various laboratories, emphasis on quality assurance procedures needed to be increased, because testing was not always being done by specialists. Consequently, a new, highly detailed specimen preparation protocol was developed in 1994.[66] This protocol was extensively validated in round-robin testing and formed the basis for updating the ASTM E1474 standard, which governs the furniture-specific details of conducting cone calorimeter tests.

Predicting the HRR Performance of Furniture

The HRR of a medium-sized sofa can reach values of around 2000 to 3000 kW (2 to 3 MW) in a very short time, only 3 to 5 minutes after ignition, with HRR around 5000 kW being common for large or sectional sofas. The context for interpreting this value is that it takes less than 2 MW to reach flashover in a room with a normal-sized door opening.[67] For health care, detention, and other high-risk occupancies, such large HRR values are not acceptable, and T.B. 133–complying (or similar) furniture should be used, as described in NFPA *101*®, *Life Safety Code*®, under the individual occupancy sections. In the consumer retail market, however, consumers traditionally have not been willing to pay the extra costs that would be incurred with T.B. 133–type furniture. Such furniture is not restricted to institutional sales and can be ordered by consumers. However, there is essentially no demand for furniture meeting these tougher regulations in the consumer sector.

In the T.B. 133 methodology, the furniture item is to be tested in full size, either in the furniture calorimeter or in a room fire test. Such a methodology should always be available, but it does have drawbacks: costs and effort in full-scale testing can be much greater than in testing small specimens. Thus, as with the fire performance of many other categories of products, bench-scale equivalents have been sought. A *predictive* bench-scale test can provide nearly as good information as a full-scale test, yet be much easier and simpler to conduct.

An initial method for predicting the HRR performance of full-size furniture items on the basis of cone calorimeter results was presented in 1985.[68] Since then, additional research took place to enhance the state of the art. The most significant such advance was embodied in the European research program, Combustion Behavior of Upholstered Furniture (CBUF). This massive study,[14] completed in 1995, yielded a new generation of predictive methods, based on very extensive testing and on advanced fire modeling work. Figure 6.6.9 shows the general design flowchart, as developed in the CBUF research; as mentioned above component-level is feasible in principle, but is not practicable. The simplest model, based on direct correlation, can be summarized as follows.

Determination of Propagating/Nonpropagating Behavior. The most important factor in determining the flaming combustion hazard of furniture for high-risk occupancies is whether the item will or will not support the propagation of fire over its surface. *Propagating* chairs spread fire over most of the surface of the item. Such behavior means that the chair was largely consumed at the end of the fire, although substantial portions of hard combustibles (wood, particleboard) may remain. *Nonpropagating* chairs show a very different behavior. With such items, once the ignition source dies out or is removed, the fire does not sustain itself. Thus, most of the padding and fabric still remains after the fire is over. Combustible materials are usually gone directly under the fire source and in its immediate vicinity; but from a short distance farther, the furniture item can appear essentially undamaged.

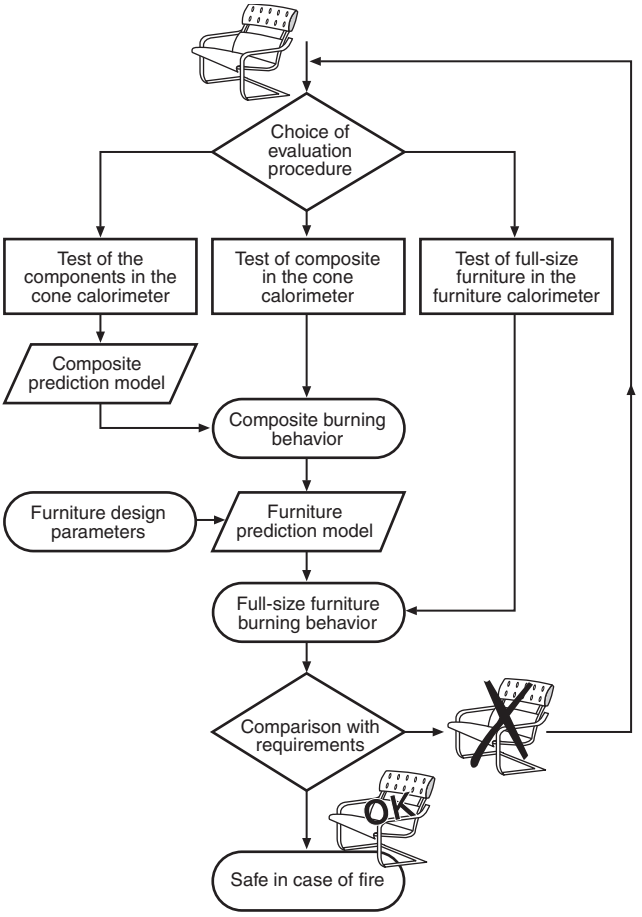

FIGURE 6.6.9 Procedure for Fire Safety Design of Upholstered Furniture

It is experimentally observed that nonpropagating full-scale chair fires normally show peak HRR values of 20 to 100 kW. One can compare this to the 80 kW level that California has selected as the pass/fail limit for T.B. 133. The propagating/nonpropagating behavior is only slightly affected by small variations in the type of ignition source used.

For a nonpropagating fire, the total HRR (and the emissions of toxic gases) is essentially identical to what is measured for the chair itself. For chairs that lead to propagating fires, however, the HRR (and toxic gas emissions) measured during a fire test represents only the *lower bound* to what may occur in a real fire. The reason is that for fires that are propagating fires, it is readily possible to ignite additional items in the room, including items that are not included in a test such as the room-test alternative of T.B. 133. The heat and radiation levels coming from a 100 kW fire are not sufficient to cause serious injury to an occupant, unless the occupant is very close to the fire, because of the room's small size or for other reasons. Thus, it can be concluded that nonpropagating fires are as *intrinsically safe* as a combustible item can ever be deemed to be.

Earlier studies[68] suggested that a propagation/nonpropagation criterion can be set as $\dot{q}'' = 75$ kW/m^2, where $\dot{q}''$ is defined as the cone calorimeter HRR average for the period starting with ignition and ending 180 seconds later. This limit was based on early experience with cone calorimeter testing, and both the irradiance and the test protocol were different from what was found necessary during the CBUF program. As a result of the CBUF study, a criterion value of $\dot{q}'' = 65$ kW/m^2 was determined.

Prediction of the Peak HRR. Analysis of the large amount of full-scale and bench-scale data collected within the CBUF program allowed equations to be developed to predict the peak HRR of the furniture (chair or sofa) item. Prediction of the peak HRR requires the use of Equations 1 through 5.

$$x_1 = (m_{soft})^{1.25}(\text{Style factor } A)(\dot{q}''_{pk} + \dot{q}''_{300})^{0.7}(15 + t_{ig})^{-0.7} \quad (1)$$

$$x_2 = 880 + 500(m_{soft})^{0.7}(\text{Style factor } A)(\Delta h_{c,eff}/q''_{tot})^{1.4} \quad (2)$$

$$\text{If } (x_1 > 115) \text{ or } (q''_{tot} > 70 \text{ and } x_1 > 40)$$
$$\text{or (Style factor} = \{3,4\} \text{ and } x_1 > 70)$$
$$\text{Then } \dot{Q} = x_2 \quad (3)$$

else,

$$\text{If } x_1 < 56$$
$$\text{Then } \dot{Q} = 14.4\, x_1 \quad (4)$$

else,

$$\dot{Q} = 600 + 3.77\, x_1 \quad (5)$$

For the above equations, the following cone calorimeter data are used:

$\dot{q}''_{pk}$ = Peak HRR (kWm^{-2}) at 35 kWm^{-2} exposure

$\dot{q}''_{300}$ = 300 seconds average HRR (kWm^{-2}) at 35 kWm^{-2} exposure

t_{ig} = Ignition time (seconds) at 35 kWm^{-2} exposure

$\Delta h_{c,eff}$ = Effective heat of combustion (MJ kg^{-1})

q''_{tot} = Total heat release (MJ m^{-2}) at 35 kWm^{-2} exposure

In addition, the total mass and the style factor of the full-scale item must be known:

m_{soft} = Mass of upholstery (fabric, filling, interliner, etc.) materials (kg)

Style Factors. Furniture style was already known to be an important variable affecting fire development from the earlier NIST studies, but the data available at that time were not adequate to derive suitable numeric expressions covering the range of commercial furniture styles. The CBUF study, by contrast, was able to include a wide variety of commercially important furniture styles. Table 6.6.16 shows the furniture styles adopted. These styles are obviously not exhaustive of the market possibilities but do include the majority of common types. Style factors are used for two purposes: (1) for predictions of peak HRR values and (2) for predictions of time to peak. Style factor A is pertinent to calculations of peak HRR, whereas style factor B pertains to calculations of time to peak.

TABLE 6.6.16 Furniture Styles Defined in the CBUF Predictive Model

Code	Style Factor A	Style Factor B	Type of Furniture
1	1.0	1.00	Armchair, fully upholstered, average amount of padding
2	1.0	0.80	Sofa, 2-seat
3	0.8	0.80	Sofa, 3-seat
4	0.9	0.90	Armchair, fully upholstered, highly padded
5	1.2	0.80	Armchair, small amount of padding
6	1.0	2.50	Wingback chair
7	—	—	Office swivel chair, plastic arms (unpadded), plastic, rear-back shell
8	—	—	High-back office swivel chair, plastic arms (unpadded), plastic back and bottom shell
9	—	—	Mattress, without innersprings
10	—	—	Mattress, with innersprings
11	—	—	Mattress and box spring (divan base) set
12	0.6	0.75	Sofa-bed (convertible)
13	1.0	0.80	Armchair, fully upholstered, metal frame
14	1.0	0.75	Armless chair, seat and back cushions only
15	1.0	1.00	Two-seater, armless, seat and back cushions only

The accuracy of the prediction of the earlier model (Equations 1 through 5) for peak HRR is shown in Figure 6.6.10.

Prediction of Total Heat Release. The total heat release is a measure of the effective fire load from the furniture item. The following equation was found to represent well the total heat:

$$Q = 0.9m_{\text{soft}} \cdot \Delta h_{c,eff} + 2.1[m_{\text{comb,total}} - m_{\text{soft}}]^{1.5} \qquad (6)$$

The effective heat of combustion comes from cone calorimeter tests of the composite (soft parts). For the full-scale article, $m_{\text{comb,total}}$ denotes the entire combustible mass—that is, all except metal frame parts or other noncombustible pieces—and m_{soft} is the mass of the upholstery system. The results of this prediction are shown in Figure 6.6.11.

Prediction of Time to Untenability. The time to untenability is defined as starting at the time when the full-scale HRR first exceeds 50 kW and ending when the smoke layer (100°C isotherm) is at 1.2 m above floor height. The measurement conditions correspond to the standard fire test room defined in ISO 9705. The untenability time, t_{UT}, is predicted by the following equation:

$$t_{UT} = 1.5 \times 10^5 \,(\text{Style factor } B)(m_{\text{soft}})^{-0.6} (\dot{q}''_{\text{trough}})^{-0.8} (\dot{q}''_{pk\#2})^{-.05} (t_{pk\#1} - 10)^{0.15} \qquad (7)$$

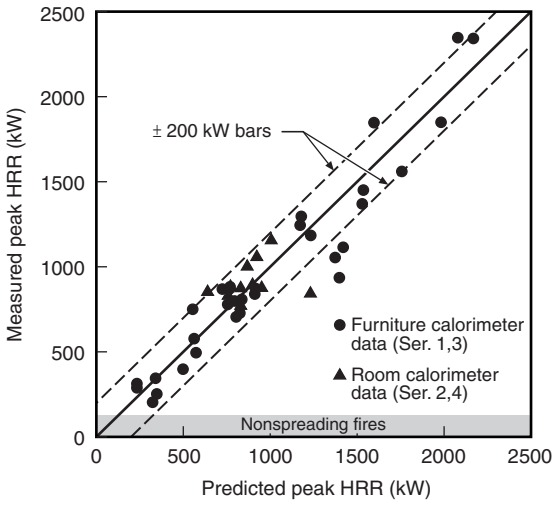

FIGURE 6.6.10 Prediction of Peak HRR of Upholstered Furniture, According to Equations 1 Through 5

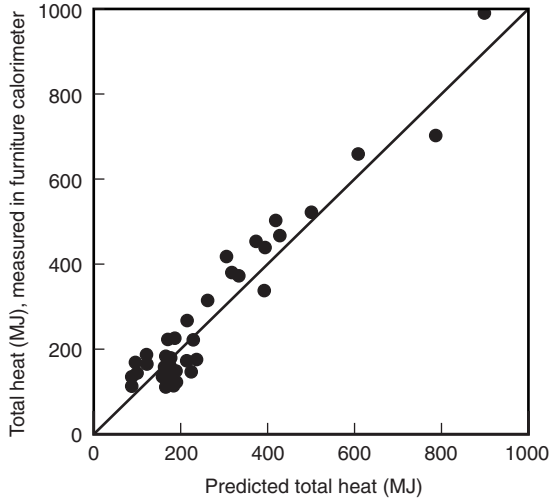

FIGURE 6.6.11 Prediction of Total HRR of Upholstered Furniture, According to Equation 6

The prediction results are indicated in Figure 6.6.12. Here, $\dot{q}''_t$ is the HRR in the cone calorimeter at the trough following the first peak; $\dot{q}''_{pk2}$ is the HRR at the second peak; and $t_{\text{pk\#1}}$ is the time to the first peak. These concepts are illustrated in Figure 6.6.13.

Prediction of Time to Peak. The time to peak is considered an important modeling parameter of a fire. This time is defined to occur when the peak value of HRR is recorded. Generally, all other hazard variables are also at or near their peak values when the HRR peak occurs. Because the ignition period of a fire can be highly varied and refers only to individual circumstances, one can consider the starting point for analysis to be the time that sustained burning first occurs, that is, when a fire level of

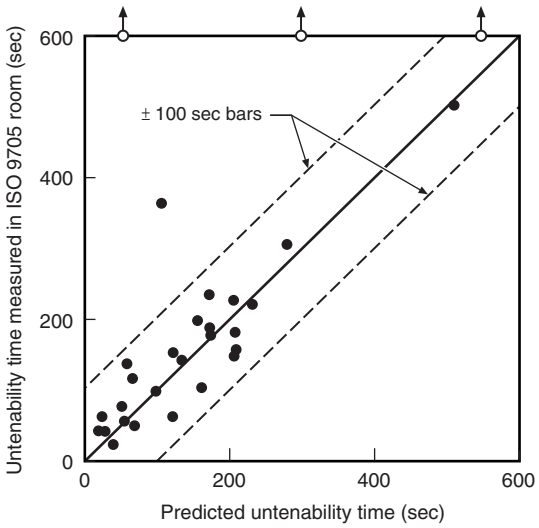

FIGURE 6.6.12 Prediction of Untenability Time, According to Equation 7

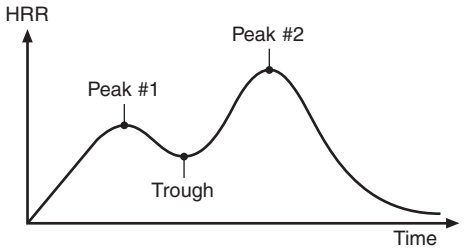

FIGURE 6.6.13 Peak and Trough Values on the Cone Calorimeter HRR Curve

50 kW is first reached. Thus, it is of interest to be able to predict the time interval starting with the time that sustained burning first occurs until the peak is reached. A predictive relationship was developed for estimating this time to peak as

$$t_{pk} = 30 + 4900(\text{Style factor } B)(mass)^{0.3} (\dot{q}''_{pk\#2})^{-0.5}(\dot{q}''_{\text{trough}})^{-0.5}(t_{pk\#1} + 200)^{0.2} \quad (8)$$

Here,

t_{pk} = Time to peak burning, from start of sustained burning (seconds)

Style factor B = Style factor B, as given in Table 6.6.16

$mass$ = Mass of upholstery (soft components only) of full-scale item (kg)

$\dot{q}''_{pk\#2}$ = Second peak of cone calorimeter HRR curve (kWm^{-2})

$\dot{q}''_{\text{trough}}$ = Trough of cone calorimeter HRR curve (kWm^{-2})

$t_{pk\#1}$ = Time to first peak of cone calorimeter HRR curve, from start of test (seconds)

The predictive results are shown in Figure 6.6.14.

Prediction of Smoke Production. The following correlation was established for predicting the smoke:

If

$$p_2 < 1800 \quad (9)$$

then,

$$SmP = p_2 \quad (10)$$

else,

$$SmP = p_1 \quad (11)$$

where

$$p_1 = 0.7 \cdot \frac{Q_{tot} \cdot \sigma_f}{\Delta h_{c,eff}} \quad (12)$$

$$p_2 = s_o - 0.15 s_o^{1.13} \quad (13)$$

with

$$s_o = \frac{Q_{tot} \cdot \sigma_f \cdot (1.25 - 0.00188 \dot{q}''_{35-60})}{\Delta h_{c,eff}} \quad (14)$$

and

$\dot{q}''_{35-60}$ = 60-second average HRR value from the cone calorimeter (kWm^{-2})

where

SmP = Full-scale smoke production (m^2)

Q_{tot} = Full-scale total heat release (MJ)

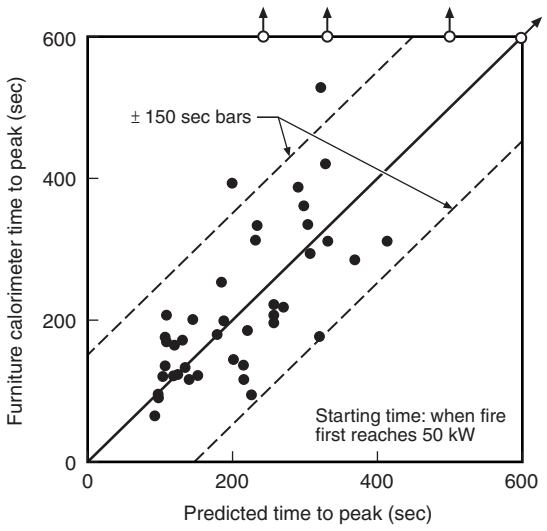

FIGURE 6.6.14 Prediction of Time to Peak Full-Scale HRR, According to Equation 8

σ_f = Cone calorimeter average specific extinction area (m^2kg^{-1})

$\Delta h_{c,eff}$ = Cone calorimeter average effective heat of combustion (MJ kg^{-1})

The results are plotted in Figure 6.6.15. The agreement for fires showing moderate smoke development (less than about 1500 m^2) is remarkably good. Even for fires with extremely large smoke production, the actual measurements are either close to predicted values or lower; thus, the model is a conservative estimate under all circumstances.

Toxic Gases. Human incapacitation and fatalities in fires are much more often due to toxic gas effects than to direct burn injuries. This circumstance would seem to suggest that test methods should, first and foremost, measure toxic gases. However, this oversimplified view does not reflect actual fire behavior realities. To understand this, it is best to consider the options to reduce the hazard of upholstered furniture from toxic fire gases. One could (1) reduce the "per-gram" toxicity of the combustion products or (2) reduce the *rate* at which combustion products are emitted. The effects of fire toxicity could be equally well mitigated by the first strategy or the second. In practice, it has been found that the first strategy is not feasible.[69] That is, materials are simply not to be found in the marketplace that show much reduced per-gram toxicities. In fact, most common materials available for constructing furniture exhibit very similar values. What is more viable, however, may be to design the furniture in such a way that the HRR is reduced. This strategy is taken by T.B. 133 for institutional furniture. More detailed bases of these conclusions are also discussed in the CBUF study.[14]

IMPROVEMENTS IN FIRE PERFORMANCE OF FURNITURE

In occupancies such as health care, incarceration, and public transportation, it is accepted that highest-level fire safety should be provided, even though such products then cost significantly more than consumer goods. For such uses, the fire behavior of upholstered furniture can be optimized by careful material selection, design considerations, and other factors. To accomplish this, materials should be selected that are resistant to cigarette ignition, resistant to small-flame ignition, and produce only limited fire involvement when confronted with a large-source ignition. Some qualitative guidance on cigarette and small-flame ignition resistance is summarized in Table 6.6.17. For fire performance once an item *is* ignited, some of the more important available strategies are summarized below. More comprehensive advice is available.[14]

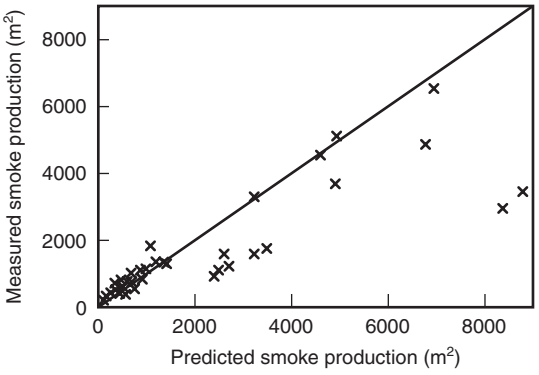

FIGURE 6.6.15 Prediction of Smoke Production, According to Equations 9 Through 14

Improving the Fabric

Fire behavior can be improved by selecting well-performing fabric categories. These include use of wool, modacrylic, FR-treated fabrics, and fabrics that do not show a strong melting tendency. For such fabrics, increased fabric weight usually corresponds to improved fire behavior. Thermoplastic fabrics are often troublesome; especially, the use of polyolefin (polypropylene) fabrics is to be avoided. Other thermoplastics usually perform better in flaming fires when they are of lighter rather than heavier weights. Loosely woven or lofted fabrics are usually less desirable than flat, tight weaves.[70] In many cases, fabric backcoatings can be successfully used. Backcoatings may not be as effective as an interliner or as a substantially improved foam; nonetheless, they can significantly improve the fire performance of many fabrics without creating adverse usability or aesthetic effects. Backcoatings have been especially favored by U.K. manufacturers.

Fabrics comprising 100 percent cellulosic fibers (cotton, rayon, linen) usually show difficulties in passing cigarette ignition tests. Cellulosic/thermoplastic blends, where the cellulosic component is less than 80 percent of the fabric weight, prove to be significantly more smolder resistant than pure cellulosics.[71] For a 100 percent cellulosic fabric to meet cigarette ignition requirements, it is very difficult if the fabric weight is greater than 13 oz/yd^2 (440 g/m^2), but is significantly less difficult[71] for fabrics lighter than 13 oz/yd^2 (440 g/m^2). Thermoplastic fabrics of any weight rarely show any problems in meeting cigarette resistance requirements. One development that has a potential to reduce ignition likelihood when presented with flaming sources or with cigarettes is a patented yarn-spinning process that is being introduced by a number of fabric manufacturers. Patent 6,287,690 describes a yarn with a two-ply core that comprises fiberglass and nylon. This core is sheathed with an inner sheath of modacrylic and melamine fibers, then with an outer sheath that comprises decorative fibers of choice. No chemical fire-retardant agents are added, yet fabrics made of this yarn may prove an attractive replacement for double-upholstering (outer fabric, plus interliner) systems.

