spread within a building. The fire conditions in a building of fire resistive construction will be markedly different from those in a building constructed entirely of combustible materials. Fire development, intensity, and spread can be far better controlled in structures of fire-resistive construction. The size of the building, both vertical and horizontal, can also have a drastic effect on the decision process that takes place during an emergency. Awareness of these features by the fire department is important in estimating the potential fire problem and ultimately confining the fire to a limited area. Figure 12.17.4 shows a team reviewing the details of a building's specialized gas detection system.

Wall Construction. The pre-incident plan should include information regarding construction materials for exterior walls, such as metal panel, masonry, or wood frame. This information will be helpful in determining the potential for exposure protection, the potential loss of structural integrity, and the ability to access the building interior.

Roof Construction. Information on roof construction is also needed. This information includes the roof support, such as wood joist, steel joist, or steel beam; the roof deck, such as steel, metal panel, wood plank, or concrete; and the roof covering, such as built-up tar and gravel or insulated membrane system. The type of roof construction can have an impact on ventilation operations, can create exposure problems, and, most importantly, can increase the dangers to fire fighters. The pre-incident plan should also note how venting will be accomplished and the location of any manual or automatic vents. The decision to place fire fighters on a building roof during a fire should be based

FIGURE 12.17.4 Operational Overview of Flammable Gas Detection System

partly on advance knowledge of the particular roof construction. Roofs unprotected by automatic sprinklers, even those of fire-resistive construction, can collapse very early during a fire incident.

While conducting the survey, look for indicators of truss construction and consider marking facilities with an easily identified symbol. One such arrangement exists in the state of New Jersey. The New Jersey Uniform Fire Code requires identifying symbols be permanently affixed to the front of structures with truss construction. "F" signifies a floor with truss construction; "R" signifies a roof with truss construction; "F/R" signifies both a floor and roof with truss construction. Samples of truss identifying symbols are shown in Figures 12.17.5 (a) (b).

Ceilings and Attics. False ceilings and common attics can lead to fire spread within a building and impair the ability of fire fighters to control the fire. These construction features can create safety hazards by permitting fires to burn undetected in areas that are not readily visible. Awareness of these structural features allows fire fighters to prevent or reduce fire spread in these areas.

Floor Construction. Like roofs, similar information should be gathered about the building's floor construction, since the same collapse potential may exist. In addition, information should be obtained regarding the floor's capabilities for drainage, especially where flammable and combustible liquids are used or stored.

Means of Egress. The location of a building's entrances and exits, interior hallways, stairs, or other travel paths can be extremely valuable information in developing strategy or directing rescue, fire control, or other tactical operations. Familiarity with building access is often key to directing fire attack efforts that will confine the fire to the involved area, rather than driving it into uninvolved portions of the structure.

Vertical Openings. Vertical openings can exist in the form of open stairways, conveyor openings, utility shafts, elevator shafts, and so on. These openings can affect the travel of fire, heat, and smoke.

(a) (b)

FIGURE 12.17.5 Truss Symbols (Courtesy of John B. Smith, Fire Sub-code Official and Fire Marshal (Retired), Raritan Township, New Jersey)

Horizontal Openings. Barriers to horizontal smoke and heat movement can exist in the form of fire walls, fire doors, smoke barriers, and so on. Attention should be given to the protection provided for horizontal openings. The types of fire doors provided and their method of closure should be noted.

Occupancy

The type of occupancy is important in establishing incident priorities and tactical operations. An awareness of a facility's operations and contents increases the fire department's ability to fight a fire in that facility effectively and safely.

Life safety considerations should be the first priority for pre-incident planning. Many factors can influence the number and location of people in industrial and commercial facilities: hours of operation, day of the week, time of year, and the physical layout of the facility all have an impact on the type of life safety concerns the fire fighters may be faced with during an incident.

The operations within a facility can be classified into several general categories, such as office, retail, manufacturing, warehouse, and so on. However, each occupancy has its own unique characteristics that should be considered during pre-incident planning. Office buildings may have extensive computer rooms or laboratory areas, retail facilities may have large storage areas, and manufacturing occupancies have many different types of specialized equipment, hazardous materials, and hazardous processes.

Material safety data sheets (MSDS) should be reviewed for information on hazardous materials. Locations of MSDS files and related data, as well as the facility personnel responsible for this information, should be included in the pre-incident plan. Such information may be provided in a lockbox and should be noted on the facility drawing.

Due to extensive chemical inventories at some facilities, consideration should be given to obtaining electronic files. Chemical inventories, material safety data sheets, and related information can be stored on compact discs, portable drives, or on the hard drive of laptop computers. For the latter, some locations may have network connection capabilities and will allow uploading or viewing of site information during emergencies.

Warehouses have a wide range of occupancy considerations: commodity classifications, storage height and configuration, controlled environments, and limited access areas. Special attention should be paid to warehouses storing large quantities of hazardous or toxic materials, flammable or combustible liquids, aerosols, roll paper, rubber tires, and plastics. All of these types of commodities have proved to be substantial fire protection challenges over the years.

The pre-incident plan should detail salvage needs, as well. Often the largest part of a loss within an industrial or commercial occupancy is due to smoke damage outside of the immediate fire area.

With all occupancies, a critical component of pre-incident planning is keeping up with changes. If the occupancy of an area changes, the adequacy of the existing sprinkler system design and available water supply must be reviewed. This is especially

important in warehouse occupancies. Changes in product commodity classification and storage height and configuration can be subtle and occur over a period of time. If the sprinkler system design or the water supply are inadequate for the type and arrangement of storage, fire control in the area of ignition is unlikely.

Protection

Knowledge of the fire protection systems in a building, of how these systems operate, and of what actions are necessary to supplement these systems are essential to pre-incident planning.

Automatic Sprinkler Systems. Sprinklers play a vital role in the protection of industrial and commercial facilities. Pre-incident planning must determine not only whether or not the building is sprinklered but also whether or not the sprinkler system (and its available water supply) is adequate for the occupancy of the building. This determination may be beyond the capabilities of the fire department personnel assigned to do pre-incident planning. Resources outside of the fire department must be utilized, if necessary, to make this determination. This is where a team approach to pre-incident planning with the facility's property insurance carrier can be crucial. The facility itself may also have personnel either locally or at the corporate level that have this information. A fire protection engineer might need to be consulted if the information cannot be determined elsewhere. If the sprinkler system is not adequately designed to meet the protection requirements of the occupancy in the building, the building is essentially an "unsprinklered" building.

Pre-incident planning should include obtaining the minimum sprinkler system flow and pressure requirements for each major area of the facility. Most sprinkler systems installed today are hydraulically designed systems, which should have a placard posted on the riser indicating the specific flow and pressure design characteristics of the system. A key point: although the placard indicates what the system was designed for, that design may not be what is needed to protect the current occupancy.

An important part of pre-incident planning for protection features is to anticipate potential sources of sprinkler system failure. These potential problems can be summarized into three major categories:

1. *Design deficiency.* The water supply feeding the sprinkler system or the sprinkler system itself is not properly designed for the occupancy. The original system design might not have been adequate, or a change to a more hazardous commodity or storage array might have resulted in an inadequate system. Even seemingly minor changes in some occupancies, such as warehouses, can compromise existing sprinkler protection.

2. *Impairment to the sprinkler system before a fire.* This generally occurs when a sprinkler system is actually shut off during new construction or building renovations, or when an obstruction, such as a rock, works its way into sprinkler piping and blocks the flow of water.

3. *Impairment to the sprinkler system during a fire.* The system is impaired when any sprinkler control valve is shut prematurely during a fire. This obviously turns off the water to the sprinklers. Well-meaning facility employees or fire fighters may shut the valve in order to reduce smoke or to control water damage; however, this action only prevents sprinklers from gaining control of a fire in its critical development stage. Even if the valve is turned on again later, the fire might have grown beyond the point where sprinklers can control it.

The location of sprinkler control valves, and the building areas they protect, must be determined during pre-incident planning. Facility management should post signs that will help fire fighters locate these valves upon arrival. Knowing where control valves are located is essential because checking to make sure they are open is one of the first actions the fire department should take when it arrives on scene. This action, combined with establishing the water supply, is key to ensuring that the designed sprinkler system is doing the job it was intended to do, that is, protect the building structure and its occupants, including fire fighters entering the building to complete final extinguishment.

The location of the fire department (threaded or quarter-turn) connections should be determined. The connections should be identified as to whether they feed the entire site, individual buildings, individual systems, or standpipes. Threads should be physically checked for compatibility with the fire department thread.

Water Supplies. The most common source of water for the sprinkler system is a public water supply. In some cases, if the volume of the public supply is adequate but the available pressure is too low, a booster pump is connected to the public supply to boost the system's pressure to the necessary level. Current water supply results should be available or tests should be conducted to obtain current information.

A static water source would usually require a fire pump to provide the necessary water volume and pressure to the system. Tanks, wells, reservoirs, and rivers are examples of these suction sources.

Where either booster pumps or fire pumps are provided, it is important to note their size, pressure settings, starting arrangement, and power and fuel supply. Fire fighters responding to an incident should check to make sure that required fire pumps have started, particularly when the fire pumps are the only adequate source of water.

Regardless of the source, a sprinkler system's water supply should be capable of meeting not only the sprinkler demand but also the demand for hose streams. The water source chosen should be carefully selected so that the primary water supply for the sprinkler system will not be reduced. The location and capacity of hydrants, both public and private, should be determined. Where hydrant systems and water mains are not available, alternative resources must be determined to deliver sufficient water to the fire scene.

Special Protection Systems. Some facilities may have other types of protection systems, such as dry chemical, foam, carbon dioxide, or other gaseous extinguishing systems. The presence of these systems should be noted, as well as the areas they protect. In most cases, these systems will be considered supplementary to automatic sprinkler systems.

Standpipes. The pre-incident plan should note if available standpipe systems are of the wet or dry type and the size of the hose discharge outlet. If pressure-reducing or other regulating valves are provided at the outlets, information on adjusting or removing these devices should be understood. Small hose stations may be provided and supplied from the sprinkler system. The pre-incident plan should note if these stations will be impaired if the sprinkler system is shut off in a particular area.

Fire Alarm System. The type of alarm system should be determined as to the type of detection provided (smoke, heat, waterflow) and the method of transmittal to the fire department. The presence of an alarm system does not eliminate the need for a follow-up telephone call from the facility confirming the nature and exact location of the alarm. Figure 12.17.6 shows fire fighters engaged in the pre-incident planning task of studying a building's layout to confirm the location of alarm devices.

Procedures should be established for facility management to notify the fire department when sprinkler systems, fire pumps, special extinguishing systems, or alarm systems are taken out of service, regardless of the duration. If alarms are out of service, a temporary notification procedure should be instituted. When the fire department is notified of an impairment, the pre-incident plan should be referred to and contingency actions considered.

Site Considerations

Access. Familiarity with local streets and roads in the area can provide the best access route to the location. Pre-incident planning can also provide alternative ways to reach the area should normal routes become unusable due to bridges with weight restrictions, narrow streets, road construction, flooding, drifting snow, railroad grade crossings, and so on. Alternative approaches for responding units also allow for the placement of additional apparatus. It is important to determine which units will respond and from what direction they will come. This information can help in the safety of apparatus approaching the same intersection from different directions. Assignments for fire companies based on probable order of arrival, including any neighboring companies that may respond on an automatic mutual aid, can increase the effectiveness of the fireground operation.

Security. Data regarding security service at the site should be obtained. The number of security personnel on duty, where they are normally located, areas of "restricted" access, and the presence of guard dogs are among the items that should be reviewed. The location of any lockboxes and their contents should also be noted. An emergency call list of facility staff for off-hours should be obtained.

Exposures. Exposures to the site can be both structural and nonstructural elements, such as neighboring buildings, fuel storage tanks, standing or tidal waters, vegetation, wooded areas, yard storage, and airport flight paths.

Utilities. All utilities for the site should be reviewed. The type of fuel, storage location, and quantities should be noted, along with the locations of the emergency shutoffs.

FIGURE 12.17.6 Team Checking the Location of Alarm Initiating Devices

The location of the entrance for electric power should be noted. Also the location of the nearest disconnecting means within the facility as well as the nearest one outside the facility should be determined. If an electric-driven fire or booster pump is provided, it is important to determine the reliability of the power supply, noting if power lines run through the facility and if an independent feed has been provided so that the pump will remain running even if the facility has been shut down.

The location of emergency generators should be noted, as well as what equipment is powered when normal power is lost. Special consideration is needed if the emergency generator also supplies power to an electric-driven fire or booster pump.

Heating, ventilation, and air-conditioning (HVAC) systems can contribute to the spread of smoke throughout a facility. The ability to engage or disengage these systems as needed and the location of automatic and manual controls for this equipment should be documented. Facility services, such as domestic water, compressed air, and steam, should also be reviewed.

Environment. Runoff of fire-fighting water contaminated with hazardous waste must be considered. Data should be gathered on the location of water drainage collection points, potable water supply locations, and any other potential exposures. The anticipated exposure should be measured against the expected fire scenario, based on the facility's other construction, occupancy, and protection features.

Outside Assistance

During many incidents, fire service personnel are assisted by other agencies or other industrial facilities capable of providing the support functions necessary to control the fire. Interagency and outside assistance can be vital to the outcome of emergency incidents.

If automatic response agreements result in a mutual-aid fire department arriving first on the scene, this department should be involved in the pre-incident planning process and should receive copies of the finished documentation.

Other assistance may include traffic control by police; the use of specialized resources, such as fire-fighting foam stored at another industrial facility; utility service control for electric, gas, and water systems; and other items, such as sand, barricades, and heavy construction equipment.

Because the amount and type of interagency assistance will vary in different areas, pre-incident plans should identify what is available and how to effectively request a timely response when it is needed.

SUMMARY

Pre-incident planning is a valuable tool for emergency responders to effectively control a fire or other emergency incident. Preparing for emergency incidents by visiting specific target hazards and recording pertinent information is required to successfully manage the incident and minimize the potential for life and property loss.

The pre-incident planning process requires a team effort in collecting information, developing the plan, and implementing the plan. Facility management, the municipal fire service or other emergency response organization, and the property insurance company are all key players. Sharing of information through open and frequent communication is an effective means to address the many facets of developing a pre-incident plan. Very few, if any, fire departments have the resources by themselves to effectively develop pre-incident plans for all types of industrial and commercial facilities within their jurisdiction. The varying nature and complexity of processes found in the industrial sector necessitate a collective approach to plan development.

Pre-incident plans must be viewed as living documents and be periodically updated as conditions warrant. A continuous improvement process should be implemented to assure emergency responders have a tool that is complete and current. Collecting pertinent data must be accomplished by site visits to the targeted facility. However, a pre-incident plan is not a fire safety inspection. Pre-incident planning assumes an emergency incident will occur. Commercially available software programs may be used to record data and develop the plan. Regardless of how the plan is developed, it should be remembered that the plan is intended for use by emergency responders. Therefore, it is necessary for the information to be clearly written, concise, and representative of current conditions.

Although there are many aspects to effectively managing an emergency incident, pre-incident planning is a critical component. Assuming that an incident will occur and preparing for it with a written plan is a proven means to minimize the potential for life and property loss.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on pre-incident planning for industrial and municipal emergency response discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 13, *Standard for the Installation of Sprinkler Systems*
NFPA 13E, *Recommended Practice for Fire Department Operations in Properties Protected by Sprinkler and Standpipe Systems*
NFPA 14, *Standard for the Installation of Standpipe and Hose Systems*
NFPA *101®*, *Life Safety Code®*
NFPA 241, *Standard for Safeguarding Construction, Alteration, and Demolition Operations*
NFPA 600, *Standard on Industrial Fire Brigades*
NFPA 1142, *Standard on Water Supplies for Suburban and Rural Fire Fighting*
NFPA 1201, *Standard for Providing Emergency Services to the Public*
NFPA 1250, *Recommended Practice in Emergency Service Organization Risk Management*
NFPA 1600, *Standard on Disaster/Emergency Management and Business Continuity Programs*
NFPA 1620, *Recommended Practice for Pre-Incident Planning*

Chapter 18

Pre-Incident Planning for Emergency Response

Revised by
John Norman

Chapter Contents

Overview of the Pre-Incident Planning Process
"COAL WAS WEALTH" Process
Information Retrieval and Dissemination

Key Terms

computer-aided dispatch, exposure hazard, height and area, pre-incident planning, site visit, size-up, standard operating procedure, water supply (fire protection)

Pre-incident planning is a vital tool for all fire departments, municipal or industrial, career or volunteer, large or small. Information gathered during a pre-incident planning visit is a key component of a fire officer's size-up during an actual incident. Size-up can be described as an evaluation of problems and conditions that affect the likely outcome of a fire. Size-up is an information-gathering process, akin to gathering intelligence in a military campaign. Pre-incident planning is done to allow fire-fighting personnel to view conditions within a structure or site, evaluate what these conditions are likely to develop into in the event of an emergency, and then develop strategies for dealing with the potential problems. The great advantage of pre-incident planning is that it is done pre-incident. Three o'clock in the morning, with high winds and heavy rain lashing your face, and fire extending in all directions as you watch, is not the best time for gathering critical information.

NFPA has recognized the necessity for pre-incident planning by issuing a series of consensus standards beginning in 1993. In 1998 the first comprehensive pre-incident standard (NFPA 1620, *Recommended Practice for Pre-Incident Planning*) was adopted and published, with an updated edition following in 2003. This standard and its accompanying appendices present a very detailed examination of the topic and process, including several examples of preplanning forms and documents. NFPA 1620 should be reviewed carefully by any department initiating a pre-incident planning program or updating an existing one. The examples presented in this chapter illustrate one particular approach and the experiences of a fire-rescue department that has engaged in pre-incident planning for many decades.

For topics related directly to this chapter, see the following chapters in Section 12: Chapter 1, "Planning for Public Fire-Rescue Protection"; Chapter 3, "Needs Assessment and Hazard Analysis"; Chapter 8, "Effect of Building Construction and Fire Protection Systems on Fire Fighter Safety"; and Chapter 12, "Disaster Planning and Response Services." For information on calculating water supply requirements, see Section 15, Chapter 3, "Hydraulics for Fire Protection."

OVERVIEW OF THE PRE-INCIDENT PLANNING PROCESS

Prior to implementing a pre-incident planning program, fire department leadership must establish the priorities that it wants to cover in the program. In an ideal world, every structure and site in a department's area of responsibility would be subject to pre-incident planning (PIP). This is a very attainable goal in some organizations, such as suburban towns consisting primarily of large segments of nearly identical tract housing, whereas it may be totally unrealistic in other areas that consist of great numbers of large complex and different buildings. In the case of the former, the PIP may have occurred in the form of past responses that have developed into standard

Deputy Assistant Chief **John Norman** is a veteran of more than 36 years in the fire service, including 27 years with the FDNY, the majority of that time in special operations units. In the days after September 11, 2001, Chief Norman was designated the search and rescue manager for the World Trade Center site. He lectures nationally on a wide variety of fire and rescue topics.

operating procedures or guidelines (SOP/SOG). Departments facing the latter situation have a tendency to preplan only "target hazards" and let SOPs or SOGs take care of the remaining structures. That is fine, as long as the fire understands that and remains cooperative, fitting into the framework of "standard" incidents. Too often though, nonstandard situations develop, and that is where PIP pays dividends. I argue for developing pre-incident plans (Figure 12.18.1) for all locations in your response area.

The Size-Up

To be effective, pre-incident planning should address the information that fire-fighting personnel, particularly the incident commander, will need in order to develop their strategy for dealing with potential incidents. Most pre-incident planning focuses on aspects of the size-up that can be known beforehand and that are likely to remain static until an event occurs, such as building construction or occupancy loads. Pre-incident planning should also be flexible enough to take into consideration temporary situations that pose unusual risks or hazards, such as a disruption to the fire protection water supplies or introduction of a one-time flammable process.

A fire officer's size-up begins at the moment the alarm is received, and it continues until the emergency is under control. Pre-incident planning can give much-needed physical information, such as the size and construction of the building or site. Other parts of a fire officer's size-up however, such as weather conditions, location and extent of the fire, and time of day of the event, cannot be completed until the emergency begins. Pre-incident planning should focus on items that are likely to be difficult to obtain at the time of an incident, such as interconnections between buildings that are not visible from the street.

Pre-Incident Site Visits

Larger departments probably have greater resources than smaller departments, but every department has constraints on the amount of resources that can be devoted to PIP. This is one reason why many departments concentrate their PIP on the target hazards. The collection of data on buildings takes time. The fact is, though, that many buildings have been standing in our communities for 50 or 100 years, just waiting for us to come to preplan them. What valid excuse is there for not having done so if a serious mishap occurs that could have been detected by a pre-incident visit sometime during the previous 100 years?

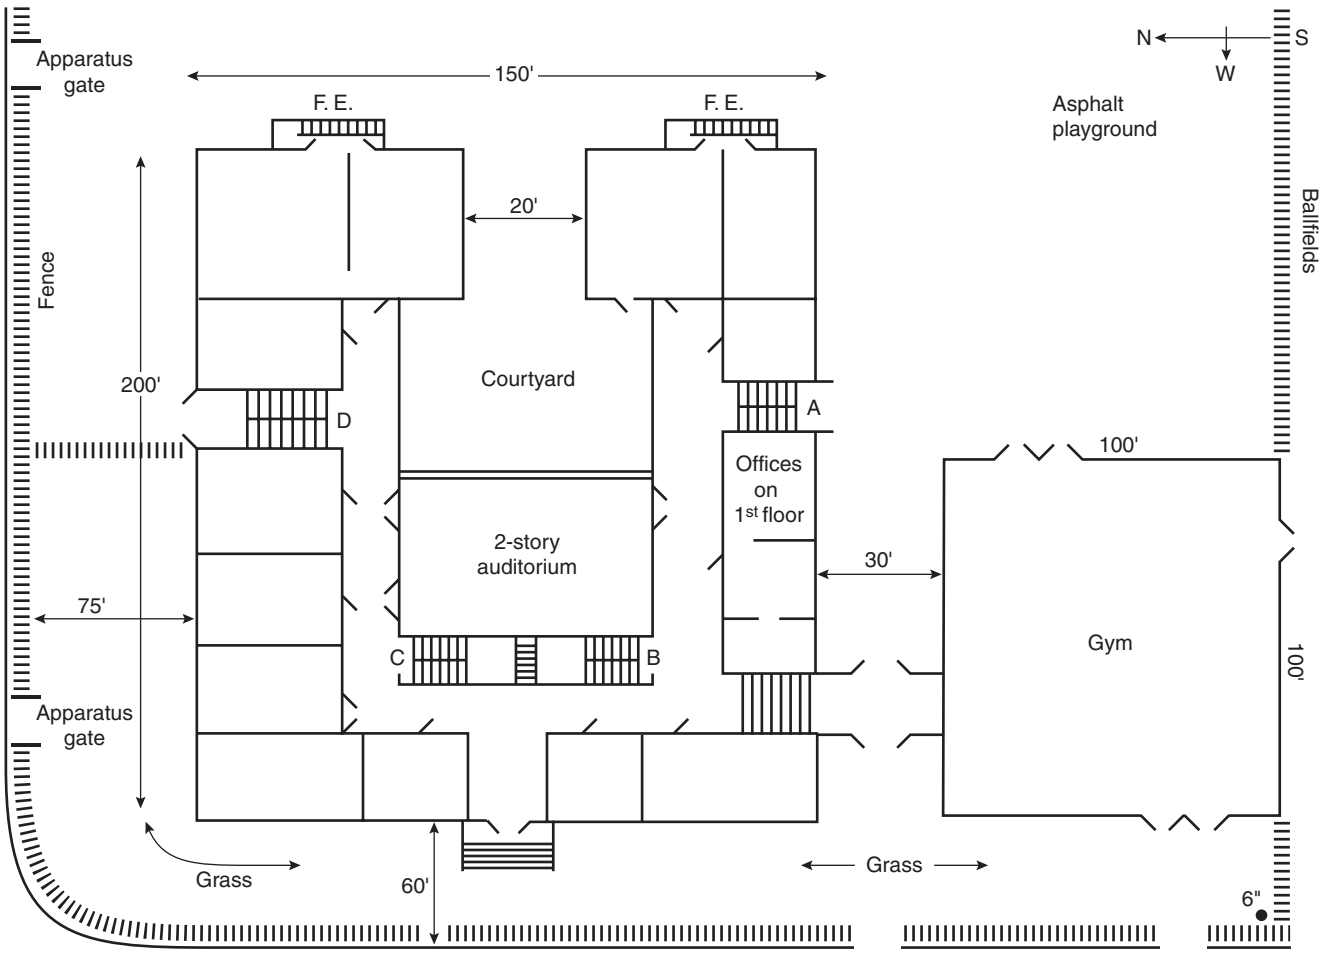

FIGURE 12.18.1 PIP Sketch of a Nonindustrial Facility

When sending fire fighters into a site for a pre-incident planning visit, tell them to approach the site as if they were going to be returning there for a serious fire 15 minutes after they conclude. They will want to examine the location for what could kill them and remember the hazards, so they can avoid them if they were to have a fire. Of course, not all fire fighters remember everything they saw in a building a year or two, or five years prior. That is the point of documenting conditions (Figure 12.18.2) and preparing a written plan or training program that can be reviewed periodically to refresh the memories of fire personnel and can also be used at the time of an actual incident to augment the incident commander's size-up as he develops his strategy and implements tactics.

Identifying Hazards and Obstacles

Pre-incident planning is not just for structural fire fighting. An all-hazards approach is as applicable to PIP as it is to other aspects of emergency services operations. Some nonfire PIP is actually mandated by federal law. For example, OSHA's standard on confined space operations requires that the rescue agency responsible for a premises be permitted access to representative spaces annually to practice rescue procedures. Clearly, this is intended to foster pre-incident familiarization with the space and develop procedures for dealing with potential incidents—that is pre-incident planning.[1]

Outlining and Analyzing Necessary Information

After establishing what types of hazards or occupancies are to be included in the program, the next step in the PIP process is to determine what information will be needed during the data collection phase. This may vary depending on the occupancy of a particular location, but should be geared to gathering the information the incident commander will need to know in order to handle a working structural fire or other emergency. Again, efforts should focus on those aspects that cannot be readily determined from the street upon arrival and create nonstandard situations for which an SOP is not suitable.

Developing a Standard Format. Once the outline of the desired information is determined, a standard format must be developed to capture the information and process it for future use. This can vary from a simple written preplan form to an electronic database that shows details such as floor plans, location of exits and/or hazards, and other details. One tool that has proven to be invaluable is a digital camera. A series of images documenting details about a structure (Figure 12.18.3) can save many miles of travel to and through a site and is extremely valuable for refresher training on a site. It would be helpful if the same person, or a small team of people, collected all the PIP data, since this would produce consistency in what is collected and how it is analyzed, but in larger jurisdictions this may be impractical. (In Phoenix, Arizona, a fire protection engineer attached to the special hazards unit is used in the data collection and formatting phase, leading to a high degree of consistency and expertise.)