Improving the Foam

Polyurethane (PU) foam is very widely used in upholstered furniture as well as in mattresses. In fact, consumers can find it difficult to find upholstered furniture without PU foam. Because of the combustible nature of PU foam, the simplest strategy to increase fire safety is to decrease the amount of foam used. As shown above, the peak HRR of a fire is highly dependent on

TABLE 6.6.17 Upholstered Furniture Components Listed in Approximate Order of Descending Ignition Resistance

Ignition Resistance	*Cover Fabric*	*Padding*	*Interliner Fabric*	*Weltcords*	*Construction Parameters*
A. Cigarette Ignition Resistance					
HIGH	Wool, PVC	Specialty foams[a]	Aluminized fabrics	Aluminized	Flat areas
↑	Heavy thermoplastics	Polyester batting	Neoprene sheets	PVC	Flat areas near weltcord
	Cellulose/thermoplastics blends (depending on thermoplastic percentages)	SR PU	Vinyl coated glass fab.	Thermoplastics	
		SR cellulosic batting	Novoloid felts	SR-treated cellulosics	Tufts
		Untreated PU	Thermoplastic fabrics	Cellulosics	Crevices
	Light thermoplastics	Mixed fiber batting	Cellulosic fabrics		
LOW	Light cellulosics	Cellulosic batting			
	Heavy cellulosics				
B. Small-Flame Ignition Resistance and Fire Growth					
HIGH	FR wool	Specialty foams[b]	Aluminized, gas impermeable fabrics	Effect of weltcord has not been investigated, believed minor	Flat areas
↑	Wool, PVC-coated cellulosics[b]	FR cellulosic batting	Neoprene sheets[b]		Vertical areas
	Cellulosics[b]	FR PU	Novoloid fabrics[c]		Corner areas
	Thermoplastics	Cellulosic batting	Aramid fabrics[b,c]		
		Polyester batting	Vinyl-coated glass fabrics[b]		
		Untreated PU	FR cellulosic fabrics[b,c]		
		Latex foam	Cellulosic fabrics[a,c]		
LOW			Thermoplastic fabrics		

Note: SR = smolder resistant; FR = flame resistant; PU = polyurethane foam. Data on the behavior of acrylic are sparse but it seems to act more like cellulosics (smolder) than thermoplastics.
[a]Neoprene; combustion modified, high-resiliency PU.
[b]Heavier materials have higher flame ignition resistance and generally higher heat release and lower flame-spread rate.
[c]Fabrics here include woven, knitted, and nonwoven structures.

the mass of the upholstery. Another strategy involves substituting ordinary grades (HR) of PU foam with an improved foam, possibly CMHR or one of the newer improved types. One solution in this area has been commercialized, whereby polyols with substantially improved fire performance[72]; it provides a way of increasing furniture fire performance without requiring fundamental changes in furniture-making techniques. Composite foam strategies can be explored. An inexpensive base foam is in some way covered or coated with a foam that has FR properties. Early efforts in this vein have not yet shown significant improvement, but the general strategy is still considered promising. In rail-car seating, neoprene foam is often used. Although neoprene foam shows excellent fire performance, it is usually too costly and too dense for other applications.

Using Interliners

Fire barrier types of interliners are among the most promising of the strategies to increase the fire performance of upholstered furniture. Considered here are only modern interliners that are lightweight, typically 70 to 170 g/m^2, and commercially available. They can be woven, knitted, or nonwoven. Nonwoven interliners, however, often have the drawback that local density cannot be well controlled. Thus, the performance may not be consistent, due to existence of thin spots. Several dozen different materials have been invented and proposed for interliner use. Commercially, the most common ones are glass fiber, aramid (e.g., Kevlar®), and a proprietary glass fiber/FR cotton construction. Apart from cost, the primary drawback to interliners is that they make the upholstery stiffer. This result would be inconsequential in, for example, subway car seating, but could be problematic in sofas where comfort is important.

The interliner offers protection, because as the PU foam underneath begins to melt, its upper surface moves steadily downward and away from the interliner, which stays in place and acts as a thermal radiation shield. It also acts as a flame barrier, preventing the flame from reaching the foam. In a noninterliner system, the retreating surface of the foam is often "chased" by the burning fabric. By using an interliner, however, the burning fabric stays where it is while the foam melts away from it. This stability decreases the heat transfer to the foam and thus slows the melting and reduces the HRR. An interliner can also release flame-retardant chemicals into the gas phase and thus reduce flaming. Most of the common interliners, including the aramid and glass-fiber types, are purely nonreactive systems. At least one proprietary interliner, however, is heavily loaded with flame retardants. "Best-quality" interliner-containing chairs show only limited burning of the fabric. The foam is fully protected. However, in some cases, the interliner provides protection to the foam only for a certain amount of time; eventually the foam burns up.

One way to use interliner technology is when the fabric supplier already laminates (attaches by fully gluing on) the interliner to the back of the upholstery fabric prior to delivering it

to the furniture manufacturer. The average chair requires the use of about 4 m^2 of interliner.

Testing[73,74] of several types of barriers for mattresses showed that impressive gains in fire safety can be achieved. In one case, a commercial mattress that showed a peak HRR of 1900 kW was retrofitted with an add-on barrier-type mattress cover, such as could be bought and fitted by the householder. The protected mattress gave an HRR of only 100 kW. Mattresses that were factory made with a barrier showed HRR values of 20 kW to 40 kW.

The general term *interliner* sometimes is taken to encompass a polyester fiber batting *topper,* which is an intermediate layer placed below the fabric and on top of the foam. Such polyester toppers are mainly a comfort feature but sometimes function to improve the cigarette resistance of furniture. They can have undesirable effects on flaming-fire behavior, however, because the low-density polyester material is readily combustible.

Improvements Due to Design

A powerful strategy is the use of panel mounting rather than webbing to support chair cushioning. Any strategies that reduce the tendency to pool burning can cause a major reduction of fire hazard. Studies in England[75] demonstrated that, in some cases, about 50 percent of the peak HRR from an upholstered chair can be accounted for by pool burning.

The effects of button tufting are not fully resolved,[14,76] but some evidence suggests that they may be problematic in certain cases.

Fire performance will be improved if cushions are tightly upholstered and not sewn in a loose or floppy fashion.[76]

A fabric skirt along the lower edge of an upholstered chair is an easily combustible feature that can add to fire severity;[76] such skirts should be avoided where possible.

Wide gaps (greater than 75 mm) between seat and back cushions and between arm cushions and seat cushions will improve the fire performance.[76]

Improvements Due to Frames

It is important to make sure that wood frame joints are strong and that metal joining plates that could fail early in a fire are not used. Thermoplastic material frames and frameless chair designs have generally unfavorable fire properties. For office chairs, it is vital to make sure that the hard-plastic materials used do not melt or ignite readily and that they have adequate HRR properties.

SUMMARY

The fire behavior of upholstered furniture is very different when presented with a smoldering ignition source (a cigarette) versus an open flame. Thus, testing or regulations cannot combine these two performance aspects. In the United States, the majority of both mattresses and upholstered furniture has been manufactured to be resistant to cigarette ignitions for several decades now. Until recently, however, CPSC has not regulated the open-flame performance of either product category. Beginning in 2007, however, mattresses will be subject to a new CPSC regulation whereby open-flame performance will be controlled. It is expected that flaming ignition of such new-generation mattresses will produce significantly less severe fires. CPSC has also been actively considering some open-flame standards (albeit much less severe) for upholstered furniture, but such regulation does not appear to be imminent.

Manufacturers of mattresses and upholstered furniture for institutional (health care, incarceration, public transport, etc.) occupancies have always been held to a much higher standard of care than is applicable to the retail consumer market. For a number of decades now, such institutional items have been expected to be produced so that they not only resist ignition from small flames but also, even if presented with a large-flame ignition source, will show appropriately low HRR values. Most manufacturers and suppliers are aware of this standard of care. But, because the regulation in these occupancies is complex, nonuniform, and sometimes self-regulated, some producers and suppliers have been supplying goods for such occupancies that do not show a fire safety level suitable for that occupancy. For mattresses, however, because the new CPSC regulations governing residential products are almost as strict as expected for institutional items, it is anticipated that inappropriate mattresses will soon no longer be offered in the institutional sector.

Chapter 7

Fire-Retardant and Flame-Resistant Treatment of Cellulosic Materials

James R. Shaw

Chapter Contents

Definitions of Terms
Basic Principles
Fire-Retardant Treating Methods and Limitations
Practical Limitations of Treatments
Wood
Wood-Based Composite Panels
Paper
Cellulosic Insulation
Misuse of Fire Retardants

Key Terms

cellulosic material, fire endurance, fire resistant, fire retardant, fire-retardant coating, flame spread rating, pressure impregnation, rate of heat release

This chapter discusses the basic principles of fire-retardant and flame-resistant treatments, their uses and limitations, and methods of treatment for wood, wood-based composite panels, paper, and miscellaneous decorative materials. Whereas the demand for fire-retardant and flame-resistant chemicals is highest in the plastics industry, there are important markets for these chemicals in treating nonplastic materials, especially for building construction materials.

Related information can be found in the following chapters: Section 6, Chapter 4, "Wood and Wood-Based Products"; Section 6, Chapter 5, "Fibers and Textiles"; Section 6, Chapter 13, "Polymeric Materials"; Section 13, Chapter 5, "Wildland Fire Management"; and Section 18, Chapter 2, "Interior Finish."

DEFINITIONS OF TERMS

Cellulosic materials are an integral part of the living environment. Homes, schools, factories, offices, shops, and so on use large quantities of cellulosic products in construction, furnishings, and decorations. Fire-retardant and flame-resistant treatments for these cellulosic materials can increase fire protection.

Popular use has created a variety of terms associated with this subject, resulting in misunderstanding, misuse, and an undesirable degree of ambiguity. Terms such as *fire resistant, fire retardant, flame resistant, flame retardant, fireproof,* and *flameproof* are often used indiscriminately and incorrectly.

The term *fire resistant* should not be used in reference to the fire-retardant treatment of combustibles. Fire resistant is used properly only to signify the ability of a structure, material, or construction assembly to resist the effects of a large-scale severe fire exposure. ASTM defines fire resistance as "the property of a material or assembly to withstand fire or give protection from it."[1] Fire-resistance rating or fire endurance is the time, in minutes or hours, that materials or assemblies have withstood a fire exposure, as established in accordance with the test procedures of NFPA 251 (ASTM E119), *Standard Methods of Tests of Fire Resistance of Building Construction and Materials.* Likewise, *fireproof* is misleading and should not be used synonymously with *fire resistant.*

Fire retardant signifies a lesser degree of protection than fire resistant. It should be used in reference to chemicals, treatments, or coatings used to reduce the combustibility of building materials and other such treated materials. ASTM International (ASTM) suggests *fire retardant* be used as a modifier only with defined compound terms, such as fire-retardant barrier, fire-retardant chemical, fire-retardant coatings, and fire-retardant treatments.[1] *Flame spread rating* refers to indices or classifications obtained according to NFPA 255 (ASTM E84), *Standard Method of Test of Surface Burning Characteristics of Building Materials,* or other flame spread tests. *Flame retardant* and *flame resistant* may be used more or less interchangeably for decorative materials that, due to

James R. Shaw, Ph.D., is a scientific advisor in the research and development division of Weyerhaeuser Company, Federal Way, Washington.

chemical treatment or inherent properties, do not ignite readily nor propagate flaming under small-to-moderate fire exposure. *Flame retardant* is the preferred term to denote chemicals, processes, or coatings used for the treatment of decorative materials, including fabrics, foliage, Christmas trees, and similar materials used as decorations or furnishings. *Flameproof* and similar descriptors are misleading and subject to misunderstanding and abuse; they should not be used.

Fire retardants and flame-retardant treatments frequently have been misused. They have a widespread appeal due in part to a general lack of understanding about the limitations of the treatments and a failure to differentiate between those that are effective and those that are not. One popular misconception is that all fire-retardant treatments give a fire-resistance rating. This is not true. Although some fire-resistant coatings may improve the fire endurance of combustible materials and assemblies, other treatments are only effective in retarding the rate of burning and the rate at which fuel is contributed by the treated material. This action, however, can reduce the fire intensity of some materials that otherwise might be very fast burning. This burning rate property is measured and reported as the *rate of heat release.*

In other words, there are practical limits to fire-retardant treatments. They are not all permanent, they are not capable of making cellulosic materials noncombustible, they affect other properties of the treated material, and they add expense. They do, however, provide protection and utility on a competing basis with non-fire-retardant treatments and coatings. For example, fire-retardant paints have been improved to the point where many provide a colorful, protective coating with comparable wear resistance and strength of normal oil- and water-based paints.

BASIC PRINCIPLES

Treatments to reduce the combustibility of wood, fabrics, and other natural materials have a long history reaching back to at least the time of Moses. The early use and development of chemical retardants was limited to materials that were accidentally found to be effective. Research in basic combustion processes and action of retardants was greatly expanded during World War II due to increased military needs for flame-resistant fabrics and fire-retardant wood. This expansion continued for several years, leading to new-generation fire-retardant formulations for wood. Because cotton textiles and wood products have by far the longest history of use and are of great economic importance, much of the research has historically been directed toward these cellulosic materials. In the past few years, the research activity in the United States has stabilized.

Burning of Cellulose

Since cellulose is the major component of wood and other cellulosic materials and the major source of combustible volatiles that fuel flaming combustion, it is appropriate to focus on its reactions in the thermal degradation process.

The chemical reactions and the mechanisms involved in the combustion of untreated cellulose are, by themselves, highly complex and not yet fully understood.[2] The complexity is magnified by the addition of fire-retardant chemicals.

Wood or cellulose normally does not burn directly. The initial reaction to high heat exposure is pyrolysis, in which some of the products given off are gases, vapors, or mists that can form flammable mixtures with air. On ignition, the combustion of these products is evidenced by visible flames. The solid residues include charcoal, which can undergo a different form of combustion by combining directly with oxygen, as evidenced by glowing. This is an important distinction, because many chemicals that are effective flame inhibitors have little or no effect in retarding flameless combustion, or afterglow. For most applications, flame retardance is more important, but there are some instances where glow resistance is equally necessary.

Theories of Fire-Retardant Mechanisms

Four general theories have evolved to explain the mechanisms by which chemicals retard flaming or glowing of cellulosic materials. It is agreed that no single theory is adequate to explain these mechanisms and that, in most cases, more than one mechanism is involved. The four theories that offer the most satisfactory explanations for the function of fire-retardant chemicals are as follows.

Thermal. There are three possible ways that fire-retardant materials work to reduce the buildup of thermal energy in the treated combustible: (1) they increase thermal conductivity to dissipate the heat of combustion, (2) they increase thermal absorption to reduce the amount of heat available for pyrolysis, and/or (3) they provide thermal insulation to reduce heat access to the substrate. Thermal insulation is the most important mechanism and is also discussed under coating theories.

Coating. Some retardants melt or fuse at relatively low temperatures and it is believed that they form an insulating coating over the fibers of the treated material, acting to exclude oxygen and inhibit the escape of combustible gases. More effective retardants exhibit a bubbling or foaming action, creating an insulating barrier. Intumescent paints and coatings protect substrates by this mechanism.

Gas. Some chemicals function by releasing nonflammable gases, such as water, ammonia, and carbon dioxide, that dilute the combustible gases sufficiently to render the mixture nonflammable in air. Other retardants catalytically inhibit the free radical chain reactions that occur in the gas phase (flaming combustion). Halogen-containing retardants exhibit this type of mechanism and, when combined with antimony, a synergistic (more than additive) effect is observed.

Chemical. Simplified representations of the chemical mechanism are shown in Figures 6.7.1 and 6.7.2. In both figures, the size of the circle is representative of the volume of product. Note the predominance of liquid and flammable gas products in Figure 6.7.1 and the predominance of solids and the severe reduction in liquids and flammable gases emanating from the liquids in Figure 6.7.2. These diagrams illustrate the different effects of fire on untreated and treated cellulose and are diagramatically explained in "Flameproofing Textile Fabrics."[3] Untreated cel-

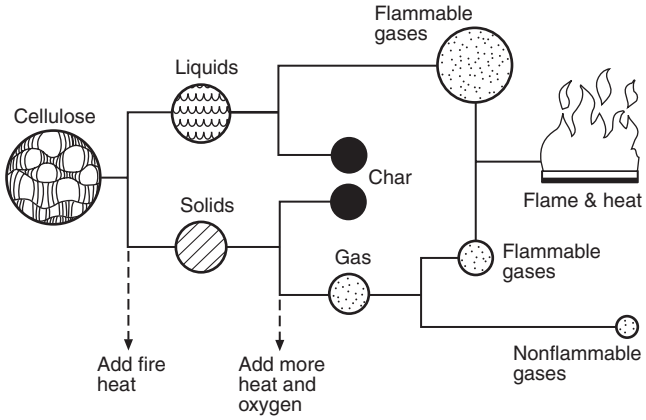

FIGURE 6.7.1 Burning Sequence of Untreated Cellulose

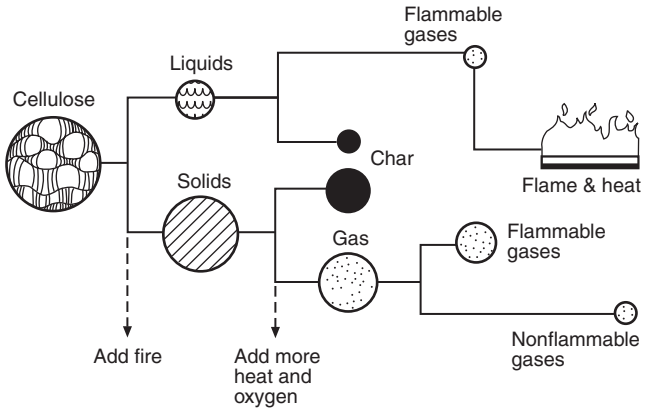

FIGURE 6.7.2 Burning Sequence of Treated Cellulose

lulose breaks down into liquids and a smaller amount of solids. The liquids, in turn, break down into flammable gases and char and the solids decompose into char and gases, some of which are flammable, some not. The flammable gases volatilized from the liquids combine with those from the solids to cause flaming and the emission of additional heat, which continues the reaction.

With treated cellulose, fewer liquids and more solids are formed and more of the solids become char. The reduced amount of liquids creates some char and some flammable gases. Because the amount of flammable gases from both the liquid and solid phases is now significantly less with treated cellulose, ignition is delayed and less heat is released. Therefore, flame resistance and a reduced burning rate is achieved. Another postulate, an expansion of the chemical theory known as the catalytic dehydration theory, has been advanced.[4]

Studies at the U.S. Forest Products Laboratory[5] have shown that pyrolysis reactions (without the presence of oxygen) for the lignin component of wood start at approximately 428°F (220°C), whereas that for the cellulose fraction starts near 518°F (270°C). However, once pyrolysis for the cellulose fraction has started, its decomposition is primarily an endothermic reaction and is nearly completed when 752°F (400°C) is reached. The lignin decomposes more slowly, in an almost entirely exothermic reaction, and loses less than half its weight in pyrolysis up to 1112°F (600°C).

Fire-retardant chemicals greatly influence the pyrolysis reaction of the cellulose fraction, frequently reducing the temperature at which decomposition starts from 518 to 446°F (270 to 230°C). As a result, the decomposition of the cellulose is promoted directly to form char and water, instead of forming intermediate flammable gases and tar products, and the char yield from the cellulose at 680°F (360°C) is increased from 15 percent up to 30 to 35 percent. The chemical treatment also increases the char yield from the lignin component from 49 percent up to 57 percent, but here the significance is less.

It was further shown that the combustion reactions for wood can be divided primarily into two exothermic stages: (1) one near 626°F (330°C) associated with flaming as the cellulose fraction of the wood undergoes decomposition into flammable gases and tars and becomes ignited and (2) a second reaction near 806°F (430°C) associated with glowing as the lignin fraction of the wood, which has been changed to charcoal, undergoes oxidation. Fire-retardant chemicals greatly reduce the intensity of the first exotherm and some chemicals also reduce the intensity of the second exotherm, thus reducing the heat released by the treated wood over a wide temperature range. Other chemicals reduce the first exotherm and intensify the second, thus requiring a second chemical to result in maximum fire-retardant performance. Heat release during the pyrolysis reactions for wood was found to be less than 5 percent of that released during the combustion reactions.

All of this data tended to prove that one of the principal reactions of fire-retardant chemicals impregnated into wood is to accelerate chemical reactions at certain temperature ranges. This reduces the release of certain intermediate products, such as levoglucosan tars and flammable gases, which may contribute to the flaming of wood, and also results in the formation of greater percentages of charcoal and water. Some chemicals are then further effective in reducing the oxidation rate for the charcoal residue. An excellent discussion of these basic principles is contained in the Forest Products Laboratory report, "Theories of the Combustion of Wood and Its Control."[6]

FIRE-RETARDANT TREATING METHODS AND LIMITATIONS

There are four basic methods of treatment to produce fire retardance in materials: (1) chemical changes (substitutions, admixtures), (2) impregnation (saturation, absorption), (3) pressure impregnation, and (4) coating. Chemical changes and pressure impregnation are limited to manufacturing processes and procedures and are not adaptable for field use. Impregnation and coating methods may be used in the field. Generally, methods employed in manufacturing processes are to be preferred, because they provide greater uniformity, permanence, and dependability. Applications in the field or subsequent to manufacture of the basic material are more subject to variation in skill and integrity of the processor or applicator. Treatments of the coating-

and pressure-impregnation type are covered in NFPA 703, *Standard for Fire Retardant–Treated Wood and Fire-Retardant Coatings for Building Materials.*

Chemical Changes

Fire-retardant chemical changes are primarily effective with plastics and with synthetic fibers, because different elements and compounds can be chosen that will alter the burning characteristics of the final product. Because the fire-retardant elements are an integral part of the chemical composition, these materials are said to be "inherently" fire retardant. Naturally occurring polymers, such as cellulose, cannot be made fire retardant by this method. However, another type of chemical fire-retardant treatment, known as chemical grafting, can be applied to natural polymers. In chemical grafting, the material is treated by a multistage process in which the material is chemically activated so that molecules of fire-retardant chemical are bonded to molecules of the material being treated. A follow-up curing step ensures permanence. This approach has not developed into a commercially viable method of producing fire-retardant-treated cellulosic products. Research efforts on chemical modification of wood continue, but the primary focus is on wood preservation and enhanced dimensional stability of wood.[7]

Impregnation

Impregnation refers to a technique for treating absorbent materials. The flame-retardant chemicals are either dissolved or dispersed in a solvent, usually water, and the material to be treated is thoroughly wetted or saturated with the solution. The solution may be applied by spraying or by immersion of the material. The latter process is used for treatment of large volumes of fabric yardage. The excess solution is extracted by passing the saturated material through squeeze rollers before drying.

In the simple water-soluble salt impregnation processes, the result is merely to deposit minute crystals of the salts within or on the surface of the fibers. The process is purely physical, that is, no chemical reaction is involved. With durable treatments, insoluble deposits are formed by chemical reactions or other means.

Certain cellulose-based products, such as paper, acoustical tile, and wood-based compositions, incorporate a wet pulp stage during the manufacturing process. It is possible to add fire-retardant chemicals at the wet pulp stage, resulting in even distribution of the chemicals through the entire mass of the finished product. This practice is prevalent in manufacturing treated papers of many types and is currently in use by several producers of building materials. Wood-fiber acoustical tile and building panels processed by this method have a NFPA 255 (ASTM E84) flame spread rating of less than 25.

Pressure Impregnation

Fire-retardant pressure impregnation is used for treating relatively dense nonabsorbent materials such as wood. This process replaces the air in the wood cells with fire-retardant chemical solutions. (The chemicals are deposited as the solutions dry.) The treating solution is usually forced into the wood by the standard vacuum pressure methods used in the wood preserving industry.[8] Compared to simple impregnation techniques, pressure impregnation provides deeper penetration and much greater chemical retention.

Coating

Several types of fire-retardant coatings are useful in treating many materials. Coatings may be applied at any stage from manufacture to use. They may either actively inhibit flame spread to some degree or present a noncombustible surface over which flame cannot spread. They are used predominantly on nonabsorbent building materials that cannot be treated by any other method; on Christmas trees and similar decorative materials; and, to a limited extent, on paper and fabrics that for various reasons cannot be treated effectively by impregnation.

The effectiveness of a coating depends on the chemical and physical properties of the material to which the coating is applied, the capability of the applier, and the thoroughness of the treatment. Because types of coatings and their effects vary depending on the material treated, they are discussed in the subsections of this chapter that cover materials.

PRACTICAL LIMITATIONS OF TREATMENTS

Ideally, a fire-retardant treatment would permanently eliminate all flame spread and smoke generation characteristics from a material; the color, feel, strength, weight, and other key characteristics of the basic material would not suffer from the treatment; and the method would be inexpensive, easy, and safe. No present-day treatments meet all these qualifications. As the different materials are discussed, the limitations of fire-retardant treatments will be identified.

WOOD

Wood can be made fire retardant by either pressure impregnation or coatings. Although both of these treatments will reduce the flame spread of wood, only some fire-retardant coatings are significantly effective in increasing the resistance of wood to degradation under sustained fire exposure or in delaying reduction of its load-bearing capacity.

Although the fire-retardant treatment that would make wood noncombustible does not exist, the spread of flame from the immediate area of an incipient fire can be retarded and, in some cases, prevented by present-day treatments, with a corresponding substantial reduction in smoke contribution. Also, the fire-resistance rating of wood structural members in buildings may be improved through the use of fire-resistant coatings.[9–11]

Fire-Retardant Pressure Impregnation

Pressure impregnation treatments deposit chemicals within the fibrous passages of wood. Many chemicals exhibit fire-retardant properties, but because of cost limitations or various other objectionable characteristics, comparatively few are considered practical. Chemicals commonly used in the past include monobasic and dibasic ammonium phosphates, ammonium sulfate, borax, boric acid, zinc chloride, and sodium dichromate, usually

in various combinations. Newer formulations tend to exclude hygroscopic salts, such as ammonium sulfate and zinc chloride, and, in some cases, include organophosphorus compounds and amino resins. Figure 6.7.3 shows the effect of some inorganic salts on the flame spread of Douglas fir. The most significant improvements in the new formulations are the high tolerance for high relative humidity conditions (up to 95 percent RH) and exterior application due to their nonleachability. The impregnation operation can be controlled to secure a predetermined absorption of solution. The important considerations are the depth of penetration and the amount of chemical deposited per unit volume of the wood.

Because the fire-retarding effect of the treatment is directly related to the amount of the chemical deposited within the wood, it is interesting to compare the effect of an ordinary brush treatment with a pressure-impregnation treatment. A 10-ft (3-m) high fence 50 ft (15.25 m) long of nominal 1-in. (25-mm) pine boards would absorb about 4 gal (15 L) of treating solution if applied by brush. The effect on flame spread would be minor (flame spread index [FSI] remains between 130 and 195, Class III). When the same boards are pressure impregnated to refusal (i.e., the point at which no more solution is absorbed by the wood), they absorb about 225 gal (852 L) of chemical and the flame spread is cut to one-fourth or less of the original (FSI less than 25, Class I).

A load or "charge" of wood is locked in a large cylinder that can be up to 8 ft (2.5 m) in diameter and over 140 ft (43 m) long. The air is then withdrawn and the resulting vacuum draws much of the entrapped air from the wood cells. After a delay to allow the vacuum to stabilize, the fire-retardant chemical solution is bled into the cylinder. After the cylinder has been filled with the treating solution, additional chemicals are forced into it under pressure. As the pressure is raised (up to 200 psi [1379 kPa]), the chemicals are forced into the empty wood voids. The process can be run to refusal and the unabsorbed salt solution drained from the cylinder. A slight vacuum may then be drawn to remove surface chemicals that would cause dripping and slow drying. After the charge is removed and dried, it is ready for shipment and use. Additional details are available from the American Wood Preservers Association (Figure 6.7.4).

This treating process has become an integral part of the definition of fire-retardant treated wood (FRTW) which is, per NFPA 255 (ASTM E84),

> any wood product impregnated with chemicals by a pressure process or other means during manufacture, and which, when tested in accordance with ASTM E84 for a period of 30 minutes, shall have a flame spread of not over 25 and show no evidence of progressive combustion. In addition, the flame front shall not progress more than 10½ ft (3.2 m) beyond the centerline of the burner at any time during the test.

Advantages. Pressure impregnation permits a large amount of fire-retardant chemical to be deposited in the wood under close control and with uniform and predictable results. Samples for tests are readily available. Of primary importance, the treatment can be considered permanently effective under normal and proper conditions of use. Since both water-soluble and nonleachable fire retardants are available, it is important that nonleachable treatments be chosen for exterior use. Treatments with low hygroscopicity should be used for interior applications where high humidity conditions exist.

Disadvantages. Early formulations of fire-retardant treatments for wood were very hygroscopic and corrosive to metal fasteners. In the late 1980s, the fire-retardant chemical producers changed to "new generation," low-hygroscopicity formulations that dramatically improved the resistance to corrosion of metal fasteners. However, there were reports of structural failures with some of these chemical formulations in fire-retardant treated plywood roofs where high temperature and humidity

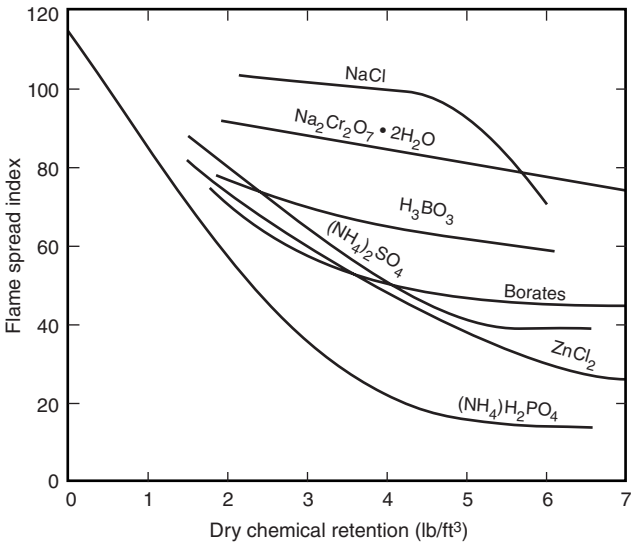

FIGURE 6.7.3 Effect of Inorganic Additives on Flame Spread Index of Douglas Fir, Measured in 8-ft (2.4-m) Tunnel[12]

FIGURE 6.7.4 Impregnated Plywood Sheets Being Removed from Pressure Cylinder

conditions exist.[13] Research efforts at the Forest Products Laboratory have shown that acidic fire-retardant chemicals, such as monoammonium phosphate, can cause premature degradation and simultaneous loss of strength at elevated temperatures [greater than 150°F (66°C)] and humidities. These conditions may be found in attics and can affect fire-retardant treated plywood sheathing and other treated structural components. It is important to note that not all fire-retardant formulations being used for wood during the eighties showed the same degree of loss of strength under the chosen laboratory conditions or field experience.

Formulations that experienced this problem in actual use were modified and retested according to developing ASTM standards, which ultimately became ASTM 5516, *Standard Test Method for Evaluating the Properties of Fire-Retardant Treated Softwood Plywood Exposed to Elevated Temperatures,* and ASTM 5564, *Standard Test Method for Evaluating the Mechanical Properties of Fire-Retardant Treated Softwood Plywood Exposed to Elevated Temperatures.* These reformulation efforts have been very successful in reducing the strength losses under these adverse conditions. At least one new formulation shows excellent flame spread performance without the use of phosphates.

Consumers should review the available literature on this subject and products, including the information available from the American Plywood Association (APA), the Engineered Wood Association, and the fire-retardant chemical producers before purchasing fire-retardant treated wood and plywood. Many technical reports on this problem published by the Forest Products Laboratory provide performance characteristics for most or all of the chemicals being used to treat wood.[14] Pressure impregnation must be done by a licensed treater after the wood has been dimensioned.

Fire Performance Characteristics. The pressure impregnation process can substantially improve the fire performance characteristics of wood, as measured by the tunnel test, the room fire test, and heat release rate tests. The effect can be illustrated by data shown in Tables 6.7.1 through 6.7.4.

Testing. The effectiveness of fire-retardant pressure impregnation treatments is tested by several methods. The Steiner tunnel test, described in Section 6, Chapter 3, "Concepts and Protocols of Fire Testing" (also see NFPA 255 [ASTM E84]), is used to determine the flame spread and smoke characteristics of pressure treated wood and many other products used in construction.[15] The *Design for Code Acceptance 1* published by the American Forests and Paper Association provides an extensive list of wood products with their flame spread index values. The *Underwriters Laboratories Building Products Directory* has listings for fire-retardant-treated wood products.

A standard room fire test of wall and ceiling materials was developed at the National Institute of Standards and Technology Center for Fire Research and is used to evaluate treated panel products. This room test method has been standardized by the International Organization for Standardization (ISO) as ISO 9705, *Fire Tests—Full-Scale Room Test for Surface Products.* (See Figure 6.3.10 in Section 6, Chapter 3.) The test uses the oxygen consumption method for calculating the rate of heat release. Data collected by this method are also used in the validation of fire mathematical models. Rate of heat release tests, such as the cone calorimeter (ASTM E1354, *Standard Test Method for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter*) and the intermediate scale calorimeter (ICAL) (ASTM E1623, *Standard Test Method for Determination of Fire and Thermal Parameters of Materials, Products, and Systems Using an Intermediate Scale Calorimeter [ICAL])* are being used successfully in distinguishing burning rate characteristics of fire-retardant-treated and untreated wood products. The ICAL test, due to the specimen size, can be used to measure the heat release from assemblies and materials. Efforts to establish correlations among the cone calorimeter results, room fire results, and tunnel results have been somewhat successful. (See Section 6, Chapter 3 for a discussion of fire test methods.)

Model codes allow the use of fire-retardant-treated wood in noncombustible construction, with some limitations. As shown in Table 6.7.1, lumber and plywood for construction can be treated by pressure impregnation to achieve a flame spread

TABLE 6.7.1 Surface Burning Characteristics of Pressure-Treated and Untreated Wood

Species[a]	*FSI*[b] *(Untreated)*	*FSI*[b] *Pressure-Impregnated*	*Smoke-Developed Pressure Impregnation*
Douglas fir (lumber)	70–100	≤25	≤25

index below 25 and to perform well in fire-resistant-rated assemblies.

Plywood. Fully treated plywood is satisfactory only when surface appearance is unimportant. For decorative purposes where the face veneer must have the beauty of natural wood, untreated face veneers of various species are laminated to treated cores. The flame spread classification of these treated plywood products varies in approximately inverse proportion with the density of the face veneer and ranges generally from 20 to 75, satisfying all but the most restrictive requirements. Fully treated plywood generally has a flame spread index less than 25 (Class I).

Relative Toxicity. Combustion toxicity testing of treated and untreated wood suggests that smoke from treated wood is "no more toxic than untreated Douglas fir."[16] This is true even though minor amounts of toxicants other than carbon monoxide are liberated from some treatments when burned.

Treated and untreated wood products tested by the University of Pittsburgh Test Method range in LC_{50} values from 7 to 72 g.[17] Many treated and untreated wood products have also been tested by the radiant furnace method. These results also indicate that smoke from treated wood is slightly less toxic than from untreated wood.[18]

Fire-Retardant Coatings

In existing structures of untreated wood or in cases where fire-retardant pressure impregnations are impracticable, fire-retardant coatings can be used. Coatings can be applied to any exposed surface of structural members, interior finish, or contents. They may be applied by means of brush, roller, sprayer, or trowel. As in the case of pressure impregnations, the degree of the flame spread reduction secured by a coating is dependent on the original combustibility of the surface to be protected, the effectiveness of the coating material used, the amount of coating used, the thoroughness of the application, and the size and severity of the exposing fire.

With normal paints, the usual aim is to get maximum coverage with minimum material. The approach is different in the application of fire-retardant coatings. Here, the objective is to provide the needed amount of coating per unit area required to ensure a definite degree of protection. Film thickness for intumescent coatings is a very important factor in their ultimate performance.

Among the many proprietary fire-retardant coatings, several have been listed by testing laboratories. Beware of any so-called fire-retardant or "fireproof" paint that has not been certified as to its flame spread characteristics by an independent

TABLE 6.7.4 Variations in Effect of Different Fire-Retardant Coatings on Unprimed Douglas Fir

	Untreated	*Painted with Coating X[a]*	*Painted with Coating Y[a]*	*Painted with Coating Z[a]*
Total coverage	—	100	100	200

Rate per coat	—	300	200	200
(ft^2 per gal [L/m^2])	—	0.82 L/m^2	1.23 L/m^2	1.23 L/m^2
Number of coats	—	3	2	1

[a]Each coating is listed by Underwriters Laboratories Inc. as meeting the minimum requirements for a fire-retardant coating.
[b]If a range of values was obtained, the figure given here is the highest obtained.

testing laboratory. There are four types of fire-retardant coatings for wood, as follows:

1. *Intumescent paints.* These coatings, on the action of heat, expand from a thin, paintlike coating to a thick, puffy, burnt-marshmallow-type coating. The puffy coating results in one or all of the following effects: insulation of fuel from heat, exclusion of oxygen from fuel, production of diluent gases, and reduction of flammable gases. It will retain its effectiveness until broken up either by high heat or by sustained heat.
2. *Mastics.* These materials are applied by trowel or by heavy-duty spray equipment and form a thick coating on the surface of the combustible material. They vary from hard, ceramic-like materials to soft, tarlike coatings. All withstand significant amounts of heat and inhibit flame spread by the impervious noncombustible membrane they form.
3. *Gas-forming paints.* These coatings, when heated, release quantities of noncombustible gas that dilute the oxygen at the protected surface so there is not sufficient oxygen to support combustion.
4. *Cementitious and mineral-fiber coatings.* Limited research has been conducted on the potential use of cementitious and mineral-fiber coatings on wood to improve its fire endurance characteristics. These coatings are commonly used on structural steel to enhance fire resistance by protecting the steel from the intense heat of a fire. Some researchers feel that structural wood systems may be protected in the same manner.

The customary finishing materials for wood, such as ordinary stains, oil paints, enamels, varnishes, shellac, lacquer, and waxes, are of no appreciable value in protecting wood against fire and, in some cases, increase combustibility. Paint, however, may be of value in preventing absorption of oil and in promoting cleanliness. It should also be noted that dry, decayed wood is more susceptible to ignition by small sparks from cigarettes than is sound wood and that paint coatings tend to prevent surface decay.

Water-based gels have been evaluated for efficacy in preventing ignition of combustible siding on residential structures during a wildland fire. Tests conducted at Omega Point Laboratories showed an increase in the time-to-ignition from 30 seconds for untreated wood siding to approximately 300 seconds for the treated wood siding when exposed to 25 kW/m^2.[19] These water-based gels are applied with a garden hose and an aspirator system and are intended for temporary protection only.

Standard test methods are being developed by ASTM to assess the fire resistance of materials and assemblies in structures exposed to wildland fires. These test methods will apply to areas in the high-hazard category. NFPA 1144, *Standard for Protection of Life and Property from Wildfire,* which provides "minimum requirements for planning, construction, maintenance, fire prevention, and management to parties responsible for fire protection, land use planning, property development, property maintenance, and others responsible for or interested in improving fire and life safety in areas where wildland fire could threaten lives, property, and other values" should be consulted for additional information.

Advantages. Fire-retardant coatings have the following advantages: (1) they can be used on combustible materials already in place, (2) they are relatively inexpensive, (3) they are easily applied, and (4) they do not cause strength loss at high temperatures and humidities.

Disadvantages. Fire-retardant coatings have the following disadvantages: (1) ease of application can lead to thin and ineffective treatments, (2) unexposed surfaces cannot be treated, (3) limited life and durability, (4) susceptibility to damage, and (5) required maintenance.

Fire Performance Characteristics. The fire performance of wood can be improved through the use of fire-retardant coatings. The amount of improvement is determined by the effectiveness of the treatment. Underwriters Laboratories Inc. has established a minimum standard of effectiveness for listed coatings to be a flame spread rating of 50 or less in the Steiner tunnel test or a 50 percent reduction in flame spread as compared to the untreated surface, whichever is lower.

Listed coatings, when properly applied, are effective in improving fire performance characteristics, some to a point well below the limits noted above. The variations in effect of listed fire-retardant coatings on Douglas fir are shown in Table 6.7.4.

Permanence. Some fire-retardant paints and coatings have good permanence when used in interior locations of relatively normal humidity and temperatures. Water-resistant, oil-based, intumescing fire-retardant coatings have been developed.[20] But the use of fire-retardant coatings in exterior locations, in areas of relatively high humidity, and in areas of high temperature has not been thoroughly tested. One difficulty in testing these exterior paints is the problem of weathering samples. Samples for small-scale tests can be placed in a weather accelerator or weatherometer and the results measured. These small-scale tests, however, do not produce significant flame spread results. There is also doubt as to the comparability of weatherometer exposure and actual long-term weathering. The samples required for the acceptable large-scale tests are too large for accelerated weathering and thus must be exposed to actual weathering, which requires long periods of time. Until this testing problem can be solved, the use of fire-retardant coatings in exterior locations is questionable.

Strength and Deterioration. Strength and deterioration of both the materials coated and their fastenings is not a problem with most fire-retardant coatings.

Moisture. Only those coatings that use hygroscopic fire-retardant chemicals are vulnerable to absorbing moisture, with consequent reduction in effectiveness.

Toxicity. The reactive toxicity of the total products of combustion of the coated material as compared to the uncoated material should be considered when examining fire-retardant coatings.

Preservative Treatments

Where subject to decay, insect attack, or attack by marine borers, timber and lumber are commonly pressure treated with coal tar creosote, pentachlorophenol, chromated copper arsenate, ammonical copper arsenate, or one of the newer, environmentally friendly chemicals, such as alkaline copper quat, copper azole, and borates. These preservative-treated products are used in piers, bridges, trestles, decks, fences, boardwalks, railroads, and some locations in buildings.

Oil-type preservatives, such as creosote, can cause an increase in fire hazard as compared with untreated wood. Fire-retardant chemicals that use the proper ratio of phosphorus–halogen mixture are effective in reducing the combustibility of the treated wood to that of untreated wood. There is, however, an initial flash of "light ends" not observed in untreated wood.[21] Neither creosote nor pentachlorophenol-treated wood is used in residential applications.

Fire can spread more rapidly and generate higher surface temperature in structures containing newly creosoted wood than in structures of untreated wood, particularly where general fire temperatures are sufficiently high to vaporize the creosote oils. Any unusual fire risk in creosoted pier substructures, however, will be due primarily to the excessive areas of wood construction without firebreaks, which are inaccessible for manual fire fighting and lack automatic sprinkler protection. As the construction industry shifts to new waterborne treatments, this concern is expected to lessen in new structures.

Waterborne salt preservatives can provide some fire-retardant effect, but normal preservative retentions are not sufficient as effective fire-retardant treatments. Conversely, some fire-retardant formulations combine fire retardancy and preservation. Borates are a good example of this dual effect.

Christmas Trees

Christmas trees can become extremely flammable when cut long in advance of use and then brought indoors where heat and low humidity accelerate drying. To reduce the hazard, the tree should be kept indoors only as long as absolutely necessary, the trunk sawed off at an angle at least 1 in. (25 mm) above the original cut end, and the tree placed in water while it is indoors. Water should be added at intervals to the pail, tub, or tree stand in which the tree is placed so that the water level is always above the cut. To achieve a satisfactory degree of flame resistance in any combustible material, including Christmas trees, it is essential to get a certain minimum quantity of effective flame-retardant chemical either into or on the surface of the material to be treated. Since Christmas trees by their nature are not absorbent, the only way to effectively treat them is to apply a surface coating. Treating Christmas trees with simple solutions of water-dissolved chemicals, such as borax-and-boric acid, diammonium phosphate, or ammonium sulfate, is not effective. To provide a significant flame-retardant value, the testing solution or coating must be thick or syrupy enough to form a fairly heavy coating.

Much misunderstanding in this area results from tests of fresh trees treated with simple water-thin solutions of the type described above. Such tests lead to the erroneous conclusion that the treatment is effective, when the fact is that the tree was naturally flame resistant due to its water content.

Pressurized aerosol containers of flame-retardant Christmas tree coatings may be convenient, but their value is questionable due to the very limited quantity of the contents. Many cans would be necessary to adequately treat all parts of larger trees, but the high cost leads the user to apply only a token (and useless) coating.

WOOD-BASED COMPOSITE PANELS

The group of materials referred to here as "wood-based composite panels" includes products such as insulation boards, hardboards, particleboards, oriented strand boards, medium-density fiberboard, and laminated paper boards. They consist of a mixture of fibers, particles, or flakes and binder formed under pressure into boardlike panels or tiles. These board or panel materials in final form retain some of the properties of the original wood but, because of the manufacturing methods, gain new and different properties from those of the wood.

Wood-based composite panels can be fire-retardant treated by chemical admixtures, impregnations, and coatings. These treatments vary in their effectiveness and are somewhat limited in their use by their effect on the physical properties of the untreated panel.

Admixtures

When mineral fibers, such as glass or rock wool, are added to a mixture of organic fibers, they will reduce the combustibility of the mixture, depending on the amount of mineral fiber used. If mineral fibers completely replace the organic fibers, the product becomes noncombustible, provided the binder used to join the fibers is noncombustible or has a sufficiently high ignition temperature. Mixtures of alumina trihydrate, boric acid, and wood fibers have been successfully combined into panel products with very low flame spread and smoke-developed values. Fire-retardant particleboard and oriented strand board are prepared by adding the fire-retardant chemicals prior to board making. These products give very consistent flame spread and smoke-developed values if chemical retentions are consistent.

Impregnations

Attempts have been made to reduce the combustibility of organic composite boards by pressure impregnation of the finished product and by treatment of the raw fiber product itself. Treatments have included soluble salts, insoluble complexes, and chemical reactions with the organic materials themselves. The effect of these treatments on combustible composite boards varied with respect to the type of treatment and type and quantity of chemicals used. Treatment by pressure impregnation has not yet proved to be commercially feasible, due in part to losses in physical properties and inadequate fire retardancy. At least one manufacturer has developed a successful wood pulp treatment process for both composite boards and acoustical tile. Similarly treated wood fiber acoustical tile is produced by other manufacturers.

Coatings

The treatments previously discussed are made during the manufacture of the material. Coatings can be applied during manufacture or to material already in use. Factory-applied coatings are usually fire-retardant paints; however, many are of questionable effectiveness when exposed to severe fire conditions. Their main effect is to cover the fuzzy surface of the untreated material.

The application of fire-retardant paints of the intumescent variety to existing composite board will provide good protection for the exposed side of the board, provided the coatings are maintained. Some composite boards exhibit considerable dimensional instability, expanding when damp and contracting when dry. This movement may expose cracks and gaps in the material that will open untreated areas to the action of heat and rapid flame spread.

Fire Performance Tests of Wood-Based Composites

The effectiveness of the treatments of composite boards can be shown with a fire test. Most of the methods listed under the section on wood can be used to evaluate their fire performance characteristics.

PAPER

Paper can be treated by impregnation to make it flame and glow retardant after the ignition source has been removed. In addition to treating various forms of paper, for example, building paper, wrapping, packing, and decorative paper, these same treatments can be used to preserve foliage, leaves, grass skirts, broom straw, excelsior, and similar materials if they are sufficiently absorbent. Adequate wetting may be achieved by dipping or spraying with some materials, whereas others may require soaking for several hours or even days.