Analyzing Information About a Site. Once the site has been visited and the basic data collected, a rational analysis of the site and the hazards present must be conducted, and a plan is created for dealing with the problems that have been detected. The solutions may take many different forms, from taking a

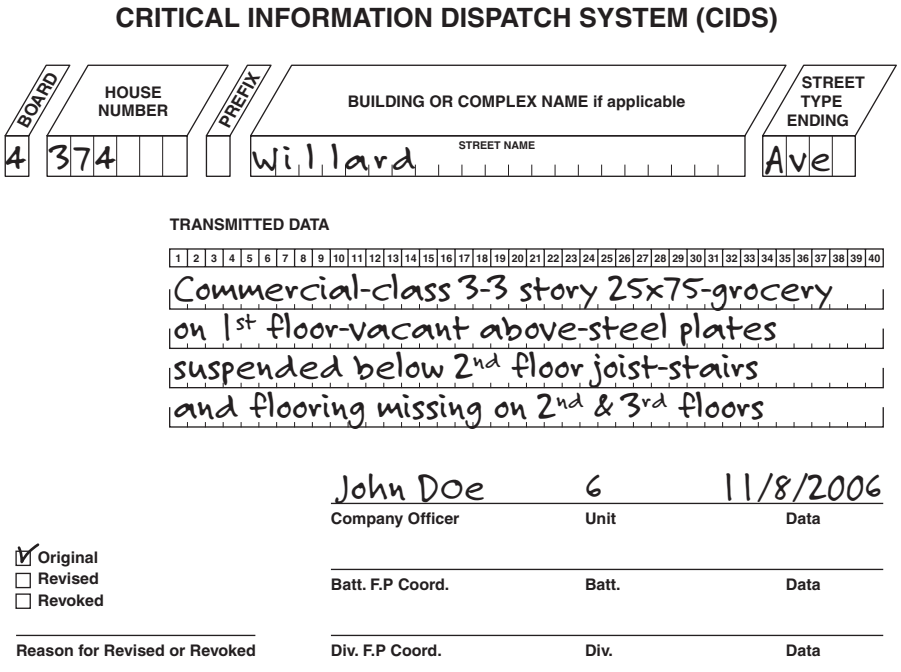

FIGURE 12.18.2 Critical Information Dispatch System Output for PIP

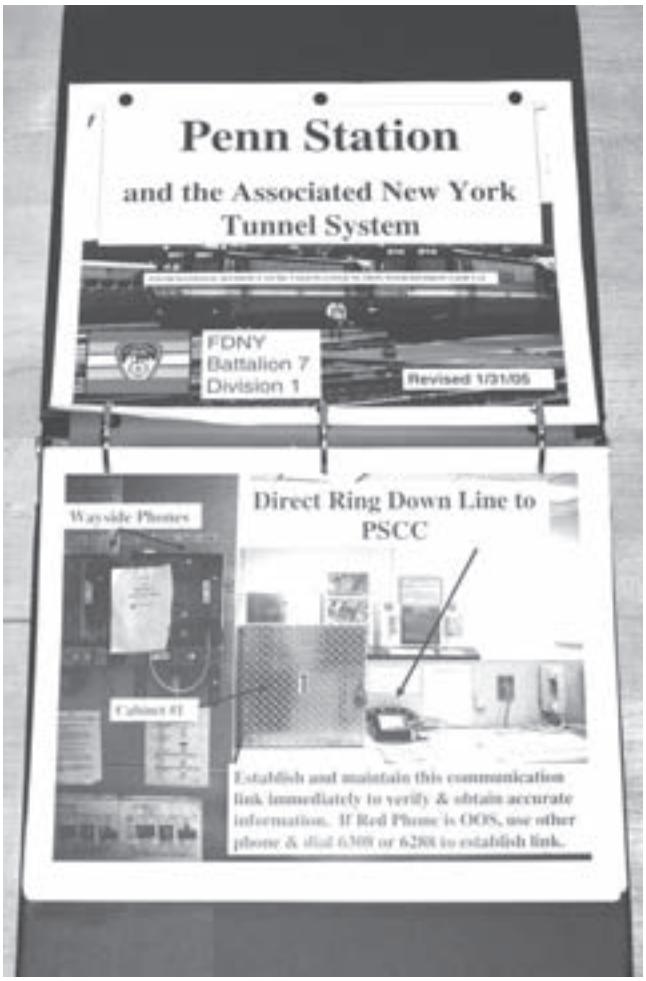

FIGURE 12.18.3 Digital Photos for Use in Pre-Incident Planning Sessions

strictly defensive posture in the event of serious fire exposing lightweight construction elements or some particularly hazardous chemical storage, to arranging for an immediate response of additional resources on the first report of an emergency, such as having an additional ladder company assigned for reports of a fire in a school with handicapped children as students. At some sites, much of the planning, such as determining critical openings in firewalls that will be reinforced with hose streams in the event of a fire, can take place during the site visit. Larger, complex sites may require several visits to complete. It may be necessary to do additional research on chemical hazards, for example. This type of research can better be performed in an office setting with suitable resources at hand. Then the fire fighters can return to the site once a basic plan is established to analyze it in place.

Selecting Personnel to Develop the Plan. The selection of personnel for developing the pre-incident plan is crucial. In many jurisdictions, an experienced chief officer is assigned this task. In some cases, departments have hired private consultants to do much of the basic information gathering. (An excellent example of the work done by one such group is the high-rise building data sheets developed by the Massey Disaster Planning Group. These multipage documents provide a written text-based summary of building features as well as visual illustrations of such elements as floor plans, elevator and stairwell arrangements, HVAC and standpipe riser diagrams, and other critical factors that are essential to the incident commander's size-up.

Avoid the temptation of assigning the task of developing the pre-incident plan to company level officers or members of the Bureau of Fire Prevention (or Special Hazards for that matter). Although they can be extremely helpful in collecting and interpreting the raw site data, the personnel who are actually responsible for fireground command should make all the strategic decisions when formulating the action plan, since they will be deciding what will actually be implemented. It is essential as well that, if a department operates as different shifts, the appropriate commanders of each shift reach a consensus on actions to be taken to avoid conflicting messages or actions.

Using the Plan

After the plan has been developed, it should not be set on the shelf as personnel move on to the next task. The job is not complete until all members who may play a role in the implementation have been thoroughly educated on it and given the opportunity to demonstrate their proficiency. That may require periodic visits to the site for drills or exercises and/or tabletop exercises using the photos and plans developed during prior site visits. These visits should occur at least annually on all affected shifts. Some structures may require more frequent visits due to changing conditions.

The general picture of pre-incident planning that was outlined in the preceding sections can be summarized as follows:

1. Determine priorities to address—that is, life hazards, firefighter traps, and critical infrastructure.
2. Decide what data is needed.
3. Develop a standardized information capture method, preplan form, and so forth.
4. Train collectors to gather information.
5. Perform visits and collect data.
6. Develop strategic and tactical plans.
7. Distribute copies to all potential users.
8. Train users on objectives.
9. Review the plan periodically (annually at minimum).
10. Revise as needed, redistribute, and retrain.

"COAL WAS WEALTH" PROCESS

When deciding what information to include in the plan, it is helpful to consider what will be required in the incident commander's size-up. New York City fire officers use a 13 point outline of factors when conducting their size-up or pre-incident planning. This process covers the majority of fireground considerations and is summarized in the acronym "COAL WAS WEALTH."[2]

The COAL WAS WEALTH process includes the following points:

C Construction
O Occupancy
A Apparatus and staffing
L Life hazard

W Water supply
A Auxiliary appliances
S Street conditions/special matters

W Weather
E Exposures
A Area and height
L Location and extent of fire
T Time
H Hazardous materials

The elements of the COAL WAS WEALTH process are often arranged in order of priority, broken down as shown in the following paragraphs.

Life Hazard

Life hazard is produced by a combination of several other size-up elements: time of day, the occupancy, location, and extent of fire all combine to endanger victims. Pre-incident planning can and should identify the occupancy, especially when there is more to the building than meets the eye. Commercial buildings that are partially occupied with residential areas are prime locations for preplanning, since responding fire units would normally not conduct an aggressive search for life at a late-night fire in what is perceived to be a commercial building. The preplan information gathered here could mean the difference between life and death for sleeping tenants in this situation. Many older cities have seen a renaissance of some of their older commercial neighborhoods as residential occupants moved into vacant manufacturing spaces in loft-type buildings. In New York City, this practice was originally begun by people in the artistic community, who valued the high ceilings and large floor spaces of the former commercial areas for artistic projects such as sculpting and painting. These urban pioneers were known as "artists in residence," and the commercial buildings that had some residential spaces were known as A.I.R. buildings. An extensive campaign was conducted by the fire department to identify these buildings, which then were required to be marked with a prescribed sign to alert responding fire fighters to the A.I.R. Later, when a computer-aided dispatch system came into use, an entry for A.I.R. buildings also served to alert fire fighters to the life hazard in the building they were responding to. Both systems represent pre-incident planning at work.

Occupancy

The occupancy of a structure has many impacts on the fire officers' strategy. One major impact, as just discussed, is the life hazard, which may vary with the time of day. Schools, for example, have a life hazard that varies greatly with the time of day. Hospitals and apartment houses, on the other hand, have a high life hazard around the clock, whereas storage warehouses and similar occupancies have a uniformly low life hazard regardless of time of day. The occupancy should serve to determine the level of risk to fire fighters that will be tolerated when developing the strategy. Where the occupancy poses great threats to fire-fighting personnel, and where the civilian life hazard is minimal, a defensive strategy should be developed.

The occupancy has a great effect on the fire load within the structure, which will dictate water supply requirements, and affect other aspects of the incident commander's strategy. Manufacturing and storage occupancies typically have large, open floor areas that may translate into fires that are beyond the scope of handline control. Large open floor spaces should alert fire fighters to look for truss construction, a collapse danger. Another aspect of occupancy is the presence of hazardous materials that may be a required part of the ongoing business conducted in a facility, such as cyanides in a plating plant. Hazards in other locations are not as obvious however, and fire fighters may have to look deeper for hazards, such as in a freight warehouse where manufacturing and use of dangerous goods does not occur (other than the use of propane for forklifts or similar items) but which can be locations for transshipping nearly any dangerous commodity produced elsewhere. The handling of hazardous materials should be noted on pre-incident planning forms, citing quantities stored, location of storage, and any special concerns such as incompatibility with water or other materials, or the need for special extinguishing agents.

Time

Pre-incident planning may not seem to have a great deal to do with time, since we cannot predict exactly when a fire will strike a given structure, but there are several time-related concerns that directly impact fire-fighting operations, including time of day, time of year, and perhaps most important, the elapsed time from when the fire began. The time of day may prompt the response of an additional ladder truck to a school with handicapped children, but only during school hours. PIP should account for seasonal changes that affect operations, such as winter plans that identify additional resources for snow removal or hydrant thawing or additional brush fire units to be staged during high fire danger periods.

Elapsed burn time is a crucial indicator of the likelihood of structural collapse. Structural collapse is very difficult to predict, due to the many variables that can be involved: the type of construction, fire loading, length of burn before the alarm is transmitted, alterations to the original structural design—either through routine structural alterations or deterioration from exposure to weather or industrial processes. It is important to remember that long before the alarm sounds, the structural engineer who designed the building set a time limit for the effectiveness of fire-fighter actions. A crucial element to understand is that the time frame starts when the fire reaches flashover and begins to attack the structural elements. The elapsed time from flashover is one of the primary indicators of an impending collapse. Knowing the class of construction is an important component of this evaluation, as it is an indicator of how long the building will resist structural failure. Pre-incident plans should make it a high priority to identify structures that will likely face collapse

dangers, especially those that are vulnerable to relatively short burn times.

Construction

A critical factor that must be included in any pre-incident plan is the building's construction. The first concern is the ability of a building to resist collapse when attacked by fire. It is not advisable to rely strictly on labels given to building assemblies such as a two-hour rated floor or wall. There are many factors that affect how long it will take a given structural element to fail, including the fire loading of the area that exposes the element, damage that has occurred to it from explosions, prior fires, weather damage, vandalism, and so on. It is good to recall that one of the "three-hour rated" World Trade Center towers collapsed in under one hour of fire exposure.[3]

Construction has other implications, including the amount of compartmentation present, which can either promote or thwart the spread of fire. Large, open floor spaces provide an opportunity for fire to spread readily throughout the exposed area and are indicators of the presence of truss construction.

A third factor is the degree to which the building itself adds to the fire load. With wood construction, the building itself may constitute a heavy fire load. Directly related to a building's combustible construction is the number of hidden voids that fire can travel in. Voids such as cocklofts, pipe chases, and channel-rail voids are responsible for the destruction by fire of more buildings than any other construction-related factor.

A comprehensive listing of all buildings in your area that are built using lightweight techniques is critical to fire-fighter survival, along with a clear department policy stating that a fire that has reached the flashover stage in one of these structures will only be fought from defensive positions until the fire has been knocked down and ventilation and lighting conditions permit a careful examination of the structural elements. This information should be recorded in a computer-aided dispatching system (CADS) message. The idea behind pre-incident planning is to allow rational decisions to be made based on the information that has been gathered during the pre-incident planning visit. Decide what you want your people to do, then write it down for them as policy, and let them know about it!

For a further discussion of the impact of building construction on fire personnel, see Section 12, Chapter 8, "Effect of Building Construction and Fire Protection Systems on Fire Fighter Safety."

Area and Height

The area and height of a given building are two obvious concerns during size-up, since they indicate the maximum potential fire area. Sometimes, however, the size of a structure is deceptive when viewed from the street. This may be because the building is built on a sloping grade, which may cause fire personnel on one side to view the structure as one-storied whereas personnel on another side see it as two-storied. A similar situation contributed to the deaths of four fire fighters at a fire in Seattle in 1995. Pre-incident planning could have established the actual size and facilitated communications during the event, as personnel on different sides of the structure refer to the same area.

The height of the building has obvious effects on the need for aerial devices. PIP can build into a department's protocols the need for calling such aerial devices, especially when they are not normally part of a routine response for that type of structure.

The area of a building is also an important item for PIP. Look for buildings that will require modifications to the standard attack, especially those buildings that exceed the reach of preconnected attack lines. It may be necessary to create a separate hose bed for larger structures, in order to provide a sufficient length attack line to cover all areas. For the most part, the frontage of a building (width and depth) visible from the street indicates the area of the structure, but the obvious is not always correct. The presence of interconnecting openings between what appears to be two separate and distinct buildings effectively combine the structures into one large potential fire area. Such an interconnection should be prominently displayed in the pre-incident plan that is developed for the structure, including a notation of the presence and condition of any opening protective devices, such as fire doors or deluge sprinkler systems.

Location and Extent of Fire

It might be impossible to determine the location and extent of the fire until after a fire starts, but PIP can often identify likely locations for a fire to begin and also give an idea of the likely extent of fire, based on an analysis of the hazards present. Certain process hazards, such as paint spraying, are notorious points of ignition, as are occupancies such as restaurant kitchens, especially those that typically deep-fry foods. Pre-incident planning should indicate the location of such hazardous areas within a facility, and also indicate the proximity to features such as fire barriers and stairwells that may be threatened.

The location of the fire will influence the tactics used to control it. The lower the fire is in a building, the more serious the hazard, since more of the building is exposed to rapid vertical fire spread. Pre-incident plans should focus on identifying any vertical arteries such as pipe and elevator shafts, as well as open stairwells that will require hose-line protection or physical examination.

Some potential fire locations create special fire-fighting problems, and as such, should warrant particular attention during PIP. The top floor of most Type III (ordinary brick and wood-joist) and Type V (frame) structures has some type of void space above the top floor. Known alternately as a cockloft or attic, this void space creates access problems for fire fighting and allows rapid fire spread over the entire top floor in many cases. Pre-incident plans should note the presence of such voids, as well as the location of any access points or fire divisions that may be present.

Exposures

Exposure hazards are another factor that is relatively easy to determine beforehand but which might be difficult to determine at the time of an emergency. The easiest way is often to view the surroundings from the roof of the structure being preplanned. Any structure that is separated from the building in question by

less than the height of the building being preplanned can be in immediate danger, due to the potential for collapse of the walls. Other factors to consider are the construction of the walls of both buildings and the number and size of openings (especially windows) in the opposing walls. Frame walls, especially those covered in combustible materials such as asphalt and vinyl siding, should be noted, and plans should be developed as part of the PIP for protecting these exposed walls with hose streams. For buildings that have exposure protection systems in place, such as exposure sprinklers (exterior, often open deluge heads, located at the eave line), those locations and controls should be noted and operating procedures developed. The examination of exposures should include all six sides of the fire area—front and rear, left and right, top and bottom. The risk to taller nearby structures is especially important to preplan for.

Apparatus and Staffing

The items discovered during PIP will assist in determining what resources are required. The pre-incident planning process should have pointed out the need for specific types of apparatus, such as an aerial device to reach areas above grade or to provide an elevated stream for fire attack or exposure protection. Other items that should be part of PIP are the length of supply lines required to reach a source of water supply that is adequate for the hazard. The pre-incident plan should indicate the number of engine companies that will be required to establish a relay if that is required, and many plans indicate items such as the location that each unit should take in order to speed the establishment of such an operation.

Pre-incident plans may have to be created to deal with contingencies that affect the staffing required at an incident. It is common practice in cold weather climates to make provisions for additional staffing during periods of peak snowfall. Similarly, agencies having large wildland areas or urban-wildland interface often place additional staffing on units or place additional units in service during peak wildfire danger periods.

Water Supply

Water supply is a key element of pre-incident planning. Water supply requirements depend on the fire load and the volume or area involved. There are several methods and formulas to determine how much water is required for a given fire area. In the case of larger facilities, in many areas, the insurance services office (ISO) may have already performed a detailed analysis of the needed fire flow. Contact the area ISO office for assistance. For PIP purposes, in most structures it is usually sufficient to utilize some variation of the Iowa State University fire flow formula to determine how much water is required. Briefly stated, the needed fire flow can be estimated by calculating the area of the structure and multiplying this figure by a factor that depends on the fire loading and construction involved. This factor ranges from 14 gpm/100 ft^2 (53.2 Lpm/9 m^2) for lightly loaded areas such as residential rooms and spaces in noncombustible buildings, to 30 gpm/100 ft^2 (114 Lpm/9 m^2) or more for locations with heavy fire loads, such as paint storage. More water is required if the building itself is of frame construction or if exposures may be threatened and require protection. As an example, a one-story, 100 ft by 100 ft (30.3 m by 30.3 m), ordinary construction furniture showroom should have at least 3000 gpm (11,400 Lpm) available to satisfy basic needed fire flow.

After determining the needed fire flow, PIP for water supply involves flow testing the water sources around the hazard, including such alternative supplies as drafting sites, relay operations, and tanker shuttles. Remember to include sources such as nearby private fire pumps taking suction from supplies separate from the municipal system.

The needed fire flow will help to determine apparatus and manpower requirements. Pre-incident planning for providing the needed fire flow involves how the water will be moved to the incident site. Arrange for sufficient numbers of pumpers, with the appropriate size and length of supply lines, to move the water from the source to the incident scene. Also consider the number and type of discharge appliances that will be required to apply the needed fire flow at the most efficient location(s). Often, a combination of handlines, fixed or portable master streams, and aerial streams will be required.

For further information on calculating water supply requirements, see Section 15, Chapter 3, "Hydraulics for Fire Protection."

Auxiliary Appliances

The presence and serviceability of auxiliary fire protection systems is an item that deserves high priority in any pre-incident plan. Sprinkler systems, standpipe systems, foam systems at bulk oil storage plants, halogenated agents, CO^2, and dry-chemical systems for special hazards such as restaurant grease ducts and spray paint booths, are all key components of a structure's fire defenses. Auxiliary appliances that are out-of-service require adjustments to the strategic plan and must be prominently displayed in any pre-incident plan. Such a condition, even if only temporary, might require further action, such as temporarily vacating the structure's occupancy, or placing fire guard personnel on duty to provide for prompt detection and suppression in lieu of the out-of-service systems. Such planned activities should be documented in the fire department's plan for the specific facility or in a standard procedure or guideline for such outages.

Pre-incident planning should identify what auxiliary appliances are present, what their operational status is, the location and method of operating controls, and what potential workarounds exist for partial service interruptions. For example, both standpipe systems and sprinkler systems are routinely supplied through a fire department siamese connection. In the event of an obstruction or failure of the siamese, is it possible to supply the system through another connection? Stretching a supply line to a first- or second-floor hose outlet of a standpipe system is one example of such a workaround. With a sprinkler system, a similar arrangement may be possible, with assistance of building engineering personnel. Document all such workarounds in detail in a section of the pre-incident plan dedicated to auxiliary appliances.

Weather

Weather conditions may not seem to be something that can be preplanned, but many specific policies can be pre-planned for common events. Large-scale, high-impact events, such as

hurricanes, blizzards, tornadoes, and so on, should each have in-depth plans for continuity of operations in communities that are subject to such events. These plans may require suspension of services during the peak of the storm, relocation of apparatus and personnel out of areas that are subject to dangerous conditions such as flooding, or added staffing prior to the arrival of the most severe conditions. The plan should be available to all personnel beforehand, so they can anticipate what may be asked of them and make arrangements to be available when called on. The fact is that these unexpected events sometimes occur when those who are most familiar with the plan are not available, and it falls on those less familiar with the planning for implementation. It helps to have seen the plan before being called on to deal with it.

Weather can have serious impacts on fire-fighting efforts. High temperature and high humidity rapidly fatigue fire fighters. Freezing temperatures hamper fire-fighting operations by causing ice accumulations and slipping hazards, and fire fighters must use caution to avoid injury. Severe cold can cause mechanical failures, frozen hydrants and freezing of other water supplies. High winds wreak havoc on fire attack, fanning flames into blowtorch-like proportions. All of these events should figure prominently into plans for dealing with their consequences and should be part of a fire department's library of contingency pre-incident plans.

Street Conditions/Special Matters

Street conditions are another item that at first glance appear to have little impact on pre-incident planning, but in fact, many factors that result from difficult street conditions can and should be dealt with in the PIP stage. Construction trenches for water, sewer, or gas mains may separate the apparatus from the fire building, preventing fire fighters from reaching the front of the building. In that situation, the aerial apparatus should enter the block, since it can reach over a trench. Meanwhile the engine company should position at the nearest intersection and hand-stretch a hose line along the sidewalk. This procedure is likely to differ drastically from most departments' normal SOP and might require modifications to apparatus hose loads, but it is a good opportunity to incorporate pre-incident planning into tactical operations.

Similarly, deep snow and ice can bury hydrants and block streets altogether. Pumpers should remain out on the cleared main artery and hand-stretch lines into the snow-clogged side streets. This is very time-consuming and may require additional personnel, an issue that should be addressed in the winter weather contingency preplan.

Another situation that requires pre-incident planning is a work stoppage of mass transit agencies. Bus and subway strikes add tremendous volumes of traffic to urban arteries and can result in emergency vehicles being gridlocked and therefore unable to reach the scene of an emergency. Planning with traffic management and law enforcement personnel should identify emergency routes that will be kept open for emergency vehicles. Again, it may be necessary to hand stretch hose greater distances than routinely envisioned. Be alert for such *temporary* situations and have a plan, and the necessary hosebed arrangements, to deal with them.

Hazardous Materials

The presence of hazardous materials is one of the most important factors to determine in any pre-incident plan. Hazardous materials pose problems for fire fighters, ranging from health hazards to accelerated fire extension. The presence of poisons or explosives could prompt the fire department to take a strictly defensive posture and not conduct any fire-fighting operations. Information about specific hazards should be researched with an emphasis on actions to be taken in the event that fire or other conditions threaten the material. Details of the name(s) and properties of the materials, quantities and locations of the hazardous materials, as well as recommended procedures for dealing with emergencies should be entered prominently into the pre-incident plan. Specialized extinguishing agents can be located and arrangements made for their use in the event of an emergency, including working out financial arrangements for paying for the agent if it is not normally part of the fire departments arsenal.

INFORMATION RETRIEVAL AND DISSEMINATION

Pre-incident planning is a multistep process that involves gathering information, analyzing that information, developing an action plan, and then making that plan available to those who need it during an emergency. This last step, information dissemination, can be as complicated as the other parts, and requires as much forethought to accomplish well.

Three-Ring Binders

The simplest pre-incident plan process involves written documents stored in three-ring binders kept on responding apparatus (Figure 12.18.4). These plans, as others, should be the subject of training sessions to ensure that all responding personnel have at least a basic awareness that such plans exists and knowledge of the more important elements of the specific plans. This training must be ongoing to be effective. One of the biggest drawbacks of the three-ring binder is the "crying wolf" syndrome that develops when it is necessary to manually check every address that you respond to. Another drawback of the three-ring binders is the size of the plans themselves. A typical high-rise building plan, for example, would require a data sheet with building personnel contact information; a site plan; riser diagrams for stairs, elevators, and standpipes; heating, ventilating and air-conditioning (HVAC) zone and riser diagrams; floor plans for typical floors; and a building profile (side view) showing any setbacks where the building changes dimensions. (A setback occurs where a building's floor plan is smaller than the floors below that point, creating a roof area outside the smaller floor. This roof area may be useful to allow fire fighters to work on the outside of the building.) Separate sheets should be provided for each hazardous material used or stored on site. Very quickly, a set of pre-incident plans for an urban response area can take up several large binders, complicating retrieval efforts in moving apparatus. Paper plans should either be laminated or stored in sealed plastic sheet protectors to protect them from the weather

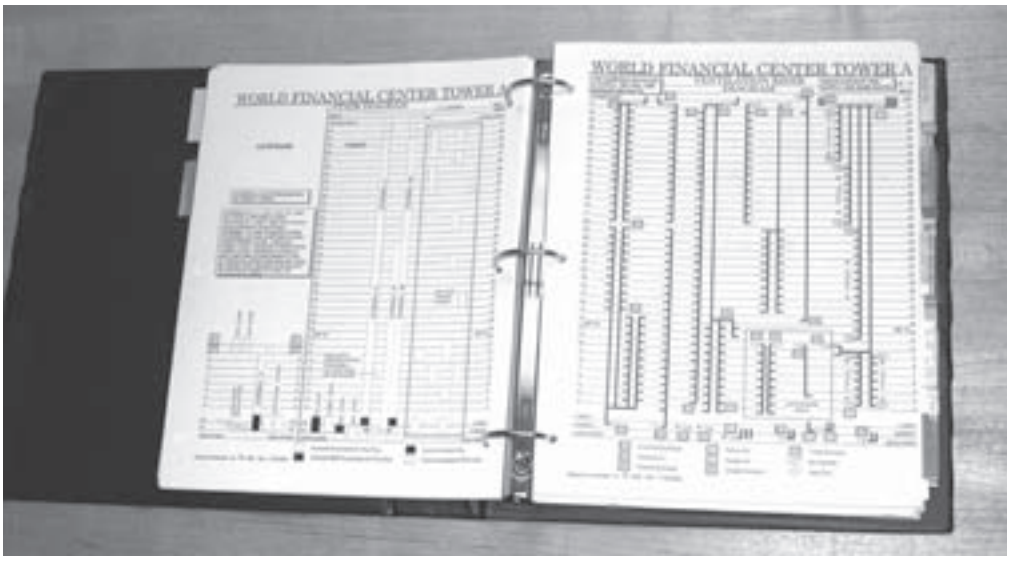

FIGURE 12.18.4 Three-Ring Binders Used to Present Pre-Incident Plan Information

and also allow use of a marker or grease pencil for writing or drawing on them.

In the past, some departments used microfiche cards to provide field commanders with a complete set of pre-incident plans for large numbers of buildings. This system was extremely cumbersome to use due to the need for multiple cards of information that had to be sorted through, as well as the need for a special microfiche reader. An additional drawback was the length of time needed to produce the microfiche cards and the expense of keeping them current.

CADS

When properly used, a computer-aided dispatching system (CADS) is by far the most effective tool for recalling PIP information. CADS surpasses the human memory and the three-ring binder as well in its ability to store and promptly retrieve information. Whereas fire personnel usually know about the most obvious and deadly hazards, other hazards may escape their initial attention. In these situations, a CADS-generated reminder could provide the crucial warning, averting what might otherwise become a fatal encounter.

Data Entry and Retrieval. PIP information should be recalled automatically whenever an alarm is transmitted from a building address that is on file. A CADS systems saves time and effort in its computer searches by only displaying hazard information when there is data on file for the address in question. Of course, any computer-generated information is only as good as the information that was entered. This means that field units must have some quick and simple method of reporting the conditions that they encounter. It also means that the information must be kept up-to-date. For this reason, any occupancy that is subject to CADS hazard display should be inspected at least annually and the information verified.

Responsibilities of Property Owners. Computers have the ability to store large quantities of complex information and display that information in detail. One difficulty is inputting all that information. In many cities, as the CADS systems have been developed or expanded, data entry issues have been resolved by requiring the property owners of certain "target hazards" such as high rise buildings, to provide the information in a standardized electronic format. Often this can be accomplished using a commonly available electronic program that architectural or engineering firms use. This reduces the amount of work required by the municipality and provides a rapid means of updating the system as new structures are erected or as major renovations occur.

Transmission of PIP Messages. Computer-generated PIP messages can be transmitted to field units by any of several means. A dispatcher can read a message to responding units as part of an alert message, highlighting the fact that there is critical information available, or the message can be displayed on a video display terminal, teletyped to each unit, or repeated over radio channels about 1 minute after the initial alarm. The recommended practice is to teletype the alert message (which gives the field unit a hard copy to refer to,) display the information on a mobile data terminal aboard the apparatus, and also broadcast the message over the radio after the units are on the road. These methods serve to present the information to anyone who may have overlooked it, as well as to verify the listing after the fire fighters have had a moment to consider it. The responders can then pull up the detailed plans for each structure and review the individual hazards they have highlighted in advance.