The development of flame-retardant products has been given impetus by the code requirements for nonflammable display and decorative material in hotels, theaters, schools, hospitals, nursing homes, and other high-occupancy buildings. Decorative crepe paper, corrugated display cardboard, textiles, and window-shade materials may be made flame resistant during manufacture, which is the most reliable method. Field treating paper is difficult due to variations in paper finishes, sizing, and color fastness. It is preferable to purchase factory-treated materials.[22]

CELLULOSIC INSULATION

Cellulosic fiber such as shredded newsprint can be treated with fire-retardant chemicals to make a safe building insulation. It is one of the most important construction products using fire-retardant chemicals. Boric acid, borax, and disodium octaborate tetrahydrate are three of the most common fire-retardant chemicals used for this purpose.[23]

MISUSE OF FIRE RETARDANTS

Fire-retardant treatments are used for reduction of flame spread on structural wood members and combustible interior finish, such as wood paneling, acoustical tile, and wood-based composite panels. Flame-retardant treatments are used for reducing the flammability of contents, furnishings, and decorative materials, such as curtains, draperies, upholstery, crepe and corrugated papers, Christmas trees, and miscellaneous dried or artificial plants and foliage. In all these applications, there are opportunities for misuse or misrepresentation. Some of the more prevalent kinds of misuse are described, as follows:

1. Promoting pressure-impregnated wood for uses where noncombustible materials are absolutely required. Such substitutions are appropriate in certain limited applications, but even the most effective treatments cannot entirely eliminate some contribution of fuel and smoke. The concept of a "limited combustibility classification" is being considered in ASTM and ISO on the basis of heat release rate characteristics. Fire-retardant-treated wood is an example of a material that could be so classified.
2. Using pressure-impregnated or coated materials that are not intended for use in locations that are exposed to the weather or unusually high humidity conditions.
3. Attempting to treat the newer synthetic fiber fabrics with common water-soluble-salt flame-retardant solutions. Such solutions are effective only on cellulose fibers, such as cotton and rayon, and the common animal fibers, such as wool and silk. They are not effective for the treatment of nylon, acetate, Orlon®, Dacron®, Acrilan®, or any of the similar synthetics presently in wide use.
4. Marketing flame-retardant solutions in small aerosol spray containers for home use. This practice is subject to many abuses, including the lack of product labels to indicate the limitations of the contents and instructions for proper application. Some advertising contains wildly exaggerated claims for the product's utility, giving the impression that the contents of one can will "flameproof" virtually everything in the home. The product itself may be excellent and convenient to use, but there is a great risk that the average user will not achieve an effective degree of flame resistance. With few exceptions, flame-retardant treatments should be left to skilled persons.
5. Advocating the use of ordinary water-soluble-salt solutions for the treatment of nonabsorbent materials. Effective treatment of nonabsorbent materials can be achieved only by means of a substantial surface coating, requiring that the treating solution be of a syrupy or paintlike consistency.

The technology of flame-retardant treatment is highly useful and can do much to increase fire safety. But because it is also a field vulnerable to entry by unskilled entrepreneurs and charlatans, the buyer should be alert to its limitations. Products that have been tested, rated, and labeled by reputable, independent testing laboratories are the consumers' best safeguard against the pitfalls listed above.

SUMMARY

Cellulosic materials common in the living environment include wood, wood-based composite panels, paper, and miscellaneous decorative materials. Fire-retardant treatment is used to reduce

flame spread on structural wood members and combustible interior finish. Flame-resistant treatment is used to reduce the flammability of contents, furnishings, and decorative materials. Treatments are able to retard flaming or glowing by several different mechanisms, including reducing thermal buildup or excluding oxygen and inhibiting the escape of combustible gases. The four basic methods of treatment are chemical changes, impregnation, pressure impregnation, and coating. Chemical changes and pressure impregnation are limited to manufacturing processes and procedures. Impregnation and coating methods are used in the field. The method applied depends on a number of factors, including the chemical and physical characteristics of the material being treated. Flame-retardant and flame-resistive treatments must be applied properly by a skilled person and tested in order to ensure effective fire protection.

Chapter 8

Dusts

Richard F. Schwab

Chapter Contents

Factors Influencing the Explosibility of Dusts
Dust Cloud Ignition Sources
Deflagration Characteristics of Selected Combustible Dusts
Factors Influencing the Destructiveness of Dust Explosions
Dust Explosion Test Apparatus and Procedures

Key Terms

combustible dust, deflagration, dust, dust cloud, dust explosion, explosibility index, explosion pressure, explosion severity, ignition sensitivity, ignition temperature, inert material, lower explosive limit, lower flammable limit, upper explosive limit

Most finely divided combustible materials are hazardous. When suspended in air and ignited, they can cause severe explosions. This phenomenon has been known for well over 200 years. The first recorded dust explosion—a flour dust explosion in a warehouse in Turin, Italy—occurred on December 14, 1785. The entire industrial spectrum, including agricultural, chemical, metallurgical, mining, plastics, and woodworking industries, continues to be plagued by this problem.[1–5] Although the basic principles for controlling dust explosions have been understood for many years, knowledge is becoming increasingly sophisticated as incidents continue to occur.[2,3–7]

This chapter looks at the factors influencing the explosibility of dusts, such as particle size, dust concentration, and moisture in dust particles. It continues with an examination of ignition sources of dust clouds and the deflagration characteristics of selected combustible dusts. The chapter also discusses factors influencing the destructiveness of dust explosions, such as the effects of rate of pressure rise, of maximum explosion pressure, of duration, of excess pressure, and of confinement. It concludes with a discussion of dust explosion test apparatus and procedures.

For related topics see also Section 2, Chapter 8, "Explosions"; Section 6, Chapter 2, "Combustion Products and Their Effects on Life Safety"; and Section 17, Chapter 8, "Explosion Prevention and Protection."

FACTORS INFLUENCING THE EXPLOSIBILITY OF DUSTS

The chance of a dust cloud igniting is governed by the size of its particles, dust concentration, impurities present, oxygen concentration, and the strength of the source of ignition. Dust explosions usually occur as a series. Frequently, the initial deflagration is rather small in volume but intense enough to jar dust from beams and ledges or even rupture small pieces of equipment within buildings, such as dust collectors or bins. Subsequently, a much larger dust cloud develops, through which a secondary explosion can propagate. It is not unusual to have a series of explosions propagating from room to room or building to building.[7]

Hazards of Dusts

The hazard of any given dust is related to its ease of ignition and the severity of the ensuing explosion. The Bureau of Mines of the U.S. Department of the Interior has developed an arbitrary scale based on small-scale tests, which is quite useful for measuring the hazard. The ignition sensitivity (IS) is a function of the ignition temperature (of the dust cloud) and the minimum energy of ignition; the explosion severity (ES) is a function of the maximum explosion pressure and the maximum rate of pressure rise. To facilitate comparisons of explosibility data in U.S. Bureau of Mines tests, all test results[8] are related to a standard Pittsburgh coal dust taken at a concentration of 0.50 oz per ft^3 (500 g/m^3), with the exception of some metal dusts.[9]

The ignition sensitivity and explosion severity of a dust are defined as:

$$IS = \frac{(T_i \times E_m \times C_m)_{\text{Pittsburgh coal dust}}}{(T_i \times E_m \times C_m)_{\text{Sample dust}}}$$

Richard F. Schwab, P.E., S.F.P.E., AIChE, (now retired) was manager of process safety and loss prevention, Honeywell International, Morristown, New Jersey.

$$ES = \frac{(P_{max} \times R_{max})_{Sample\ dust}}{(P_{max} \times R_{max})_{Pittsburgh\ coal\ dust}}$$

where

T_i = Ignition temperature of a dust cloud

E_m = Minimum ignition energy of a dust cloud

C_m = Minimum concentration for a combustible dust cloud

P_{max} = Maximum explosion pressure

R_{max} = Maximum rate of pressure rise in the test apparatus

The explosibility index (EI) is the product of the ignition sensitivity and explosion severity. This method allows one to rate the relative hazard of the dusts as shown in Table 6.8.1. The concept of using this scale to measure the hazard of a combustible dust has in recent years been found to be outdated though it is still widely used.[10]

Table 6.8.2 gives the explosibility index, ignition sensitivity, explosion severity, maximum explosion pressure, maximum rate of pressure rise (not necessarily at the concentration of 0.50 oz per ft^3 [500 g/m^3]), ignition temperature of both the dust cloud and a layer, the minimum ignition energy of the dust cloud, minimum explosion concentration, and the limiting oxygen concentration in a spark-ignition chamber.

Particle Size

The smaller the size of the dust particle the easier it is to ignite the dust cloud, insofar as the exposed surface area of a unit weight of material increases as the particle size decreases. It is also true that particle size has an effect on the rate of pressure rise. For a given weight concentration of dust, a coarse dust will show a lower rate of pressure rise than a fine dust. The lower explosive limit (LEL) concentration, ignition temperature, and the energy necessary for ignition will decrease as the dust particle size decreases. Numerous studies by various investigators show this effect for a variety of dusts.[11]

Decrease in particle size also increases the capacitance of dust clouds, that is, the size of electrical charges that can accumulate on particles in the cloud.[12,13] Because capacitance of solids is a function of surface area, the possibility of developing electrostatic charges of sufficient intensity to ignite a dust cloud increases as average particle size decreases. However, to produce such electrostatic charges requires, among other things, large quantities of dust in large volumes, with relatively high dielectric strengths and consequent long relaxation times. Because of the high ignition energies required for dust clouds to ignite in comparison with ignition energies of gases, attributing the cause of dust explosions to static electricity should be held suspect unless definite evidence exists to show that static electricity was a likely cause.[3,7]

TABLE 6.8.1 Relative Hazard of Dusts

Type of Explosion	*Sensitivity*	*Severity*	*Index*
Weak	<0.2	<0.5	<0.1
Moderate	0.2–1.0	0.5–1.0	0.1–1.0
Strong	1.0–5.0	1.0–2.0	1.0–10
Severe	>5.0	>2.0	>10

Concentration

As with flammable gases and vapors, there is a specific range of dust concentration within which a dust explosion can occur. It is customary to express the concentration figures in terms of weight per unit volume; however, without knowledge of the particle size distribution of the sample, this expression is meaningless. The results presented in Table 6.8.2 were developed by the U.S. Bureau of Mines and were obtained with dusts small enough to pass through a 200-mesh screen (74 microns or smaller). In data published in Germany,[4,14,15] based on the data shown in Table 6.8.3, the median particle size was shown for every test. These German tables were condensed from far more extensive tables,[14] which also included the particle size distribution for most of the reported tests.

Variations in minimum explosive concentration will occur with changes in particle diameter; that is, the minimum explosive concentration is lowered as the diameter of particles decreases. Sample purity, oxygen concentration, strength of ignition source, turbulence of dust cloud, and uniformity of dispersion also affect the lower explosive limits (LEL) of dust clouds.

Upper explosive limits for given cloud combustible dust cloud have been determined for very few samples. There are many experimental difficulties associated with gathering this information and, from a practical point of view, this information is of questionable use.[16]

Curves formed by plotting explosion pressures and rates of pressure rise against concentration show that explosion pressures and rates of pressure rise are at a minimum at the lower explosive limit, then rise to a maximum value at a given optimum concentration, and then slowly decrease from this point. It is to be noted that the maximum pressure and the maximum rate of pressure rise do not always occur at precisely the same concentration. The destructive effect is determined primarily by the rate of pressure rise.

It appears that the most violent explosion occurs at a concentration slightly above that required for reaction with all of the oxygen in the atmosphere. At lower dust concentrations, less heat is generated and smaller peak pressures are developed. With dust concentrations greater than those causing the most violent explosions, absorption of heat by unburned dust is apparently the reason for less-than-maximum explosive pressures.

Moisture

Moisture in dust particles raises the ignition temperature of the dust because of the heat absorbed during heating and vaporization of the moisture. The moisture in the air surrounding a dust particle has no significant effect on the course of a deflagration once ignition has occurred. There is, however, a direct relationship between moisture content and minimum energy required for ignition, minimum explosive concentration, maximum

[a]1 psi = 6.894 kPa.
[b]°F = 9/5 (°C + 32).
[c]0.1 oz/ft³ = 100 g/m³.
[d]Numbers in this column indicate percentage whereas the letter prefix indicates the diluent gas. For example, the entry "C13" means dilution to an oxygen content of 13 percent, with carbon dioxide as the diluent gas. The letter prefixes are C = carbon dioxide and N = nitrogen.

Sources: Compiled from the following reports of the U.S. Department of Interior, Bureau of Mines: RI 5753, "The Explosibility of Agricultural Dusts"; RI 6516, "Explosibility of Metal Powders"; RI 5971, "Explosibility of Dusts Used in the Plastics Industry"; RI 6597, "Explosibility of Carbonaceous Dusts"; RI 7132, "Dust Explosibility of Chemicals, Drugs, Dyes, and Pesticides"; and RI 7208, "Explosibility of Miscellaneous Dusts."

pressure, and maximum rate of pressure rise. For example, the ignition temperature of cornstarch may increase as much as 122°F (50°C), with an increase of moisture content from 1.6 percent to 12.5 percent. As a practical matter, however, moisture cannot be considered an effective explosion preventive, since most ignition sources provide more than enough heat to vaporize the moisture and to ignite the dust. In order for moisture to prevent ignition of a dust by common sources, the dust would have to be so damp that a cloud could not be formed.

Inert Material

The presence of an inert solid powder reduces the combustibility of a dust because it absorbs heat, but the amount of inert powder necessary to prevent an explosion is usually higher than concentrations that would normally be found or could be tolerated as foreign material. The addition of inert material reduces the rate of pressure rise and increases the minimal dust concentration. Rock dusting of coal mines is a practical application of the use of inert dust to prevent explosion of combustible dust. For general rock dusting of coal mine entries, enough rock dust is usually added to provide an inert dust concentration of at least 65 percent of the total dust.[4,7] In industries other than mining, adding inert dust is seldom applicable due to contamination and other problems.

Inert gas is effective in preventing dust explosions because it reduces the oxygen to a concentration too low to support combustion. In selecting a suitable inert gas, care must be taken to choose one that is not reactive with the dust. Certain metallic dusts, for example, react with carbon dioxide or nitrogen.[9] Helium and argon are suitable diluents in such instances.[17]

Oxygen Concentration, Turbulence, and Effect of Flammable Gas

Variations in oxygen concentrations affect the ease of ignition of dust clouds and the explosion pressures. With a decrease in the partial pressure of oxygen, the energy required for ignition increases, ignition temperature increases, and maximum explosion pressures decrease. The type of inert gas used as the diluent for reduction of the oxygen concentration also has an effect apparently related to molar heat capacity.

The combustion of dust takes place at the surfaces of the dust particles. The rate of reaction, therefore, depends on intimate mixing of the dust and oxygen. It is for this reason that turbulent mixing of dust and air results in more violent explosions than those obtained by ignition in more relatively quiescent mixtures.[1,18,19] The data presented in Table 6.8.2 were gathered by igniting the dust under violently turbulent conditions; thus, they cannot be compared to explosion data for flammable gases that were gathered under comparatively quiescent conditions.

Addition of a small amount of flammable gas to a dust cloud and igniting the resultant aerosol greatly increases the violence of the explosion, particularly at lower dust concentrations. The resultant rates of pressure rise are very much higher than usually anticipated. Without the dust, the remaining fraction of the total combustible in air, represented by the flammable vapor, would be in itself below the lower flammable limit (LFL). In certain drying operations, involving the evaporation of a flammable vapor from a combustible powder with entrainment of the combustible dust along with the flammable vapor, explosions occurred that were far more violent than anticipated when only the fraction represented by the flammable vapor alone was considered.[1,3,4,20] Indeed, explosions occurred in such flammable vapor-combustible dust-air mixtures when the flammable vapor-air portion was below the LFL. When encountered, these situations need special safeguards, such as inert gas dilution, explosion suppression, very large explosion vents, and careful static electricity elimination designs. (See Figure 18.6.1 in Section 18, Chapter 6.)

When the oxygen content is reduced by the addition of an inert gas, ignition of the subsequent dust cloud reduces the maximum pressure and the rate of pressure rise obtained from the ignition of the dust cloud in addition to requiring an increase in the minimum ignition energy. This also has the effect of reducing the K_{St} value and results in a reduction of the amount of vent area needed to effectively vent a dust explosion. It has been suggested by Eckhoff[21] that this can be used as a protection technique to design appropriate control measures to protect against the dust explosion hazard.

DUST CLOUD IGNITION SOURCES

Dust clouds have been ignited by open flames, lights, smoking materials, electric arcs, hot filaments of lightbulbs, friction sparks, high-pressure steam pipes and other hot surfaces, spontaneous heating, welding and cutting torches and sparks from these operations, and other common sources of heat for ignition. The dust cloud ignition temperatures given in Table 6.8.2 for the most part fall between 300 and 600°C, and a large majority of the reported minimum spark ignition energies were between 10 and 40 mJ. This can be contrasted to flammable vapor ignition energies with a range for the most part between 0.2 and 10 mJ. As a general rule, combustible dusts require 20 to 30 times the ignition energies of flammable vapors.[3]

Because ignition temperatures and ignition energies for dust explosions are much lower than the temperatures and energies of most common sources of ignition, it is not surprising that dust explosions have been caused by common sources of ignition. For this reason, the elimination of all possible sources of ignition is a basic principle of dust explosion prevention. Ignition sources in dust-handling operations are identified and recommendations for their elimination are described in various NFPA standards for the prevention of dust explosions (see bibliography).

DEFLAGRATION CHARACTERISTICS OF SELECTED COMBUSTIBLE DUSTS

Table 6.8.3 is based on information obtained from *Forschungsbericht Staubexplosionen: Brenn und Explosions Kenngrossen von Stauben*[14] and *Brenn und Explosions Kenngrossen von Stauben.*[15] For each dust, the tables show the median particle size of the material tested, as well as the following test results obtained in a 1 m^3 vessel: minimum explosible concentration, maximum pressure developed by the explosion (P_{max}), and the maximum rate of pressure rise $(dP/dt)_{max}$. Also shown are the

Note: This table is derived from the data published in Eckhoff,[4] which in turn were condensed from data published by the BIA.[15]

K_{St} value, which is the equivalent to $(dP/dt)_{max}$ because of the size of the test vessel, dust hazard class, cloud and layer ignition temperatures, combustibility rating, and test number.

The dust explosion test data presented in Table 6.8.3 are only a qualitative indication of the dust explosion hazard of a particular dust. It should not be used for design purposes. The dust explosion hazard depends on the size of the dust particles (particle size distribution), the method of grinding or pulverization affecting the particle shape, moisture content of dust sample, and possible solvent content of the dust sample. An evaluation of the hazard of a specific combustible dust is needed to design appropriate protection features such as deflagration (explosion) venting, explosion prevention methods such as provision of inert gas blankets, and explosion suppression techniques. Each of these protection features depends on test data of the specific representative dust sample.

The median particle size gives a median or average value of the dust sample particle size. Most of the samples listed in Table 6.8.3 were tested on the "as received" basis and in some cases were passed through a No. 200 mesh screen.

Most of the tabulated data in Table 6.8.3 were determined in a 1-m^3 sphere ISO vessel or in the 20-L Siwek sphere. Experience has shown that the latter value gives lower values than the 1 m^3 sphere often by a factor of two. The C_{min} in brackets is the concentration of the dust determined in the 1.2-L Hartmann bomb. These values tend to be higher than the true C_{min} determined in the 1-m^3 test vessel.

The P_{max} is the maximum pressure if the dust is ignited at the optimum concentration in a nonvented test vessel and is reported in bar (gauge). The numbers in brackets were obtained with a 20 L vessel using a simplified test procedure.

The K_{St} [bar meter/s] is defined as the maximum rate of pressure rise in a nonvented vessel times the cube root of the volume. The data were determined in a standard in a 1-m^3 test vessel or a 20-L Siwek spherical test vessel calibrated to give the same results as the 1-m^3 test vessel.

Minimum Ignition Temperature of Dust Clouds

The minimum ignition temperature data in Table 6.8.3 were acquired using the Godbert-Greenwald furnace or the BAM furnace. The data in brackets were obtained using a modified elongated version of the Godbert-Greenwald furnace yielding somewhat lower values than the version proposed as an IEC standard.

Minimum Ignition Energy (MIE)

The values reported in Table 6.8.3 are the so-called soft values, those with long discharge times (high inductance) based on the experimental technique described by Berthold (1987) (VDI method) and Eckhof (1976) (CMI method). The VDI and CMI methods differ from the earlier U.S. Bureau of Mines method. It has been found that the MIE determined by the U.S. Bureau of Mines included an appreciable fraction of the $\frac{1}{2} CV^2$ energy that was lost in the transformer supplying energy to the spark igniting the dust clouds, as a result, the U.S. Bureau of Mines MIE data are generally higher than those determined by the newer VDI and CMI methods. The U.S. Bureau of Mines values are high capacitance (short time) sparks.

Glow Temperature

The glow temperature data were obtained with a 5-mm-thick layer of dust resting on a hot plate of known controllable temperature (equivalent to proposed standard IEC method for determining the minimum ignition temperature of a dusty layer on a hot surface).

Flammability

The dusts are classified according to their ability to propagate a combustion wave when deposited as a layer. Ignition is accomplished using either a gas flame or a glowing platinum wire at 1000°C. The test sample is a 2-cm wide by 4-cm long dust ridge resting on a ceramic plate. Ignition is performed at one end. The definitions are:

- Class 1: No self-sustained combustion
- Class 2: Local combustion of a short duration
- Class 3: Local sustained combustion, but no propagation
- Class 4: Propagating smoldering combustion
- Class 5: Propagating open flame
- Class 6: Explosive combustion

The class numbers refer to a modified test procedure according to which 20 weight percent diatomaceous earth is mixed with the powder or dust to be tested. By this means some materials that otherwise would not propagate a flame because they melt may show sustained flame propagation.

FACTORS INFLUENCING THE DESTRUCTIVENESS OF DUST EXPLOSIONS

Although the destructiveness of a dust explosion depends primarily on the rate of pressure rise, other contributing factors are the maximum pressure developed, the duration of the excess pressure, the degree of confinement of the explosion (deflagration) volume, and the oxygen concentration.

Effect of Rate of Pressure Rise

The rate of pressure rise can be defined as the ratio of the increase in explosion pressure to the time interval of that increase. It is the most important single factor in evaluating the hazard of a dust and principally determines the destructiveness of a deflagration.

The rate of pressure rise is also an important consideration in the design of explosion (deflagration) vents, since it largely determines the size of the vent. In many cases, an extremely rapid rate of pressure rise indicates that an explosion vent design is either impractical or, at best, extremely difficult. In those cases, alternate protective schemes, such as use of inert gases,[21] explosion suppression, or containment, should be considered. (See NFPA 69, *Standard on Explosion Prevention Systems.*)

Effect of Maximum Explosion Pressure

The maximum explosion pressures reported by recognized test procedures are, for the most part, in excess of 50 psig (345 kPa) and, sometimes, in excess of 100 psig (690 kPa). These figures are valid only for test conditions and are subject to changes by variation in particle size, concentration, and other variables. Considering that an ordinary brick wall 12 in. (0.3 m) thick can be destroyed by less than 1 psi (6.89 kPa) pressure, it is evident that it is not practical to construct a building strong enough to resist the maximum pressures resulting from a dust deflagration. One reason why the degree of destruction is not greater in many dust explosions is that the dust is not uniformly dispersed throughout the explosion volume. A dust cloud is rarely ignited under optimum concentration conditions with respect to the development of maximum explosion pressures.