Data Storage. Advances in information storage and retrieval systems have made it feasible to store large amounts of data on laptop or notebook-size computers. In conjunction with wireless communications devices, access to mainframe databases is

FIGURE 12.18.5 Wireless Data Transmission for Field Access to Mainframe Capabilities

possible, placing extremely detailed pre-incident planning information at the incident commander's fingertips (Figure 12.18.5). In the near future, it will be possible for an incident commander to be in touch with multiple sites, providing real-time modeling of events such as a chemical release. Such information, in conjunction with information previously gathered and evaluated during the pre-incident planning stage, will increase the safety of all persons affected by an event. Security of such information must be considered in the age of potential terrorist threats, but this should not stop an emergency response organization from pursuing the gathering and use of as much vital information as is available.

SUMMARY

The pre-incident planning process is a critical component of an incident commander's size-up and decision making process. The failure to gather information about a hazard that could claim the life of a responder and is available beforehand borders on reckless behavior. Emergency responders owe it to themselves, their families, and their communities to avail themselves of as much information as possible about the situations they may face. The specifics of what type of information to gather for each type of structure or occupancy may vary. A military unit would never plan an operation without attempting to gain intelligence about the opposing force. Neither should our emergency responders.

The last decade has seen a significant change in the scope of mission for most fire departments in the United States and Canada, as well as many other nations around the world. It is difficult to find a fire department today that strictly deals with fire suppression. Rather, fire departments have expanded their mission to reflect the changes in society and historical events such as 9/11. Today most fire departments are involved in some level of prehospital medical care varying from first response to advanced life support transport. Some departments, such as the Phoenix Fire Department, are working with local public health providers to assist with preventive health care.

Other programs have grown significantly. Following the Oklahoma City bombing, the first attack on the World Trade Centers, and the 9/11 attacks, many departments have developed technical rescue programs to deal with events involving confined space rescue, whitewater rescue, and high-angle rescue. Also, many fire departments are becoming actively involved in disaster preparedness and response. Hurricane Katrina emphasized the need for the fire department to be an active participant in a community's preparedness for natural disasters.

These changes also extend into the area of prevention. Once a program dedicated to only preventing fires, prevention programs now address such issues as preventing childhood injuries, reducing the impact from disasters, and so on. This expansion of the prevention mission mirrors the growth of other fire department responsibilities. In short, fire departments are now active participants in reducing and mitigating many various risks in the community. This "all-risk" mission is having an impact on how fire departments do business in the new millennium. Specifically, the all-risk mission has resulted in departments utilizing a community-based comprehensive strategy to reduce the highest priority risks faced by the community.

This new all-risk approach to community risk reduction is taken from the approach successfully used by public health agencies for decades. This multifaceted approach builds on the traditional three "E"s of prevention—education, engineering, and enforcement—to include *emergency response* and *economic incentives.* The original three "E"s were first noted in President Harry Truman's 1947 Conference on Fire Prevention. The addition of the two latter "E"s specifically reflects the role of emergency response in risk reduction, something that was previously considered part of prevention. Collectively the five "E"s are known as *mitigation strategies.*

Another significant change in strategy is the active involvement of the community in identifying the risks and participating in the risk reduction process. Again, this strategy is frequently used by public health agencies, especially when working with target groups that are at high risk from illness and injury. With this change fire departments may no longer stay in the shadows and be the silent heroes. The local fire department must become actively engaged in the community, including high-risk groups and neighborhoods that are hard to reach and engage. It is important to look at each of these components of community risk reduction.

Edward Kirtley, M.A., is the International Fire Service Training Association/curriculum projects coordinator at Oklahoma State University/Fire Protection Publications. A retired fire chief, he is the former chair of NFPA 1035, Technical Committee for Professional Qualifications for Fire and Life Safety Educator.

COMPONENTS AND FUNDAMENTALS OF A COMMUNITY RISK REDUCTION INITIATIVE

Components

Two major components of a community risk reduction program are use of the five "E"s and engaging the community. The first component, using the five "E"s, is part of a comprehensive approach to reduce the chosen risks. It should be noted that there are numerous risk reduction planning processes that can be employed by a community to determine the leading risk(s) to be addressed. Many are variations of the traditional five-step planning process introduced by the U.S. Fire Administration 30 years ago. For this introduction to community risk reduction the planning process will not be discussed.

The second component of community risk reduction is engaging the community, especially the groups that are mostly likely to be negatively impacted by the risk(s). Engaging the community involves the fire department becoming active in community organizations, participating in community events, and so on. Community engagement taken one step further involves the emergency response crews and companies becoming involved in their specific neighborhoods. The goal of engaging the community is to gain the trust of those living the neighborhoods and community, and from that trust and credibility eventually gaining their support for risk reduction activities.

Both components are discussed in more detail later in this chapter.

Fundamentals

Three fundamentals of community risk reduction help to clarify how and when the five "E"s are applied to risk reduction. These fundamentals are use of a risk reduction planning process, use of the resources of multiple organizations, and use of multiple mitigation strategies.

Risk Reduction Planning. A risk reduction planning process is used to select the highest risk(s), identify the risk factors and contributing factors, and then select the mitigation strategy or strategies—that is, 5 "E"s—which have the highest probability of success with the resources available.

Resources of Multiple Organizations. The community risk reduction process must utilize the resources of multiple organizations to effectively implement the mitigation strategies. A single fire department will seldom—if ever—have adequate resources to implement the five "E"s to the level necessary to reduce risk. Rather, the department seeks out government and community partners who have resources and influence that can be consolidated into one communitywide risk reduction initiative.

Use of Multiple Mitigation Strategies. Any community risk reduction initiative is most effective when all five mitigation strategies are applied to the risk issue. Studies conducted by the United States Centers for Disease Control[1] are clear: the use of only one strategy is unlikely to result in any change in the community risk. Ideally, all five strategies will be applied. However, this is not always possible due to a lack of resources, specific risk factors, and so on. The point is that whenever possible during the planning process as many of the strategies as practical should be applied.

The importance of using several mitigation strategies is clearly demonstrated in the 2000 David and Lucile Packard Foundation report, *The Future of Children: Unintentional Injuries in Childhood.*[2] In its preface, editor Richard E. Behrman, M. D., calls on those in the field to go beyond education alone and to address preventable childhood injury through a multifaceted public health approach:

> . . . the most effective injury prevention efforts are often those that focus on public policy change, reinforced through legislation or regulations. Public policies—such as requirements that young children be restrained in car seats, that prescription medications have child-resistant caps, and that children's sleepwear be flame retardant—save the lives of thousands of children each year. Yet there are many more opportunities to reduce childhood injuries through policy change that have not been seized. Uniform statewide requirements that children and teen bicyclists wear helmets, fences that enclose swimming pools on all sides, and environmental changes that slow the speed and density of traffic in residential areas are just a few strategies that could further reduce childhood injuries if widely implemented.[2]

Dr. Behrman concludes his statement of purpose with an important caveat:

> These public policy strategies have a greater likelihood of being implemented and enforced if they are coupled with community-wide efforts to change social norms about the acceptability of safety behaviors, and adequate financial resources to ensure the availability of safety devices.

THE FIVE "E"S

The five "E"s are the mitigation strategies of education, enforcement, engineering, emergency response, and economic incentives (Figure 12.19.1). Each strategy is summarized below.

Engineering

The objective of engineering is to build safeguards into products and materials that, by their design, eliminate or reduce the risk. These engineering safeguards are built into the environments where we live and into the products we use. For example, the use of fire-resistant sheetrock in residential construction restricts and slows the spread of fire in the home. The resident does not have to take any action for the sheetrock to work. This passive nature of engineering safeguards is a key to their success. Although most fire departments do not specifically design engineering safeguards, fire prevention personnel routinely apply

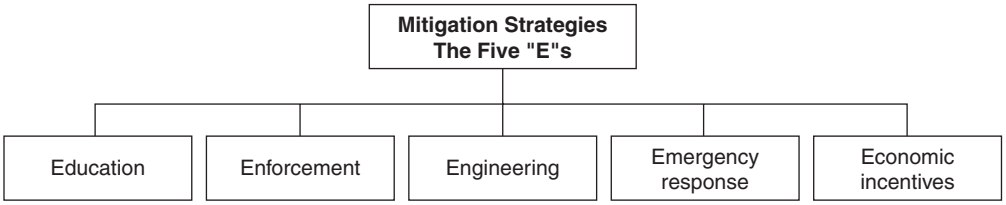

FIGURE 12.19.1 The Five "E"s as Mitigation Strategies for Community Risk Reduction

the safeguards through fire and building codes in both new and existing construction.

Education

Education is a widely used strategy by the fire service. The objective of an education strategy is to raise public awareness and understanding about fire, thereby changing high-risk personal behaviors. This change in behavior results in lowering the incidents of fire as well as reducing the injuries from fire. Public education programs such as the National Fire Protection Association's *Learn Not to Burn*®, *Risk Watch*®, and *Remembering When* have made a significant and measurable impact on reducing the fire problem. As of August 2006, NFPA had documented the following:

- 203 save incidents resulting in 558 lives saved from *Learn Not to Burn*
- 38 save incidents resulting in 71 lives saved from *Risk Watch*[3]

Because public education is so widespread and in some cases easy to implement, this strategy is perceived to be highly effective. Unfortunately, public education when used alone is the least effective of the five strategies.[4] Still, fire safety education remains a vital strategy in community risk reduction. This contribution has resulted, at least in part, in an impressive track record. Fire deaths in the United States and Canada have each fallen by roughly half in the past 25 years and fire deaths relative to population by even more. The role of education in this reduction, although believed to be important, has not been substantiated.

Education is also an important component in changes arising from engineering and enforcement mitigation strategies. North Americans made great strides in both safety technology and the safe use of technology. As of 2004, for example, 96 percent of homes in the United States had at least one smoke alarm, the highest rate of home smoke alarm usage in the world. Changes have been made in the United States and many other countries in the design of products ranging from upholstered furniture to mattresses to lighters to space heaters to manufactured homes. And the well-established systems by which model codes and standards are developed, adopted into law by reference, and enforced by national, state, and local authorities ensure that engineering achievements involving products, structures, vehicles, processes, and systems tend to move fairly rapidly into programmatic achievements at the grass-roots level.

However, much remains to be done. And with most fire departments now also responsible for providing emergency medical services to their communities, a fire department's role in prevention education has expanded to encompass a much broader range of issues.

Enforcement

The goal of the enforcement strategy is to reduce risk through the use of codes and standards. In this regard, enforcement utilizes many engineering innovations. For enforcement to be effective, the local department must have the ability to require compliance with the adopted codes and standards. This is accomplished through the use of code inspectors, building plan reviews, engine company inspections, and so on. As departments move into other risk areas compliance will require cooperation with other agencies that have similar authority.

Economic Incentives

The use of economic incentives is another strategy commonly employed along with other strategies. The goal of economic incentives is to influence personal or corporate behavior through financial incentives or disincentives. For example, when a department provides smoke alarms at no cost to home owners, economic incentive is being used. Similarly, when a developer chooses to install residential fire sprinklers in order to be able to build more houses in the same area under the building code, an economic incentive is being employed.

Emergency Response

Emergency response has always been a fire department function, but the types of emergencies to which fire fighters respond have increased. Consequently, the evolving scope of emergency response makes it the newest addition to the traditional three "E"s of engineering, education, and enforcement. Communities and risk reduction planners have realized that there are many risks that simply cannot be mitigated effectively through the other strategies. In these cases there must be an adequate emergency response capability to mitigate the problem when it occurs. For example, communities in Southern California have adopted codes and standards to minimize the risk of wildland fires. Well-designed public education programs have been delivered. Yet, wildland fires still occur and threaten hundreds of homes each season. Only a well-equipped and well-trained emergency response force can contain and control the fire to protect lives and

property. Although the other strategies contribute to mitigating the risk, ultimately fire fighters and fire apparatus are required.

ROLE OF COMMUNITY ENGAGEMENT

The second component of community risk reduction is engaging the community, especially the groups that are mostly likely to be negatively impacted by the risk(s). Engaging the community involves the fire department becoming active in community organizations, participating in community events, and so on. Community engagement taken one step further involves the emergency response crews and companies becoming involved in their specific neighborhoods. The goal of engaging the community is to gain the trust of those living in the neighborhoods and community, and from that trust and credibility eventually gaining their support for risk reduction activities.

For community engagement to have a positive impact on a community risk reduction initiative it must precede the risk reduction initiative. In addition, community engagement should be viewed by the fire department leadership and membership as an everyday approach to doing business in the community. This approach has proven to be very effective for local law enforcement agencies which use the term "community policing" to describe community engagement.

Principles of Community Engagement

The Centers for Disease Control have identified four principles of community engagement.[1] The principles should be built into any fire department effort of engaging the community. The four principles are as follows:

1. The goal of the engagement process must be clearly stated with each neighborhood or community group engaged. In other words, the public must be aware of the goal of the engagement activities. In this case the goal is to build a positive relationship and then get the groups involved in a community risk reduction process.

2. The decision makers and leaders in the fire department must be knowledgeable about the community and the groups living there. Most communities today are diverse and include groups from several ethnic and cultural backgrounds. The leaders must also understand current issues in the community such as the economy, political structures, and so forth.

3. A key foundation of community engagement is establishing a relationship of mutual trust and communication with each stakeholder group in the community. These relationships are built by both senior leaders *and* personnel at the company level who actually provide emergency and nonemergency services to the groups.

4. The senior leaders must understand, and appreciate, that each stakeholder group and neighborhood has the right to self-determination when it comes to the engagement and risk reduction processes. If a group does not want to participate in the risk reduction planning process, the group has that right. The groups also have the right to disagree or even challenge the fire department on risk reduction issues. This principle must be applied during times of conflict if a trusting relationship is to be built and maintained.

Relationships with Stakeholders from Other Cultures

Many of the groups who have a vested interest in the reduction of community risk, called stakeholder groups, will be from cultures that are different from the prevailing community culture. These groups are generally immigrants or members of a minority group. Building relationships with these groups may be the greatest challenge in engaging the community. The University of Kansas's Community Tool Box has developed the following nine recommendations for building relationships with other cultures:[5]

1. Make a conscious decision to establish friendships with people from the other cultures and stakeholder groups. This begins with a commitment by the fire chief to engage the stakeholder groups.
2. Put yourself in situations where you will meet people of other cultures. This is most easily achieved by response companies, code inspectors, and so forth, that is, those who regularly have the opportunity in the course of daily business to meet with the public.
3. Examine your biases about people from other cultures. This should begin when interactions begin.
4. Ask people questions about their cultures, customs, and views.
5. Read about other people's cultures and histories. This information is readily accessible through the Internet.
6. Listen to people tell their stories. This requires spending time with members of another culture.
7. Notice differences in communication style and values; don't assume that the majority's way is the right way.
8. Risk making mistakes. Most members of other cultures will understand and be patient.
9. Learn to be an ally. This is a key to building a trusting relationship.

NFPA Champion Model of School-Based Delivery

Another approach to engaging the community in a prevention or risk reduction initiative was developed by NFPA. Even though the model was designed specifically for a public education application, many of the principles will apply to a community risk reduction initiative. The NFPA Champion Model of School-Based Delivery has been taught as part of the NFPA Champion program since 1995. The NFPA identified several fundamental qualities that appear to correlate with long-term success in implementing public education programs. Together, they comprise the NFPA Champion Model of implementation.

The Champion Model relies on 10 components or "'C's to Success" and these qualities can be used as a checklist to assess a community's readiness to initiate, evaluate, and institutionalize a comprehensive public safety program in the school environment and the community at large. The 10 "C"s provide

a framework for success, proven to be effective in establishing and delivering messages and lessons that modify behavior, reduce injuries, and save lives. The 10 "C"s to Success are coalition, champion, careful planning, compelling case, credentials, collaboration, continuity, creativity, camaraderie, and commitment. The information described in each "C" references public education, but the same approach applies to a risk reduction initiative utilizing any or all of the 5 "E"s.

Coalition. For reasons discussed earlier, NFPA has concluded that the most effective way to reduce unintentional injuries is to work through a community coalition. That coalition should include (at a minimum) a representative from each of the following organizations: the fire department; the police department or local law enforcement agency; a health organization (hospital, health department, school nurse, or local SAFE KIDS representative); a school administrator (principal or curriculum director); and a classroom teacher from a school where the program will be implemented.

Champion. Every coalition needs to select a leader (or "Champion") who will be responsible for the coalition's efforts, from planning and implementation to evaluation and expansion of the public education project. Long-term success depends on the Champion's ability to think strategically, to motivate and coach others toward common goals, and to document and communicate program results to key decision makers, coalition members, teachers, other participants, and the public.

Careful Planning. Successful coalitions need to develop a written strategic plan outlining a clear set of written goals, measurements, and timeframes. Although each participating organization will have its own individual priorities, successful coalitions will be able to come to consensus on an achievable number of objectives toward which every member can make a contribution. The strategic plan will assign responsibility for each of the following areas: program development; training and implementation; support, promotion, and communication; strategic alliance building and fundraising; and research and evaluation. Progress needs to be documented. As the coalition develops, the plan must be updated and the leadership structure redefined.

Compelling Case. By analyzing the incidence of unintentional injuries in a community and focusing first on those neighborhoods or areas at highest risk, a Champion coalition can achieve dramatic results early in the program and use that momentum to gain support for further expansion. Start small, document the team's progress, and use concrete examples of the program's effectiveness to justify expansion. The extent to which a coalition can articulate an urgent need and define the tangible benefits of its program will largely determine the level of media attention, funding, and community involvement the program receives. To learn more about how to reach those at highest risk to fire, see Section 5, Chapter 5, "Reaching High-Risk Groups."

Credentials. A program's reputation will be determined by the quality of the materials used and the manner in which they are delivered. A coalition should select an established curriculum that has been thoroughly evaluated by independent researchers. Put professional educators in the lead role of teaching the core subject matter, since they have the necessary training and consistent access to guide student learning. Seek the participation of well-qualified, highly respected experts to serve on the coalition with the common goal of supporting the classroom teachers. Strive to enhance professional development and keep informed of new trends and innovations in the injury control field.

Collaboration. Successful public education initiatives are those that enjoy a high level of commitment from the community: the board of education, teachers, the fire department, the police department, and other agencies that have a specific mission to prevent childhood injuries. After teachers have introduced the core safety lessons to their students, local safety experts can then visit classrooms and reinforce lessons with their "real-world" perspective. NFPA suggests giving experts a copy of key lesson points to ensure consistency and accuracy of messages delivered by outside experts.

Continuity. Because people learn best through repetition and practice, the most effective way to teach injury prevention skills is through repeated, age-appropriate learning opportunities extended over a period of years. A successful program will target each age group in the program with messages they can understand. Injury risks to children change as they grow older; therefore, safety messages should become more comprehensive and complex as students mature. Also, growth brings the ability to understand and absorb more complex information and associated behaviors, and so safety messages should be tailored to a child's development, finding the right time to teach them all they will need to know throughout their lives.

Creativity. Communities are encouraged to supplement public education programs with elements (such as performance experiences) designed to address local needs. The creative use of safety trailers, clowns and puppets, coloring and comic books, and so on helps customize the program and provides an important sense of ownership. Creative reinforcement techniques can also enhance student knowledge gain and retention, so long as the information presented does not replace or conflict with the program's core messages. Educational programs delivered infrequently and with insufficient student preparation and reinforcement have not been shown to yield positive results.

Camaraderie. NFPA always makes time for fun during its public education training workshops. And the same concept can be applied in any community coalition. Sharing meals, attending planning retreats together, even playing an ice-breaker game before meetings can help build strong, trusting relationships and keep everyone on the team coming back for more.

Commitment. Successfully implementing a public education program is a major initiative for any community, regardless of its size or available resources. It requires hard work, the commitment of individuals and community organizations, and, most importantly, persistence. Although your initiative may be filled

with challenges, there will also be rewards, including knowing that fewer children are being injured and that your community is a safer place to live, work, and play.

Both engaging the community and building relationships with other cultures requires a strong commitment on the part of the department leadership to community risk reduction. Without this strong commitment from leadership most community risk reduction initiatives are doomed to failure.

ROLE OF LEADERSHIP IN COMMUNITY RISK REDUCTION

Society relies on a basic infrastructure that gives shape to the quality of life in a community. Transportation, utilities, code enforcement, school, and recreational systems are but a few examples of the diverse parts of this infrastructure that allow community residents to make individual choices in an interactive social context. Policy makers understand that weaknesses in these infrastructure systems can result in performance failures at a given point in time and everyone will get less of what they want. Plans that are developed today revolve around design and maintenance of "system" components rather than simply addressing programs and issues separately without considering the impact of decisions on overall system performance. In other words, every problem is considered in a broad systems context, and special care is taken to maintain the infrastructure components that allow systems solutions to work most effectively in a dynamic environment.

Any systems approach begins by laying out the infrastructure of organizations, technologies, incentives, laws, and internal arrangements that seek to give structure to those interactions, so that needless inefficiency and disruption is minimized. Fire departments and other fire service organizations should address community risk reduction more holistically in terms of community infrastructure and systems approaches, rather than as separate programs that may at times appear disconnected from each other.

Systems Management and Leadership Model

A community risk reduction system describes basic components required to protect life and property in a community. The components may be programs or groups or the infrastructure that allows them to work together effectively towards solutions. There is not one single program or intervention strategy that will address the many ways that people can be killed or injured and property destroyed as a result of fire, natural disasters, terrorist attacks, or other causes. Furthermore, every program strategy is affected by many groups, whether it is designed to include them or not.

A system describes the component parts of a whole and their interactions. Each piece depends on the others for overall system effectiveness. Within a fire service organization, its components of this community risk reduction system can be divided into line and staff responsibilities.

Line Services. Line services are mission-driven and include risk reduction involving public education programs, emergency response, and emergency management:

- *Prevention through consensus codes and built-in protection.* These codes for prevention and mitigation govern structures, hazardous facilities and contents, as well as built-in protection, such as automatic fire sprinklers, and so on. Code-related services also include fire investigation, inspection, and enforcement activities.
- *All-risk public education programs designed to teach people how to prevent harmful situations and to survive should a situation occur.*
- *Response to emergency incidents such as fires, medical emergencies, natural disasters, hazardous materials events, or technical rescues.* This would include nonemergency service requests answered by emergency responders and the area of emergency (disaster) management.

Staff Services. Staff services are in place to support the primary mission and are provided to *internal* customers. Too often, risk reduction has been considered a support program to the emergency response system. However, community risk reduction is a line service as its customers are *outside* the fire department. Like any service provided within the mission of the organization, community risk reduction requires adequate staff support to be successful:

- *Prepare members to perform their roles.* This includes training the people in the organization to perform in their assigned roles within all areas.
- *Management of finances and human resources.* Support for the members who actually provide the line and staff services externally and internally. This includes issues such as adequate compensation, policy direction, definitive planning, safety issues, humane treatment, and other areas related directly to making people as effective as possible.
- *Community partnerships, relationships, and politics.* This includes maintaining positive and productive relationships internally and externally, an appreciation for (and understanding of) the importance of developing effective strategic alliances, and functioning effectively in the political arena with policy makers. This is achieved through engaging the community and its stakeholder groups whenever and wherever possible by all members of the department.
- *Management of physical resources and technology.* This means building and maintaining the infrastructure and equipment necessary to be effective. This includes management of facilities, the fleet, dispatch and communications systems, and other nonhuman resources.

These represent the component parts of the community risk reduction infrastructure. The mission is delivered effectively to the extent that these are brought together and managed in a systems approach. Failure of any of the individual parts of the system can result in failure of the mission in a given situation.

Executive Level Commitment

It is almost impossible for any program to be successful without the support and commitment of the chief executive officer of the organization. Programs that function in spite of the chief struggle every day. Be it fire suppression, health and safety, labor

relations, fire prevention, media relations, fire and life safety education, EMS, training, or special operations—without the visible, active support of the chief, program results will usually be mediocre at best.

Community risk reduction programs that have full executive level support within the organization are effective, meaningful components of the service delivery system. This executive level support is demonstrated by actions such as the following:

- Representing the importance of community risk reduction inside and outside the organization
- Describing how community risk reduction integrates into the mission
- Identifying community risk reduction as a recognized program within the organizational structure
- Assigning responsibility and accountability for community risk reduction to a specific manager
- Ensuring a community risk reduction voice in decision making and planning processes
- Providing adequate personnel and other resources dedicated to community risk reduction programs
- Supporting the ongoing professional development of those involved in community risk reduction by allocating funds to attend regional and national meetings and trainings or conferences
- Including community risk reduction in strategic and operational plans, as well as budget packages
- "Opening doors" for community risk reduction staff inside the organization and within the community

Community risk reduction, like any other program, is successful in fire departments where the chief and other leaders want it to be successful and consistently act that out. It is treated and represented as a key organizational responsibility and a critical component of the community risk reduction infrastructure of a community.

SUMMARY

NFPA recommends a multifaceted, coordinated risk reduction process at the community level to address local risks. This requires engaging all segments of the community, identifying the highest priority risks, and then developing and implementing strategies designed to mitigate the risks.

Fire departments can serve a vital role in the concerted community risk reduction effort. The public safety needs of communities increasingly place fire department personnel in the role of emergency responders—first on the scene not only in a fire emergency, but in medical emergencies, natural disasters, and acts of terrorism as well. With a proven record in prevention and responding effectively to fire emergencies, fire safety advocates often have the credibility and expertise to organize their communities around broader safety and risk issues. Most fire department leaders are encouraging their members to get more involved in their communities to strengthen organizational credibility and influence. There are a variety of ways this can be accomplished, and community risk reduction is the program that provides perhaps the greatest opportunity.

SECTION 13

Organizing for Public Sector Emergency Response

Gary Tokle

13.1 Fireground Operations
13.2 Organizing Rescue Operations
13.3 Fire Streams
13.4 Alternate Water Supplies
13.5 Wildland Fire Management
13.6 Public Fire Protection and Hazmat Management
13.7 Aircraft Rescue and Fire Fighting (ARFF)
13.8 Managing the Response to Hazardous Material Incidents
13.9 Emergency Medical Services and the Fire Department

For the first time, the *Fire Protection Handbook*® includes one section that concentrates on non-emergency fire department functions (Section 12) and a second section on organizing for public sector emergency response. Section 13 on emergency response is composed of nine chapters, including new chapters on airport rescue fire fighting and on emergency medical services.

Chapter 1, "Fireground Operations," describes the role of standard operating procedures, the incident commander, the national incident management system, pre-incident planning and size-up, and offensive and defensive fire extinguishment, as well as ventilation and overhaul. Fire fighter safety and property conservation are addressed.

Chapter 2, "Organizing Rescue Operations," introduces a highly specialized fire service function. Discussion of community resource planning (CRP), confined space rescue, rescue operations, rope rescue, technical rescue, specialized technical rescue, the technical rescue team, and trench rescue are included.

Fire streams, the topic of Chapter 3, "Fire Streams," are an integral part of fire extinguishment operations. The chapter covers fire department pumpers, solid-stream and spray nozzles, hose line fire stream calculations for flow rate and friction loss, and aerial devices.

Expanded treatment of water shuttle operations is a feature of Chapter 4, "Alternate Water Supplies." The chapter presents information on determining minimum water requirements and estimating available water supply, structure and site surveys, and natural and developed sources of water. Agreements, permits, water supply vehicles, and drivers are also considered.

Chapter 5, "Wildland Fire Management," provides a brief summary of past wildland fires and establishes the characteristics of wildland fire, then discusses the ways to prevent fires in wildlands or the wildland/urban interface and mitigate their effects. "Firewise" communities, prescribed burning, and fire fighter safety are also discussed.

Chapter 6, "Public Fire Protection and Hazmat Management," defines hazardous materials and summarizes the variety of laws, regulations, and consensus standards that govern them.

Chapter 7, "Aircraft Rescue and Fire Fighting (ARFF)," is new to the *Fire Protection Handbook.* The chapter explains the tools, techniques, agents, and objectives of aircraft rescue and fire fighting. Also provided is a review of the regulations and industry standards that influence the levels of training, staffing, and equipment at airports, as well as information about typical aircraft emergencies and ARFF response procedures.