Effect of Duration of Excess Pressure

Closely associated with maximum pressure and rate of pressure rise as indications of the destructiveness of dust explosions is the length of time the excess pressure is exerted on the surroundings. The area under the time-pressure curve determines the total impulse exerted. It is this total impulse rather than the force exerted at any moment that will determine the amount of destruction. This is shown in Figure 6.8.1, where the pressure-time history of a gas explosion is compared with that of a dust explosion in identical vented enclosures and with the same vent opening pressure. Note that the faster burning gas develops a higher maximum peak pressure than does the dust, but the overpressure decreases more quickly. The area under the dust explosion curve is larger than the area under the gas explosion curve, indicating a greater total impulse and, therefore, potentially more damage. This relationship between destructiveness and total impulse explains why dust explosions, which generally have slower average rates of pressure rise than gas explosions, can be more destructive than gas explosions.

Effect of Confinement

When a dust explosion occurs, gaseous products are formed and heat is released, which raises the temperature of the air in the enclosure. Since gases expand when heated, destructive pressures will be exerted on the surrounding enclosure, unless enough vent area is provided to release the gas pressure before dangerous pressures are reached.

Bartknecht,[1,22] Nagy and Verakis,[23] Field,[24] Palmer,[7] Cross and Farrer,[12] and Hartmann et al.[11] have examined the effect in some detail. The work of Bartknecht and his associates is generally considered to be the most comprehensive, leading to basic design methods for deflagration vents, and is the basis for the procedures shown in NFPA 68, *Standard on Explosion Protection by Deflagration Venting.* Generally his procedures relate to vessels or enclosures that are capable of withstanding 1.5 psig (10.4 kPa) or more. The work of Swift and Epstein[25] is the basis of the design procedures for low-strength structures (weaker than 1.5 psig [10.4 kPa]) in NFPA 68.

In some instances, it may be impractical to provide sufficient vent area to reduce pressures to a safe level. In these situations, the dust-producing operation can be conducted in the open, under an inert atmosphere, or protected by an explosion suppression system. The explosion suppression system consists of a flame or pressure detector and a flame-quenching agent that is expelled rapidly during the incipient stage of a deflagration.

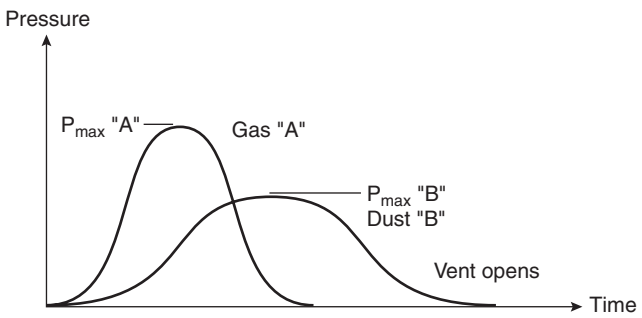

FIGURE 6.8.1 Total Impulse of Gas Explosion Compared to Total Impulse of Dust Explosion

Effect of Inerting on Explosion Pressures and Rates of Pressure Rise

Data published by the U.S. Bureau of Mines[26] and Bartknecht[22] show that reduction in the oxygen concentration in the atmosphere, and mixture of inert powder (Fuller's earth or rock dust) or moisture with the combustible dust, reduces the maximum explosion pressure and rates of pressure rise. These data are shown in Figures 6.8.2 and 6.8.3 for explosions of 0.50 oz per ft^3 (500 g/m^3) of cornstarch. A slight reduction in the atmospheric oxygen concentration or slight additions of inert powder or moisture have little effect on the explosion pressure. The effect of the inerting on the dust explosion becomes marked only when limiting values are approached. The maximum rate of pressure rise developed by the explosion (deflagration) appears to decrease almost linearly with use of inerting.

DUST EXPLOSION TEST APPARATUS AND PROCEDURES

There are a number of different types of dust explosion test chambers and even more procedures for using them, each of which can profoundly affect the test results for any given dust sample. For example, the result of the dust explosion test in a closed chamber is affected by the geometry of the chamber, that is, interior dimensions (cubical, spherical, cylindrical, etc.), and by the method of creating the dust cloud in the chamber (the method affects the turbulence of the cloud and uniformity of particle dispersion). This situation causes considerable difficulty in attempting to compare results obtained by various methods. In fact, unless several test results on the same dust sample are made in different chambers, and a consequent correlation is developed between the test methods, it can be said without reservation that any comparison of data obtained by different

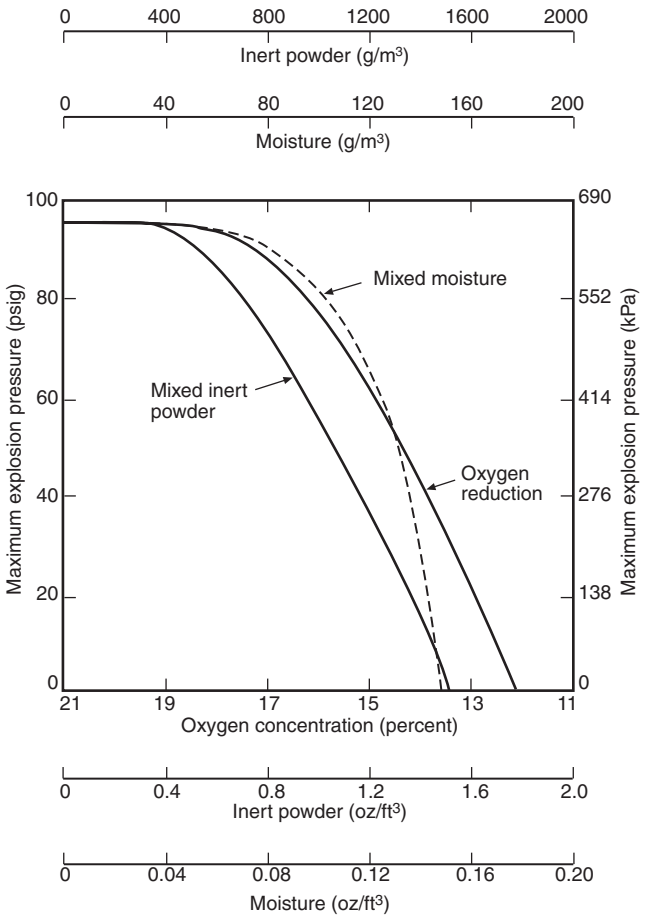

FIGURE 6.8.2 Effect of Inerting on Maximum Pressure Developed by Explosion of 0.50 oz/ft^3 (500 g/m^3) of Cornstarch

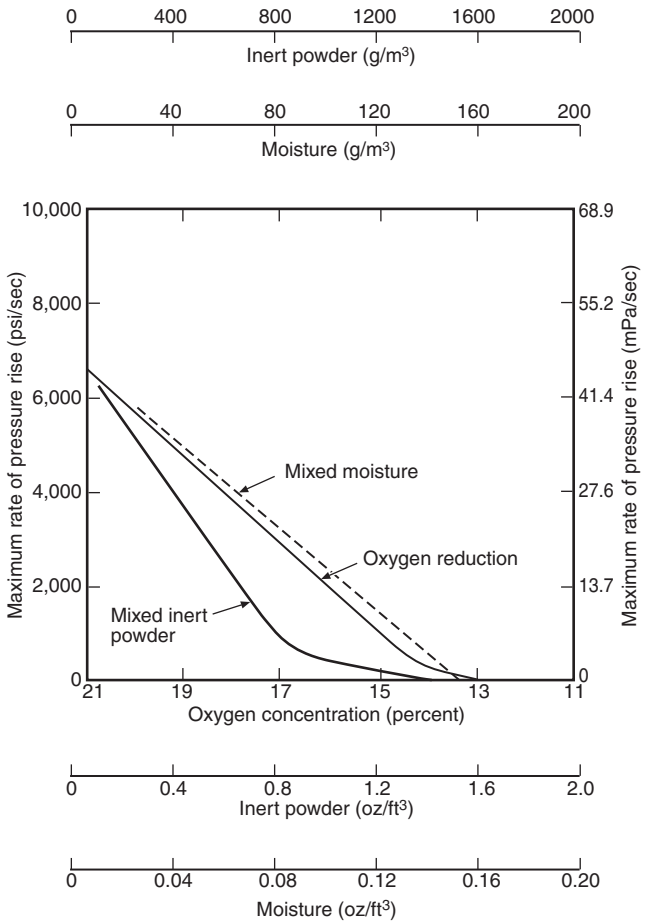

FIGURE 6.8.3 Effect of Inerting on Maximum Rate of Pressure Rise Developed by Explosion of 0.50 oz/ft^3 (500 g/m^3) of Cornstarch

test methods is, at best, only qualitative. For example, attempts to correlate test results obtained in the Hartmann bomb with the 5.29 gal (20 L) spherical bomb developed by Bartknecht have been unsuccessful.

Lack of uniformity in test procedures also rules out any attempt to compare the pressures and rates of pressure rise resulting from tests on flammable vapors and dusts. By far, the largest amount of dust explosion test data has been obtained from tests conducted by the U.S. Bureau of Mines. The U.S. Bureau of Mines' test equipment and procedures are described in RI 5624.[27] The test equipment used by the U.S. Bureau of Mines is a cylindrical vessel of about 75 in.^{3} (1.2 L), standing about 13 in. (0.33 m) high, referred to as the Hartmann apparatus[28] (Figure 6.8.4). All of the data recorded in Table 6.8.2 has been collected in this type of test apparatus. This type of data is not satisfactory for designing explosion (deflagration) relief vents.

Recent data, particularly that intended for use in designing explosion (deflagration) vents, were collected in spherical vessels. Bartknecht and his associates developed a 20-L (about 5-gal) spherical bomb[29,30] (Figure 6.8.5). Data collected in these containers tend to give more consistent results and follow

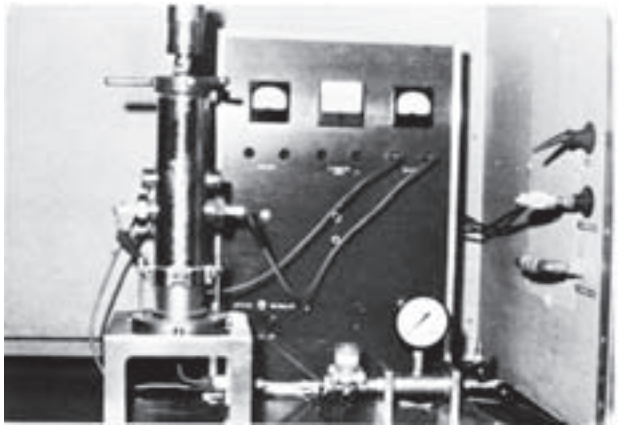

FIGURE 6.8.4 Hartmann Apparatus (Source: U.S. Bureau of Mines)

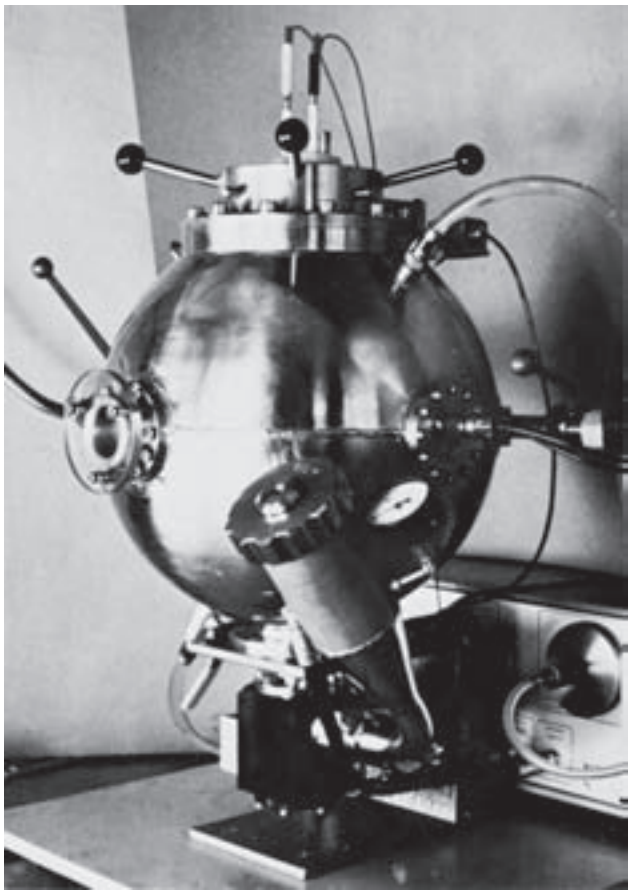

FIGURE 6.8.5 Bartknecht Apparatus (Source: W. Bartknecht)

the "cubic law" (described later). Data collected in a spherical bomb, properly calibrated, have been shown to generally follow the "cubic law" over a range from 20 L to 250 m^3. The data obtained in this vessel can be used as a basis for the design of explosion vents. Data obtained from test results obtained in the Hartmann apparatus cannot be used for this purpose.

Interpretation and Application of Dust Explosion (Deflagration) Test Data

Dust explosion test data are gathered in a variety of chambers, from a highly turbulent dust cloud to a practically stagnant cloud. Most modern test data are gathered in calibrated spherical test vessels that follow the "cubic law," which is represented for dusts as follows:

$$\left(\frac{dP}{dt}\right)_{\max} \times V^{1/3} = K_{St}$$

where

P = Pressure (bar)

t = Time (sec)

V = Volume (cu. meters)

K_{St} = Dust characterization factor (bar meter/sec)

This can also be expressed by the following relationship:

$$\frac{R_l}{R_s} = \left(\frac{V_s}{V_l}\right)^{1/3} = \frac{A_l}{A_s}$$

where

R_l = Rate of pressure rise in the large chamber

R_s = Rate of pressure rise in the small chamber

V_l = Volume of the large chamber

V_s = Volume of the small chamber

A_l = Vent ratio of the large chamber

A_s = Vent ratio of the small chamber

(All variables must be in consistent units.)

This law indicates that the test data gathered in small chambers can be extrapolated to larger chambers with some degree of confidence, though care must be taken to keep the shape of small chambers and large chambers within reasonable limits. If the test is done in small spheres, the results cannot be expected to hold up in the design of explosion (deflagration) relief for a long, narrow vessel.

Ignition Temperature

One piece of apparatus developed at the U.S. Bureau of Mines consists essentially of an electrically heated vertical cylindrical tube at the top of which is a small container holding a weighed amount of dust. The dust is projected down through the tube as a uniform cloud by a controlled blast of compressed air directed at the dust sample. The ignition temperature is considered to be the lowest temperature at which flame issues from the open bottom end of the tube. Differences in results are due to differences in the size and shape of test containers.[27] This test is used to determine the ignition temperature of the dust cloud.

The furnace is also used to determine the ignition temperature of a dust layer sample, ½ in. (12.5 mm) deep, 1 in. (25.4 mm) diameter, in a container suspended in the furnace heated by a stream of hot air flowing at 30 $in.^3$ per min (½ L/min) past the sample.[27] Other recognized testing agencies use hot plates with the dust layers ¾ in. (19 mm) deep.[14,15] Other researchers have reported test data using different test procedures[31,32] designed to investigate ignition sources encountered under industrial conditions.

Ignition in Inert Atmospheres

For the determination of the ignitability of dust in various inert gas-air mixtures, the apparatus consists of a vertical cylindrical tube containing tungsten electrodes to produce a spark for ignition. The tube is designed so that it can be flushed with the inert gas-air mixture prior to the test. The dust sample in a container near the top of the tube is projected downward as a cloud by a controlled blast of the inert gas-air mixture. Flame issuing from the open bottom of the tube signifies ignition.[31,32] Bruderer[31] has also investigated limiting oxygen concentrations for various ignition sources in his work.

Minimum Energies for Ignition

Apparatus developed at the U.S. Bureau of Mines, used to determine minimum energies needed to cause ignition of dust clouds, consists of a vertical cylindrical lucite tube. In this test, the dust is dispersed upward in the tube by controlled discharge of compressed air into the dust chamber at the bottom of the tube. A spark discharged by an electrical condenser is used as the ignition source, and by using condensers with different capacities, spark energy can be varied. Discharge of the condenser is synchronized with the formation of the dust cloud. Visible flame in the tube signifies ignition.

The data presented in Table 6.8.2 for cloud ignition energies has been gathered in this fashion. Recent work [27,33,34] has shown that, if the spark is generated in a different fashion with a high resistance in series with the capacitance discharge, it is possible to obtain ignition of the dust cloud considerably below that reported by the U.S. Bureau of Mines technique. Generally speaking, the data reported by the U.S. Bureau of Mines might be expected to be a factor of 3 to 5 times too high.[12]

Eckhoff[33] has managed to ignite some of the more sensitive dusts, such as aluminum (5 μm) and sulfur, at energies of 1 mJ or less. The U.S. Bureau of Mines quotes 15 mJ for these materials. It is questionable whether a circuit that produces such a low-level spark of the nature required would occur naturally. Ignitability is not solely a function of spark energy but also a function of spark duration, with long-duration sparks igniting dusts more easily than short-duration sparks.[12]

Explosion Pressures

Apparatus described by the U.S. Bureau of Mines[27] for determining maximum explosion pressures and rates of pressure rise consists of a vertical cylindrical steel bomb into which a weighed sample of dust can be dispersed upward by a jet of compressed air. Pressures are measured by a strain gauge transducer mounted in the top of the bomb. A pressure-time record is obtained on an oscillograph using a light beam galvanometer system.

SUMMARY

Dust cloud explosions are a hazard common to a number of industries, including agricultural, chemical, metallurgical, mining, plastics, and woodworking. The chance of a dust cloud igniting is governed by the size of its particles, dust concentration, impurities present, oxygen concentration, and the strength of the source of ignition. Measures that can reduce the risk or damage of explosions include inert material or gas dilution, elimination of sources of ignition, explosion suppression, very large explosion vents, and careful static electricity elimination designs. The U.S. Bureau of Mines has conducted many tests on the properties and explosibility of dusts; the data collected will continue to aid in designing safeguards.

Aluminum
Radioactive Metals
Metals Not Normally Combustible

Key Terms

alkali, calcium, combustible metal, dust, explosibility, hafnium, magnesium, process hazard, radioactive metal, titanium, zinc, zirconium

Combustible metals are those metals that are either combustible or explosive. The hazards of combustible metals can occur while the metals are being produced, processed, finished, handled, or stored. The hazards also exist in related processes such as process ventilation systems. This chapter covers the fire hazard properties of combustible metals and the means to prevent their ignition or explosion.

For information on the hazards of metal dusts see Section 6, Chapter 8, "Dusts."

OVERVIEW

General

Nearly all metals will burn in air under certain conditions. Some oxidize rapidly in the presence of air or moisture, generating sufficient heat to reach their ignition temperatures. Others oxidize so slowly that heat generated during oxidation is dissipated before the metals become hot enough to ignite. Certain metals, notably calcium, hafnium, lithium, magnesium, niobium, plutonium, potassium, sodium, tantalum, thorium, titanium, uranium, zinc, and zirconium, are referred to as combustible metals because of the ease of ignition of thin sections, fine particles, or molten metal. However, the same metals in massive solid form, with the exception of the alkali metals, are very difficult to ignite.

The alkali metals (cesium, francium, lithium, potassium, rubidium, sodium, and alloys of these metals, such as NaK) are water reactive. They react with water to generate hydrogen. The amount of metal or its particle size does not contribute to the risk of ignition. Generally, contact with water will result in a reaction that may include fire or explosive forces. Metals such as lithium, sodium, potassium, and NaK react with water at room temperature. Other alkali metals may only react when they are heated or involved in a fire.

Fire and Life Safety Requirements

Requirements for specific metals can be found in NFPA 484, *Standard for Combustible Metals.* This standard covers the significant combustible metals, with each metal having its own chapter covering the specifics of that metal. Two important changes have been made to NFPA 484. First, a chapter has been added on the assessment of whether the materials of concern should be treated as combustible metals. The assessment is composed of two tests, one for combustibility and the other for explosivity, as described in Figure 6.9.1. When a material fails either test, the material in question is considered a combustible metal and the precautions of NFPA 484 are applicable. The second major change to NFPA 484 is the addition of a chapter that provides some general precautions for combustible metals not specifically addressed by any individual chapter.

Tom Christman began working with combustible metals in 1976. In 1994 Mr. Christman was appointed as a principal member of the Combustible Metals Committee, which had the responsibility for individual standards on aluminum, lithium, magnesium, titanium, and zirconium. He presently is the chair of NFPA 484, *Standard for Combustible Metals.*

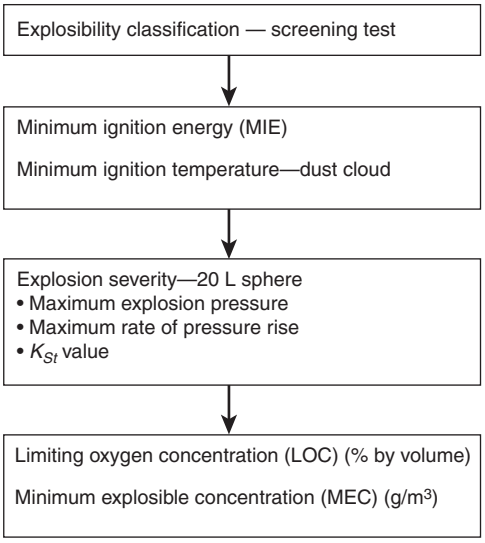

FIGURE 6.9.1 NFPA 484 Determination of Explosibility (Source: NFPA 484, *Standard for Combustible Metals,* 2006 ed., Figure 4.3.1)

Combustibility Factors and Hazards

Some metals, such as iron and steel, which are not normally thought of as combustible, can ignite and burn when finely divided or when in contact with other burning materials. Clean, fine steel wool, for example, can be ignited fairly easily. Particle size, shape, quantity, and alloy are important factors to consider when evaluating metal combustibility.

Clouds of most metal dusts in air are explosive. Therefore, fugitive dusts must be controlled to prevent a fire or explosion. Housekeeping must be especially good in areas where fugitive dust is present to ensure against the buildup of dust. In general, if the layer of dust is thick enough to obscure the color of the surface below or is thick enough to write your name in it, it *is* an explosion hazard.

Alloys, which are essentially mixtures of different metals combined in varying proportions, may differ widely in combustibility from their constituent elements. Metals tend to be most reactive when finely divided and some powders may require shipment and storage under inert gas or in liquid or might have to be coated to reduce fire risks.

Hot or burning metals may react violently on contact with other materials, such as certain extinguishing agents or agents normally used on fires involving ordinary Class A combustibles or flammable liquids. A few metals, such as thorium, uranium, and plutonium, emit ionizing radiation (e.g., gamma rays or beta and alpha particles) that can complicate fire fighting and introduce a contamination problem.

Temperatures produced by burning metals are generally much higher than temperatures generated by burning flammable liquids. Some hot metals can continue burning in atmospheres of carbon dioxide, nitrogen, or steam where combustion of ordinary combustibles or flammable liquids would not be sustained.

Properties of metal fires cover a wide range. For example, burning titanium produces little smoke, whereas burning lithium smoke is dense and profuse. Some water-moistened metal powders, such as zirconium, burn with near-explosive violence; the same powder wet with oil burns quiescently. Sodium melts and flows while burning; calcium does not. Some metals (e.g., uranium) acquire an increased tendency to burn after prolonged exposure to moist air, whereas prolonged exposure to dry air may make it more difficult to ignite the metal.

Another hazard of combustible metals is the possible formation of eutectics. A eutectic is an alloy that has a melting point below any of its constituent metals and that has the potential for reaction at lower temperatures than that of its constituents. Often this reaction can be vigorous and exothermic. Practical examples of catastrophic occurrences involving eutectic mixtures have been heating a titanium plate in a furnace where a large excess of steel scale (iron oxide) might contact a thin edge or corner of the plate or heating a niobium base alloy on a nickel base plate, even in a vacuum furnace. Pressure and finely divided forms of either material can help trigger such reactions. One particularly unpleasant consequence is that the eutectic composition will liquefy at a temperature below the melting point of either material and the hot liquid will spread by flow.

In general, all particulate forms of combustible metals, especially thinner chips and fine powders, should be stored in individual sealed metal containers rather than in bulk-type storage. Above 80 mesh or thicknesses greater than 0.015 in. (381 microns), the reactivity and resultant hazard is somewhat reduced. Finer particulates or thinner cross sections represent an increasing hazard.

Storage of some powders and fines can be done under the cover of water, but care must be taken if the fine particulates begin to dry out. At some critical moisture level, particularly with fine powders, spontaneous combustion may occur. Sometimes, personnel may not realize that a wet grinding or polishing operation is creating wet metal fines that can become very sensitive as the water or other liquid carrier dries out. A good informal rule is to tailor packaging sizes to quantities utilized in processing as opposed to bulk packaging. Where product contamination is not a concern, bagging in polyethylene under the cover of argon and then placing inside a metal container is recommended.

Thin sheet, strip, or foil in pickle baths or hot, caustic descaling vats can ignite or be ignited due to heat of reaction and this phenomenon may be exacerbated by stray electrical currents, which may cause arcing.

In the case of "fluffy," light, loosely packed turnings or powders, care must be exercised not to disperse the burning particulates with forceful application of an extinguishing agent. Another concern with fine particulates is trails in corners and crevices, which can permit sparks to travel some distance to other areas. Frictional forces can also cause ignition of fines due to pinch points and rubbing in machinery.

A good basic philosophy when handling thin section products of these materials and their alloys is to assume that at some time a fire will occur. Good housekeeping and careful logistics of material handling can limit the damage when a fire does occur.

One particularly insidious aspect of working with fine particulates of these materials is the inconsistency of reaction. There will be times when they seemingly cannot be ignited and others when the static from a poly bag or scuffing of a foot on hard surface will generate enough energy to cause ignition. A long period of "being lucky" can lead to a false sense of security.

FIRE PREVENTION AND PROTECTION

Extinguishment

Extinguishing a combustible metal fire is a difficult task when significant quantities of metals are involved. Portable Class D fire extinguishers or extinguishing agents specifically for the combustible metal involved may be used to control small fires. The basic principle of extinguishment is that the burning metal will have to be completely covered with a compatible agent. Given that portable fire extinguishers and wheeled fire extinguishing units have a limited quantity of agent, the amount of burning metal must be significantly less than the agent on hand can handle to achieve an effective extinguishment.

Most fires will involve multiple classes of burning material. Fire-fighting efforts to extinguish Class A materials with water will significantly increase the amount of fire and reactions with the combustible metals. The reaction from applying water to a combustible metal fire is exothermic and will result in violent reactions with potential explosions. The paradigm of applying water to a combustible metal fire to speed of the reaction is akin to applying gasoline to a house fire. The molecular structure of the water is broken down when applied to combustible metal releasing quantities of hydrogen and oxygen that contribute to the fire.

Application of water to combustible metals fires is, therefore, very risky and must be fully understood. The risk of applying water to a motor block that was machined out of magnesium is clearly not worth the risk of getting any fire fighter or bystander injured by the molten magnesium that will be thrown through the air. Putting the fire in perspective is a key element in the size-up of the fire scene.

Some combustible metals are processed with combustible liquids during machining or in packaging. A fire under these conditions will involve both Class B and Class D material burning simultaneously. The fire will likely continue to burn unless both classes of fire are extinguished together. Caution must be used if the combustible liquid in the fire has already been preheated to a temperature that will continue to produce vapors after the flame front has been extinguished. The resulting vapors have the potential to cause an explosion or flash fire.

Training and Planning

Inasmuch as the extinguishment of fires in combustible metals involves techniques not commonly encountered in conventional fire-fighting operations, it is good practice for those responsible for controlling combustible metal fires to gain experience in this area prior to an actual fire emergency. Fire fighters should practice extinguishing fires in those metals in an isolated outdoor location. Part of the practice should include the controlled application of water to a combustible metal fire to acquaint emergency responders with the risks associated with the application of water to a Class D fire.

A key element in being able to control a combustible metals fire is prefire planning. Fire departments responsible for protecting businesses or industries that use combustible metals need to be aware of the conditions that may be present on their arrival. A small machine shop in the jurisdiction may machine small quantities of combustible metals that would result in chips and fines in relatively small quantities. A manufacturing plant that uses very fine aluminum powder may have a significant fugitive dust problem throughout the processing area that could result in an explosion and total destruction of the building or processing area. Emergency response organizations, usually the fire department, must be aware of hazards prior to arrival at an emergency.

MAGNESIUM

Properties

The ignition temperature of massive magnesium is very close to its melting point of 1202°F (650°C) (Table 6.9.1). However, ignition of magnesium in certain forms may occur at temperatures well below 1202°F (650°C); magnesium ribbons and shavings can be ignited under certain conditions at about 950°F (510°C), and finely divided magnesium powder can ignite below 900°F (482°C).

TABLE 6.9.1 Melting, Boiling, and Ignition Temperatures of Pure Metals in Solid Form

	Temperature					
	Melting Point		Boiling Point		Solid Metal Ignition	
Pure Metal	*°F*	*°C*	*°F*	*°C*	*°F*	*°C*
Aluminum	1220	660	4445	2452	1832[a,b]	1000[b]

Zinc	786	419	1665	907	1652[a]	900[a]
Zirconium	3326	1830	6470	3577	2552[a]	1400[a]

[a]Ignition in oxygen.
[b]Above indicated temperature.
[c]Spontaneous ignition in moist air.
[d]Below indicated temperature.

Metal marketed under different trade names and commonly referred to as "magnesium" may be one of a large number of different alloys containing principally magnesium, but also significant percentages of aluminum, manganese, and zinc. Some of these alloys have ignition temperatures considerably lower than that of pure magnesium, and certain magnesium alloys will ignite at temperatures as low as 800°F (427°C). Flame temperatures can reach 2500°F (1371°C), although flame height above burning metal is usually less than 12 in. (305 mm).

Thin, small pieces of magnesium, such as ribbons, chips, and shavings, may be ignited by a match flame, whereas castings and other large pieces are difficult to ignite even with a torch because of the high thermal conductivity of the metal. In order to ignite a large piece of magnesium, it is usually necessary to raise the entire piece to the ignition temperature. Magnesium melts as it burns and may form puddles of molten magnesium, which present explosion hazards in the presence of water.

Scrap magnesium chips or other fines may burn as the result of ignition of waste rags or other contaminants. Chips wet with water, water-soluble oils, and oils containing more than 0.2 percent fatty acid may generate hydrogen gas. Chips wet with animal or vegetable oils may burn if the oils ignite spontaneously. Fines from grinding operations generate flammable hydrogen when submerged in water, but the metal particles themselves cannot be ignited if kept immersed. If fines from grinding operations are stored in drums, adequate ventilation must be provided to prevent a buildup of hydrogen gas, which could explode when the drum is opened. Holes can be made in the lid or a nonsealing lid can be used. Grinding fines that are slightly wetted with water may generate sufficient heat to ignite spontaneously in air, burning violently as oxygen is extracted from the water with the release of hydrogen, which can also ignite.

Storage and Handling

The more massive a piece of magnesium, the more difficult it is to ignite. Once ignited, however, magnesium burns intensely and is difficult to extinguish. The storage recommendations in NFPA 484 take these properties into consideration. Recommended maximum quantities of various sizes and forms to be stored in specific locations are covered in this standard. The storage building should be noncombustible and the magnesium should be segregated from combustible material.

With easily ignited lightweight castings, segregation from combustible materials is especially important. In the case of dry fines and fine magnesium scrap, storage in noncombustible covered containers in separate fire-resistive storage buildings or rooms provided with explosion venting is preferable. For combustible buildings or buildings containing combustible contents, NFPA 484 recommends automatic sprinkler protection to ensure prompt control of a fire before the magnesium becomes involved.

Because of the possibility of hydrogen generation and of spontaneous heating of fines wet with coolants (other than neutral mineral oil), it is preferable to store wet scrap fines outdoors. Covered noncombustible containers should be vented.

Magnesium in powder, pellet, or ribbon form is shipped as a flammable solid and must be appropriately labeled according to U.S. Department of Transportation (DOT) requirements. Massive pieces or castings do not require special shipping safeguards.

Process Hazards

In machining operations involving magnesium alloys, sufficient frictional heat to ignite the chips or shavings may be created if the tools are dull or deformed. If cutting fluids are used (machining of magnesium is normally performed dry), they should be mineral-oil types that have high flashpoints. Water or water-oil emulsions are hazardous, since wet magnesium shavings and dust liberate hydrogen gas and burn more violently than dry material when ignited. Machines and the work area should be frequently cleaned and the waste magnesium kept in covered, clean, dry steel, or other noncombustible drums, which should be removed from the building at regular intervals. Magnesium dust clouds are explosive if an ignition source is present. Grinding equipment should be equipped with a liquid precipitation separator (Figures 6.9.2, 6.9.3, and 6.9.4) and should be interlocked with the liquid precipitation system so that it can operate only if the exhaust blower and water spray are functioning properly. The equipment should be restricted to magnesium processing only. Because the disposal of wet sludge presents a problem, NFPA 484 permits the use of dry cyclone collectors that are located and protected in accordance with that standard. Collection media are required to be located outside the building and protected in such a manner that an explosion or fire in the media collector will not injure personnel in the area.

Molten magnesium presents a serious fire problem if not properly handled. Sulfur dioxide or melting fluxes are commonly used to prevent oxidation or ignition of magnesium during foundry operations. The action of sulfur dioxide is to exclude air from the surface of the molten magnesium; it is not an extinguishing agent.

Pots, crucibles, and ladles that may contact molten magnesium must be kept dry to prevent steam formation or a violent

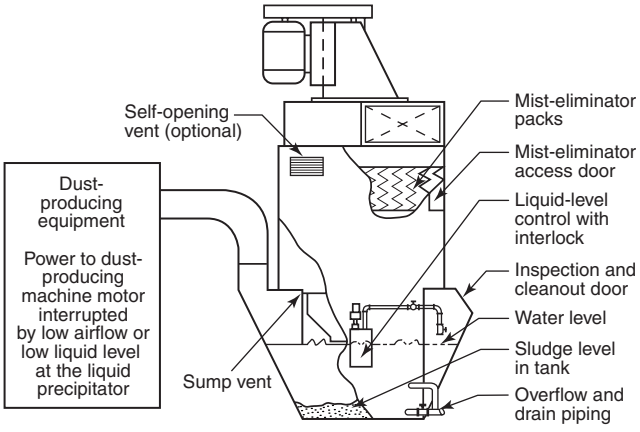

FIGURE 6.9.2 Typical Liquid Precipitation Collector for Fixed Dust-Producing Equipment (Source: NFPA 484, *Standard for Combustible Metals,* 2006 ed., Figure A.6.3.4.4(a))

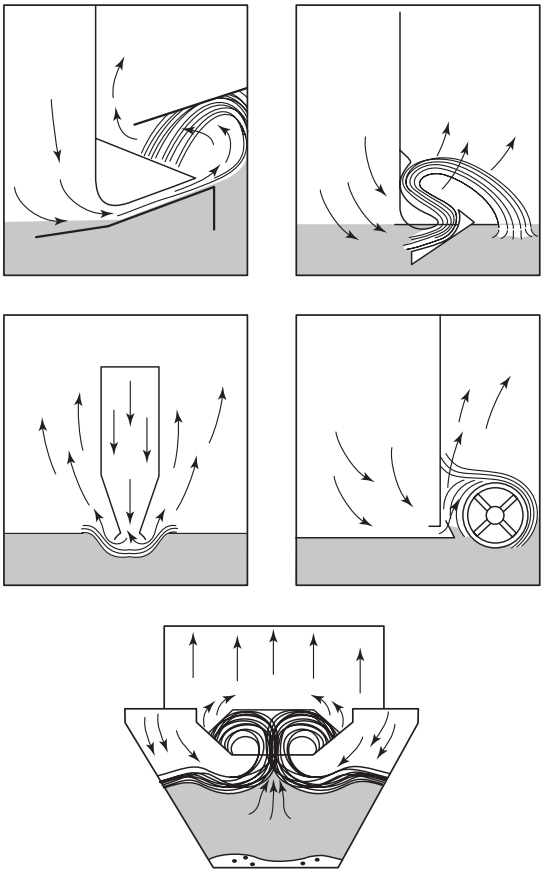

FIGURE 6.9.4 Five Methods of Precipitating Dust in Precipitators (Source: NFPA 484, *Standard for Combustible Metals,* 2006 ed., Figure A.6.3.4.4(c))

metal-water reaction. Containers should be checked regularly for any possibility of leakage or weak points. Steel-lined runoff pits or pits with tightly fitting steel pans should be provided, and the pans must be kept free of iron scale. Leaking metal contacting hot iron scale results in a violent thermite reaction. Use of stainless steel pans or linings will eliminate this possibility.

Heat-treating ovens or furnaces, where magnesium alloy parts are subjected to high temperatures to modify their properties, present another special problem. Temperatures needed to secure the desired physical properties are often close to the ignition temperatures of the alloys themselves and careful control of temperatures in all parts of the oven is essential. Hot spots leading to local overheating are a potential cause of these fires. Large castings do not ignite readily, but fine "casting fins" and sprues, as well as chips or dust, more readily ignite. For this reason, castings should be thoroughly cleaned before heat-treating. Magnesium castings in contact with aluminum in a heat-treating oven will ignite at a lower temperature than when placed on a steel car or tray.

Magnesium should not be heat-treated in nitrate salt baths. Certain commonly used molten mixtures of nitrates and nitrites can react explosively with magnesium and magnesium alloys, particularly at temperatures over 1000°F (538°C).

Fighting Magnesium Fires

Magnesium and its alloys present special problems in fire protection. Magnesium combines so readily with oxygen that, under some conditions, water applied to extinguish magnesium fires is decomposed into its constituent elements (i.e., oxygen and hydrogen). The oxygen combines with the magnesium and the released hydrogen burns and adds to the intensity of the fire. With the exception of the noble gases, such as helium and argon, none of the commonly available inert gases is suitable for extinguishing magnesium fires. The affinity of magnesium for oxygen is so great that it will burn in an atmosphere of carbon dioxide. Magnesium may also burn in an atmosphere of nitrogen to form magnesium nitride. For these reasons, any of the common extinguishing methods that depend on water, water solutions, or inert gases (other than the noble gases) are not effective on magnesium chip fires.

Halogen-containing extinguishing agents (halons and many halon replacement agents) react violently with burning magnesium, the chlorine or other halogen combining with the magnesium. However, inerting with noble gases (e.g., helium or argon) will extinguish burning metal.

The method of extinguishing magnesium fires depends largely on the form of the material. Burning chips, shavings, and small parts must be smothered and cooled with a suitable dry extinguishing agent (e.g., graphite and dry sodium chloride). Where magnesium dust is present, care must be taken to prevent a dust cloud from forming in the air during application of the agent because this may result in a dust explosion.

Fires in solid magnesium can be fought without difficulty if attacked in their early stages. Often it may be possible to remove surrounding material, leaving the small quantity of magnesium to burn itself out harmlessly. Considering the importance of prompt attack on magnesium fires, automatic sprinklers are

desirable because they provide automatic notification and control of fire. Although the water from the sprinklers may have the immediate effect of intensifying magnesium combustion, it will serve to protect the structure and prevent ignition of surrounding combustible material.

Magnesium fires in heat-treating ovens can best be controlled with powders and gases developed for use on such fires. By using melting fluxes to exclude air from the burning metal, fires in heat-treating furnaces can be successfully extinguished. Boron trifluoride gas is an effective extinguishing agent for small fires in heat-treating furnaces.

TITANIUM

Properties

Titanium, like magnesium, is classified as a combustible metal, but here again the size and shape of the metal determine to a great extent the ease of ignition. Castings and other massive pieces of titanium are not combustible under ordinary conditions; however, they can burn in the presence of other burning fuels or in high-oxygen atmospheres. Small chips, fine turnings, and dust ignite readily and, once ignited, burn with the release of large quantities of heat. Tests have shown that very thin chips and fine turnings can be ignited by a match, and heavier chips and turnings can be ignited by a Bunsen burner. Coarse chips and turnings 1/32 in. by 3/28 in. (0.79 mm by 2.7 mm) or larger may be considered as difficult to ignite, but, unless it is known that smaller particles are not mixed with the coarser material, it is wise to assume that easy ignition is possible.

Dry titanium fines collected in cyclone separators can ignite spontaneously when allowed to drop freely through the air. Ignition temperatures of titanium dust clouds in air range from 630 to 1090°F (332 to 588°C) and of titanium dust layers from 720 to 950°F (382 to 510°C). Titanium dust can be ignited in atmospheres of carbon dioxide or nitrogen. Titanium surfaces that have been treated with nitric acid, particularly with red fuming nitric acid containing 10 to 20 percent nitrogen tetroxide, become pyrophoric and may be explosive.

Fine titanium chips coated with water-soluble oil have spontaneously ignited. The unusual conditions under which massive titanium shapes will ignite spontaneously include contact with liquid oxygen, in which case they can detonate on impact. It has been found that under static conditions, spontaneous ignition will take place in pure oxygen at pressures of at least 350 psi (2413 kPa). If the oxygen was diluted, the required pressure increased, but in no instance did spontaneous heating occur in oxygen concentrations less than 35 percent. Another requirement for spontaneous heating is a fresh surface that oxidizes rapidly and exothermically in an oxygen atmosphere.[1]

Storage and Handling

Titanium castings and ingots are so difficult to ignite and burn that special storage recommendations for large pieces are not included in NFPA 484. Titanium sponge and scrap fines, on the other hand, do require special precautions, such as storage in covered metal containers and segregation of the containers from combustible materials. Because of the possibility of hydrogen generation in moist scrap and spontaneous heating of scrap wet with animal or vegetable oils, a yard storage area remote from buildings is recommended for scrap that is to be salvaged. Alternate recommended storage locations are detached scrap storage buildings and fire-resistant storage rooms. Buildings and rooms for storage of scrap fines should have explosion vents.

Process Hazards

Contact of molten metal with water is the principal hazard during titanium casting. To minimize this hazard, molds are usually thoroughly predried and vacuum or inert gas protection is provided to retain accidental spills.

The heat generated during machining, grinding, sawing, and drilling of titanium may be sufficient to ignite the small pieces formed by these operations or to ignite mineral-oil-based cutting lubricants. Consequently, water-based coolants should be used in ample quantity to remove heat and cutting tools should be kept sharp. Fines should be removed regularly from work areas and stored in covered metal containers. To prevent titanium dust explosions, any operation that produces fugitive dust should be equipped with a dust collecting system discharging into a liquid precipitation separator (see Figures 6.9.2, 6.9.3, and 6.9.4).

Descaling baths of mineral acids and molten alkali salts may cause violent reactions with titanium at abnormally high temperatures. Titanium sheets can ignite upon removal from descaling baths. This hazard can be controlled by careful regulation of bath temperatures.

Titanium melting furnaces use an electric arc to melt a consumable electrode inside a water-cooled crucible maintained under a high vacuum. Stray arcing between the consumable electrode and crucible, resulting in penetration of the crucible, permits water to enter and react explosively with the molten titanium. Indications are that such explosions can approach extreme velocities. The design and operation of these furnaces require special attention in order to prevent explosions and to minimize damage when explosions do occur.

Fighting Titanium Fires

Carbon dioxide, foam, and dry chemical extinguishers are not effective on titanium fires, but good results can be obtained with extinguishing agents developed for use on magnesium fires. The safest procedure to follow with a fire involving small quantities of titanium powder is to ring the fire with a Class D fire extinguishing agent or materials that have been found to be effective in the control of combustible metal fires and allow the fire to burn itself out. Care should be taken to prevent formation of a titanium dust cloud by the application of high velocity extinguishing agents.

ALKALI METALS: SODIUM, POTASSIUM, NaK, AND LITHIUM

Properties

Sodium. At room temperature, sodium oxidizes rapidly in moist air, but spontaneous ignitions have not been reported except when the sodium is in a finely divided form. When heated

in dry air, sodium ignites in the vicinity of its boiling point (1616°F [880°C]). Sodium in normal room air and at a temperature only slightly above its melting point (208°F [98°C]) has been ignited by placing sodium oxide particles on its surface. This indicates the possibility of ignition at temperatures below the boiling point. Once ignited, hot sodium burns vigorously and forms dense white clouds of caustic sodium oxide fumes. During combustion, sodium generates about the same amount of heat as an equivalent weight of wood.

The principal fire hazard associated with sodium is its rapid reaction with water. It floats on water (density 0.97), reacting vigorously and melting. The hydrogen liberated by this reaction may be ignited by the heat of the reaction. Sodium (like other burning, reactive metals) reacts violently with halogenated hydrocarbons, with halogens (e.g., iodine) and with acids.

Potassium. The fire hazard properties of potassium are very similar to those of sodium, with the difference being that potassium is usually more reactive. For example, the reaction between potassium and the halogens is more violent and, with bromine, a detonation can occur. There is also an explosive reaction with sulfuric acid. Unlike sodium, potassium forms some peroxides during combustion. These peroxides may react violently with organic contaminants. Unreacted potassium may form an oxide known as potassium superoxide, KO_2. This oxide is bright yellow in color and can be shock sensitive in the presence of organics.

NaK (Sodium-Potassium Alloys). "NaK" is the term used when referring to any of several sodium-potassium alloys. The various NaK alloys differ from each other in melting point, but all are liquids or melt near room temperature. NaK alloys possess the same fire hazard properties as those of their component metals, except that the reactions are more vigorous. Under pressure, NaK leaks have ignited spontaneously.

Lithium. Lithium undergoes many of the same reactions as sodium. For example, both react with water to form hydrogen, but whereas the sodium-water reaction can generate sufficient heat to ignite the hydrogen, the far less violent lithium-water reaction does not. On the other hand, the lack of ignition may cause a buildup of hydrogen gas in the area, which could lead to an explosive cloud of hydrogen. Therefore, adequate ventilation must be ensured.

Lithium ignites and burns vigorously at a temperature of 356°F (180°C), which is near its melting point. Unlike sodium and potassium, it can burn in nitrogen. Noble gases, such as helium and argon, are used for inerting in equipment and storage containers involving lithium. The caustic (oxide and nitride) fumes accompanying lithium combustion are more profuse and dense than those of other alkali metals burning under similar conditions. Lithium is the lightest of all metals. During combustion, it tends to melt and flow.

Storage and Handling

Because of their reactivity with water, alkali metals require special precautions to prevent contact with moisture. Drums and cases should be stored in a dry fire-resistant room or building used exclusively for alkali metal storage. Since sprinkler protection would be undesirable, no combustible materials should be stored in the same area. However, if exposure fires could jeopardize equipment containing alkali metals, sprinkler protection should be considered and is permitted by NFPA 484 for lithium storage. It is good practice to store both empty and filled alkali metal containers in the same area, and all containers should be on metal skids. There should be no water or steam pipes, but sufficient heat should be maintained to prevent moisture condensation due to atmospheric changes. Ventilation at a high spot in the room is desirable to vent any hydrogen that may be released by accidental contact of alkali metal with moisture.

Large quantities of alkali metal are often stored outdoors in aboveground tanks. In such installations weatherproof enclosures should cover tank manholes and the free space within the tank should contain a nitrogen atmosphere. Argon or helium atmospheres should be substituted for nitrogen in the case of lithium.

Lithium is routinely stored and shipped with a light coating of mineral oil over the ingot. In some cases, the lithium is submerged in dry mineral oil for long-term storage or transportation.