Chapter 8, "Managing the Response to Hazardous Materials Incidents," provides a focus on hazardous materials response by considering hazard classes and divisions, weapons of mass destruction (WMD), bulk packaging, damage assessment, decontamination, and elevated temperature material. Personal protective equipment for hazardous materials response is also covered.

Gary Tokle is assistant vice-president (retired) of NFPA's Public Fire Protection Division.

During the past fifty years, fire service–based delivery of emergency medical services (EMS) has grown to be the principal operational delivery program in the majority of fire departments. In recognition of the significant role of EMS in the fire service, the section closes with another new chapter, Chapter 9, "Emergency Medical Services and the Fire Department." This chapter identifies the various factors, standards, and performance measures that can be utilized by fire departments in their analysis and improvement of the emergency medical services program. A Process Performance Indicator Index is also introduced.

Chapter 1

Fireground Operations

Bernard J. Klaene ■ Russell Sanders

Chapter Contents

Standard Operating Procedures
Pre-Incident Planning
Size-Up
Incident Action Plan
Deployment and Organization
Life Safety
Extinguishment
Property Conservation

Key Terms

Beverly Hills Supper Club fire, defensive fire extinguishment, emergency action plan, fire fighter safety, incident commander (IC), national incident management system (NIMS), offensive fire extinguishment, overhaul, pre-incident planning, size-up, standard operating procedure, ventilation (fire fighting)

Combating structure fires is the reason fire departments were created, and structure fires remain one of the most formidable challenges facing modern fire departments. Structure fires are often labor-intensive, complex operations requiring a large number of people and equipment resources. Therefore, it is not surprising that the largest share of fire fighter injuries and deaths occurs on the fireground.

When fire prevention and public education efforts fail, or built-in fire protection equipment is unable to completely extinguish the fire, fire suppression by a fire department is the last line of defense for a building and its owner and occupants. In this respect, structural fire fighting today is much the same as it was 100 years ago. The primary tactic then, and now, is applying water directly to the burning fuel. However, over the past century, there have been numerous innovations to aid the modern fire fighter in conducting safe and effective fireground operations. These innovations include the following:

- Application of risk management principles to fireground operations
- Computerized pre-incident planning information
- National incident management system (NIMS)
- Improved fireground communications
- Fire fighter safety standards and regulations
- Improved and standardized personal protective clothing
- Widespread use of lightweight attack fire hose
- Large-diameter water-supply hose
- Thermal imaging devices

Successful fire departments prepare for potential fire operations prior to actual alarms. In pre-incident planning for fires within its jurisdiction, the fire department provides staffing, apparatus, and equipment based on a survey of the fire potential within the department's response area.

Training is also an important part of pre-incident preparation. Therefore, fire fighters receive extensive training on the proper use of apparatus, tools, and equipment, as well as on fireground tactics and strategy.

This chapter follows a logical methodology. It begins with a discussion of preparatory measures, followed by commentary on evaluating a specific fire situation and by the development of an incident action plan based on that evaluation or size-up. The chapter concludes with a review of the deployment and organization of fire department resources needed to safely and effectively limit the loss of life and property.

See also the following chapters in Section 12: Chapter 1, "Planning for Public Fire-Rescue Protection"; Chapter 7, "Safety, Medical, and Health Issues and Programs"; Chapter 8, "Effect of Building Construction and Fire Protection Systems on Fire Fighter Safety"; Chapter 12, "Disaster Planning and Response Services"; Chapter 17, "Pre-Incident Planning for Industrial and Municipal Emergency Response"; and Chapter 18, "Pre-Incident Planning for Emergency Response."

Bernard J. Klaene was the safety/training chief (retired) with the Cincinnati, Ohio, Fire Department.

Russell Sanders is the former chief of the Louisville, Kentucky, Fire Department. He now serves as NFPA's central regional manager, as executive secretary of the Metro Chiefs Section, and as an NFPA representative to Europe.

STANDARD OPERATING PROCEDURES

Some departments prefer very specific procedures; others allow more flexibility. In either case, it is essential that fire fighters be given instructions regarding initial activities at the fire scene. These instructions take the form of standard operating procedures or standard operating guidelines. The term *standard operating procedures* is used here to refer to either standard operating guidelines or standard operating procedures.

Standard operating procedures (SOP) address any operation that can be handled using a standard approach. Some SOPs are the same from one community to the next; others are not. For example, the tactics necessary to extinguish an automobile fire in both a large metropolitan setting and a rural setting are much the same. However, the SOPs for combating a large structure fire in an urban setting with conveniently located fire hydrants versus the same structure fire in a rural setting with a limited water supply would be very different. Furthermore, a high-rise SOP would be useless to a small rural department that does not protect high-rise buildings either within its jurisdiction or within a mutual-aid response area.

As incident situations and resources vary, so should SOPs. However, all departments should have SOPs on some common items, including the following:

- Command
- Company operations
- Water supply
- Staging
- Accountability systems
- Rapid intervention crews
- Use of protective clothing
- Operations in buildings with built-in fire suppression equipment
- Special occupancy operations

When SOPs are being written, regional planning and cooperation are important. Incident management system, accountability system, and rapid intervention crew SOPs are especially important at the scenes of large incidents, because often these incidents require more resources than a single fire department can provide. When mutual-aid operations are likely, it is important for all responding departments to use the same procedures and conduct joint training operations to ensure safe and predictable on-scene operations.

PRE-INCIDENT PLANNING

The pre-incident plan provides information for a specific building or group of buildings. Pre-incident planning is essential to successful operations in large or complex structures and in buildings that are protected with built-in fire protection systems.

The first step in pre-incident planning is to prioritize the buildings that are to be planned. Pre-incident planning is a labor-intensive activity. Few departments have the resources needed to pre-incident plan all buildings within their jurisdiction. Furthermore, rarely would there be the need to develop pre-incident plans for all buildings in a fire department's response district.

Buildings that present an extraordinary hazard to fire fighters and those with a potential for a large loss of life or property top the list of buildings that must be pre-incident planned. In addition, large commercial and industrial facilities usually require a pre-incident plan, as do structures with confusing floor plans and buildings with built-in fire protection systems. (See NFPA 1620, *Recommended Practice for Pre-Incident Planning,* Section 12, Chapter 17, "Pre-Incident Planning for Industrial and Municipal Emergency Response," and Section 12, Chapter 18, "Pre-Incident Planning for Emergency Response.")

Once information is assembled on a specific property, the incident commander (IC) must be able to quickly and easily access the information at the incident scene. Three-ring binders may be an acceptable way to handle a limited number of pre-incident plans, but computerized pre-incident plans are more easily and more quickly searched and can place more information at the IC's fingertips. Pre-incident plan information should be formatted to be user friendly and be limited to information of value to the IC.

When facing a fire at a large or complex property, the IC is placed at a great disadvantage if he or she does not have advance knowledge of the building's contents or layout. Due to the stress and distractions associated with emergency conditions, the IC should be familiar with the pre-incident plan before arriving at the incident scene. Ideally, the IC would take an active role in developing the plan and conducting training sessions using the pre-incident plan.

There are several degrees of pre-incident planning, ranging from formal pre-incident plans to a simple notation regarding hazardous conditions at a specific building. Formal pre-incident plans usually include a narrative in outline form that briefly describes important features of the property. More important, formal pre-incident plans will typically include drawings depicting features important to the IC. Formal pre-incident plan drawings for an industrial complex with several buildings will show the location of various buildings within the complex as shown in Figure 13.1.1. There will also be drawings of each individual

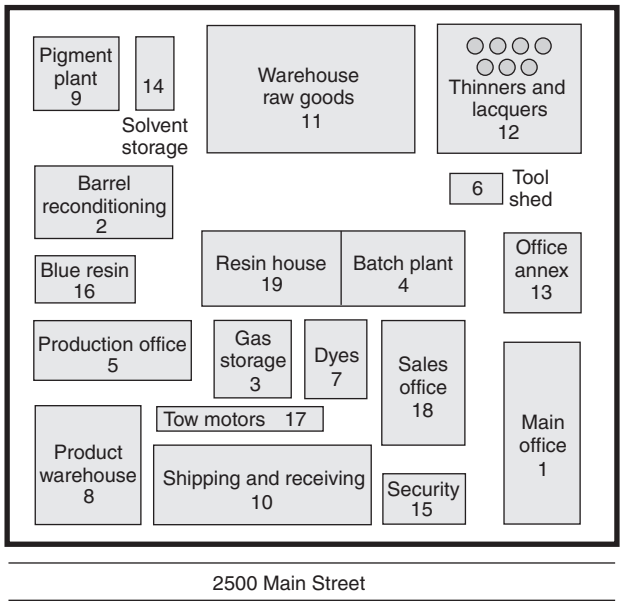

FIGURE 13.1.1 Complex Pre-Incident Plan Drawing

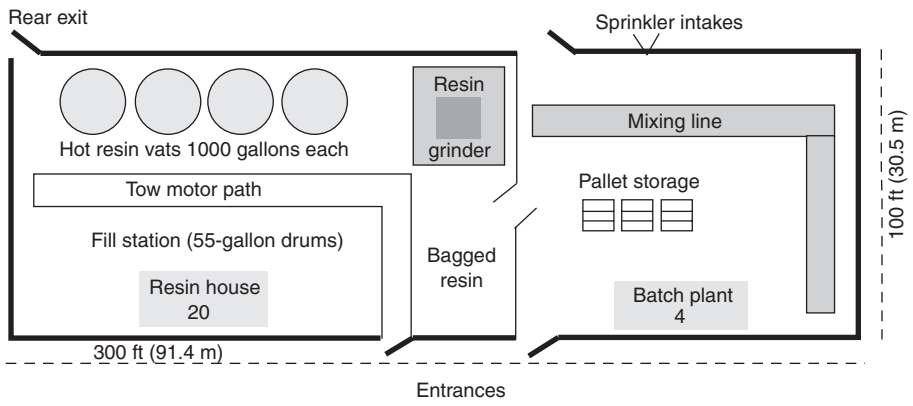

FIGURE 13.1.2 Formal Pre-Incident Plan Drawing

building as shown in Figure 13.1.2. Pre-incident plans for an apartment complex may show only the location of buildings within the property.

Fire officers should survey their response areas on a regular basis, noting hazards, such as deteriorated and vacant buildings, hazardous work locations (overhead cranes, chemicals, heavy machinery, etc.), and anything else that poses a significant safety hazard to responding fire fighters. One of the key reasons for conducting pre-incident planning surveys is to identify potentially dangerous structural conditions and related hazards. These hazardous conditions should immediately be reported and corrected, thereby eliminating hazards that could prove deadly during incident-scene operations. (See Section 12, Chapter 8, "Effect of Building Construction and Fire Protection Systems on Fire Fighter Safety.")

An analysis of the probability of extinguishment should be accomplished during pre-incident planning. Several rate-of-flow formulas are used by fire departments.[1] These formulas are useful in determining the probability of extinguishment, as well as the resources needed to extinguish a fire in large, undivided areas. Most of the rate-of-flow formulas use rudimentary mathematics, but they are very difficult to calculate at the incident scene when interior dimensions may not be known and the IC is busy developing an incident action plan and deploying and organizing fire companies. Therefore, the rate-of-flow formula for large, undivided areas (areas beyond the capability of two standard preconnected hose lines) should be calculated as part of the pre-incident plan.

Both pre-incident plans and standard operating procedures contain information that is critically important to the IC when making his or her incident-specific size-up. Therefore, the IC and all responding fire fighters should have a thorough understanding of these documents and routinely conduct training exercises to reinforce this information.

SIZE-UP

Size-up is the evaluation of factors as they exist at the time of an incident. Many of these factors can be known in advance through pre-incident planning, but some will not be known until the incident occurs.

The relative importance of size-up factors is subject to change. As an example, weather can be categorized as critically important when at the extreme or as unimportant under mild conditions. When occupants are known to be inside a burning building, life safety factors are pre-eminent. Time factors can be closely related to life safety. A high-rise office building may have thousands of occupants during normal business hours but only a few people at other times. Thus, time of day can be a critical size-up factor. Quite often structural conditions are the single most important factor in the size-up. Fire officers must understand the basic structural design elements, their weaknesses, and signs that the building is in danger of collapse. The NFPA publication *Building Construction for the Fire Service*[2] should be considered essential reading for anyone serving as an IC or safety officer at a structure fire.

The significance of size-up factors is directly related to the following operational priority list:

1. Life safety
2. Extinguishment
3. Property conservation

Additional considerations are environmental impact, heritage protection, and business/mission continuity. The size-up list in Figure 13.1.3 includes the major factors affecting size-up.

The size-up process continues throughout the incident as the IC continuously evaluates and reevaluates each critical incident factor. There is a direct correlation between the IC's size-up and the quantity and quality of information available. The more quality information that is available to the IC, the more accurate the size-up. The more accurate the size-up, the better the odds that the incident will be managed in a safe and efficient manner.

INCIDENT ACTION PLAN

The IC uses the information in the SOPs and the pre-incident plan, through the size-up process along with information gathered to develop a safe and effective incident action plan. The result should be a straightforward, easy-to-understand strategy emphasizing the IC's major tactical objectives.

Size-Up Checklist

LIFE SAFETY
- Structural stability
- Collapse zone
- Probability of extinguishment
- Building complexity and layout
- Adherence to SOPs (use of SCBA, etc.)
- Organization and coordination of the operation
- Primary and alternative egress routes
- Accountability and rapid intervention
- Smoke and fire conditions
- Occupancy type
- Evacuation status
- Estimated number of people in the building
- Occupant proximity to fire
- Mobility of occupants
- Awareness of occupants
- Occupants' familiarity with building
- Rescue options (stairs, ladders, others)
- Staffing needed to complete primary search and rescue
- Staffing needed to complete secondary search and rescue
- Medical status of occupants

EXTINGUISHMENT
- Offensive/defensive
- Automatic suppression equipment (sprinkler, deluge, other)
- Manual suppression equipment (standpipe)
- Water supply
- Pump capacity
- Rate of flow
- Fuel load of contents
- Fuel load of the structure (walls, ceilings, support members, etc.)
- Number and size of hose lines needed for extinguishment
- Additional hose lines needed
- Staffing needed for fire lines
- Internal exposures
- External exposures
- Ventilation status

PROPERTY CONSERVATION
- Salvageable property
- Location of salvageable property
- Property susceptability to water damage
- Probability of smoke damage
- Damage resulting from entry and ventilation
- Water pathways to salvageable property
- Salvage methods available
- Alternative water removal methods

STRUCTURE
- Signs of collapse
- Construction type
- Roof construction
- Previous damage
- Live and dead loads
- Water load
- Access/forcible entry
- Extension probability
- Age
- Height and area
- Location of large undivided areas
- Enclosures and fire separations
- Exit facilities

RESOURCES
- Staffing needed versus staffing available
- Additional staffing available (on call, on duty, or mutual aid)
- Staffing available in staging
- Apparatus needed versus apparatus on scene
- Additional apparatus available (department or mutual aid)
- Additional apparatus available in staging
- Water supply needed versus water supply available
- Special resource needs

TIME
- Time of day
- Day of week
- Time of year
- Special (e.g., holiday season)

WEATHER
- Temperature
- Humidity
- Precipitation
- Winds

FIGURE 13.1.3 Size-Up Checklist

Like size-up, the incident action plan is a dynamic process. The IC revises the incident action plan as information gathered through size-up reflects the changing conditions at the incident scene. In developing and revising the incident action plan, the IC compares the fire fighters' risk exposure to potential outcomes (risk-benefit analysis). In structural fire fighting the offensive-defensive decision is often the most critical factor in the risk-benefit analysis and is, therefore, the foundation on which the incident action plan is developed.

The offensive-defensive decision is subject to change based on the IC's ongoing size-up, specifically the risk-benefit analysis. Occupants or fire fighters exposed to extreme risk may warrant placing additional fire fighters at risk. However, once savable occupants and/or fire fighters are evacuated from the building, the benefit side of the risk-benefit analysis is reduced, as is the level of acceptable risk. NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program,* provides the basis of this risk-benefit analysis, stating:

- Activities that present a significant risk to the safety of members shall be limited to situations where there is a potential to save endangered lives.
- Activities that are routinely employed to protect property shall be recognized as inherent risks to the safety of members, and action shall be taken to reduce or avoid these risks.
- No risk to the safety of members shall be acceptable when there is no possibility to save lives or property.
- In situations where the risk to fire department members is excessive, activities shall be limited to defensive operations.

DEPLOYMENT AND ORGANIZATION

With the incident action plan in place, fire-fighting crews and support resources are deployed to accomplish the tactical objectives identified in the incident action plan. As needed, the IC assigns the necessary subordinate sections, branches, divisions, groups, strike teams, and task forces to reduce the span of control and create an effective incident management organization. The IC coordinates, organizes, and manages the overall operation, being careful to avoid dangerous tactics, such as combining offensive and defensive attacks.

Assigning company-level operations should be included in the fire department's SOPs. Fire-fighting task assignments are usually divided into two categories: (1) tasks typically performed by an engine company crew and (2) tasks typically performed by a truck company crew.

Simply put, engine company work involves extinguishing the fire. Members assigned to truck company duties assist engine companies in gaining entry, laddering the building, controlling the spread of fire through ventilation, and evacuating occupants. This assignment of tasks into two basic categories does not mean that an engine company crew could not be assigned to a truck company task, such as search and rescue, or that a truck company crew could not be assigned tasks directly related to extinguishment. However, dividing company-level operations into these two general roles simplifies the deployment of forces and contributes to safe and efficient incident-scene operations. Even departments that do not have an aerial apparatus should divide operating crew assignments into these general types of tasks.

As long as the apparatus carries the right tools and the fire fighters receive proper training, it doesn't matter what type of apparatus delivers the fire fighters and equipment to the scene. What does matter is that both the traditional truck and engine company duties are accomplished in a coordinated manner by properly equipped, well-trained fire fighters.

LIFE SAFETY

The fire fighter's life is valued as being as important as any other human life, and the fire fighter is the most valued resource of any fire department. Measures taken to reduce the risk posed to fire fighters are essential and critical components of the life safety priority. NFPA 1500 identifies many provisions to improve fire fighter safety at the incident scene. (See Section 12, Chapter 7, "Safety, Medical, and Health Issues and Programs.")

NFPA *101®*, *Life Safety Code®*, requires minimum egress facilities for occupants of a building. In many cases, the occupants of a building will use these egress facilities to evacuate on their own, once they realize there is a need to escape. When possible, using the building's normal egress facilities to evacuate is preferred. The design features of the building's egress system, with the exception of elevators, are typically the safest way to exit a burning building and sometimes provide places of safe refuge within the structure. If stairways have not been compromised, they offer the easiest and safest egress routes from the upper floors of a building. Other evacuation methods are available to the fire department, but these tend to be more staff intensive and hazardous.

Rescue and evacuation via interior stairs, fire escapes, aerial apparatus, and ground ladders are common rescue methods used by fire departments. Elevators, scaling ladders, ropes, helicopters, life nets, and air bags are atypical rescue methods and often expose the rescuer and the victim to extraordinary danger.

In terms of search and rescue operations, large, complex buildings present a greater challenge for the IC and increase the risk to fire fighters. Buildings with flexible floor plans or with multiple additions often result in a mazelike configuration that results in confusing paths to egress routes. The tragic fire at the Beverly Hills Supper Club is an example of this problem (Figure 13.1.4).

To protect occupants, the IC must have sufficient staffing to extinguish (or at least contain) the fire, assign adequate personnel to search and rescue operations, and treat and transport the injured while preventing re-entry. The staffing needed to meet the requirements of the life safety priority will depend on several factors, such as the following:

- Number of occupants at risk
- Rescue method(s) used (e.g., stairway, fire escape, aerial apparatus, portable ladder, life line/rope)
- Condition of the occupants at risk
- Fire size and intensity
- Smoke conditions
- Weather conditions
- Accessibility (need to force entry)

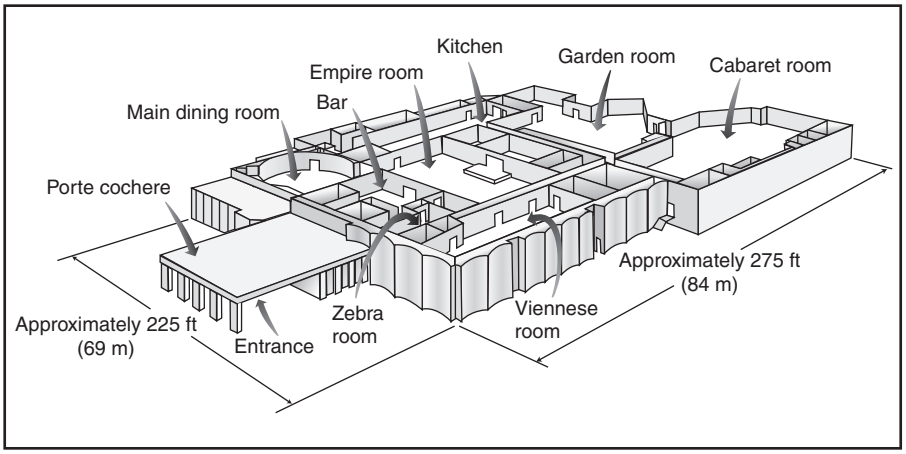
EXTINGUISHMENT

Offensive Fire Extinguishment

There are two general types of operations at a structure fire: offensive and defensive. During offensive operations fire fighters enter the burning building and conduct interior life safety, extinguishment, and property conservation duties. Offensive operations are preferred whenever they can be conducted safely and effectively. Even though extinguishment is the second incident priority, offensive extinguishment is often the most important life safety tactic.

Manually extinguishing a fire on the interior of a building is an arduous task. The objective of the offensive fire attack is to apply a sufficient quantity of water directly on the burning

(a)



(b)

FIGURE 13.1.4 (a) Mazelike Floor Plan of the Beverly Hills Supper Club, Southgate, Kentucky; (b) Beverly Hills Supper Club Fire, 1977

fuel to achieve extinguishment. Once fire fighters determine the location of the fire, the essential question to be answered is how many gallons per minute (gpm) (liters per minute [L/min]) are required to extinguish a given fire with properly placed hose lines. Calculating the rate of flow allows the IC to match the number and size of fire hose lines to the waterflow necessary to extinguish the fire.

Calculating Rate of Flow. Some ICs prefer to use trial-and-error methods in determining the rate of flow. Using a trial-and-error method, the IC continues to add hose lines until the fire is knocked down or extinguished. The problem with trial-and-error methods is that fire fighters generally start with the department's standard preconnected hose line and simply continue adding more hose lines of the same type and size, when larger-diameter hose is actually needed.

There are three basic calculation methods used to determine the rate of flow:

$$\text{Royer/Nelson: } \frac{\text{Volume in ft}^3}{100} = \text{gpm} \qquad \frac{\text{Volume in m}^3}{0.748} = \text{L/min}$$

$$\text{U.S. National Fire Academy: } \frac{\text{Area in ft}^2}{3} = \text{gpm} \qquad \frac{\text{Area in m}^2}{0.074} = \text{L/min}$$

Sprinkler calculations: Flow based on fire load

Most practitioners agree that there is a minimum flow requirement needed to extinguish a given fire, and that rate-of-

flow calculations are useful. However, there is disagreement as to which of the calculations is best. Each of these formulas are useful, but each also has limitations. Some rate-of-flow calculations are entirely empirical in nature; others are based on a considerable body of research and testing. Even the calculations based on research and testing are inaccurate under certain conditions because of the assumptions made and/or research conditions. Thus, rate-of-flow formulas are used to develop a rough approximation of the gpm (L/min) needed to extinguish a fire in a specific compartment.

The rate-of-flow calculations shown on page 13-8 are designed to calculate the required flow for offensive fire attacks within enclosed areas. When using rate-of-flow calculations, the IC's objective is to meet or exceed the calculated flow requirements by assigning the appropriate hose, nozzles, and water supply necessary to deliver, at a minimum, the total flow requirements. To properly calculate the rate of flow, the compartment size or fire area must be determined. Often this is extremely difficult at the incident scene. Therefore, as a practical matter, it is much better to determine the required flow during pre-incident planning and include this information in the pre-incident plan. Likewise, all department members should know the flow rates of the nozzles and hose combinations used by their department.

Protecting Properties with Fire Protection Systems. When fire protection systems protect the structure, the offensive attack takes on an entirely different character. A properly operating and maintained fire suppression system means that manual fire fighting will most likely be limited to supporting the building's suppression system and letting the system do the job it is intended to do. Efforts should be directed toward maintaining the system in a fully operational status and providing backup hose lines to complete extinguishment. Departments protecting properties with fire protection systems should have SOPs addressing operations in these buildings. Pre-incident planning is essential for any building protected by an automatic fire suppression system, as improper tactics could diminish the effectiveness of the building's built-in fire protection systems.

Protecting Properties with Standpipe Systems. Standpipe systems are not automatic fire suppression systems because they require human intervention. However, a standpipe system is an extremely valuable tool when conducting an offensive attack. In fact, in high-rise structures it may be impossible to conduct an effective interior operation on upper stories without a standpipe system. Fire departments should have standpipe SOPs in place and should have prepared pre-incident plans for these buildings. Departments protecting buildings with standpipe systems will normally have standpipe equipment available based on the needs identified within their response area.

An important part of the pre-incident planning process involves determining the flow capacity of fire pumps and the pressures available at various levels throughout the building. If the standpipe is a low-pressure system equipped with pressure-reducing valves or reducing adapters, provisions should be taken to either increase the pressure available at the standpipe outlet or provide hose and nozzles capable of providing an adequate flow at low pressures.

Defensive Fire Extinguishment

A defensive or nonattack strategy is used whenever the risk-benefit analysis reveals that the risk to fire fighters outweighs any possible benefit that might be achieved by conducting an offensive attack. Fighting a fire in a building that is unstable and where there are no lives to be saved is a clear example of the risk to fire fighters outweighing the possible benefits, thus justifying a defensive strategy. However, it is not always that clear-cut, as the IC will often have inadequate information or conflicting reports. The IC's training and experience are key factors in selecting the proper attack (or nonattack) mode.

Defensive attacks are almost always exterior operations and are generally conducted in the following situations:

- A risk-benefit analysis indicates that risk is too great in terms of what can be saved.
- Building's structural integrity or fire conditions prohibit entry.
- Resources needed for an offensive attack are greater than resource capabilities.

When a fire threatens the structural integrity of a building, fire fighters and apparatus should be moved outside the collapse zone. Given the uncertainties associated with how a building will collapse, the collapse zone should be equal to the height of the building plus an allowance for debris to scatter. The inability to apply water from a distance equal to the height of a building may lead to a nonattack decision for tall buildings in danger of collapse.

When evaluating an external exposure, operational priorities remain the same: (1) life safety, (2) extinguishment, and (3) property conservation. With these operational priorities in mind the IC must recognize a total loss when they are confronted with one. During a defensive attack, the building of origin is sometimes written off in favor of saving nearby property.

A question arises during a defensive attack as to whether it is better to apply water directly to the burning building or onto external exposures. Applying hose streams directly into the burning structure is an exposure protection tactic that has merit, but the intensity and depth of the fire may be such that it is impossible to significantly reduce the volume of fire in this manner. If a large volume of fire cannot be contained, and other structures are in close proximity to the fire building, it is best to apply water to the outside of the exposed buildings. Radiant heat will travel through transparent substances such as water. Therefore, directing a stream of water between the buildings is less effective than applying water directly to the exposed buildings. Furthermore, the distance between the exposed structures and the volume and location of the fire have much to do with prioritizing exposure protection. Wind direction and speed also play a role in this decision.

For the majority of defensive fire attack operations, master streams are the streams of choice. The IC should be aware that, if improperly placed, these very powerful streams could push the main body of fire toward areas that are not yet exposed, including into nearby buildings. Once master streams are in position, on-scene personnel must be controlled. Rarely are there too many fire fighters on the scene of an offensive operation.

However, when an unsuccessful offensive operation is discontinued and a defensive operation initiated, it is common to have more fire fighters than needed on the scene. Therefore, it is imperative for the IC to maintain strict control and accountability of on-scene personnel. Personnel inside the fire zone should be kept to a minimum, and offensive attack lines that are no longer needed should be disconnected. These and similar actions will reduce the temptation for fire fighters to freelance and attempt unsafe tactics.