Dry alkali metal is customarily shipped in watertight steel barrels or drums. It is also shipped as a solid in tank-car quantities. The DOT specifies the type of barrels, drums, and tank cars that are to be used in interstate transportation.

Transfer of an alkali metal to and from tank cars and storage tanks requires heating the metal to its melting point. This is accomplished by circulating hot oil through pipes within the tank. The alkali metal is transferred by evacuating a receiver with a vacuum pump and, as the metal is removed from the tank, it is replaced by nitrogen. An alkali metal-level indicator should be provided and a low-pressure warning device should be part of the nitrogen system.

An alkali metal covered with an organic solvent may be shipped in 1 qt (946 mL) metal cans, each can placed in another can and cushioned with soda ash. The cans are shipped in wood boxes of 100 lb (45.4 kg) maximum gross weight. Liquid alkali metal alloys may be shipped in pressure-tested metal vessels that are purged with an inert cover gas.

For small-scale transfer of solid alkali metal from a storage area to its area of use, a metal container with a tight cover is recommended. Alkali metal should be removed from storage in as small quantities as practicable. When stored on workbenches, it should be kept under kerosene or oil in a closed container. Alkali metal, with its great affinity for moisture, may react at the time it is sealed in a container with any atmospheric moisture. Due to the possible presence of hydrogen, containers should not be opened by hammering on the lid.

Process Hazards

Liquid alkali metals are valuable as high-temperature heat transfer media. For example, they are used in hollow exhaust valve stems in some internal combustion engines and in the transfer of heat from one type of nuclear reactor to a steam generator.

In the latter process or in other large-scale uses of molten alkali metal, any equipment leak may result in a fire. Where molten alkali metal is used in process equipment, steel pans are located underneath to prevent contact and violent reaction of burning sodium with concrete floors.

Processing of alkali metal involves essentially melting it to form sticks or bricks or to add it as a liquid to closed transfer systems. During this handling, contact with moist air, water, halogens, halogenated hydrocarbons, and sulfuric acid must be avoided.

Fighting Sodium, Potassium, NaK, and Lithium Fires

The common extinguishing agents, such as water, foam, and vaporizing liquids, should never be used because of the violent reactions of alkali metals with these agents. Special dry powders (essentially graphite) developed for metal fires, dry sand, dry sodium chloride, dry lithium chloride, and dry soda ash can be effective. These finely divided materials blanket the fire while the metal cools to below its ignition temperature. Alkali metal burning in an apparatus can usually be extinguished by closing all openings.

For sodium, potassium, and NaK, blanketing with nitrogen is also effective. In the case of lithium, argon or helium atmospheres should be used instead of nitrogen. Copper powder is a very effective extinguishing agent for lithium fires.

When alkali metals are handled in solidified form in tanks or drums and hot oil heating is required, the extinguishing agents to be used for any hot oil spill fire must be compatible with the alkali metal. Usually, large dry powder systems are used.

Fire residue can contain unburned alkali metal and must be promptly cleaned up and disposed of.

ZIRCONIUM AND HAFNIUM

Properties

Zirconium. The combustibility of zirconium appears to increase as the average particle size decreases, but other variables, such as moisture content, also affect its ease of ignition. In massive form, zirconium can withstand extremely high temperatures without igniting, whereas both clouds and layers of dust in which the average particle size is about 3 microns can spontaneously ignite at room temperature. Spontaneous heating and ignition are also possibilities with scrap chips, borings, and turnings if fine dust is present.

Dust clouds of larger particle size can be readily ignited if an ignition source is present and such explosions can occur in atmospheres of carbon dioxide or nitrogen just as well as in air. Zirconium dust will ignite in carbon dioxide at approximately 1150°F (621°C) and in nitrogen at approximately 1450°F (788°C). A cloud of zirconium dust in air presents a serious flash-fire hazard, in addition to its potential explosion hazard. Combustion of zirconium dust in air is stimulated by the presence of limited amounts (5 to 10 percent) of water. When very finely divided zirconium powder is completely immersed in water, it is difficult to ignite, but once ignited it burns more violently than in air. With respect to layers of the dust, the depth of the layer and its moisture content are important variables for ignition. Layers of 6-micron-diameter dust can ignite when heated to 374°F (190°C).

Massive pieces of zirconium do not ignite spontaneously under ordinary conditions, but ignition will occur when an oxide-free surface is exposed to sufficiently high oxygen concentrations and pressure. The explanation for this reaction is the same as that cited for a similar titanium reaction. Zirconium fires (like fires involving titanium and hafnium) attain very high temperatures but generate very little smoke.

Explosions can occur while zirconium is being dissolved in a mixture of sulfuric acid and potassium acid sulfate. Zirconium can explode during and following pickling in nitric acid, and also during treatment with carbon tetrachloride or other halogen-containing materials. Spontaneous explosions can occur during handling of moist, very finely divided, contaminated zirconium scrap.

Hafnium. Hafnium has combustion properties similar to those of zirconium. Hafnium burns with very little flame, but it releases large quantities of heat. Unless inactivated, hafnium in sponge form may ignite spontaneously.

Hafnium is generally considered to be somewhat more reactive than titanium or zirconium of similar form. Damp hafnium powder reacts with water to form hydrogen gas, but at ordinary temperatures this reaction is not sufficiently vigorous to cause the hydrogen to ignite. Under some conditions, however, ignition of the hydrogen may be expected to proceed explosively.

Storage and Handling

Special storage precautions are not required for zirconium castings because of the very high temperatures massive pieces of the metal can withstand without igniting. Zirconium powder, on the other hand, is highly combustible; consequently, it is customarily stored and shipped in 1 gal (3.8 L) containers with at least 25 percent water by volume. For specific details, refer to NFPA 484.

Zirconium powder storerooms should be of fire-resistant construction equipped with explosion vents. Cans should be separated from each other to minimize the possibility of a fire in one can spreading to others and to permit checking of the cans periodically for corrosion. Some manufacturers of zirconium have established the practice of disposing of cans containing powder that have been on the shelf for six months.

Process Hazards

In general, processing recommendations for zirconium and hafnium are the same. Whenever possible, handling of zirconium powder should be under an inert liquid or in an inert atmosphere. An inert atmosphere of argon or helium in equipment and storage containers is a method used to prevent flash fires and explosions. If zirconium or hafnium powder is handled in air, extreme care must be used because the small static charges generated may cause ignition.

To prevent dangerous heating during machining operations, a large flow of mineral oil or water-based coolant is required. In some machining operations, the cutting surface is completely immersed. Turnings should be collected frequently and stored under water in cans. Where zirconium dust is a by-product, dust-collecting equipment that discharges into a liquid precipitation separator is a necessity (see Figures 6.9.2, 6.9,3, and 6.9.4).

Fighting Zirconium and Hafnium Fires

Zirconium and hafnium fires can be fought in the same way. Fires exposing massive pieces of zirconium, for example, can be fought with water. The discharge of water as a spray has no adverse effect on burning zirconium turnings. When a sprinkler opens directly above an open drum of burning zirconium scrap, there is a brief flare-up, followed by continued quiet burning. When a straight stream of water at a high rate of flow is discharged into the drum, water overflows and the fire is extinguished.

Where small quantities of zirconium powder or fines are burning, the fire can be ringed with a Class D extinguishing agent or other agents that have been shown to be effective with zirconium to prevent its spread. After the fire has been contained, the fire can be allowed to burn out. Special extinguishing powders can be effective in extinguishing small zirconium fires. When zirconium dust is present, the extinguishing agent should be applied gently, so that a dust cloud is not formed. If the fire is in an enclosed space, it can be smothered by introducing argon or helium.

CALCIUM AND ZINC

Properties

Calcium. The flammability of calcium depends considerably on the amount of moisture in the air. If ignited in moist air, it burns without flowing and at a somewhat lower rate than sodium. It decomposes in water to yield calcium hydroxide and hydrogen, which may burn if ignited by the heat of the reaction. Finely divided calcium will ignite spontaneously in air. It should be noted that barium and strontium are similar to calcium in their fire properties.

Zinc. Zinc does not introduce a serious fire hazard in sheets, castings, or other massive forms because of its difficulty of ignition. Once ignited, however, large pieces burn vigorously. Moist zinc dust reacts slowly with the water to form hydrogen, and, if sufficient heat is released, ignition of the dust can occur. Zinc dust clouds ignite in air at 1110°F (599°C). Burning zinc generates appreciable smoke.

Storing, Processing, and Fighting Calcium and Zinc Fires

The requirements of NFPA 484 for magnesium can be applied to calcium and zinc.

ALUMINUM

Properties

The usual forms of aluminum have a sufficiently high ignition temperature so that its burning is not a factor in most fires (see Table 6.9.1). However, aluminum can burn vigorously in the presence of other burning materials. In particular, aluminum in contact with magnesium burns readily, perhaps due to the formation of an alloy at the interface. Very fine chips and shavings are occasionally subject to somewhat the same type of combustion as described for magnesium.

Aluminum pastes are subject to fires, especially where the paste is solvent-wet and the solvent vapors have a low ignition temperature. Dry aluminum powder or flake is capable of exploding under some conditions, if the surface of the particles has not oxidized sufficiently. The degree of explosivity increases as the particle size decreases. NFPA 484 provides requirements for the storage and handling of aluminum powders, flakes, and pastes.

Aluminum processing and finishing operations, such as machining, sawing, grinding, or buffing, produce fines and dust that are highly explosive. The dust collection systems for such operations are also subject to fires or explosions. Wet or dry collectors can be used. Requirements for collector installation are provided in NFPA 484. Collectors for aluminum must be dedicated to the collection of aluminum since the collection of iron or steel can lead to a thermite-type reaction in the system. Dust collections systems are located outdoors to help in the mitigation of damage should an explosion occur.

Fire Suppression

Extinguishing agents for aluminum fires depend on the form of the aluminum. For example, a fire in other combustible materials usually ignites large castings. These fires can be extinguished with large quantities of water or other typical fire-extinguishing agents. Fires involving aluminum fines or powder, however, must be treated carefully to prevent the dispersal of the material into the air where it often explodes. Such fires are best handled by hand application of dry sand or a Class D extinguishing agent. Water, dry powder, carbon dioxide, or halogen-containing agents must not be used.

RADIOACTIVE METALS

Radioactivity does not influence nor is it influenced by the fire properties of a metal. Radioactive metals include those few that occur naturally (e.g., uranium and thorium) and those produced artificially (e.g., plutonium and cobalt-60). Since radioactivity cannot be altered by fire, radiation will continue wherever the metal is spread during a fire. Smoke from fires involving radioactive materials can cause more property damage than the fire. The damage, however, is not physical, but results from radioactive contamination that must be cleaned up to avoid exposure.

Naturally occurring radioactive metals consist of a mixture of atoms having slightly different mass. These are called isotopes. For example, the radioactivity of each uranium isotope is different and it follows that the radiation hazards from any given

piece of uranium will change with its isotopic composition, which can be varied by special processing. Change of isotopic content of a piece of uranium alters the nature and magnitude of its radiation hazard but does not alter its chemical or fire properties. The same is equally true of thorium and plutonium.

Uranium, thorium, and plutonium are easily ignited in the form of chips, turnings, and fines. They will react slowly with water to form hydrogen. In addition, collection of fines under water in containers larger than 1 gal (3.8 L) can result in a fire as the water is not able to cool the fines at the center of the containers. The fines at the center of the mass produce heat and hydrogen. The heat is sufficient to boil off the water and ignite the remaining fines in the container. Limiting collection of fines to quantities less than 1 gal (3.8 L) in volume has been shown to be effective in preventing spontaneous ignition.

Uranium

Normal uranium is a radioactive metal that is also combustible. Its radioactivity does not affect its combustibility but can have a bearing on the significance of the fire loss. Most metallic uranium is handled in massive forms that do not present significant fire risk unless exposed to a severe and prolonged external fire. Once ignited, the massive metal burns very slowly. A 1-in. (25.4-mm) diameter rod requires about one day to burn out after ignition. In the absence of strong drafts, uranium oxide smoke, due to its density, tends to deposit in the immediate area of the burning metal. Unless covered with oil, massive uranium burns with virtually no visible flame. Burning uranium will react violently with carbon tetrachloride, 1,1,1 trichloroethane, the halons, and many halon replacements. For power reactors, uranium fuel elements are always encased in a metal jacket (usually zirconium or stainless steel).

Uranium in finely divided form is readily ignited, and uranium scrap from machining operations is subject to spontaneous ignition. This reaction can usually be avoided by storage under a coolant (oil- or water-based). Moist dust, turnings, and chips react slowly with water to form hydrogen. Containers used to store uranium with water-based coolants, water, or stored underwater, must be vented to prevent the buildup of hydrogen. Grinding dust can ignite even under water and fires can occur spontaneously in drums of coarser scrap after prolonged exposure to moist air. Disposal of chips and fines in a timely manner is essential to managing the fire risk. Larger pieces generally have to be heated en masse to their ignition temperature before igniting. Uranium surfaces treated with concentrated nitric acid are subject to explosion or spontaneous ignition in air.

Thorium

Thorium, like uranium, is a naturally occurring element. Both are known as "source materials," the basic materials from which nuclear reactor fuels are produced. The powdered form of thorium requires special handling techniques because of its low ignition temperature. In the dry state, it must be handled under a helium or argon atmosphere. The dry metal powder should not be in air because even the friction of the particles falling through the air or against the edge of a glass container may produce electrostatic ignition of the powder.

Powdered thorium is usually compacted into solid pellets weighing about 1 oz (28 g) each. In this form it can be safely stored or converted into alloys with other metals. Improperly compacted thorium pellets have been known to slowly generate sufficient heat through absorption of oxygen and nitrogen from the air to raise a steel container to red heat.

Thorium is handled by remote control due to the toxicological effects of the metal.

Plutonium

Plutonium is somewhat more susceptible to ignition than uranium and is normally handled by remote control in an inert gas. In finely divided form, such as dust or chips, plutonium is subject to spontaneous ignition in air.

Plutonium metal is generally not exposed to water, in part because of fire considerations. The massive metal ignites at about 1112°F (600°C) and burns in a manner quite similar to uranium, except that plutonium oxide smoke damage (i.e., airborne radioactive contamination) is more difficult to control and also more hazardous. The steam generated by the use of water on a plutonium fire significantly increases the spread of contamination. Because of certain nonfire hazard considerations, it is necessary to limit the quantity of plutonium kept at one location, thus limiting the maximum size of a fire in this metal. Plutonium, which ignites spontaneously, is normally allowed to burn under conditions limiting both fire and radiological contamination spread.

Fire Suppression

Prefire planning is particularly important where radioactive materials are involved. Automatic sprinkler protection is generally provided for facilities containing radioactive materials. However, in general, the use of water to control a radioactive metal fire is not recommended due to the generation of steam that is likely to spread contamination throughout the area of the fire and beyond. Fires involving uranium, thorium, and plutonium burn relatively quickly through fines and turnings. Limiting the amount of turnings throughout the machining area is important so that a small, localized fire does not propagate to other turnings or combustible materials that may be located in the machining area. Fire tests have shown that providing an air gap of approximately 4 in. (100 mm) between containers used to collect chips and turnings can prevent propagation of a fire from one container to another.

Due to the radioactive contamination that is produced during a fire, manual intervention is not recommended unless a self-contained breathing apparatus (SCBA) is worn. The worst type of exposure to the radioactive metals is inhalation and ingestion.

METALS NOT NORMALLY COMBUSTIBLE

Iron and Steel

Iron and steel are not usually considered combustible; in massive form, as in structural steel and cast-iron parts, they do not

burn in ordinary fires. In the form of fine wool or dust, however, they can be ignited by the flame of a torch or the sparks from a grinding operation. Fires can occur in piles of steel turnings and fines that contain some oil and other materials that might facilitate combustion. Spontaneous ignition of water-wet borings and turnings in closed areas, such as in the cargo hold of a ship, can also occur.

SUMMARY

Combustible metals are metals that have either combustible or explosive properties because of their inherent properties or because of their physical form. Nearly all metals will burn in air under certain conditions. Metals, such as magnesium, titanium, sodium, potassium, sodium-potassium alloys, lithium, zirconium, hafnium, calcium, and zinc, are easily ignited and have certain properties that impact their storage, handling, and processing. The processing of aluminum can generate dusts that are highly explosive. Other metals, such as iron and steel, are not normally considered combustible. Radioactive metals present special hazards because their radioactivity is not altered by fire and the effects of radioactive contamination must be a consideration during fire-fighting activities.

Good housekeeping, removal of turnings, chips and fines, and the collection of fugitive dust are essential in the processing, machining, and handling of combustible metals. Failure to follow the basic principles of handling combustible metals is likely to result in significant fire loss and the potential of personal injury.

Chapter 10

Gases

Theodore C. Lemoff

Chapter Contents

Gases Defined
Classification of Gases
Basic Hazards of Gases
Gas Emergency Control
Specific Gases

Key Terms

boiling liquid expanding vapor explosion (BLEVE), compressed gas, corrosive gas, cryogenic gas, deflagration, explosion, flammable gas, gas, liquefied gas, nonflammable gas, overpressure, pyrophoric gas, reactive gas, toxic gas

The term *gas* describes the physical state of a substance that has no shape or volume of its own but will take the shape of and fill the entire volume of whatever container or other enclosure it occupies. This state is in contrast to a liquid, which has no shape of its own but does have volume, and to a solid, which has both its own shape and volume. Gases are composed of extremely minute particles in constant motion. This motion affects the properties and behavior of gases, for example, the higher the temperature, the more rapid the motion.

The categories of gases described in this chapter are consistent with those found in NFPA 55, *Standard for the Storage, Use, and Handling of Compressed Gases and Cryogenic Fluids in Portable and Stationary Containers, Cylinders, and Tanks,* which was first issued in 1993. The categories in NFPA 55, in turn, are the same as those used by the U.S. Department of Transportation for labeling requirements for shipments of gases.

The goal of this chapter is to provide information on the properties of gases, their classification, and the equipment needed to store gases safely, including key safety devices. It explains boiling liquid expanding vapor explosion (BLEVE), an important and frequently misunderstood failure mode of liquefied compressed gases, and other types of gas explosions. Information is provided on the properties of selected gases. The chapter also provides information on the properties, storage, and hazards of gases for fire safety professionals. The hazards that gases present in storage differ from those presented when gases escape—both kinds of hazards are discussed along with the control measures to follow in an emergency. The chapter concludes with a summary of the properties and behavior of some common gases. For each gas, information is provided about its classification, chemical properties, physical properties, usage, hazards inside containers, hazards when released from containment, and emergency control.

For additional information see Section 2, Chapter 8, "Explosions"; Section 7, Chapter 3, "Storage of Gases"; Section 9, Chapter 17, "Oxygen-Enriched Atmospheres"; Section 17, Chapter 4, "Foam Extinguishing Agents and Systems"; and Section 17, Chapter 8, "Explosion Prevention and Protection."

GASES DEFINED

Because all substances can exist as gases, depending on the temperature and pressure applied to them, the term *gas,* as used in this chapter, is applied only to substances that exist in the gaseous state at normal temperature and pressure (NTP) conditions—approximately 70°F (21°C) and 14.7 psia (an absolute pressure of 101 kPa). However, even at normal or near NTP conditions, many substances can exist as either liquids or gases. The terms *gas* and *flammable liquefied gas* are defined in NFPA 55 as follows:

> *Flammable Gas.* A material that is a gas at 20°C (68°F) or less at an absolute pressure of 101.325 kPa (14.7 psia), that is ignitable at an absolute pressure of 101.325 kPa (14.7 psia) when in a mixture of 13 percent or less by volume with air, or that has a flammable range at an absolute pressure of 101.325 kPa (14.7 psia) with air of at least 12 percent, regardless of the lower limit.

Theodore C. Lemoff, P.E., is the principal gases engineer on the staff of NFPA.

Flammable Liquefied Gas. A liquefied compressed gas that, when under a charged pressure, is partially liquid at a temperature of 20°C (68°F) and is flammable.

These definitions are the same as those used in U.S. Department of Transportation regulations and, therefore, are identical to the definitions used for labeling of gases in transportation in the United States. These definitions are essentially identical to those used in United Nations protocols for international gas shipments.

CLASSIFICATION OF GASES

Classification According to NFPA 55

The classifications of gases from NFPA 55 are as follows:

1. Physical hazards, which include the following:
   - Flammable gas
   - Nonflammable gas
   - Oxidizing gas
   - Pyrophoric gas
   - Unstable reactive (detonable) gas, Class 3 or Class 4
   - Unstable reactive (nondetonable) gas, Class 2 or Class 3
2. Health hazards, which include the following:
   - Corrosive gas
   - Cryogenic fluids
   - Highly toxic gas
   - Toxic gas
   - Irritant gas

Flammable Gases. The definition of *flammable gas* has been provided previously. Every flammable gas has a lower and upper flammable limit. Mixtures of a flammable gas and air will ignite only within this range of flammability and when the minimum ignition energy is provided. In a few cases, the narrow width of the flammable range or a high lower limit of flammability, or both, results in classification of a gas that can be made to burn in air as nonflammable because the chances of ignition of the gas in air is low under most conditions. Anhydrous ammonia is an example of such a gas. Although it is a flammable gas in the context of the previous paragraph, it is classified by the U.S. Department of Transportation (DOT) as a nonflammable gas for purposes of transportation in interstate commerce.

The term "explosive range" is sometimes used as a synonym for flammable range for flammable gases. With the extensive work done on the use of hydrogen as a vehicle fuel, it has been determined that hydrogen has an explosive range that is different from the flammable range. (The explosive range is narrower than the flammable range.) Because of this difference, care must be taken to use the correct terms, and although to date hydrogen is the only gas with a recognized, published explosive range, the term should not be used except when dealing with hydrogen.

Although flammable liquid vapors and flammable gases exhibit similar combustion characteristics, the term *flashpoint,* which describes a common and useful combustion property of flammable liquids, has no practical significance for flammable gases. The flashpoint is the temperature at which a flammable liquid produces sufficient vapors for ignition to occur. This temperature is always below the normal boiling point. A flammable gas exists normally at a temperature exceeding its normal boiling point, even when the gas is in the liquid state (as it often is in shipment and storage). Therefore, a flammable gas exists at a temperature that not only exceeds its flashpoint but also that is usually well above it. In other words, a flammable liquid must be above a certain temperature (flashpoint) to produce sufficient vapors to ignite while flammable gases can always ignite.

Nonflammable Gases. Nonflammable gases are those that will not burn in any concentration of air or oxygen. Among the most common are nitrogen, argon, helium, and other rare gases in the atmosphere, as well as carbon dioxide and sulfur dioxide. (There are some metals, however, that are combustible and can react vigorously in carbon dioxide or nitrogen atmospheres, e.g., magnesium.) Although oxidizing gases are nonflammable, they are categorized separately by NFPA 55.

Pyrophoric Gases. Pyrophoric gases are flammable gases that spontaneously ignite in air. Examples are silane and phosphine. Their storage is of special concern, as they do not require a source of ignition to burn. They are not used widely but are most likely to be found in semiconductor manufacturing facilities.

Oxidizing Gases. Oxidizing gases support combustion. They are generally either oxygen or mixtures of oxygen and other gases, such as oxygen-helium or oxygen-nitrogen mixtures, or certain gaseous oxides, such as nitrous oxide. These mixtures contain considerably more oxygen than is present in the oxygen-nitrogen mixture that comprises air. Oxygen and nitrous oxide are examples of oxidizing gases.

Unstable Reactive Gases. Unstable reactive gases are gases that, in the pure state or as commercially produced, will vigorously polymerize, decompose, or condense, become self-reactive, or otherwise undergo a violent chemical change under conditions of shock, pressure, or temperature.