PROPERTY CONSERVATION

Property conservation tactics can substantially reduce property loss. Property conservation is the last priority on the operational priority list; being the last priority should not be misconstrued, however, as being unimportant. Given the fact that fire departments are expected to save both lives and property, property conservation measures are an important part of the incident operation.

Life safety and extinguishment activities are assigned first, with property conservation being delayed until staffing is sufficient to address all life safety and extinguishment tasks. However, personnel should be assigned to specific property conservation duties, such as covering or removing exposed furniture as soon as possible. Also, it is important to remember that when life safety and extinguishment activities are performed properly, property damage is kept to a minimum. For instance, attacking the seat of the fire with the proper size and type of attack line—one that flows at or above the rate of flow—will quickly extinguish the fire and result in less water damage. Likewise, proper ventilation will direct smoke and heat away from the unexposed structure and contents. Once staffing permits, the IC should simultaneously attend to all three operational priorities during offensive fire attacks.

Overhaul

The purpose of overhaul is to ensure that the fire is completely extinguished. When sizing up the building prior to initiating overhaul operations, the IC must determine if the fire has severely damaged the building's structural components. If not, it should be safe to allow fire fighters to enter the building and complete overhaul duties. In some cases, where there is only minor damage to the structure and/or contents, it might be safe to allow the building's occupants to reenter.

To keep property damage to a minimum and to ensure that the fire is completely extinguished, overhaul must be accomplished in a well-planned, systematic manner. Walls, ceilings, and other structural components are checked and, if necessary, opened during overhaul. Opening concealed areas will release smoky, toxic, and smoldering materials into the work area. Ceilings, walls, and floors may contain asbestos or other harmful materials. Therefore, fire fighters and fire investigators operating inside a building during overhaul operations must be in full protective gear, including self-contained breathing apparatus (SCBA), until the building is completely free of smoke and airborne contaminants.

Ventilation

Ventilation is one of the IC's most important tactical considerations. In the past a tactic known as indirect application was popular. The indirect application method involves the application of a finely divided stream of water into an unventilated enclosure to gain maximum heat absorption from the water by converting it to steam. This tactic presents a hazard to occupants who have not escaped the building as it disrupts the heat balance making it much hotter at the floor level, and produces large quantities of steam within the enclosure.

Modern tactics call for a direct fire attack, coordinated with natural or mechanical ventilation. The direct attack involves applying water directly on the burning fuel. While the extinguishment crew applies water on the seat of the fire, a second crew ventilates the building to relieve the structure of heat and toxic products of combustion.

Proper ventilation can have a positive effect on all three operational priorities (life safety, extinguishment, and property conservation). Conversely, improper ventilation can adversely affect all three operational priorities and place both victims and rescuers in grave danger. The effects of proper and improper ventilation on the operational priorities are shown in Figure 13.1.5.

	Proper Ventilation	*Improper Ventilation*
Life Safety	• Pulls fire away from trapped occupants or their means of egress	• Draws fire toward victims or can extend fire through their exit path
Extinguishment	• Limits fire spread by channeling fire toward nearby openings and allows fire fighters to safely attack the fire	• Spreads the fire into previously undamaged areas • Can cause a backdraft or let the fire gain headway while lines are being advanced
Salvage	• Limits smoke, heat, and water damage by allowing an interior attack and removing the products of combustion, which are often the primary cause of damage	• Causes excessive and unnecessary damage • Does not relieve the damaging products of combustion but rather spreads them throughout the building

FIGURE 13.1.5 Effects of Proper and Improper Ventilation

SUMMARY

Pre-incident planning and standard operating procedures (SOPs) are essential elements of successful fireground operations. Pre-incident planning is particularly important in large and complex structures. Advance knowledge of some of the factors leading to strategic decisions before an incident occurs will reduce the information processing needs of the IC in the crucial early moments of an operation. Predesignating initial fireground operations using SOPs allows the IC to process information while a predictable course of action is taking place.

Next the IC develops an incident action plan based on an initial size-up and deploys forces to carry out the strategic objectives. The incident management system then provides the means to organize and manage the on-scene operation. The goal of this process is to fully utilize available resources in a safe, effective, and efficient manner.

This chapter is intended to provide a cursory overview of fireground operations. A complete discussion of this topic is beyond the scope and space limitations of this handbook. For a more detailed study of this and related topics, see the Bibliography.

Chapter 2

Organizing Rescue Operations

Richard Wright

Chapter Contents

Specialized Technical Rescue
Community Resource Planning (CRP)
Development of a CRP Database
CRP Agreements
Information Maintenance
Conceptualization and Planning Process
Technical Rescue Teams and Program Examples

Key Terms

community resource planning (CRP), confined space rescue, rescue operations, rope rescue, specialized technical rescue, technical rescue, technical rescue team, trench rescue

The term *rescue* literally means to remove from confinement or danger. Rescue operations constitute a significant part of the functions typically performed by emergency response organizations worldwide. Although some of the more "typical" rescue operations, such as rescuing someone from a burning building, are regarded by some as commonplace, emergency response agencies must be prepared for the more complex situations that require highly specialized training, techniques, and equipment. The complexity of rescue responses can vary greatly with the incident and may prove to be overwhelming to an unprepared response agency. Typically, the training and experience of these responding agencies will be the principal factors in a safe and successful outcome of a rescue operation.

See also Section 12, Chapter 1, "Planning for Public Fire-Rescue Protection"; and Section 13, Chapter 1, "Fireground Operations."

SPECIALIZED TECHNICAL RESCUE

Rescuer Safety

Whatever the circumstances surrounding an incident, perhaps the most important consideration is the preservation and safety of the rescue personnel. An appropriate motto for rescue personnel should be, "Don't become a victim." This advice is especially significant when we consider the number of well-intentioned rescuers who, while attempting to save someone else's life, have lost their own lives due to a total disregard for personal safety. Unfortunately, these heroic individual efforts will often thwart an otherwise effective team effort by adding yet another victim to an already difficult situation. Response organizations should establish a systems safety approach to all rescue operations in order to limit the risk to rescuers while maintaining a viable and effective response and operational capability. *Systems safety approach* may be defined as a definitive system within the scope of technical rescue operations, whereby all rescue equipment, procedures, and operating personnel are continually analyzed in accordance with an established set of safety guidelines to reduce the potential for system or operational failure. The analysis may include both visual and tactile checks of rescue systems and system components as well as confirmations of readiness for those responsible for operating them.

Typical Versus Specialized Technical Rescue

There are several forms of rescue in the world of emergency response. Some of those considered more "typical" may include interior search and rescue within the scope of fireground operations and extrication of entrapped occupants from automobiles involved in motor vehicle crashes. The term *typical* denotes an event that is common. Although each situation is slightly different, this

Richard Wright, president of Wright Rescue Solutions, Inc., based in Panama City, Florida, is a nationally recognized specialist in confined space and industrial/urban rope rescue applications. He is actively involved in national standards and training development and serves as principal member on both NFPA 1670 and 1006 committees.

regular occurrence allows the task to become somewhat routine. The emergency response organization generally finds it easier to maintain a desired level of competency with these types of rescue operations because they perform them so frequently.

Contrasted with the everyday rescue situations are those that require rescuers to have specialized training and techniques far above the norm in order to handle the emergency situations appropriately and without additional incident. These rescue operations may be seldom used but are vital when needed. Because of their infrequency of use, they may also pose the greatest risk to response agencies due to the potential for errors in judgment or inefficiencies in the level of skill associated with less familiar territory.

Until a few years ago, very little had been done to identify the most common of these situations and to determine the qualifications necessary for agencies performing these operations. However, the National Fire Protection Association (NFPA) has sought to address these concerns through the establishment and continuing development of two standards: NFPA 1670, *Standard on Operations and Training for Technical Search and Rescue Incidents,* and NFPA 1006, *Standard for Rescue Technician Professional Qualifications.*

NFPA 1670, *Standard on Operations and Training for Technical Search and Rescue Incidents*

NFPA 1670 focuses on *organizations* that wish to achieve a certain level of competency in one of several different technical rescue disciplines. This standard does not address the qualifications for individuals but rather establishes the level of operational capability needed for organizations wishing to perform technical rescue.

Forms of Technical Rescue. Although more disciplines may be added as the document evolves, there are currently seven different forms, or disciplines, of technical rescue identified within this standard, with plans to add additional disciplines in the next revision. The seven forms are as follows:

1. *Structural collapse rescue.* The location and removal of victims from collapsed buildings or other structures
2. *Rope rescue.* The use of rope and associated equipment to raise, lower, access, or otherwise move victims and rescuers in a specific environment; the methods used will vary based on the response area of the authority having jurisdiction
3. *Confined space rescue.* The removal of persons ill or injured within enclosed structures having specific characteristics, including all of the following:
   - Having limited access and egress
   - Able to be bodily entered (a person can get his or her entire body into the space)
   - Not intended for continuous human occupancy
   - Having one or more serious life or safety hazards or, in some cases, merely the potential to contain these hazards
4. *Vehicle and machinery rescue.* The extrication of persons entrapped in various transportation conveyances as well as fixed machinery
5. *Water rescue.* The rescue of persons in one or more of the following four water-related disciplines:
   - Dive
   - Ice
   - Surf
   - Swift water
6. *Wilderness search and rescue.* The location and removal of persons trapped or stranded within a wilderness environment
7. *Trench and excavation rescue.* The location and removal of persons from collapsed trenches or other excavations (Figure 13.2.1)

Note that most of the disciplines classify rescue operations within a specific environment; others (e.g., rope rescue) deal with techniques that are commonly used in almost every environment. Regardless of the discipline, each chapter identifies certain capabilities that must be developed by an organization in order to achieve one of three levels of technical ability: awareness level, operations level, or technician level. Through a hazard analysis and risk assessment, the authority having jurisdiction determines which of the technical rescue disciplines to acquire and the associated level of capability needed.

These requirements, along with those for incident response planning, operational and personal protective equipment, and safety, are all covered within the scope of the chapter on general requirements and are applicable to the responding organization regardless of the technical rescue discipline or disciplines and associated capability they decide to develop.

Levels of Capability. The following is a paraphrased synopsis of the general scope of each of the three levels of capability stated within NFPA 1670.

Awareness: Awareness-level organizations should be capable of recognizing and avoiding the hazard. Intervention is minimal, although allowed in certain circumstances (e.g., external retrieval of a person in a full-body harness that is attached to

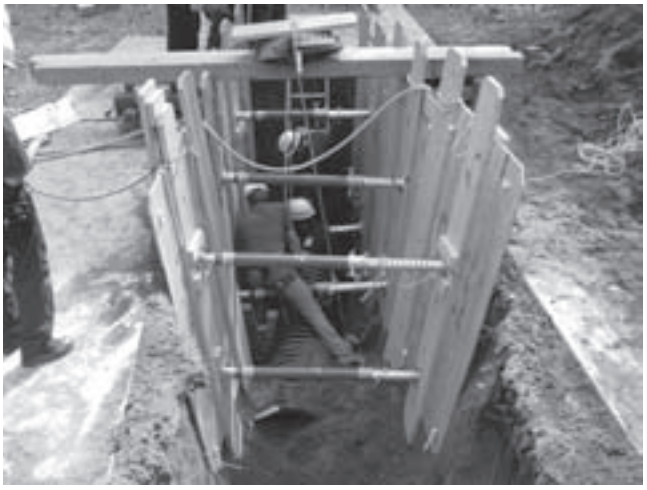

FIGURE 13.2.1 Trench Rescue (Photo courtesy of Wright Rescue Solutions, Inc.)

a mechanical winch device). One of the primary responsibilities of an awareness-level organization is to isolate the scene and call for appropriate qualified assistance to handle the situation.

Operations: Operations-level organizations are able to perform certain simpler rescues and are required to have all of the capabilities necessary for the awareness-level agency with additional skills and abilities as listed within that technical rescue discipline. The organization's ability to intervene is greatly enhanced, although the organization must still plan for the deployment and utilization of appropriate specialized assistance.

Technician: Technician-level organizations have determined that they will achieve the highest level of capability afforded by the standard in a particular technical rescue discipline. Although this is the highest level of capability, having this listed capability is not an assurance that the organization is able to handle every situation. There are obviously incidents so complex that even technician-level capabilities may not prepare the organization to mitigate the hazards without specialized assistance.

At each of the levels of capability, a successful technical rescue operation depends on assessing the need for, planning, and acquiring the necessary special equipment and services. Organizations should also note that many of the technical rescue disciplines cited in the standard require certain levels of compliance with other related disciplines. For instance, confined space rescue at the operations level requires both operations-level rope rescue and operations-level trench and excavation rescue, due to the close association of these three technical rescue disciplines.

NFPA 1006, *Standard for Rescue Technician Professional Qualifications*

In contrast to NFPA 1670, NFPA 1006 is directed toward assuring proficiency in *individual* rescue team members. Like NFPA 1670, this standard contains many of the same technical rescue disciplines, but there is currently only one level of capability—the technician level. Rescuers wishing to be compliant with this standard must complete a number of job performance requirements (JPRs) to achieve the status of "rescue technician." The standard utilizes a "core plus one" philosophy—that is, a person who wishes to become a specific type of rescue technician must complete a group of core JPRs that are common to all technical rescue disciplines plus the specific JPRs listed within the chapter for that particular technical rescue discipline. These core requirements are listed in Chapter 3 of the standard and involve four different areas:

1. *Site operations.* The activities to be undertaken at a specific site to manage the rescue incident
2. *Victim management.* The manner of treatment given to those requiring rescue assistance
3. *Maintenance, inspection, cleaning and repair of protective equipment, clothing, and tools*
4. *Ropes/rigging*

Although additional disciplines will be added to future editions, the rescue technician disciplines listed within the current version of NFPA 1006 are as follows:

- Structural collapse rescue
- Rope rescue
- Confined space rescue
- Vehicle and machinery rescue
- Surface water rescue
- Trench rescue

Although the core requirements are common to all of the specific rescue disciplines listed, a person cannot become a generic "rescue technician." Instead, he or she must become a technician specific to one or more rescue disciplines. Most of the technical rescue disciplines correspond to those listed in NFPA 1670. The greatest difference between the two standards is that NFPA 1006 applies to *individuals* and NFPA 1670 applies to *organizations.*

It is interesting to note that, at the time of this writing, the technical committee for NFPA 1006 is proposing significant changes to the structure of the document. In future editions, there may be sections for "Operations" and "Technician" levels for individuals within certain or all disciplines. To a degree, these individual qualifications would correspond with NFPA 1670's organizational requirements. If such changes are implemented, the name of the standard will be modified to a more appropriate title that will address professional qualifications for "technical rescuer" rather than "rescue technicians."

Technical Rescue Operations: The Bigger Picture

NFPA 1006 and 1670 deal with a variety of specific technical rescue disciplines, but many other types of specialized situations occur that require extraordinary expertise not commonly available in most communities. The following is a listing of some, but not all, specialized forms of rescue not addressed within NFPA 1670 and NFPA 1006:

- Urban search and rescue
- Hazardous materials (hazmat) rescue operations
- High-rise rescue
- Helicopter rescue
- Tunnel rescue
- Heavy rescue applicable to air, rail, and maritime
- Large-scale disaster response rescue (of both the natural and human variety)

The need for specialized rescue teams is typically based on a thorough analysis of community risk, which should typically include a review of both present conditions and past situations. Through this analysis, an acceptable level of risk may be determined. What is considered "acceptable" must be identified and balanced with the capabilities of the emergency response organization and the availability of additional specialized assistance. Armed with this information, the response community may take action to become better prepared for those rare but potentially devastating incidents.

The effectiveness of the preparation is based on the degree of awareness, knowledge, training, resources, and planning that has been achieved. Simply identifying the risk and actions necessary to address future incidents is not adequate preparation. Only through structured implementation of the action plan will the response organization be ready and capable of handling the specialized rescue operation.

The development of an effective technical rescue capability requires a thorough understanding of and commitment to every facet of need. The obvious necessities include appropriate training, personnel, and equipment required to safely mitigate the hazards and accomplish the rescue goals. In addition, a high degree of commitment (from all organizational levels, including both motivational and financial support for these programs), good logistical planning, and a thorough investigation into the legal ramifications are necessary to achieve a successful rescue operation. Based on the assessed risk, the cost of the support mechanism may be sizable in terms of money and time. It may very well add up to more than the average response organization can come up with by itself.

The development of specialized technical rescue teams will continue to be a major influencing factor in the national emergency service community. The need for the specialist versus the generalist approach toward operations will drive the development of this unique delivery system. The emergency service community must maintain both proficiency in the delivery of its services and the safety of the personnel who perform those various responsibilities. Identification of and planning for specialized rescue situations enhance incident response capability. The successful outcome of special rescue incidents relies on skills, training, planning, and deployment of adequately prepared and outfitted personnel and resources.

COMMUNITY RESOURCE PLANNING (CRP)

Common technical rescue incidents can often provide significant challenges that border on the overwhelming for smaller organizations. However, even the largest of emergency response agencies can be taxed by the demands of those rescues when associated with large-scale disasters. Despite the effective placement of an incident management system, the planning and logistical demands placed on incident managers, coupled with the requirements for meeting tactical deployment requests, can impede or impair the most efficient of organizations or departments. Because of the potential complexities associated with certain rescue situations and the variety of conditions and parameters that may be present at site-specific or large-scale disaster incidents, outside resources from other agencies and jurisdictions may have to be solicited, and then allocated and deployed when acquired, to enhance and support operational incident requirements.

The need for comprehensive community risk assessment has been well demonstrated and is considered a necessary first step in planning for the complexities of technical rescue. One component of community risk assessment planning focuses on the development of a database of outside resources that could be used to facilitate strategic and tactical objectives.

Through community resource planning (CRP) an agency or jurisdiction can identify internal deficiencies and provide a system for outside resource allocation so the agency's ability to respond to and operate at rescue incidents is augmented and so on-scene incident commanders will have the necessary resources. As with any incident response, the successful intervention, operation, and termination of the incident are directly related to the availability and deployment of resources, coupled with the effectiveness of the tactical assignment of these resources, the incident objectives, and the time management parameters.

A community resource plan delineates the resources needed for various anticipated rescue incidents and, thus, decreases the time required to identify, locate, and request the necessary resources. CRP is not a new concept within the fire and emergency service delivery system. Identifying and using mutual-aid agencies to augment daily fire, rescue, and emergency medical service (EMS) alarm assignments is commonplace in many jurisdictions. Supplementing local personnel and equipment with mutual-aid agency resources allows the receiving agency to deploy adequate resources at a given incident and increases its ability to mitigate the incident conditions.

The size, organizational structure, internal capabilities and resources, operating environment, and technical rescue capabilities of the department, along with the identified community risk hazards, will govern the development of the community resource plan. The magnitude, severity, and frequency of incidents will also dictate the methodology of the planning process.

The method used to identify and formulate the various resources and develop the community resource directory (CRD) is unique to each agency's community resource plan. The CRP and CRD augment the jurisdiction's capabilities during rescue operations and provide the framework and operating structure to build effective, safe, and timely rescue operations. The community resource plan establishes contacts; identifies procedures; and initiates agreements with local, jurisdictional, regional, and/or state and national entities for the procurement of identified resources. Through careful and thorough research and planning, a useful database can be developed that includes procurement procedures and memoranda of agreement.

DEVELOPMENT OF A CRP DATABASE

There are four basic functional areas that can be generally associated with the categories of resource planning for rescue response. These include but are not limited to (1) equipment, (2) supplies, (3) services, and (4) technical support.

Since the CRP and CRD are established and defined by the agency's or department's limitations or deficiencies, they are also directly related to the risk potential to which the community and jurisdiction are susceptible. The agency's current operational capabilities and its existing mutual-aid agreements and assignments are factored in with the community risk profile and analysis in order to determine the agency's limitations and deficiencies.

The resulting information forms the foundation for the research and development of an external resources database. The following lists provide an overview of items that could be included in the database. These lists are not all-inclusive.

Equipment

- Aerial lifts
- Air tools

- Backhoes
- Bulldozers
- Cellular phone companies
- Compressors
- Computer equipment supply and rental companies
- Concrete construction form suppliers
- Concrete cutting, breaking, and sawing firms
- Construction equipment
- Conveyors and material handlers
- Cranes, rigging/erectors
- Excavators
- Fire equipment and supply firms
- Flood lighting and searchlights
- Forklifts
- Generators
- Ham radio operators groups
- Hydraulic, pneumatic, and mechanical equipment
- Hydraulic tool distributors
- Light and heavy equipment firms
- Loaders, trenchers, skid-steer loaders
- Portable pumps
- Public works agencies
- Radio communications and equipment suppliers
- Sawing and cutting equipment
- Scaffolding
- Shoring
- Television and communications companies
- Tent suppliers and distributors
- Welding supply companies

Supplies

- Bag, burlap, and canvas manufacturers
- Battery distributors
- Building materials supply firms
- Chemical supply and distributor companies
- Compressed gases supply distributors
- Fire equipment and supply firms (local/regional)
- Fuel distributors
- Grocers and food suppliers
- Hardware supply firms
- Ice
- Lumberyards
- Medical supply companies
- Portable shelter and tent firms
- Power tool suppliers
- Rental service and supply companies
- Restaurants
- Utility companies

Services

- Aviation/helicopter services
- Awning and canopy manufacturers
- Baking companies
- Banquet and party supply companies
- Beverage suppliers and distributors
- Boat supply companies
- Bottled water distributors
- Buses: public, private, school district
- Catering companies
- Fencing companies
- Glass/windshield repair companies
- Ice distributors
- Motorcycle, all-terrain/ATV firms
- Portable restroom supply companies
- Rubbish/dumpster suppliers and haulers
- Tire distributors/repair firms
- Towing services
- Transportation services
- Tree- and debris-removal firms
- Trucking and leasing companies

Technical Support

- American Concrete Institute
- American Institute of Architects
- American Institute of Steel Construction
- American Public Works Association
- American Society of Consulting Engineers
- American Society of Safety Engineers
- Association of Building Contractors
- Association of Engineering Geologists
- Association of General Contractors
- Concrete Reinforcing Steel Institute
- Construction Specification Institute
- International Association of Bridge, Structural, and Ornamental Iron Workers
- Local and regional professional societies, associations, and trade groups
- National Society of Professional Engineers
- Physicians and surgeons professional associations

Contractors

- Demolition contractors
- Drilling and boring contractors
- Excavation contractors
- General contractors
- Heavy-equipment operators
- Steel erectors and fabricators
- Utility contractors

Consulting Engineers and Architects

- Architects
- Chemical engineers
- Civil engineers
- Construction engineers
- Environmental engineers
- Marine consultants
- Mechanical engineers
- Safety, health, and hygiene engineers
- Sanitary engineers
- Soil engineers
- Structural engineers
- Surveying engineers

Other

- Electric equipment and supply distributors
- Environmental and remedial contractors

- Hazardous waste abatement companies
- Highway and transportation agencies
- Industrial rescue teams
- Land surveyors
- Search-and-rescue dog handlers
- Wilderness search groups/associations

After the appropriate CRP database items are determined, the data collection process must identify local, regional, state, or other appropriate contacts, that is, companies, firms, agencies, or individuals that will ultimately provide the identified resources.

CRP AGREEMENTS

The next phase in the community resource plan requires the initiation, preparation, and adoption of appropriate types of agreements that clearly define the scope and conditions for the provision of services, equipment, and/or supplies established by the CRP. These agreements can take the following forms:

- Memoranda of agreement (MOA)
- Mutual-aid agreements (MAA)
- Service agreements (SA)
- Service retainer or contracts (SR/SC)

These agreements should be reviewed and approved by the legal council having jurisdiction within the department to ensure that the agreement and its parameters are equitable, concise, and that all liability issues have been addressed.

INFORMATION MAINTENANCE

The documents and data contained within the CRD "yellow pages" for complex incident management provide for the timely identification, call-out, and deployment of required resources, based on specific incident parameters. As with any other resource or reference document, the CRD and database should be updated and revalidated on an annual basis, so as to ensure that individual contact names, phone numbers, and conditions are valid and current. In addition, it is important to identify and document any changes in the resource listing that may affect its usefulness within the database. It is not uncommon for products, services, or materials to change or be withdrawn, especially when dealing with equipment, supply, or service companies, thereby compromising the dependability and/or function of the CRP.

Financial constraints, budget curtailments, staffing limitations and reductions, and limited resource acquisitions can prevent the initiation of programs or delay expansion of existing services. All proposals must be thoroughly assessed, properly planned, and adequately developed in order to effectively implement program goals. Technical rescue team development relies heavily on a thorough understanding of the issues surrounding the needs associated with such a team, coupled with an appropriate planning process that will ultimately lead an agency toward its established goal of enhanced rescue capabilities or deployment of specially trained and adequately outfitted personnel for technical rescue responses.

CONCEPTUALIZATION AND PLANNING PROCESS

The conceptualization and planning process is defined by the following 10 parameters. Each of the following must be thoroughly identified and addressed:

1. What type of specialized rescue team(s) is required?
2. What risk factors are present or potential within the jurisdiction?
3. What level of expertise currently exists within the organization?
4. How can system enhancement be best achieved?
   - Short term
   - Intermediate
   - Long term
5. What level or degree of technical capabilities can the plan achieve?
6. How can the services be best achieved?
   - Interdepartmental
   - Local
   - Regional
   - Countywide
   - Intercounty
   - Cooperative agreements with industrial or private teams
   - Outside agencies
7. What is the current projected level of interest of staff and personnel?
   - Interest
   - Motivation
   - Availability for staffing requirements
   - Previous levels of special/specific training
   - Employment/trade experience
   - Fire/rescue/EMS response experience
   - Educational background
   - Time commitment requirements
   - Personal risk factors
   - Dedication
8. What are the projected financial considerations and impacts?
   - Short term
   - Intermediate
   - Long term
9. What influencing regulations/standards must be complied with in the United States?
   - NFPA
   - OSHA
   - ANSI
   - NIOSH
   - DOT
   - DOL
   - API
   - NASAR
   - AAUS
   - Other
10. What is the time commitment for organization, development, and implementation of the program initiative?

Efforts must be made early in the conceptualization and planning process to ensure that the commitments and objectives being developed can be achieved within the organization. Initial interest may be high with any new program but may quickly wane as the demand of increased training and time commitments take their toll.

State/Federal Regulations

Regulatory impact of associated state/federal regulations, along with the influence of recognized national standards (such as those previously discussed of the NFPA), will also influence and help direct the planning, organization, and training process. These regulations and standards may assist the planning group or committee in identifying relevant issues that may impact the development of objectives, goals, and organizational scope for the subsequent team's deployment.

Research and Data Gathering

Efforts should be made by the relevant departments and agencies to research and obtain information from other departments and teams around the country in order to gain the wealth of information that can be analyzed and disseminated, with applicable information applied and augmented in order to meet with local conditions, factors, and team objectives. By eliminating redundancy in program planning and technical rescue team applications, this research and data-gathering network can save a tremendous amount of time and effort. Information gathered from departments that have developed technical response teams in the past added to information about operation methods and equipment and about changes to the methods and equipment as the result of field-proven experience can only help to provide a time-tested and time-proven foundation of data.

TECHNICAL RESCUE TEAMS AND PROGRAM EXAMPLES

Technical Rescue Teams

Departments and agencies that are considering developing specialized technical rescue teams must understand the long-term commitments and the level of dedication required to fulfill the operability and usefulness of team activation. A department or agency must identify the appropriate types and levels of technical service(s) necessary as the needs or risks within the jurisdiction or community change. In the 1980s, many jurisdictions hastily implemented hazardous materials teams as the wave of this concept and the need for a hazmat response swept through the emergency services only to find that the demands of time, financial support, and commitment levels necessitated a reevaluation of their level of commitment and degree of involvement.

Technical Rescue Program Examples

The following examples are typical technical rescue program elements that can facilitate the development of rescue operation capabilities for technical rescue specialties. Although the detailed skills are typical, the time frames for the initial delivery of such programs vary significantly from jurisdiction to jurisdiction. Unless regulated by standards, the time needed to run through the program should be determined by how long it takes to be thoroughly introduced to the necessary skills. This initial session must be followed with ongoing practice sessions and performance evaluations to ensure competency in the skills acquired. Initial training without ongoing practice will allow rescue personnel to forget the specialized techniques vital to the successful completion of a technical rescue operation.

The initial program delivery times represent those commonly seen within today's emergency response community. They should not be misconstrued to be a standard. An appropriate time frame for initial delivery and, more importantly, ongoing refresher training may vary significantly, depending on the learner's experience and level of routine emergency response activity. For instance, a fire fighter assigned to a busy rescue unit may require less formal continuing education time than does a volunteer industrial rescue team member who is normally assigned as an operator on a process unit. The fire fighter is more closely associated with the required skills on a routine basis, which may act as an on-the-job training session. This is not to imply that on-the-job trial and error is the most efficient way to train rescue team members but rather to illustrate that some people may require more formal training than others to achieve the same level of competency. Obviously, the time required to achieve competency will also vary based on the complexity of the subject matter presented.

These examples utilize NFPA 1670 as the basis for their content and outline all three levels of capability. NFPA 1670 provides a basic outline for course content in any one of the seven disciplines currently listed.

Rope Rescue. Rope techniques are a basic underlying skill for most other types of rescue. Most fire fighters will be familiar with basic rope techniques and knot tying as part of the basic fire fighter curriculum. An awareness of rope rescue operations can be taught to most rescuers in only a day (Figure 13.2.2).

FIGURE 13.2.2 Rope Rescue (Photo courtesy of Wright Rescue Solutions, Inc.)

The initial awareness-level training session should include basic size-up and recognition of the need for rope rescues, information on what resources are necessary for rope rescues and how to procure them, mechanisms and procedures for on-scene site management, recognition of general hazards associated with rope rescue and methods for mitigating them, and development and implementation of procedures for the identification and use of personal protective equipment.

An operations-level training session could cover rope rescue techniques such as knot tying, orientation to rope and rope-related equipment, rigging principles and edge protection, single- and multiple-point anchor systems, belay systems, lowering systems, rope/pulley mechanical advantage for raising, both ascending and descending a fixed rope, and using litter attendants (tenders) in rope rescue systems. With the prerequisite of awareness, it is likely to take three days (24 to 30 hours) to bring an average group to familiarity with operations-level systems and procedures. A combined awareness- and operations-level training session may be commonly presented in a five-day format.

With the awareness- and operations-level programs as prerequisites, the technician-level program can possibly be presented within approximately one week (40 hours). The technician-level program may cover more complex anchoring and rigging techniques, more advanced use of rope/pulley mechanical advantage, high-line rope systems, passing knots through components of the rescue system, and use of other, more specialized rope rescue techniques within the high angle environment. In NFPA 1670, the term *high angle* denotes those environments in which the load is supported predominantly by the rope rescue system. *Low angle* refers to a situation in which the load is supported mostly by itself and not by the rope rescue system.

All sessions, regardless of the time frame, should include a balanced regimen of both classroom and practical application. The rope techniques and systems must also be tailored to the environment in which they will be used. Although conceptually identical, system configurations and application may vary significantly based on the environment and their intended purpose (i.e., mountain rescues versus structural/urban rescues).

Unfortunately, response organizations often dismiss rope rescue technique training because of the absence of high-rise structures or mountainous terrain. A risk assessment may reveal an absence of elevated structures or terrain but it may still reveal the presence of a high degree of risk for incidents associated with removal of victims from depths such as pits, channels, or ravines. These situations may require the same, or greater, level of rope rescue capability as do emergency rescue situations within a community of high-rise structures.

Confined Space Rescue. NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program* and OSHA's 29 CFR 1910.146 define the term *confined space* similarly. Both standards say that a confined space must have all of the following characteristics:

- Be large enough and so configured that a person can enter and perform assigned work
- Have limited or restricted means for entry or exit
- Not be designed for continuous human occupancy
- Have a serious safety or health hazard or, in some cases, the mere potential for such

The hazards within confined spaces are no different from those experienced in other incidents on a regular basis. The real danger of rescue from confined spaces lies in the inability to readily escape those hazards. Because persons are forced to work within these sometimes cramped, poorly ventilated, and congested areas in close proximity to equipment and processes, the potential for incident is significant (Figure 13.2.3).

The OSHA regulation makes provision for those spaces in regulated industry that do not contain actual or potential hazards; the NFPA does not. Because the NFPA standards deal with response for rescue, they assume that any incident to which an emergency rescue team is called may have the potential for some sort of hazard within that space. This is the better-safe-than-sorry approach and constitutes sound reasoning. Another difference is that OSHA deals with worker safety and rescue occurring only within regulated facilities. The NFPA standards are intended for rescue operations regardless of their location, whether within a petrochemical facility or a backyard well. When comparing the two standards, we can see that they are similar in content but different in the scope of application. For this reason, terminology between the two standards may differ slightly even though the goals are similar.

An awareness of confined space rescue may usually be taught within a day. Content should include size-up of existing and potential conditions, initiation and establishment of contact with patients/victims, recognition and identification of hazards

FIGURE 13.2.3 Confined Space Rescue

associated with nonentry rescues, site control and scene management methods, recognition of confined spaces, and procedures for nonentry type rescues.

Organizational training at the operations level is associated with rescues from spaces whose configuration creates minimal potential for difficulty during entry-type rescues. For instance, spaces that have a clear line of sight with the patient/victim, contain no entanglement or other hazards, have an opening large enough to enter with a self-contained breathing apparatus (SCBA) worn in the manner intended by the manufacturer, and can accommodate two or more rescuers should present less difficulty for rescuers than a space that is greatly congested with an 18-in. (0.45-m) round entry portal and a patient/victim who is out of sight, 30 ft (9.1 m) from the entry point.

These training sessions should include certain basic rope systems required for safe entry and egress from less hazardous configurations, protective measures for rescue entrants, methods for assuring that the entrants can physically and psychologically handle working in tight spaces, understanding the duties of the various team functions within the scope of a confined space emergency, atmospheric monitoring procedures, use of appropriate packaging methods for these spaces, procedures for performing an entry-type rescue in these spaces, and some method of transferring patient/victim information to emergency medical services on delivery. Initial training sessions for the operations level are commonly taught within three to five days (24 to 40 hours).

Technician-level organizations should receive training to allow entry-type rescues into more complicated spaces. The initial training for technician-level organizations should include continuing size-up of changing conditions during rescue operations, information on medical surveillance programs for rescue team members, planning response for entry-type rescues into hazardous environments, and implementation of that planned response. Although program duration varies significantly, most technician-level programs are taught within two to five days (16 to 40 hours). Operations-level training should be considered a prerequisite for technician-level training.

SUMMARY

The daily demands imposed on fire and emergency service agencies can, at times, overwhelm the best-prepared and best-trained departments and their personnel. Support for specialized technical rescue operations is often neglected due to already overburdened response demands and budgetary constraints. Although it is true that these highly specialized techniques are not used as frequently as more routine basic rescue and fire suppression techniques, they have a no less vital role in saving human life within the realm of emergency response. Incidents of this type *will* occur. Rescue response organizations *must* have the skills and/or resources necessary for safe and effective deployment and subsequent operations. Departments and agencies should prepare appropriately to meet the challenges and demands associated with the risk potential and hazards present or projected for their jurisdiction and community.

The area of specialized technical rescue operations must be an integrated emergency system. Through proactive planning, community-based risk assessment and evaluation, preparedness training, resource development, and contingency planning, fire and emergency service agencies can effectively prepare and anticipate the manner in which they can handle incident responses, while maintaining the highest degree and consideration for the safety and well-being of their personnel and emergency responders. Technical rescue operations require a fine balance of training, knowledge, skills, risk management, and resources.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on rescue operations discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 220, *Standard on Types of Building Construction*
NFPA 472, *Standard for Professional Competence of Responders to Hazardous Materials Incidents*
NFPA 473, *Standard for Competencies for EMS Personnel Responding to Hazardous Materials Incidents*
NFPA 1001, *Standard for Fire Fighter Professional Qualifications*
NFPA 1006, *Standard for Rescue Technician Professional Qualifications*
NFPA 1201, *Standard for Providing Emergency Services to the Public*
NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program*
NFPA 1521, *Standard for Fire Department Safety Officer*
NFPA 1561, *Standard on Emergency Services Incident Management System*
NFPA 1600, *Standard on Disaster/Emergency Management and Business Continuity Programs*
NFPA 1670, *Standard on Operations and Training for Technical Search and Rescue Incidents*
NFPA 1983, *Standard on Life Safety Rope and Equipment for Emergency Services*

Chapter 3

Fire Streams

Michael A. Wieder

Chapter Contents

Fire Department Pumpers
Nozzles
Hose Line Fire Stream Calculations
Reaction Forces in Hose Lines, Nozzles, and Aerial Devices

Key Terms

aerial ladder, Bernoulli's equation, continuity equation, Darcy-Weisbach formula, elevating platform, fire department pumper, fire stream, flow rate, friction loss, hose line, hydraulics calculations, nozzle (solid stream), nozzle (spray), pump discharge pressure

Water has always been and remains the primary fire-extinguishing agent. Therefore, the movement of water from its source to the fire is a significant operation in most kinds of fire fighting. A typical fire department delivery system consists of the following:

- A water supply source
- One or more fire department pumpers
- Various types of fire hose to move the water from the source to the fire pump and from the pump onto the fire
- Nozzles for the final delivery

Fire apparatus driver/operators and fire officers must understand the basic principles of water movement through the aforementioned elements in order to establish effective fire suppression operations.

This chapter includes a description of the most important details of producing effective fire streams, including fire department pumpers, nozzles, hose line fire stream calculations, and reaction forces in hose lines and nozzles.

See also Section 13, Chapter 4, "Alternate Water Supplies"; and Section 15, Chapter 3, "Hydraulics for Fire Protection."

FIRE DEPARTMENT PUMPERS

Purpose and Components of Fire Department Pumpers

The primary purpose of fire department pumpers is to move water with adequate pressure from a source to the fire. Water supply sources can be divided into two basic groups: static and pressurized. Static sources include lakes, streams, ponds, rivers, and water shuttle dump tanks. Pressurized sources include fire hydrants, elevated storage tanks, or supply hoses from another fire department pumper. More information on water supply sources can be found in Section 15 of the *Fire Protection Handbook.*

In addition to pumping water for fire streams, fire department pumpers serve other functions, including transporting fire fighters; auxiliary extinguishing agents (foam, dry chemical agents, etc.); and other fire-fighting, emergency medical, and rescue equipment to an incident scene.

Fire pumps may also be installed on other types of fire apparatus, such as mobile water supply apparatus (tenders/tankers), aerial apparatus, aircraft rescue and fire-fighting (ARFF) vehicles, wildland apparatus, rescue vehicles, and fireboats. Design requirements for pumpers, aerial apparatus, water tender/tankers, and rescue vehicles are contained in NFPA 1901, *Standard for Automotive Fire Apparatus.* Design requirements for wildland fire apparatus are contained in NFPA 1906, *Standard for Wildland Fire Apparatus.* Design requirements for ARFF vehicles are contained in NFPA 414, *Standard for Aircraft Rescue and Fire-Fighting Vehicles.*

Michael A. Wieder, assistant director at IFSTA/Fire Protection Publications in Stillwater, Oklahoma, holds undergraduate and graduate degrees in fire protection, safety, and adult education. He has written or edited more than two dozen fire-fighting texts and manuals, including the textbook *Fire Service Hydraulics and Water Supply.*

Modern fire department pumpers, also called engines, wagons, and triples, are generally equipped with a centrifugal-type pump as their main fire pump. The centrifugal pump, a nonpositive displacement pump, consists essentially of one or more rotating discs called impellers. The impellers are mounted on a shaft that may turn from 2000 to 4000 rpm in order to transmit energy in the form of velocity to the water. A casing surrounds each impeller to collect the water and convert the velocity to pressure. A fire pump that has a single impeller on the shaft is called a *single-stage pump.* If the shaft has two impellers mounted on it, the pump is called a *two-stage pump.* Two-stage pumps have transfer valves that allow water to be discharged from one impeller to the next (called series operation; used for maximum discharge pressures) or through both impellers at the same time (called parallel operation; used for maximum discharge volumes). Centrifugal pumps also have the equipment necessary to provide pressure regulation and to prime the pump when using a static water supply source.

Piston, rotary gear, and rotary vane pumps are positive displacement-type pumps that provide a fixed amount of water with each movement of the pump. They are no longer used as the primary pumps on fire apparatus. They are, however, used for special purposes, such as high-pressure booster pumps and as priming pumps for centrifugal pumps.

Characteristics of Fire Pumps

Two important characteristics of fire pumps are (1) the discharge volume and (2) the discharge pressure. They make up the final output of the pump. The discharge volume is the amount of water pumped per unit of time, such as gallons per minute (gpm) or liters per minute (L/min). Apparatus may be equipped with flowmeters to measure the discharge volume being provided by the pump. The discharge pressure is the pressure at which the pump is discharging water. The discharge pressure is measured in pounds per square inch (psi) or kilopascals (kPa). It is also sometimes measured in bar with 1 bar equal to 100 kPa. The discharge pressure (as well as the intake pressure, if any) is measured by pressure gauges attached to the pump piping.

Pumps are rated according to their discharge volume at 150 psi (1035 kPa) when drafting through 20 ft (6 m) of intake hose at a lift of 10 ft (3 m). Apparatus fire pumps are also required to provide 70 percent of their rated capacity at 200 psi (1380 kPa) and 50 percent of their rated capacity at 250 psi (1725 kPa). These ratings are summarized in Table 13.3.1. Common capacities for pumps used on modern fire apparatus range from 500 gpm (2000 L/min) to 2500 gpm (10,000 L/min), although larger-capacity pumps are available.

Pumping operations start with water from either a pressurized source, such as a hydrant, or from a static water source, such as a pond. Drafting operations are required in the latter case. The factors that affect the height (lift) limitations to which water can be drafted and the flow rate are interrelated. These factors are as follows:

- Atmospheric pressure
- Water temperature
- Friction loss in the intake hose and strainer
- Velocity energy

TABLE 13.3.1 Standard Pumps

Rated Flow Rate		70% of Rated Flow Rate		50% of Rated Flow Rate	
gpm @ 150 psi	*L/min @ 1035 kPa*	*gpm @ 200 psi*	*L/min @ 1380 kPa*	*gpm @ 250 psi*	*L/min @ 1725 kPa*
500	2000	350	1400	250	1000
750	3000	525	2100	375	1500
1000	4000	700	2800	500	2000
1250	5000	875	3500	625	2500
1500	6000	1050	4200	750	3000
1750	7000	1225	4900	875	3500
2000	8000	1400	5600	1000	4000
2250	9000	1575	6300	1125	4500
2500	10,000	1750	7000	1250	5000

The lift at a given flow rate can be determined by

Lift = Atmospheric pressure minus water vapor pressure
minus strainer and intake hose friction loss
minus velocity energy

Atmospheric pressure varies from day to day according to the weather conditions and the elevation above sea level. Since drafting is essentially the creation of a partial vacuum in the pump and intake hose, the total energy available for moving the water from the source to the pump is the atmospheric pressure. The nominal atmospheric pressure, 14.696 psi (101.333 kPa) absolute at sea level, usually rounded to 14.7 psi (100 kPa) absolute, can theoretically provide a lift of almost 34 ft (10.5 m). However, remember atmospheric pressure drops about 0.5 psi (3.4 kPa) for each 1000 ft (305 m) above sea level.

As mentioned earlier, fire pumps receive their capacity ratings based on their drafting ability through 20 ft (6 m) of intake hose at a lift of 10 ft (3 m). As the amount of lift is increased, the discharge volume capacity of the pump will be decreased accordingly. Under actual conditions, a pump in excellent condition and able to pump its rated capacity at sea level should be able to draft and pump at least some water at lifts of up to 25 ft (7.6 m).

Often atmospheric pressure is given in inches of mercury. If this is the case, it must be converted to feet of water using:

$$h_w = 1.13 h'_{\text{Hg}}$$

where

h_w = Feet of water

h'_{Hg} = Inches of mercury

The vapor pressure reduces the amount of vacuum that is possible and, consequently, reduces the total lift. Vapor pressure depends on the water temperature and is measured in terms of feet (meters) of water. Table 13.3.2 lists common values of vapor pressure as a function of water temperature.

Another factor affecting the total lift is the friction loss in the suction hose and the strainer. The friction loss in the suction hose depends on the hose diameter, hose length, and the

flow rate of the water. Equations for the friction loss in various sizes of suction hose are shown in Table 13.3.3. The friction loss through the strainer is a function of the flow rate and the strainer diameter. The friction equations for the various strainer sizes are shown in Table 13.3.4.

[a] q = gpm/100.
[b] q = L/min/100.

The velocity head also affects the total lift of the pump. The velocity head is given by $V^2/2g$, where V is the water velocity in feet per second (meters per second) and g is the acceleration due to gravity and is equal to 32.2 ft/sec^2 (9.81 m/sec^2). The velocity can be found by using the continuity equation, $Q = VA$ where Q is the flow rate in cubic feet per second (cubic meters per second) and A is the cross section of the suction hose in square feet (square meters). However, the flow rate is usually given in gallons (liters) per minute and the suction hose diameter is in inches (millimeters). Consequently, Table 13.3.5 can be used to determine the velocity head in the suction hose without tedious calculations.

To find the friction loss in parallel suction hoses (FL_P), divide the friction loss (FL_T) by the square of the number of lines, that is,

$$FL_P = \frac{FL_T}{\#\ \text{lines}^2}$$

For example, with two parallel suction hose lines of the same size and length, divide the calculated suction hose friction loss by 4.

In solving the lift equation, all units must be compatible, that is, converted to the equivalent feet (meters) of water or kilopascals. Atmospheric pressure is usually given in terms of inches of mercury (or kilopascals). Table 13.3.6 can be used to convert the atmospheric pressure to the equivalent pressure in feet (meters) of water.

For SI units: 1 in. Hg = 3.385 kPa; 1 psi = 6.895 kPa; 1 ft = 0.305 m.

EXAMPLE: Find the lift in feet of water (or kilopascals, which can be converted to meters of water by multiplying by 9.84).

Atmospheric pressure = 27.00 in. of mercury (91 kPa)

Water temperature = 60°F (16°C)

Flow rate = 1100 gpm (4163 L/min)

Suction hose diameter (strainer diameter) = 5 in. (125 mm)

Suction hose = Two lengths, 10 ft (3 m) each

SOLUTION: U.S. customary units

From Table 13.3.6, atmospheric pressure of 27.00 in. of mercury equals 30.556 ft of water.

From Table 13.3.2, vapor pressure at 60°F equals 0.59 ft of water.

Using Table 13.3.3, the friction loss for 10 ft of 5 in. suction hose is $0.0162q^2$. Q = 1100 gpm. However, q is in 100s of gpm and $Q/100 = q$.

Therefore, q = 11.

Thus: Friction loss = $(0.0162)(11)^2$ = 1.96 ft for 10 ft
or (2)(1.96) = 3.92 ft for 20 ft

From the suction strainer equation listed in Table 13.3.4:

$$\text{Friction loss} = 0.0517q^2$$

Where q = 11 as in the suction hose equation

$$\text{Friction loss} = (0.0517)(11)^2 = 6.26 \text{ ft}$$

The velocity head (from Table 13.3.5) is 5 ft.

Therefore, lift = 30.56 – 0.59 – 4 – 6.26 – 5 = 14.71 ft.

SOLUTION: Metric units

Atmospheric pressure = 91 kPa

From Table 13.3.2, vapor pressure at 16°C equals 1.7 kPa.

Using Table 13.3.3, the friction loss for 3 m of 125 mm suction hose is $0.0034q^2$. Q = 4163 L/min. However, q is in 100s of L/min, and $Q/100 = q$.

Therefore, q = 41.63.

Thus: Friction loss = $(0.0034)(41.63)^2$ = 5.89 kPa for 3 m
or (2)(5.89) = 11.78 kPa for 6 m

From the suction strainer equation listed in Table 13.3.4:

$$\text{Friction loss} = 0.0108q^2$$

Where q = 41.63 as in the suction hose equation

$$\text{Friction loss} = (0.0108)(41.63)^2 = 18.71 \text{ kPa}$$

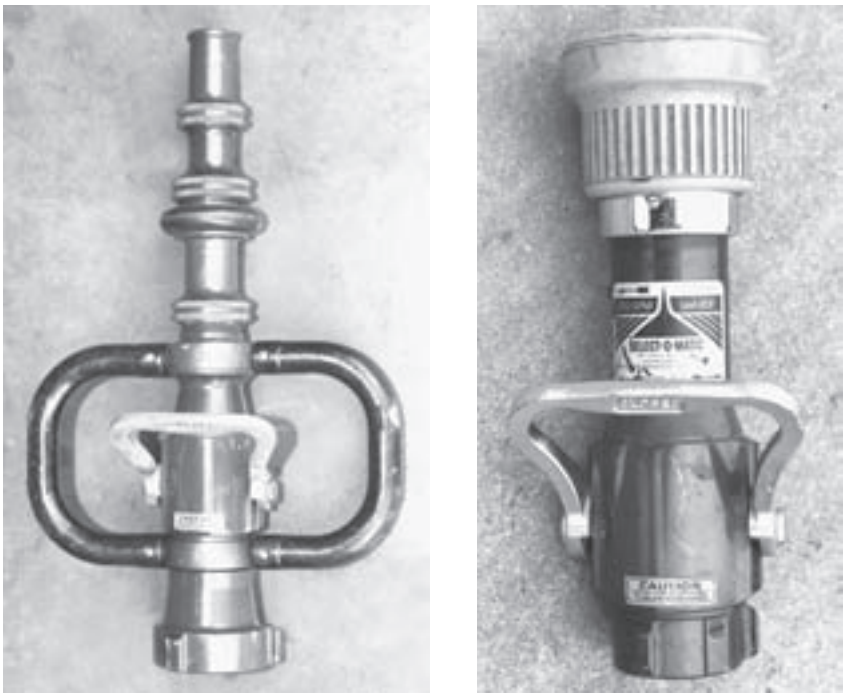
The velocity head (from Table 13.3.5) is 14.9 kPa.

Therefore, lift = 91 – 1.7 – 11.78 – 18.71 – 14.9 = 43.91 kPa
(converting to meters, 43.91/9.84 = 4.46 m)

NOZZLES

The purpose of a nozzle is to shape the stream and convert pressure energy to velocity (kinetic) energy. In this way, the water can be applied to the fire in the appropriate quantity and from an adequate distance. The two most common basic types of fire service nozzles are solid stream and spray (fog) nozzles (Figure 13.3.1).

The governing hydraulic characteristics of nozzles are flow rate, diameter, and nozzle pressure. Flow rate is the amount of water flowing out of the nozzle per unit time and is measured in gallons per minute or liters per minute. Nozzle pressure is most



(a) (b)

FIGURE 13.3.1 (a) Solid-Stream Nozzle; (b) Spray Nozzle

commonly measured at the tip of the nozzle in units of pounds per square inch (psi) or kilopascals (kPa).

Solid-Stream Nozzles

Solid-stream nozzles are classified according to the nozzle tip diameter. The diameters range from ¼ to 2½ in. (6 to 65 mm) or larger. The nozzle sizes are generally available in ⅛ in. (3 mm) graduations. Nozzles up to 1⅛ in. (29 mm) or perhaps 1¼ in. (32 mm) are generally considered to be for "handlines," that is, those held manually. As a rule of thumb, handline solid-stream nozzles are usually operated at a nozzle pressure of 50 psi (345 kPa).

Solid-stream nozzles larger than about 1¼ in. (32 mm) have such large reaction forces that they must be mechanically restrained. These are called master stream nozzles. They may be mounted to the apparatus, affixed to a portable base, or attached to an aerial device. As a rule of thumb, master stream solid-stream nozzles are operated at a nozzle pressure of 80 psi (552 kPa).

Solid streams are useful where extreme range is desired, where it is necessary to penetrate soft material, such as peat, or when thermal degradation of spray streams prevents proper penetration to the seat of the fire. Solid streams are also less affected by wind currents than are spray streams. Solid-stream nozzles are also the preferred nozzle for use with compressed air foam streams (CAFS).

Solid-stream nozzles are also useful in measuring waterflows, since both their diameter and discharge pressure can be easily measured. The discharge pressure is measured by holding a Pitot tube and gauge in the fire stream (Figure 13.3.2).

The Pitot tube is inserted in the stream at a point that is equal to one-half the diameter of the nozzle tip away from the tip. From this information, the flow rate can be computed. It is related to the diameter and nozzle pressure by the following equations:

$$Q = 29.7d^2\sqrt{NP}$$

FIGURE 13.3.2 A Typical Pitot Tube and Gauge

where

Q = Flow rate (gpm)

d = Nozzle diameter (inches)

NP = Nozzle pressure (psi)

For SI units, the flow equation is:

$$Q = 0.0666 d_m^2 \sqrt{NP_m}$$

where

Q = Flow rate (L/min)

d_m = Nozzle diameter (mm)

NP_m = Nozzle pressure (kPa)

Theoretical flows from various nozzles at different nozzle pressures can be found in Section 15, Chapter 3, "Hydraulics for Fire Protection."

Solid streams, with a lower surface-area-to-volume ratio, do not have as good heat-transfer characteristics as do spray nozzles and, consequently, are not as effective in absorbing heat. Another disadvantage of a solid stream is that it is a better conductor of electricity than a spray stream.

Spray (Fog) Nozzles

Spray nozzles, or fog nozzles as they are sometimes called, produce varying degrees of a water spray pattern. Most modern spray nozzles are adjustable from a straight stream to a very wide-angle spray pattern. The stream pattern angle is customarily measured at the angle between the outer limits of the pattern core and expressed in terms of degrees (e.g., a 30 degree pattern or a 60 degree pattern).

Spray nozzles are generally classified according to the size of their hose coupling and their flow rate in gallons per minute (liters per minute). The flow rate capacity of a spray nozzle will depend on the design of the particular nozzle. There are two basic designs for spray nozzles: (1) fixed gallonage nozzles and (2) automatic nozzles. Fixed gallonage nozzles are designed to flow a set number of gallons of water at a specified nozzle discharge pressure. Most of these nozzles have rated flow volumes when the nozzle pressure is at 100 psi (690 kPa). However, some newer nozzles are designed to operate at lower nozzle pressures. These are particularly useful when operating from a standpipe system in high-rise fire-fighting operations as the pressures may not be available to supply nozzles at 100 psi (690 kPa). Fixed gallonage nozzles may be designed to allow only one specified flow rate, or they may have an adjusting collar that allows the nozzle to be set for one of four or five predetermined flow settings.

Automatic nozzles are the most common type of spray nozzles in use today. Automatic nozzles, also referred to as constant pressure nozzles, are basically variable flow nozzles with pattern-change capabilities and the ability to maintain the same nozzle pressure. If the volume supplied to the nozzle changes, the automatic nozzle maintains approximately the same nozzle pressure and pattern. This feature is made possible by a baffle that moves automatically, varying the spacing between the baffle and the throat.

A stream from an automatic nozzle can "look good" but may not be supplying sufficient water for extinguishment or protection. It should be the goal of the driver/operator to provide an acceptable flow of water at the discharge pressure for which the nozzle is designed. As with fixed gallonage nozzles, most automatic nozzles are designed for a 100 psi (690 kPa) discharge pressure.

The discharge volume available from a spray nozzle will vary depending on the size of the nozzle and hose line and the pressure being supplied from the fire pump. Keep in mind, for example, that a 1½ in. (38 mm) automatic spray nozzle may be used on either a 1½, 1¾, or 2 in. hose line. Table 13.3.7 shows typical flow rates from automatic spray nozzles.

Flow rates are determined experimentally, either by a flowmeter or by flowing water into a tank and measuring the time for a given quantity. Flow rate information is obtained from the manufacturer and, as mentioned previously, is usually reported as the flow rate at 100 psi (690 kPa) nozzle pressure.

Flows for other pressures may be obtained by using the flow equation:

$$Q = 29.7 d^2 \sqrt{NP}$$

and finding the equivalent nozzle diameter d_e, using

$$d_e = \sqrt{Q / 29.7 \sqrt{NP}}$$

where

Q = Flow rate (gpm)

29.7 = A constant

d_e = Equivalent nozzle diameter (in.)

NP = Nozzle pressure (psi)

For SI units the flow formula is

$$Q = 0.0666 d_m^2 \sqrt{NP_m}$$

and finding the equivalent nozzle diameter d_e, using

$$d_e = \sqrt{Q / 0.0666 \sqrt{NP_m}}$$

where

Q = Flow rate (L/min)

0.0666 = A constant

TABLE 13.3.7 Flows from Typical Automatic Spray Nozzles

	Flow Rate	
Nozzle Type	*gpm*	*L/min*
¾ to 1 in. (19 to 25 mm) automatic nozzle	10–60	38–227
1½ in. (38 mm) automatic nozzle	30–250	114–946
2½ in. (64 mm) automatic nozzle	125–350	473–1,325
Master stream automatic nozzles	350–10,000	1,325–37,854

d_e = Equivalent nozzle diameter (mm)

NP_m = Nozzle pressure (kPa)

HOSE LINE FIRE STREAM CALCULATIONS

The end goal of most fire service hydraulics calculations is for the driver/operator to determine the necessary discharge pressure setting on the fire pump needed to supply the desired amount of water to the nozzle(s) or the next pumper in a relay pumping operation. This pressure setting is most commonly referred to as the *pump discharge pressure (PDP),* although in the past it was also known as the "engine pressure." The methods for mathematically calculating the pump discharge pressure are described here. However, algebraic manipulation of the equations can yield any variable, providing the other quantities are known.

Special techniques, known as "field hydraulics" or "rule of thumb," are used by driver/operators for approximate results. The methods shown here give more precise results, but they are generally too involved for field applications. Details on rule-of-thumb fire stream calculations can be found in the fire-fighting hydraulic texts listed in the bibliography.

The calculation of the pump discharge pressure depends on a number of variables, including the required nozzle pressure, friction loss in the hose layout, and pressure loss or gain due to elevation changes. As previously discussed, the required nozzle pressure will depend on the type of nozzle being used. Handline solid-stream nozzles are operated at 50 psi (345 kPa), master stream solid-stream nozzles are operated at 80 psi (552 kPa), and all standard spray nozzles are generally operated at 100 psi (690 kPa). There are some spray nozzles now available that are designed to operate at 75 psi (518 kPa). The hose friction loss is a function of the hose diameter, hose length, discharge volume, and any appliances, such as wyes or monitors, used in the hose layout.

Elevation pressure (*EP*) is the loss or gain of potential energy due to elevation changes between the pump and the nozzle. This is determined by the equations:

$$EP = 0.434h \text{ (SI units: } EP_m = 9.81h_m)$$

where

EP = Elevation pressure in psi (kPa)

h = Elevation change or head in ft (m) of water

For ease of calculation, in the fire service these equations are commonly rounded as follows:

$$EP = 0.5h \text{ (SI units: } EP_m = 10h_m)$$

The basis of these calculations revolves around three fundamental hydraulic principles: Bernoulli's equation, Darcy-Weibach equation, and continuity equation.

Bernoulli's Equation

This equation is a special form of conservation of energy. For a pumper hose line system this becomes:

$$PDP = NP + FL \pm EP$$

where

PDP = Pump discharge pressure in psi (kPa)

NP = Nozzle pressure in psi (kPa)

FL = Friction loss in psi (kPa)

EP = Elevation pressure in psi (kPa)

Darcy-Weisbach Equation

$$FL = (fV^2L)/(2gD)$$

where

g = Acceleration due to gravity, ft/sec^2 (m/sec^2)

f = Friction factor, a dimensionless number

L = Hose length in ft (m)

D = Hose diameter in in. (mm)

V = Velocity in ft/sec

Continuity Equation

This equation is a special form of conservation of mass.

$$Q = VA$$

where

Q = Flow rate, ft^3/sec (m^3/sec)

V = Velocity, ft/sec (m/sec)

A = Area, ft^2 (m^2)

These equations can be manipulated to result in friction loss equations and a modern version of the Underwriters equation.[1]

Friction loss is the loss of energy resulting from the internal friction between the moving particles of water and the friction between the water and the lining of the hose. The friction loss depends on water viscosity, flow rate, hose diameter, hose length, and the roughness characteristics of the hose lining. Although the viscosity is partly a function of the water temperature, the change is insignificant in the ranges of the temperature of water commonly used for fire fighting. The flow volume, hose diameter, and hose length are variables that are determined by the fire-fighting requirements. The roughness of the hose lining cannot be easily measured and is generally determined experimentally and reported as the friction factor. Consequently, all variables, except the flow volume, hose diameter, and hose length, are embodied in the friction factor, *f,* of the Darcy-Weibach equation and in the continuity equation. Putting all constants into one constant factor results in the modern fire service friction loss equation:

$$FL = cq^2l$$

where

FL = Friction loss in the total hose layout in psi or kPa

c = A coefficient based on the size and type of hose

q = Flow of water through the entire layout in hundreds of gallons per minute or hundreds of liters per minute ($q = Q/100$).

l = Length of hose in hundreds of feet or meters ($l = L/100$)

The suggested coefficients for various sizes and types of hose are shown in Table 13.3.8. These coefficients should be considered averages for the size and type of hose to which they are applied. The friction factor for modern fire hose varies from manufacturer to manufacturer. For more specific information on the exact coefficient for any particular brand of hose, contact the manufacturer of the hose.

The preceding equation replaces the old, less accurate, and more complex equation $FL = (2q^2 + q)l$. The old equation required all sizes of hose, other than 2½ in. (65 mm), to first be converted to equivalent lengths of 2½ inch (65 mm) hose before being plugged into the equation. However, the old equation was based on hose technology from the 1930s and 1940s. The results produced by this equation did not reflect the actual friction loss in modern (smoother) fire hose. Those interested in the old equation are referred to the bibliography.

The following are examples of calculating pump discharge pressure using the information described earlier:

EXAMPLE: Calculate the pump discharge pressure necessary to adequately supply 300 ft (90 m) of 2½ in. (65 mm) rubber-lined hose that is equipped with a solid-stream handline nozzle with a 1¼ in. (32 mm) tip. The position of the nozzle is 10 ft (3 m) above the level of the pump.

SOLUTION: U.S. customary units

$$Q = 29.7d^2\sqrt{NP}$$

$$Q = 29.7(1.25)^2\sqrt{50}$$

$$Q = 29.7(1.5625)(7.07)$$

$$Q = 328 \text{ gpm}$$

$$q = 328/100 = 3.28$$

$$FL = cq^2l$$

$$FL = (2)(3.28)^2(300/100)$$

$$FL = (2)(10.7584)(3)$$

$$FL = 64.55 \text{ or } 65 \text{ psi}$$

$$EP = 0.5h$$

$$EP = (0.5)(10) = 5 \text{ psi}$$

$$PDP = NP + FL \pm EP$$

$$PDP = 50 + 65 + 5$$

$$PDP = 120 \text{ psi}$$

SOLUTION: Metric units

$$Q = 0.0666 d_m^2 \sqrt{NP_m}$$
$$Q = 0.0666(32)^2\sqrt{345}$$
$$Q = (0.0666)(1024)(18.5742)$$
$$Q = 1267 \text{ L/min}$$
$$q = 1267/100 = 12.67$$
$$FL = cq^2l$$
$$FL = (3.17)(12.67)^2(90/100)$$
$$FL = (3.17)(160.5289)(0.9)$$
$$FL = 457.99 \text{ or } 458 \text{ psi}$$
$$EP = 10h$$
$$EP = (10)(3) = 30 \text{ kPa}$$
$$PDP = NP + FL \pm EP$$
$$PDP = 345 + 458 + 30$$
$$PDP = 833 \text{ kPa}$$

When using the foregoing formulas to determine the pump discharge pressure for wyed hose lines of the same size and length, keep in mind the following considerations:

1. The friction loss for the total hose lay is the sum of the losses in the supply hose, *one* of the wyed lines, and the wye appliance (if applicable).
2. When determining the flow in the hose line that is supplying the wye, remember to add the flows from *all* of the wyed lines.
3. If the total flow through the wye appliance is less than 350 gpm (1325 L/min), do not consider the friction loss through wye to be important. If the flow exceeds this amount, add 10 psi (70 kPa) to the friction loss in the hose.

EXAMPLE: Calculate the pump discharge pressure necessary to adequately supply 400 ft (120 m) of 4 in. (100 mm) hose that is wyed off into two 150 ft (45 m), 2½ in. (65 mm) rubber-lined attack hose lines. Each attack line is equipped with a spray nozzle that is designed to flow 250 gpm (946 L/min) at 100 psi (690 kPa). There is no elevation change in the hose lay.

SOLUTION: U.S. customary units

$$FL = cq^2l$$
$$FL_{2½ \text{ inch}} = (2)(250/100)^2(150/100)$$
$$FL_{2½ \text{ inch}} = (2)(6.25)(1.5)$$
$$FL_{2½ \text{ inch}} = 18.75 \text{ or } 19 \text{ psi}$$
$$FL_{4 \text{ inch}} = (0.2)(500/100)^2(400/100)$$
$$FL_{4 \text{ inch}} = (0.2)(25)(4)$$
$$FL_{4 \text{ inch}} = 20 \text{ psi}$$
$$FL_{\text{Total}} = FL_{2½ \text{ inch}} + FL_{4 \text{ inch}} + \text{Appliance loss}$$
$$FL_{\text{Total}} = 19 + 20 + 10$$
$$FL_{\text{Total}} = 49 \text{ psi}$$
$$PDP = NP + FL_{\text{Total}} \pm EP$$
$$PDP = 100 + 49 + 0$$
$$PDP = 149 \text{ psi}$$

SOLUTION: Metric units

$$FL = cq^2l$$
$$FL_{65 \text{ mm}} = (3.17)(946/100)^2(45/100)$$
$$FL_{65 \text{ mm}} = (3.17)(89.49)(0.45)$$
$$FL_{65 \text{ mm}} = 127.66 \text{ or } 128 \text{ kPa}$$
$$FL_{100 \text{ mm}} = (0.305)(1892/100)^2(120/100)$$
$$FL_{100 \text{ mm}} = (0.305)(357.97)(1.2)$$
$$FL_{100 \text{ mm}} = 131 \text{ kPa}$$
$$FL_{\text{Total}} = FL_{65 \text{ mm}} + FL_{100 \text{ mm}} + \text{Appliance loss}$$
$$FL_{\text{Total}} = 149 + 131 + 70$$
$$FL_{\text{Total}} = 350 \text{ kPa}$$
$$PDP = NP + FL_{\text{Total}} \pm EP$$
$$PDP = 690 + 350 + 0$$
$$PDP = 1040 \text{ kPa}$$

If determining the friction loss in wyed lines that have differing flows, hose sizes, or hose lengths, calculate the friction loss in each of the wyed lines and use the highest result added to the supply line and appliance loss (if applicable) in determining the total friction loss for the hose layout and ultimately the required pump discharge pressure.

The friction loss formula described previously may also be used when determining the friction loss in siamesed lines of equal length. However, in this case a different set of coefficients is required. The coefficients for siamesed lines are contained in Table13.3.9. When determining the friction loss in siamesed lines using this formula, q should be determined by using the total flow through both lines.

EXAMPLE: Calculate the pump discharge pressure necessary to adequately supply a portable master stream device equipped with a 500 gpm (1892 L/min) spray nozzle operated at 100 psi (690 kPa) being supplied by two 3 in. (77 mm) with 3 in. (77 mm) couplings, each 600 ft (180 m) long. There is no elevation change in the hose lay, but assume that the master stream appliance creates a 10 psi (70 kPa) pressure loss.

SOLUTION: U.S. customary units

$$FL = cq^2l + \text{Appliance loss}$$
$$FL = (0.17)(500/100)^2(600/100) + 10$$
$$FL = (0.17)(25)(6) + 10$$
$$FL = 25.5 + 10$$

TABLE 13.3.9 Recommended Friction Loss Coefficients for Siamesed Lines of Equal Length

Number of Hose Lines and Their Diameters in in. (mm)	Friction Loss Coefficient *psi*	*kPa*
Two 2½ in. (65 mm)	0.50	0.789
Three 2½ in. (65 mm)	0.22	0.347
Two 3 in. (77 mm) with 2½ in. (65 mm) couplings	0.20	0.316
Two 3 in. (77 mm) with 3 in. (77 mm) couplings	0.17	0.268
One 3 in. (77 mm) with 2½ in. (65 mm) couplings, one 2½ in. (65 mm)	0.30	0.473
One 3 in. (77 mm) with 3 in. (77 mm) couplings, one 2½ in. (65 mm)	0.27	0.426
Two 2½ in. (65 mm), one 3 in. (77 mm) with 2½ in. (65 mm) couplings	0.16	0.253
Two 3 in. (77 mm) with 2½ in. (65 mm) couplings, one 2½ in. (65 mm)	0.12	0.189

FL = 35.5 or 36 psi

$PDP = NP + FL \pm EP$

PDP = 100 + 36 + 0

PDP = 136 psi

SOLUTION: Metric units

$FL = cq^2l$ + Appliance loss

$FL = (0.268)(1892/100)^2(180/100) + 70$

$FL = (0.268)(357.97)(1.8) + 70$

FL = 172.68 + 70

FL = 242.68 or 243 kPa

$PDP = NP + FL \pm EP$

PDP = 690 + 243 + 0

PDP = 933 kPa

Attempting to mathematically calculate the pressure loss or pump discharge pressure in siamesed lines of unequal length is an extremely complicated process that involves advanced mathematical techniques. Because these situations are so rare in real-life operations, a detailed description of these operations is omitted here. Consult the references listed in the bibliography of this section for more information on this matter.

REACTION FORCES IN HOSE LINES, NOZZLES, AND AERIAL DEVICES

When water is discharged from a hose line, there are two reaction forces acting on the line: (1) hose line reaction and (2) nozzle reaction. Both contribute in varying degrees to the total reaction that is present in any hose nozzle flow configuration. For purposes of simplicity, each is treated separately in this chapter.

Hose Line Reaction Forces

Reaction forces occur in hose lines when the direction of waterflow is changed by a bend in the hose. Between the hydrant and nozzle, the velocity is constrained in the hose and the acceleration is zero, as shown by the equation

$$Q = AV$$

where

Q = The flow rate

A = The cross-sectional area

V = The average velocity

Figure 13.3.3 illustrates a typical handline situation where enough push must be applied at the bend to resist the reaction force F_3. There is no problem where the hose bends off the ground.

Figures 13.3.4 and 13.3.5 are charts by which values of the reaction F_3, in pounds force, can be directly determined. To obtain reactions in other sizes of hose, Figure 13.3.4 includes a table of conversion factors to use in calculating reaction forces, expressed in pounds force, in hose of other diameters; and Fig-

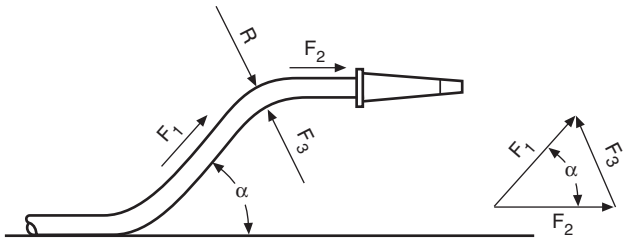

FIGURE 13.3.3 Reaction in a Hose Line

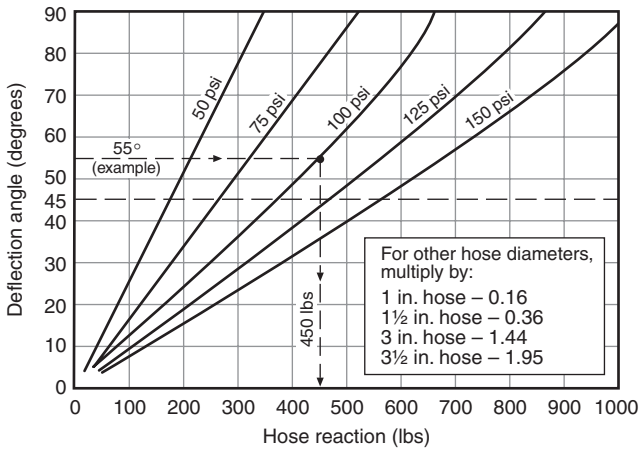

FIGURE 13.3.4 Reaction Forces in 2½ in. Hose

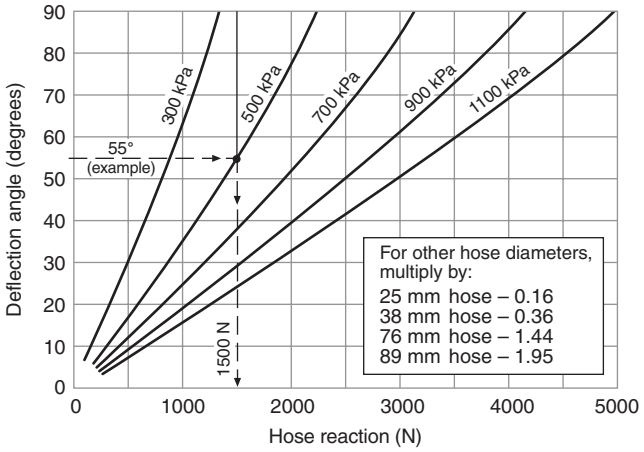

FIGURE 13.3.5 Reaction Forces in 65 mm Hose

ure 13.3.5 includes a table of conversion factors to use in calculating reaction forces, expressed in newtons (N), in hose of other diameters.

EXAMPLE: What is the reaction at a 55 degree bend in 1½ in. (38 mm) hose if the pressure is 100 psi (690 kPa)?

SOLUTION: On the deflection angle side, move horizontally from the 55 degree bend to intersection with the 100 psi (690 kPa) curve. From there go down vertically to the reaction scale and read 450 lb (204 kg). From Figures 13.3.4 and 13.3.5, note that the factor for 1½ in. (38 mm) hose is 0.36. Multiplying 450 (204 kg) by 0.36, the answer is 162 lb (73 kg).

Nozzle Reaction

Water discharging from a nozzle produces a reaction that is opposite the flow of water and known as nozzle reaction. As flow and pressure are increased, the nozzle reaction increases. Nozzle reaction of solid-stream nozzles may be calculated by means of the following formula:

$$NR = 1.5d^2NP$$

where

NR = Nozzle reaction (lb)

1.5 = A constant

d = Nozzle diameter (in.)

NP = Nozzle pressure (psi)

For SI units:

$$NR = 0.0015d_m^2NP_m$$

where

NR = nozzle reaction (N)

0.0015 = A constant

d_m = Nozzle diameter (mm)

NP_m = Nozzle pressure (kPa)

EXAMPLE: Determine the nozzle reaction created when a 1¼ in. (32 mm) solid-stream nozzle is being operated at a discharge pressure of 50 psi (345 kPa).

SOLUTION: U.S. customary units

$$NR = 1.5d^2NP$$

$$NR = (1.5)(1.25)^2(50)$$

$$NR = (1.5)(1.5625)(50)$$

$$NR = 117.19 \text{ lb}$$

SOLUTION: Metric units

$$NR = 0.0015d_m^2NP_m$$

$$NR = (0.0015)(32)^2(345)$$

$$NR = (0.0015)(1024)(345)$$

$$NR = 529.92 \text{ N}$$

Another formula that may be used for both solid-stream and spray nozzles is:

$$NR = 0.0505Q\sqrt{NP}$$

where

NR = Nozzle reaction (lb)

0.0505 = A constant

Q = Nozzle discharge (gpm)

NP = Nozzle pressure (psi)

For SI units:

$$NR = 0.0226Q_m\sqrt{NP_m}$$

where

NR = Nozzle reaction (N)

0.0226 = A constant

Q_m = Nozzle discharge (L/min)

NP_m = Nozzle pressure (kPa)

EXAMPLE: Find the nozzle reaction when a 250 gpm (946 L/min) spray nozzle is operating at 100 psi (690 kPa).

SOLUTION: U.S. customary units

$$NR = 0.0505Q\sqrt{NP}$$

$$NR = (0.0505)(250)(\sqrt{100})$$

$$NR = (0.0505)(250)(10)$$

$$NR = 126.25 \text{ lb}$$

SOLUTION: Metric units

$$NR = 0.0156Q_m\sqrt{NP_m}$$

$$NR = (0.0226)(946)(\sqrt{690})$$

$$NR = (0.0226)(946)(26.27)$$

$$NR = 561.64 \text{ N}$$

Reaction Forces in Aerial Ladder and Elevating Platform Streams

The reaction of master streams, either solid or spray, discharged from aerial ladders or elevating platforms creates a tremendous amount of stress on the aerial device. Some of these stresses, such as leverage effects and displacement of centers of gravity, are magnified as the aerial device is further extended. Thus, the stability of the whole structure could be threatened if the aerial device is extended, or if the elevated master stream is operated, beyond its design limitations. Likewise, a sudden loss of pressure when a hose line bursts or a pump stops may cause a whipping action that can result in damage to the aerial device. Because there are many variable forces acting on aerial ladders, elevating platforms, or water towers in service, it is quite impractical to devise tables of specific reactions.

Fire fighters must be particularly cautious with detachable ladder pipes and hose that are used in conjunction with light-duty aerial ladders. In this circumstance, the detachable ladder pipe should always be operated in line with the main beams or trusses of the aerial ladder. Light-duty aerial ladders have little resistance to torsional effects, so detachable ladder pipes should be incapable of horizontal travel exceeding 15 degrees. Rotation of the ladder turntable is the correct way to rotate the stream from these ladder pipes. When possible, these detachable ladder pipes should be operated from the turntable of the apparatus using sets of ropes to control the up-and-down motion of the nozzle. This eliminates the need to place a fire fighter in the precarious position of directing the stream from the tip of the ladder.

Care should be used also in elevating and lowering the stream, because this changes the direction of the thrust on the ladder mechanism. The fly ladder should not be raised or lowered while a ladder pipe is discharging, and under no circumstances should the vehicle be moved with the ladder pipe discharging. All such streams should be gated to permit movement of the ladder and vehicle without shutting down the pump.

Finally, consult the apparatus manufacturer's recommendation when choosing the size of hose to be used to supply the detachable ladder pipe. Most aerial ladders are designed for a single 3 or 3½ in. supply hose to be run up the ladder to the ladder pipe. Using a larger hose could result in overloading the ladder, thus risking a catastrophic failure of the device.

In general aerial ladders with piped waterways and elevating platforms are equipped with remote-controlled nozzles that are capable of a wider range of motion than are detachable ladder pipes. The remote controls for these devices will typically not allow the nozzle to operate a stream outside of the safe operating area. Driver/operators should be familiar with the recommended operating procedures and safe loading parameters for these devices.

SUMMARY

The effective supply of water through hose lines to nozzles is one of the most basic tenets of fire fighting and municipal fire protection. Fire apparatus driver/operators must be able to effectively calculate the required flows and pressures needed to adequately supply fire fighters operating attack lines. This calculation is important from both an operational and a safety standpoint. The information contained in this chapter allows fire-fighting professionals to realistically calculate waterflow pressure and quantity through hose lines and nozzles. It also allows for the calculation of the resultant reaction pressure that will be created at the nozzle. The application of this information will assist in providing useful pre-incident planning and fire scene tactical operations.

Chapter 4

Alternate Water Supplies

Laurence J. Stewart

Chapter Contents

Sources of Alternate Water Supplies
Occupancy Hazard Classification
Structure and Site Survey
Natural Water Sources
Developed Sources of Water
Agreements/Permits
Estimating Available Water Supply Capacity
Water Supply Vehicles, Water Shuttle Operations, and Drivers

Key Terms

alternate water supply, cistern, construction (type of), dry hydrant, minimum water requirement, occupancy hazard classification, water shuttle operations, water source (developed), water source (natural), water supply (mobile)

This chapter provides information for the planning and utilization of a water supply or supplies that the fire department creates and uses for fire suppression. Fire suppression cannot be accomplished without water sources and the ability to move the water by some selected method. The water in the "supply" created by all types of alternative water supply methods should always be considered nonpotable water.

The development of alternative water supplies is a four-step planning process centering on answers to the following questions:

- How much water is required?
- Where is the water?
- How can dry hydrants help?
- How can water be moved to the fire?

This chapter does not cover (1) the providing of water to any government-operated or government-subsidized water system that is either out of water or has its supply drastically curtailed or (2) the providing of water to forest fire suppression units.

See also Section 15, Chapter 1, "Fixed Water Storage Supplies for Fire Protection"; and Section 15, Chapter 6, "Water Distribution."

SOURCES OF ALTERNATE WATER SUPPLIES

A fire department operating without a water system with hydrants or one with a very limited number of hydrants has two means of getting water: (1) from supplies on the fireground, which can be constructed or natural, or (2) from supplies transported to the scene. Alternative water supplies for fire department operations come from water obtained directly from either static water, flowing water, or water contained within some type of storage tank. Water from these sources is not part of a pressurized water system. Alternative water supply operations can also encompass the use of water from fire hydrants that are part of a pressurized water system. In such a case, the water from the hydrants is "loaded" into mobile water supply apparatus and shuttled to a distant fire scene, or it may be moved both within and beyond the "boundaries" of the pressurized water system through the use of hose. The distinctive feature of this type of water use is that the fire department provides the water by means of hose, varying types of pumping apparatus, and/or mobile water supply apparatus. (The latter will be referred to in this chapter as MWS apparatus.)

Proper planning in developing water supplies for fire fighting requires that built-up areas and water supply needs be identified within the response area. The fire service has always experienced fire control difficulties in isolated areas. One of the main problems is the lack of an adequate water supply. The availability of an adequate amount of water for control and extinguishment is an important consideration for fire chiefs and a factor that influences the majority of their fire-fighting decisions. A portion of the training of suburban and rural fire departments emphasizes the need for the conservation of the meager water supply available in many areas. A limited amount of water at a working fire challenges all phases of fire fighting. Once the areas with waterflow needs have been identified, a building/site survey should be conducted to determine the water supply needed for fire protection.

Laurence J. Stewart is a fire service specialist for the NFPA Public Fire Protection Division. He has 23 years of experience within the fire and emergency services.

Minimum water supplies are determined by the following criteria:

- Classification of occupancy hazard
- Classification of construction
- Structure dimensions
- Exposures, if any

In order to establish the necessary quantity of water available for fire suppression, various criteria must be converted into numerical equivalencies. Tables 13.4.1 and 13.4.2 provide the data for establishing the variables used in the water supply formula. The following occupancy hazard classes number and Table 13.4.2 classification number will be used in the formulas calculating minimum water requirements.

OCCUPANCY HAZARD CLASSIFICATION

Occupancies are divided into categories based on the risk and the development of fire spread. The occupancy hazard classification number is a mathematical factor to be used in calculating minimum water supplies. The lowest occupancy hazard classification number is 3; it is assigned to the highest hazard group. The highest occupancy hazard classification number is 7; it is assigned to the lowest hazard group. NFPA 1142, *Standard on Water Supplies for Suburban and Rural Fire Fighting,* provides the minimum water supply requirements, based on occupancy classification, construction classification, and total volume of the structure.

Occupancy Hazard Class 3

Occupancies in Class 3 are considered severe hazard occupancies, in which quantity and combustibility of contents are high. A fire in a Class 3 occupancy would tend to develop very rapidly and have high rates of heat release. Examples of this classification include occupancies having conditions similar to the following:

- Cereal or flour mills
- Combustible hydraulics facilities
- Cotton picker and opening operations (cotton gins)
- Die casting facilities
- Explosives and pyrotechnics manufacturing and storage facilities
- Feed and gristmills
- Flammable liquid spraying facilities
- Flow coating/dipping facilities
- Linseed oil mills
- Manufactured homes/modular building assembly facilities
- Metal extruding facilities
- Plastic processing facilities
- Plywood and particle board manufacturing facilities
- Printing plants using flammable inks
- Rubber reclaiming facilities
- Sawmills
- Solvent extracting facilities
- Facilities with straw or hay in bales
- Textile picking facilities
- Facilities upholstering with plastic foams

Occupancy Hazard Class 4

Occupancies in Class 4 are high hazard occupancies, in which quantity and combustibility of contents are high. Examples of this classification include occupancies having conditions similar to the following:

- Barns and stables (commercial)
- Building materials supply storage facilities
- Department stores
- Exhibition halls, auditoriums, and theaters
- Feed stores (without processing)
- Freight terminals
- Mercantile facilities
- Paper and pulp mills
- Paper processing plants
- Piers and wharves
- Repair garages
- Rubber products manufacturing and storage facilities
- Warehouses (e.g., those used for furniture, general storage, paint, paper, and woodworking industries)

Occupancy Hazard Class 5

Occupancies in Class 5 are considered moderate hazard occupancies, in which the quantity or combustibility of contents is

TABLE 13.4.2 Construction Classification Numbers

0.5	*0.75*	*1.0*	*0.75*	*1.50*
Type I construction (fire resistive)	Type II construction (noncombustible)	Type III construction (ordinary)	Type IV construction (heavy timber)	Type V construction (wood frame)

expected to develop moderate rates of spread and heat release. Examples of this classification include occupancies having conditions similar to the following:

- Amusement centers
- Clothing manufacturing plants
- Cold storage warehouses
- Confectionery product warehouses
- Farm storage buildings (e.g., corn cribs, dairy barns, equipment sheds, hatcheries)
- Laundries
- Leather goods manufacturing plants
- Libraries (with large stockroom areas)
- Lithography shops
- Machine shops
- Metalworking shops
- Nurseries (plant)
- Pharmaceutical manufacturing plants
- Printing and publishing plants
- Restaurants
- Rope and twine manufacturing plants
- Sugar refineries
- Tanneries
- Textile manufacturing plants
- Tobacco barns
- Unoccupied buildings

Occupancy Hazard Class 6

Occupancies in Class 6 are considered low hazard occupancies, in which the quantity or combustibility of contents is expected to develop relatively low rates of spread and heat release. Examples of this classification include occupancies having conditions similar to the following:

- Armories
- Automobile parking garages
- Bakeries
- Barber or beauty shops
- Beverage manufacturing plants/breweries
- Boiler houses
- Brick, tile, and clay product manufacturing plants
- Canneries
- Cement plants
- Churches and similar religious structures
- Dairy products manufacturing and processing plants
- Doctors' offices
- Electronics plants
- Foundries
- Fur processing plants
- Gasoline service stations
- Glass and glass products manufacturing plants
- Horse stables
- Mortuaries
- Municipal buildings
- Post offices
- Slaughterhouses
- Telephone exchanges
- Tobacco manufacturing plants
- Watch and jewelry manufacturing plants
- Wineries

Occupancy Hazard Class 7

Occupancies in Class 7 are considered light hazard occupancies, in which the quantity or combustibility of contents is expected to develop a relatively light rate of spread and heat release. Examples of this classification include occupancies having conditions similar to the following:

- Apartments
- Colleges and universities
- Clubs
- Dormitories
- Dwellings
- Fire stations
- Fraternity or sorority houses
- Hospitals
- Hotels and motels
- Libraries (except large stockroom areas)
- Museums
- Nursing and convalescent homes
- Offices (including data processing)
- Police stations
- Prisons
- Schools
- Theaters without stages

STRUCTURE AND SITE SURVEY

Information needed to compute the minimum water supplies that should be collected during the structure/site survey (Figure 13.4.1) includes the following:

- Area of all floors, including attics, basements, and crawl spaces
- Height between floors or crawl spaces and in attics from floor to ridgepole
- Construction materials used in each structure, including walls, floors, roofs, ceilings, interior partitions, stairs, and so forth

FIGURE 13.4.1 On-Site Survey of Structure

- Occupancy (occupancies) of structures
- Occupancy (occupancies) of yard areas
- Exposures to structures and yard storage and distances between them
- Fire protection systems, such as automatic and manual protection systems, hydrants, yard mains, and other protection facilities
- On-site water supplies, including natural and constructed sources of water

Classification of Construction

There are five recognized types of construction, with the type of materials used in each type of construction listed and the type of construction assigned a numerical number. The assigned number becomes another mathematical factor to be used in the formula for calculating minimum water supplies. The slowest burning or lowest hazard type of construction (i.e., fire resistive) is construction classification number 0.5. The fastest burning or highest hazard type of construction (i.e., wood frame) is construction classification number 1.5. Where there is more than one type of construction in a structure, the higher classification number should be used for the entire structure.

Construction classifications listed in Table 13.4.2 have been simplified for quick use. If more complete definitions are needed, refer to NFPA 220, *Standard on Types of Building Construction.*

Calculating Minimum Water Requirements

Before determining such things as the type of pumpers and MWS apparatus to use and how to pump water from a source, the fire department should focus on the water requirements of the response area. This means determining how much water is required to extinguish a fire at each structure in the response area. To calculate this amount, three pieces of information are needed: the materials stored in the building, the building's construction, and the size (total volume) of the structure. This information can be gathered during the on-site surveys of the buildings in the response area outside of the pressurized water system. (The formulas were developed by an NFPA 1142 committee.)

Structures without Exposure Hazards: Minimum water supply

$$= \frac{\text{Total volume of structure}}{\text{Occupancy hazard classification number}} \times \text{Construction classification number}$$

Structures with Exposure Hazards: Minimum water supply

$$= \frac{\text{Total volume of structure}}{\text{Occupancy hazard classification number}} \times \text{Construction classification number} \times 1.5$$

NATURAL WATER SOURCES

Using natural water sources, such as streams, springs, lakes, ponds, and wells, provides a relatively inexpensive quantity of water. Reliability must also be considered when planning water supply distribution. Research may be necessary to determine that a source can supply the minimum water requirements in all seasons and during all variations in weather. Inspection of water sources is an ongoing process. Records should be updated with any seasonal fluctuations, flood or drought conditions, and freezing problems noted.

Streams

Streams, including rivers, bays, creeks, and irrigation canals, can represent a continuously flowing source of substantial capacity. When considering water from flowing streams as potential water sources, the fire department should take into account the following factors:

- *Flowing capacity.* The stream should deliver water in capacities compatible with the water requirements determined necessary for the hazard.
- *Climatic characteristics.* Streams that deliver water throughout the year and are not susceptible to drought are desirable for fire protection. However, if such streams are not available, a combination of supplies might be necessary. In many sections of the country, streams cannot be relied on during drought seasons. If the stream is subject to flooding or freezing, special measures might be necessary to make the stream usable under such conditions (Figure 13.4.2). Similar circumstances might exist during wet periods or when the ground is covered with snow.
- *Accessibility.* A water site should provide the necessary access to ensure availability to the site in all normally expected weather conditions encountered in the area 24 hours per day, 365 days per year. Distance and terrain from the all-weather road to the source should be such as to make the water readily available. In some cases, special equipment should be used to obtain the water, especially in areas where the water surface may become frozen. Where roadways to the water supply are provided, they should be constructed with a suitable approach for fire department access.

Ponds

Ponds tend to offer lower quantities of water but may be numerous in the area. Reliability issues are similar to those of streams. Ponds can include lakes or farm ponds used for watering livestock, irrigation, fish culture, recreation, or other purposes while serving a secondary function for fire protection. Valuable information concerning the design of ponds can be obtained from county agricultural agents, cooperative extension offices, county engineers, and so forth. Most of the factors listed relative to streams are pertinent to ponds, with the following items to be considered:

- The minimum annual level should be adequate to meet the water supply needs of the fire problem the pond serves.
- Silt and debris can accumulate in a pond or lake, reducing its actual capacity, while its surface area and level remain con-

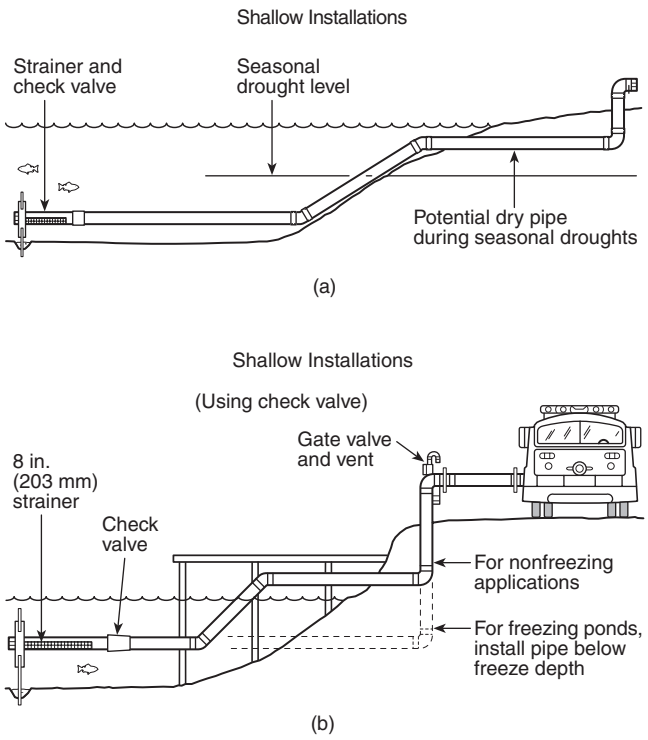

FIGURE 13.4.2 Dry Hydrant Installation (a) Shallow Stream Installation Based on Seasonal Drought (b) Shallow Stream Installation Based on Seasonal Drought and Freezing Conditions (Courtesy of Stan Merrett, ETT, L.L.C.)

stant. This can provide a deceptive impression of capacity and calls for at least seasonal inspections.

- Accessibility should always be considered. Many recreational lakes are provided with access by roads, driveways, and boat-launching ramps and are available for fire department use. Some large lakes, formed by a dam on a river, might have been constructed for purposes such as generating power, controlling floods, or regulating the flow of a river. During certain periods of the year, droughts, drawdowns, and so forth can cause such lakes to have very low water levels. The water under such conditions might not be accessible to the fire department for drafting by the fire department pumping unit, even where a paved road for boat launching has been provided and extended into the water at normal water levels for several feet or meters. Under such conditions, other provisions should be made to make the water supply fully accessible to the fire department.

Other Natural Water Sources

Other natural water sources might include springs and artesian wells. Individual springs and occasional artesian water supplies exist in some areas. These other natural water sources are generally of more limited capacity, but they can be useful for water supply, subject to reasonable application of the recommendations listed for ponds and streams. In many cases, it might be necessary to form a temporary natural pool or form a pond with a salvage cover, for example, to collect water for the use of the fire department when using a spring or an artesian well.

DEVELOPED SOURCES OF WATER

The developed sources of water supplies adapted for fire fighting are limited only by the innovation of the fire department. Developed sources include cisterns, swimming pools, quarries, mines, automatic sprinkler system supplies, stationary tanks, driven wells, and dry hydrants.

Cisterns

Cisterns, one of the oldest sources of emergency water supply, are important sources of water for fire fighting, domestic consumption, and drought storage in many rural and beach areas. Cisterns should have a minimum usable volume as determined by the authority having jurisdiction, using the methods described in NFPA 1142. There is no real limit to the maximum capacity. A cistern should be accessible to the fire apparatus or other pumping device, but it should also be located far enough from the hazard so that personnel and equipment are not endangered. The water level of a cistern can be maintained by rainfall, by water pumped from a well, by water hauled by a MWS apparatus, or by the seasonal high water of a stream or river. Because its surface is often relatively inaccessible and the water is stagnant, the cistern can present a freezing problem. One method for minimizing freezing is to use a dry hydrant protruding into the water at a point below the local frost line. Cisterns should be capped for safety, but they should have openings to allow inspections and use of suction hose where needed. There should also be some type of protective boundary for the area in which the cistern is located to prevent unauthorized entrance to the area.

If a dry hydrant is not installed in a cistern, then (depending on local conditions) a heavy pipe or a pike pole can be adequate to break an ice formation. In fact, the weight of the suction hose itself can be sufficient to break the ice, provided there is no danger of damaging the strainer, the hose, or the hose threads. Floating a log, a bale of hay, or a bale of straw or placing a partly filled, floating barrel on the surface of the water are some methods for providing an ice-free surface area in a cistern or other water source.

The construction of cisterns is governed by local conditions of soil and material availability. Practical information can be obtained from local governmental departments or agricultural agencies.

Some engineering considerations to be taken into account in designing cisterns include the following:

- The base, walls, and roof should be designed for the prevailing soil conditions and for the loads encountered where heavy vehicles are parked adjacent to each other.
- If groundwater conditions are high, the cistern should not float when empty.
- Suction piping should be designed to minimize whirlpooling.
- Vent piping should be of sufficient size (as shown in NFPA 1142).

Maintenance factors to be considered by the fire department include the problem of the evaporation of water or other low water conditions and the freezing problems previously discussed.

Swimming Pools

Swimming pools are an increasingly common source of water for fire protection. Even in some areas with normally adequate hydrant water supplies, swimming pools have been a factor in providing protection, such as in cases in which water demands have exceeded availability. Swimming pools provide an advantage in that they are sources of clean water, but they have major drawbacks due to the weight of fire department vehicles and poor accessibility for large apparatus.

Swimming pool distribution is better than hydrant distribution in some areas of the country. If the fire department intends to use a swimming pool as a water supply, it should develop these water sources by working with property owners through pre-incident planning.

If fire department accessibility is considered when designing the pool, a usable water supply should be available to the fire department for supplying direct hose lines or a source of water for MWS apparatus filling. Most swimming pools are built in areas requiring security fencing or walls, and these can complicate accessibility. Fences and walls can be designed for fire department use. However, should there be an incident in which fire department use of the pool has been permitted and there has been no other method provided for access through the protective area created by a fence, the fence can be lifted to allow the suction hose to be used (Figure 13.4.3).

A swimming pool located virtually under the eaves of a burning house can be a very poor location from which to pump if there are problems of fire exposure to the work area. Pumping from a neighboring pool, if it is close enough, or setting the water-hauling program in motion is frequently preferable to pumping from the pool of the burning house.

In most cases, a solution to the problems of accessibility can be achieved through pre-incident planning and might call for long lengths of suction hose, portable pumps, dry hydrants, siphon ejectors, or properly spaced gates. Portable (or floating) pumps, which are designed for large-volume delivery at limited pressures to deliver water to portable folding tanks or fire department pumpers, are frequently ideal for use where accessibility problems exist.

FIGURE 13.4.3 Fire Fighters Entering a Fenced-Off Swimming Pool Area

Fire fighters must take care to ensure that structural damage will not occur to a pool and the surrounding area if the water is used for fire fighting. Lightly built cement or poured concrete pools can be subject to structural damage, cracking, or collapse when drained. In addition, a pool in extremely wet soil will tend to float upward when drained; therefore, it might be necessary to refill the pool as soon as the fire is under control and MWS apparatus can be released from fire duties.

Some pools are holes of compacted earth covered by a plastic surfacing or light-gauge metal panels placed against such earth or a special fill. Such pools can collapse internally if emptied. It might be possible to use a limited portion of such water sources but not the entire available water supply. Therefore, not using these pools at all might be prudent.

Another consideration is whether the ground surrounding a pool will support the weight of a fire department vehicle without collapsing. The fire department should study and know the various pool limitations within the area served by consulting with the builders and installers of these pools.

Livestock Watering Ponds and Tanks

The local fire department representative responsible for planning water supplies should contact the owner of a farm, ranch, or similar type of area where livestock are kept and make him or her aware of the need for, and amount of, water required for that fire department to supply fire suppression to any/all buildings. Such tanks and ponds should be sized to be adequate in volume for both farm and fire department use and should be located to be readily available to the fire department. Tanks should be placed on the edge of the barnyard and on a side accessible to the fire department, with the pumper or pump taking suction through a connection on the tank or by suction hose. These watering tanks and ponds are often filled and maintained by a pump operated by a windmill or by an electric pump (Figure 13.4.4).

Wells and Well Systems

Wells and well systems are becoming increasingly popular as water supplies for fire-fighting purposes at industrial properties, shopping centers, subdivisions, and farmhouses located in rural areas beyond the reach of a municipal water distribution system.

In areas with suitable soil conditions—for instance, areas that have soils of a very sandy nature—driven wells or water-jetted wells might be used to obtain water for fire fighting. These wells are pipes that have been driven into the ground and that usually have perforations about the base to allow the entry of water. From the threaded pipe head (or a fitting attached to the body of the pipe), a pump connection can be made to draft water, much as from a well hydrant. A high water table is a prerequisite to using this method of obtaining water. Fire-fighting units in areas conducive to this technique should have the necessary equipment

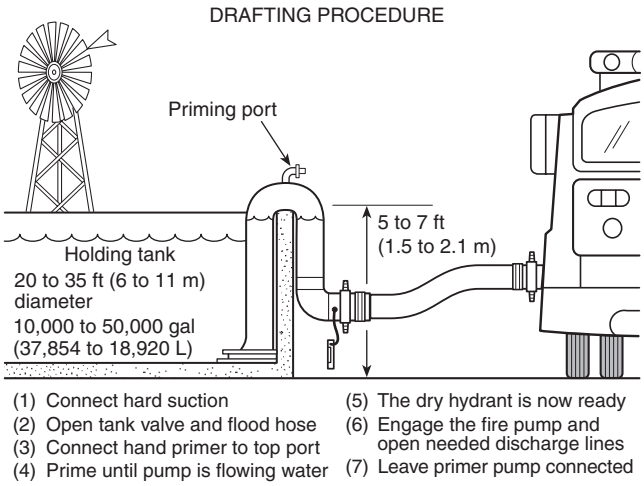

FIGURE 13.4.4 Drafting Procedure for Farm Holding Tanks (Courtesy of Stan Merrett, ETT, L.L.C.)

FIGURE 13.4.5 Dry Hydrant

for such installations. Some state and local governments have regulations or licensing requirements that govern well construction. Such restrictions will probably increase in the future.

Where water is supplied by one or more electricity-driven or engine-driven pumps used for irrigation or industrial use and where fuses and/or batteries are removed during periods when the water is not needed, the fire department should make provisions with the pump owner to ensure that power can be made available when needed for water supply.

Dry Hydrants

Per NFPA 1142, a dry hydrant is defined as "an arrangement of pipe permanently connected to a water source other than a piped, pressurized water supply system that provides a ready means of water supply for fire-fighting purposes and that utilizes the drafting (suction) capability of fire department pumpers" (Figure 13.4.5). Dry hydrants have the following features:

- Consist of a nonpressurized pipe system
- Use relatively inexpensive piping materials and other supplies
- Are permanently installed in existing lakes, ponds, streams, and cisterns
- Provide a means of access whenever needed, regardless of weather
- Allow years of simple operation with a minimum of maintenance

Dry hydrants should be installed at reliable water sources. The placement of dry hydrants at water sites should follow a process of planning, design criteria based on the site and water location, permit (i.e., land owner permission), and the construction and installation of the hydrant on site. A strategically placed dry hydrant system, with all-weather road access, significantly reduces water point setup and turnaround time to the fireground, improves the life safety of the fire fighter, and may reduce insurance costs.

Design Characteristics. Local topography, climatic conditions, and access to materials, among other factors, will determine the design characteristics of each installation (Figures 13.4.6 and 13.4.7). Distance to the water combined with the difference in elevation between the hydrant head and the water source and the desired gallon-per-minute (liter-per-minute) flow will affect the pipe size that needs to be used. All installations should use, as a minimum, 6 in. (152 mm) pipe. With longer lateral runs and higher volume flow, 8 in. (203 mm) or 10 in. (254 mm) pipe sizes can become necessary for the horizontal lengths.

Local preferences and experience, along with access to materials, will determine the type of pipe and fittings best suited for the job. In some parts of the country, brass and bronze caps and steamer connections, along with iron, steel, and bituminous cement pipe and fittings, are being used for hydrant materials.

In many parts of the country, however, Schedule 40—and in areas where there are freezing conditions expected as normal

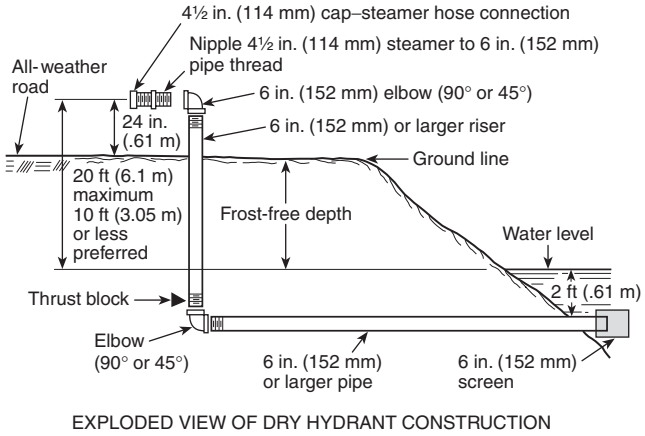

FIGURE 13.4.6 Dry Hydrant Construction Using Iron, Steel, or PVC Pipe

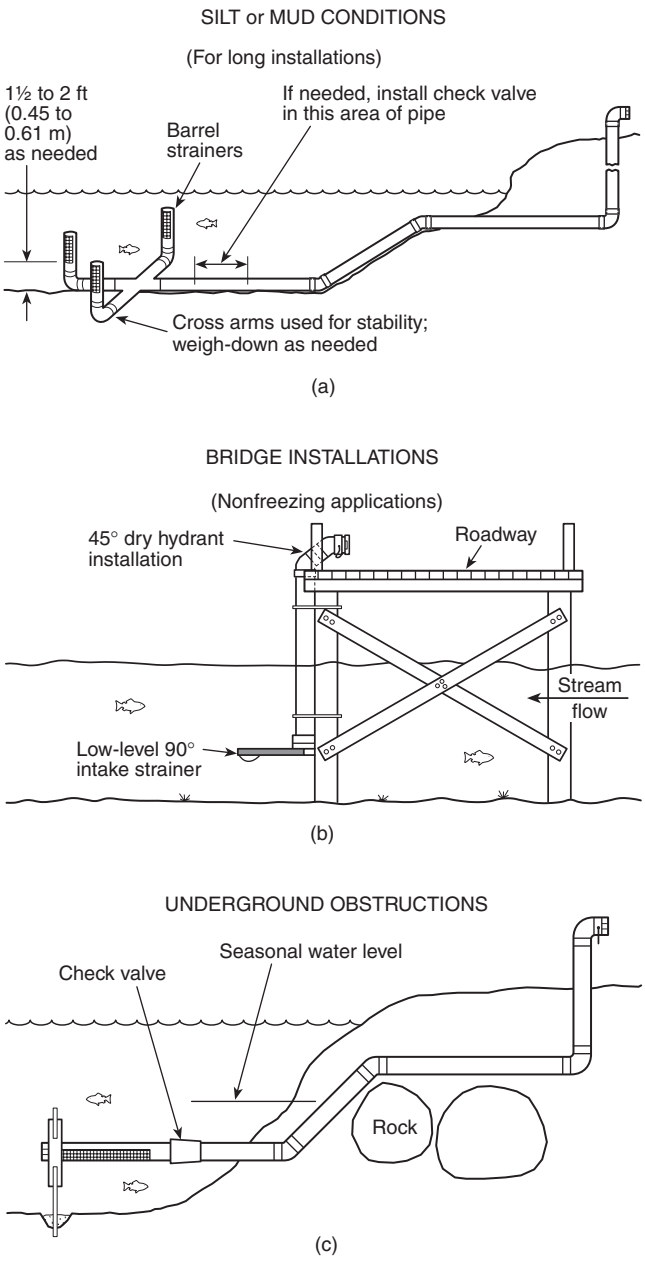

FIGURE 13.4.7 Dry Hydrant Installation (a) for Silt and Mud Conditions, (b) from a Bridge, and (c) Overcoming Underground Obstructions (Courtesy of Stan Merrett, ETT, L.L.C.)

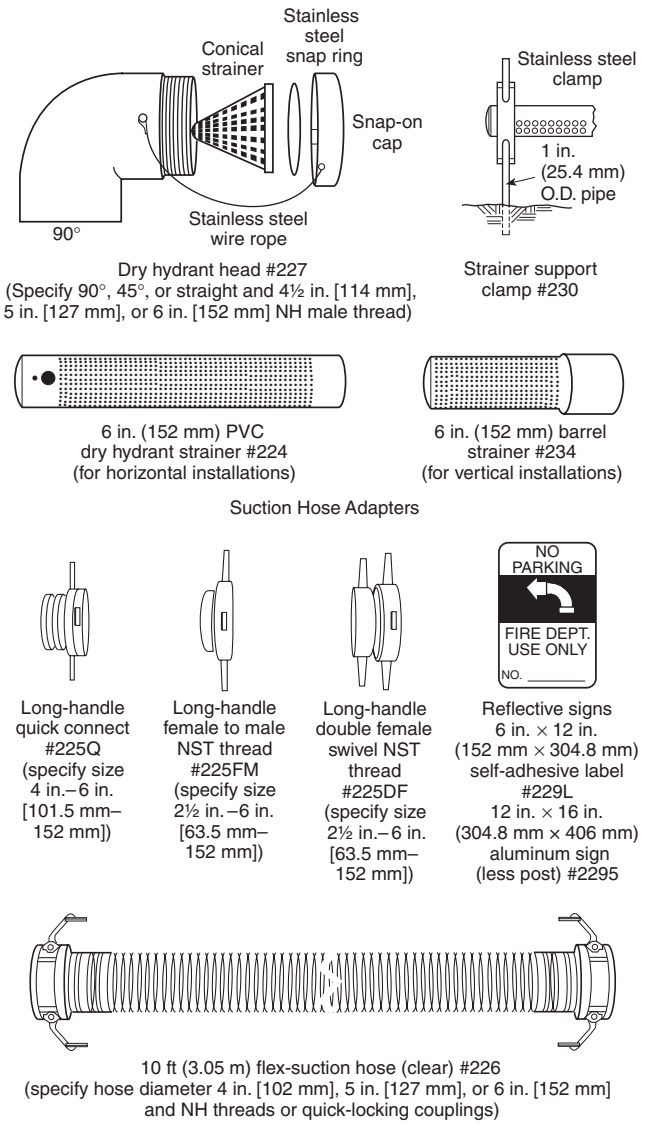

FIGURE 13.4.8 Commercially Available Dry Hydrant Components (Source: Wisconsin Department of Natural Resources)

weather criteria, Schedule 80—PVC pipe, fittings, and connections are used (Figure 13.4.8). Many fire service manufacturers are now offering premade and preassembled suction screens, hydrant heads, and supports that come ready to attach to the pipe. Steamer fittings should be compatible with the fire department's hard suction hose size and thread type.

The dry hydrant design has features that make its use accessible to many rural fire departments and property owners in terms of personnel and financial resources. The type and class of pipe for a particular dry hydrant installation should be determined through the consideration of the following conditions: soil, corrosion susceptibility, climate, and susceptibility of pipe to other external loads, including earth loads and traffic or vehicle loads. All exposed surfaces should be primed and painted to protect the pipe and prevent deterioration of the material.

Preferably no more than two 90 degree elbows should be used in the total dry hydrant system. Also desirable is the installation of long-sweep elbows at the bottom of the riser where the lateral run connects. Long-sweep elbows can be constructed with two 45 degree elbows and a 2 ft (0.6 m) length of pipe. If any portion of the dry hydrant above ground level becomes damaged in any manner that would make the hydrant unusable when connection is made to pump suction hose, the use of a long-sweep elbow could allow drafting to continue, although at a much reduced rate of flow.

NFPA 1142 contains numerous design criteria, such as a recommendation for a 6 in. (150 mm) minimum inside diameter of the pipe and limit of 10 to 12 ft (3 to 3.7 m) for static lift. See Figure 13.4.9 for a checklist of dry hydrant design features.

Dry Hydrant Design Features Checklist

Design factors are affected by:

- ☐ Desired flow from the hydrant in gpm
- ☐ Suitability of pipe materials
- ☐ Size and type of available fire aparatus pumper

The following design features are suggested for dry hydrants using PVC pipes:

- ☐ Use 6-in. (150-mm) diameter pipe as a minimum.
- ☐ Use Schedule 40 pipe as a minimum.
- ☐ Prime and paint all exposed pipe.
- ☐ Use a minimum number of elbows.
- ☐ Joint and cement all connections properly.
- ☐ Purchase or construct a suction screen with adequate hole openings.
- ☐ Ensure that total area of strainer holes exceeds four times the area of the diameter of the pipe.
- ☐ Ensure that installation depth is below the frost-free depth for the area. (Consult local university extension service or state Department of Natural Resources.)
- ☐ Ensure that installation depth is sufficiently below the average 50 year drought or appropriate state criteria for drought. (Consult engineer, soil conservationist, or hydrologist.)
- ☐ Place horizontal pipe level on minus grade of 1 to 2 in. (25.4 to 50.8 mm) per 100 ft (30.5 m), unless depth of cut is too great.
- ☐ Note that for streambed installation (with low flow depth less than 2 ft [0.6 m]) the strainer section may be buried below bed of stream and covered with gravel.
- ☐ Install dry hydrant as close as practical to the water source.
- ☐ Note that a flow of 600 to 1000 gpm (2271 to 3785 L/min) from the hydrant is desirable.