Class 2 Unstable Reactive Gas. A Class 2 unstable reactive gas is a material that readily undergoes violent chemical change at elevated temperatures and pressures.

Class 3 Unstable Reactive Gas. A Class 3 unstable reactive gas is a material that is itself capable of detonation or explosive decomposition or explosive reaction but that requires a strong initiating source or that must be heated under confinement before initiation.

Class 4 Unstable Reactive Gas. A Class 4 unstable reactive gas is a material that is itself readily capable of detonation or explosive decomposition or explosive reaction at normal temperatures and pressures.

Corrosive Gases. Corrosive gases are gases that causes visible destruction of or irreversible alterations in living tissue by chemical action at the site of contact.

Cryogenic Gases. Cryogenic gases are liquefied gases that exist in their container at temperatures below –130°F (–90°C). A principal reason for this distinction with respect to a liquefied gas is that a cryogenic gas cannot be retained indefinitely in a container. Heat from the atmosphere, which can be slowed but not prevented from entering the container, continually raises the container pressure. If the gas is confined, the resulting pressure could greatly exceed any feasible container strength.

These descriptions of gas classifications by physical properties pertain only to usage in context of this chapter. Somewhat different descriptions of the terms *compressed gas, liquefied gas,* and *cryogenic gas* can be found in codes and regulations, particularly the DOT hazardous materials regulations applicable to interstate transportation. For example, in the United States, many liquefied gases are classified as compressed gases by DOT. Some pertinent physical properties of cryogenic gases, are given in Table 6.10.1.

Toxic Gases. Certain gases can present a serious life hazard if they are released into the atmosphere. These gases, which are poisonous or irritating when inhaled or contacted, include chlorine, hydrogen sulfide, sulfur dioxide, ammonia, carbon monoxide, and arsine. The presence of these gases may complicate fire-fighting efforts by exposing fire fighters to a toxicity hazard. Toxic gases are labeled "poison gas" for shipment.

Toxic Gas. A toxic gas is a gas with a median lethal concentration (LC50) in air of more than 200 ppm, but not more than 2000 ppm by volume of gas or vapor, or more than 2 mg/L, but not more than 20 mg/L of mist, fume, or dust, when administered by continuous inhalation for 1 hour (or less if death occurs within 1 hour) to albino rats weighing between 0.44 and 0.66 lb (200 and 300 g) each.

Highly Toxic Gas. A highly toxic gas is a chemical that has a median lethal concentration (LC50) in air of 200 ppm by volume or less of gas or vapor, or 2 mg/L or less of mist, fume, or dust, when administered by continuous inhalation for 1 hour (or less if death occurs within 1 hour) to albino rats weighing between 0.44 lb and 0.66 lb (200 g and 300 g) each.

Irritant Gas. An irritant gas is a chemical that is not corrosive but that causes a reversible inflammatory effect on living tissue by chemical action at the site of contact. A chemical is a skin irritant if, when tested on the intact skin of albino rabbits by the methods of 16 CFR 1500.41, for an exposure of 4 or more hours or by other appropriate techniques, it results in an empirical score of 5 or more. A chemical is classified as an eye irritant if so determined under the procedure listed in 16 CFR 1500.42, or other appropriate techniques.

Classification by Physical Properties

Physical properties are of primary fire protection concern because they affect the physical behavior of gases while they are inside containers and after any accidental release from containers. Until they are used, gases must be completely confined in containers. This includes transportation, transfer, and storage. It is a matter of economic necessity and the ease of usage that gases be packaged in containers that contain as much gas as is practical. These requirements have resulted in transportation and storage of gases in the liquid as well as the gaseous state. Distinguishing between gases in a liquid or gaseous state is important for the application of sound fire prevention and protection practices.

Source: Compiled from data in the *Handbook of Compressed Gases,* Compressed Gas Association.

Compressed Gases. A compressed gas is defined in NFPA 55 as follows:

> *Compressed Gas.* A material, or mixture of materials, that (1) is a gas at 68°F (20°C) or less at an absolute pressure of 14.696 psia (101.325 kPa) and (2) that has a boiling point of 68°F (20°C) or less at an absolute pressure of 14.7 psia (101.325 kPa) and that is liquefied, nonliquefied, or in solution, except those gases that have no other health or physical hazard properties are not considered to be compressed gases until the pressure in the packaging exceeds an absolute pressure of 40.6 psia (280 kPa) at 68°F (20°C).

This definition means that a compressed gas is one that exists solely in the gaseous state under pressure at all normal atmospheric temperatures inside its container. The pressure depends on the pressure to which the container was originally charged, how much gas remains in the container, and the gas temperature. There are no universally defined lower or upper limits to the container pressure. In the United States, the lower limit is customarily considered 25 psi (273 kPa) at normal temperatures (70 to 100°F [21 to 38°C]). The upper limit is restricted only by the economics of container construction and is usually in the range of 1800 to 3600 psi (12,512 to 24,923 kPa).

A container of compressed gas is limited in the weight of gas it can hold. For example, the largest common portable cylinder of compressed oxygen contains only about 20 lb (9 kg) of oxygen or about 245 standard ft^3 (SCF) (6.9 m^3) of oxygen measured at NTP of 70°F (21°C) and 14.7 psia (101 at absolute pressure of kPa).

Liquefied Gases. A liquefied gas is one that, at 68°F (20°C) inside its closed container, exists partly in the liquid state and partly in the gaseous state and is under pressure as long as any liquid remains in the container. The pressure depends on the temperature of the liquid, although the quantity of liquid can affect this under some conditions.

A liquefied gas is much more concentrated than a compressed gas. For example, the compressed oxygen cylinder mentioned previously could hold about 116 lb (53 kg) of liquefied oxygen or about 1400 ft^3 (39.6 m^3) of oxygen measured at NTP, which is about six times greater. This comparison is valid for illustrative purposes only, because compressed oxygen and liquefied oxygen will not be found in the same type of container.

Classification by Usage

Historically, some common gases have been categorized by their principal use. This is reflected in some codes, such as NFPA 54, *National Fuel Gas Code.* This classification scheme is not as precise as classification by physical property and there is much overlap in uses with the gases.

Fuel Gases. Fuel gases include those flammable gases customarily burned in appliances with air to produce heat (and sometimes light), which in turn is used as a source of heat (comfort and process), power, or light. By far the principal and most widely used fuel gases are natural gas and the liquefied petroleum gases (butane and propane).

Industrial Gases. Industrial gases include the entire range of gases classified by chemical properties customarily used in industrial processes for welding and cutting, heat treating, chemical processing, refrigeration, water treatment, and so on.

Medical Gases. By far the most specialized usage classification, medical gases are used for medical purposes, such as anesthesia and respiratory therapy. Oxygen and nitrous oxide are common medical gases.

BASIC HAZARDS OF GASES

An evaluation of gas hazards distinguishes between the hazards presented by a gas when it is confined in a container and the hazards presented when it escapes from a container—even though both of these hazards may be simultaneously present in a single incident.

Hazards Within Containers

Gases expand when heated, producing an increase in pressure on a container. This can result in release of the gas through an overpressure-relief valve or can cause container failure. In addition, containers can lose their strength and fail during a fire. Compressed and liquefied gases are affected somewhat differently when heated.

A compressed gas (solely in the gaseous state) simply attempts to expand and follow the classic gas behavior laws. No actual gas follows these laws exactly, but the laws of Boyle and Charles are sufficiently accurate to predict the behavior of compressed gases under commonly encountered conditions. A consistent set of measurement units, either U.S. customary or SI units, must be used in calculations. Temperature and pressure must be given in "absolute" values, not in the units commonly used. In the formulas that follow, T is the absolute temperature, expressed in degrees Rankine or degrees Kelvin (°F + 459 = °R; or °C + 273 = °K), P is the absolute pressure (gauge pressure in $lb/in.^2$ + 14.7 psi; or kPa), and V volume in ft^3 or m^3 or any other suitable unit of volume.

Boyle's Law

Boyle's law states that the volume occupied by a given mass of gas varies inversely with the absolute pressure if the temperature is not allowed to change, or

$$PV = \text{Constant}$$

Charles's Law

Charles's law states that the volume of a given mass of gas is directly proportional to the absolute temperature if the pressure is kept constant. Thus,

$$V/T = \text{Constant}$$

Therefore, for most gases, within practical working limits, the relation among temperature, pressure, and volume may be closely approximated by the following formula:

$$\frac{T_1}{T_2} = \frac{P_1 V_1}{P_2 V_2}$$

T_1, P_1, and V_1 refer to initial conditions; T_2, P_2, and V_2 refer to changed conditions to be determined.

EXAMPLE 1: Assume a 10 ft^3 cylinder of compressed gas at 70°F at sea level has a gauge pressure of 1000 psi. Assume that the temperature is increased to 150°F. What will be the pressure?

T_1 = 70°F + 459 = 529°R

P_1 = 1000 psi (gauge)
+ 14.7 (atmospheric pressure at sea level)
= 1014.7 psi (absolute)

V_1 = 10 ft^3

T_2 = 150°F + 459 = 609°R

P_2 = to be determined

V_2 = 10 ft^3

Substituting in the formula,

$$\frac{529}{609} = \frac{1014.7 \times 10}{P_2 \times 10}$$

$$P_2 = 1014.7 \times \frac{609}{529} = 1170$$

Therefore, gauge pressure will be 1170 psia – 14.7, or 1155.3 psig.

EXAMPLE 2: Assume a 2.0 m^3 cylinder of compressed gas at 20°C at sea level has a gauge pressure of 1200 kPa. Assume that the gas is further compressed into a 1.0 m^3 cylinder and maintained at 50°C. What will be the gauge pressure?

T_1 = 20°C + 273 = 293 K

P_1 = 1200 kPa
+ 101 (atmospheric pressure at sea level)
= an absolute pressure of 1301 kPa

V_1 = 2.0 m^3

T_2 = 50°C + 273 = 323 K

P_2 = to be determined

V_2 = 1.0 m^3

Substituting in the formula,

$$\frac{293}{323} = \frac{1301 \times 2.0}{P_2 \times 1.0}$$

P_2 = 2868 kPa absolute, or 2767 kPa gauge

A liquefied gas, including a cryogenic gas (which is partly in the liquid state), exhibits a more complicated behavior because the net result of heating is the combination of the following three effects:

1. The gas phase is subject to the same effect as for a compressed gas.
2. The liquid attempts to expand, compressing the vapor.
3. The vapor pressure of the liquid increases as the temperature of the liquid increases.

The combined result of these effects is an increase in pressure when the container is heated.

A steep pressure rise can occur if the liquid expansion results in the container becoming full of liquid (the initial gas-phase condensing). If this happens, a small amount of additional heating results in a large increase in pressure. For this reason, it is vital never to place more liquefied gas in the liquid phase into a container than can be accommodated—leaving a vapor space—if the liquid temperature is raised to a level commensurate with the expected ambient temperatures. The proper quantity varies with the liquefied gas and the factors that affect expected temperature rises, such as the temperature of the liquid when placed into the container, the size of the container, and whether the container is insulated or installed above or below ground. The quantities permitted are commonly expressed as "filling densities" or "loading densities" and are specified for individual gases (in some cases, groupings of similar gases) by codes, standards, and regulations. Filling densities expressed in terms of weight are absolute values; that is, the designated weight of gas may always be placed into the container. Filling densities expressed in terms of volume, however, must always be qualified by specifying the liquid temperature.

Table 6.10.2 shows an example of how filling densities are expressed for liquefied gases—in this case, liquefied petroleum gases stored at normal temperatures in uninsulated containers. Note that larger quantities of higher specific gravity materials are permitted (reflecting the fact that these liquids tend to expand less) and that larger containers can be filled more than smaller ones can (reflecting the fact that it takes longer for them to absorb heat from atmospheric temperatures or solar radiation). Also, underground containers can be filled even more (reflecting the fact that their ambient temperatures are relatively constant and well below summer atmospheric temperatures).

Containers of compressed or liquefied gases can represent high levels of potential energy release due to the concentration of matter by compression or liquefication. Container failure releases this energy—often extremely rapidly and violently—with a simultaneous release of gas to the surroundings and propulsion of the container or container pieces. Compressed gas container failures are distinguished more by the flying missile hazard than by the results of gas release, because these containers contain lesser quantities of gas. Liquefied gas container failures can release larger quantities of gas.

Overpressure-Relief Devices

In the United States, Canada, and other countries, spring-loaded pressure-relief valves, bursting discs, or sometimes both, are provided on most compressed and liquefied gas containers to limit container pressure to a level the container can safely withstand. Fusible plugs are sometimes used on smaller containers. The start-to-discharge pressure settings of pressure relief

[c]60°F = 15.6°C.

devices are determined by the strength of the container. In most cases, the relieving capacity (in terms of gas flow rate through them) is based on the maximum heat input rates resulting from fire exposure, because this is generally the largest anticipated source of heat. In some installations, such as underground or insulated containers, other sources of overpressure may be the dominant effect, such as overfilling of the container.

As noted, the relieving capacity of these devices is based on discharge of the gas. In the case of liquefied gas containers exposed to fire, it is possible to have conditions such that liquid will be discharged instead of gas, for example, when the container is tipped over. Under such conditions, the relieving capacity will be reduced—in some cases as much as 60 to 70 percent because liquids are more viscous than gases and flow more slowly through valves. With the possible exception of the fire exposure condition, this reduction is of little practical significance. Even in the case of fire exposure, this situation is not as critical as it may appear because prevention of container failure under fire exposure conditions requires other safeguards in addition to the overpressure relief device. Inspection, maintenance, and replacement of these devices are essentially unregulated and they are subject to potentially harmful influences.

Containers of certain poisonous and highly toxic gases do not have overpressure relief devices because the overall hazard of a prematurely operating or leaking relief device outweighs the hazard of container failure from overpressure. Overpressure safety is accomplished by a lowered filling limit.

It is also the practice in some countries, especially in Europe and countries using European standards, not to provide overpressure protection on liquefied gas containers. This practice reflects the widespread use and installation of such containers inside buildings, including homes, and commercial and institutional buildings. In such cases, the hazard of gas release indoors due to operation of the relief device is believed to outweigh the hazard of container failure due to overpressure.

Liquefied Gas BLEVE

Instances where containers of liquefied gases fail and break into two or more pieces when exposed to fire are common enough to warrant treatment in some detail. This failure is termed *boiling liquid expanding vapor explosion* (BLEVE), a type of pressure-release explosion.

All liquefied gases are stored in containers at temperatures above their boiling points at NTP and remain under pressure only so long as the container remains closed to the atmosphere. This pressure ranges from less than 1 psi (6.9 kPa) for some cryogenic gas containers to several hundred psi for noncryogenic liquefied gas containers at normal storage temperatures. If the pressure is reduced to atmospheric pressure, such as through container failure, the substantial heat that is in effect "stored" in the liquid causes very rapid vaporization of a portion of the liquid. This vaporization occurs to a degree directly proportional to the temperature difference between that of the liquid at the instant of container failure and the normal boiling point of the liquid. For many liquefied flammable gases, this temperature difference at normal atmospheric temperatures can result in vaporization of about one-third of the liquid in the container.

Because overpressure-relief devices are set to discharge at pressures above the operating pressure of the pressure vessel, the liquid temperature will be well above the normal atmospheric boiling point. For example, propane at 275 psig (gauge pressure of 1.9 mPa)—the maximum pressure-relief valve setting—has a boiling point of about 135°F (57°C), well above the atmospheric boiling point of about –40°F (–140°C). Therefore, the liquid temperature is higher than this if container failure oc-

curs when a relief device is functioning. More liquid is vaporized under these conditions—often over one-half of the liquid in the container—than in a BLEVE caused by something other than fire exposure. The remaining unvaporized liquid is cooled by the "self-extraction" of heat when the pressure is reduced to atmospheric and is cooled to near its normal boiling point. In the event of a BLEVE caused by other than fire exposure, the amount of liquid vaporized will be less. A significant hazard still exists.

Liquid vaporization is accompanied by a large liquid-to-vapor expansion. It is this expansion process that provides the energy for propagation of cracks in the container structure, propulsion of pieces of the container, rapid mixing of the vapor and air resulting in the characteristic fireball upon ignition by the fire that caused the BLEVE, and atomization of the remaining cold liquid. Many of the atomized droplets burn as they fly through the air. However, it is not uncommon for the cold liquid to be propelled from the fire zone too quickly for ignition to occur and fall to earth still in liquid form.

Reduction of internal pressure to atmospheric level in a container results from the container losing its ability to hold the pressure it was designed to contain. This failure is most often due to weakening of the container metal from flame contact but can also be the result of mechanical failure of the container due to wall thinning from corrosion, puncture, or gouging. It is important to remember that a BLEVE is what happens after the container fails, not how the container fails.

As shown in Figure 6.10.1, the strength of carbon steel steadily decreases with temperature increases above about 400°F (204°C). Figure 6.10.1 is based on a typical low-carbon steel. The curves will vary quantitatively with other steels, but

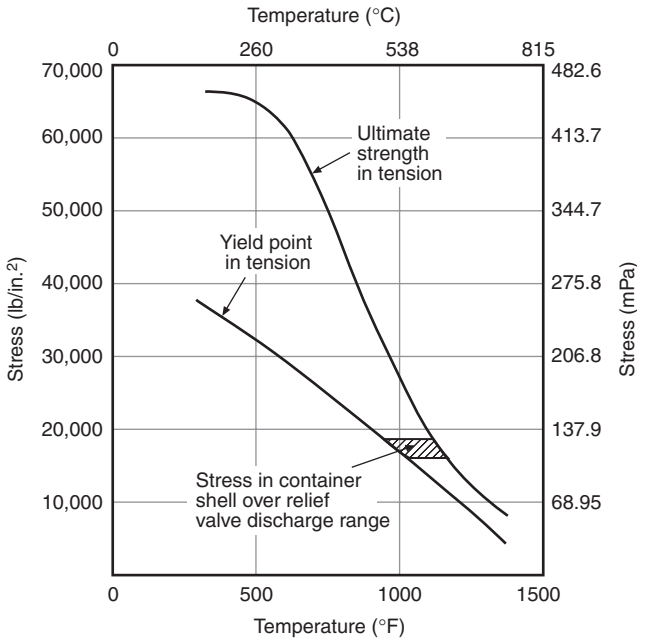

FIGURE 6.10.1 Behavior of Liquefied Gas Container Metal (Carbon Steel) When Exposed to Fire

the loss of strength with increasing temperature is valid for all common metals, and the critical temperatures are well below those attainable in a fire.

Figure 6.10.1 also shows why entirely satisfactory performance of a spring-loaded relief valve to design parameters cannot prevent a BLEVE. By its nature, such a valve cannot reduce the pressure to atmospheric but only to a point somewhat below its start-to-discharge pressure. Therefore, the liquid will always be at a temperature above its normal boiling point, pressure will remain inside the container, and the container structure will be stressed in tension. This stressed area is shown as the shaded portion in Figure 6.10.1 for a common type of LP-gas container having a pressure-relief valve set for 250 psi (172 kPa). Although this area will vary for different metals or pressure vessel relief valve design characteristics, it is evident that if the metal is heated above this range (which is quite possible in the event of direct flame contact), the metal will not withstand the stress and the container will fail.

It is extremely difficult to significantly heat the container metal where it is in contact with liquid because liquid conducts the heat away from the metal and acts as a heat absorber as the liquid is converted to vapor. For example, when the relief valve cited in this example is discharging, the propane liquid stays in the 120 to 140°F (49 to 60°C) range. As a result, the metal temperature is well within safe limits. This situation does not exist for the metal in the vapor space of the container, as vapor is a relatively poor heat conductor and has little heat-absorbing capacity. This is regularly demonstrated in most kitchens, when a tea kettle with water is placed on a heating element to boil water. If water is in the kettle, the kettle bottom will not melt and can be used indefinitely. If the kettle becomes dry, the bottom will overheat and can melt.

In BLEVEs where the failure is due to metal overheating, the container failure typically originates in the metal in contact with the vapor space. The heated tank metal shell stretches and thins out at the point of flame impingement. As the metal stretches and thins, a longitudinal tear begins and gets longer until a critical length is reached. When the critical length is reached, the metal becomes brittle and the tear propagates at sonic velocity through the metal tank shell in both the longitudinal and circumferential directions. As a result, the container typically comes apart in two or more pieces.

Most liquefied gas BLEVEs that involve container failure result from fire exposure. However, a few BLEVEs have occurred due to container failures from other causes, such as corrosion or impact from an outside force. Impact failures are particularly noticeable in transportation accidents involving railcars and cargo vehicles. In these cases, the BLEVE generally occurs simultaneously with impact. In one instance, however, a 30,000 gal (113.5 m^3) tank car of LP-gas was only severely weakened by impact during derailment and did not BLEVE until more than 40 hours later.[1] The tank car had been lifted and moved without incident in the interim. At the time of failure, however, the internal pressure was increasing as the ambient temperature was rising.

Magnitude of a BLEVE. The size of a BLEVE depends on the weight of the container pieces and on how much liquid vaporizes

when the container fails. This is analogous in many respects to the performance of rockets, as far as propulsion of container parts is concerned. Most liquefied gas BLEVEs occur when containers are from slightly less than one-half to about three-fourths full of liquid. The liquid vaporization-expansion-energy to container-piece weight ratio is such that pieces are propelled for distances up to approximately ½ mile (0.8 km). Deaths from such missiles can occur as far as 800 ft (244 m) from larger containers. Fireballs several hundred feet in diameter can occur, and fatal burns can be suffered by persons as much as 250 ft (76 m) from the larger containers.

A major LP-gas disaster with multiple BLEVEs occurred on November 19, 1984, near Mexico City, Mexico.[2] According to a Swedish investigator who cooperated with NFPA, this incident occurred at about 5:00 a.m. on a Monday while the terminal was being filled by pipeline from a refinery in another part of Mexico. According to information provided to NFPA, a failure in a component of the 12-in. (25.4-mm) fill line resulted in a line break and the development of a large LP-gas cloud that ignited upon reaching a ground-level flare about 20 minutes later. The resulting explosion and fire are believed to have been the major factor in the 500 deaths reported. The flame issuing from the broken pipeline impinged on one of the four 10,000 barrel (1590 m^3) spheres that caused a BLEVE about 10 minutes later. In all, approximately 15 BLEVEs were noted on seismic charts among the four 10,000 barrel (1590 m^3) spheres and 48 horizontal tanks.

The two 15,000-barrel (2384 m^3) spheres remained on their foundations but were severely damaged (Figure 6.10.2). (Note how far out of vertical they are due to partial failure of the container supports.) The four 10,000 barrel (1590 m^3) spheres were found in pieces both on and off the terminal site. All 48 horizontal tanks were damaged in varying degrees with major sections as far as 3600 ft (1.1 km) from the site. Figure 6.10.3 illustrates the spectacular dimensions a BLEVE can reach.

Time Intervals for Fire-Caused BLEVEs. The time between initiation of flame contact and a BLEVE varies because it depends on such widely varying factors as the size and nature of the fire as well as the container itself. Uninsulated containers located aboveground can be subject to a BLEVE in the absence of water cooling in a matter of a very few minutes in the case of small containers to a few hours for very large containers. Data on insulated containers are meager because only cryogenic containers, some reactive-gas containers, and a few propane containers are usually insulated. However, there is no doubt that insulation designed for fire-exposure conditions can delay BLEVE times significantly. In one case involving an insulated LP-gas railroad tank car, the BLEVE did not occur until 20½ hours of fire exposure—undoubtedly an extreme example. In comparison, using fire tests on LP-gas railroad tank cars, a BLEVE occurred in 93 minutes in the insulated case, as opposed to 25 minutes for the uninsulated tank.

FIGURE 6.10.2 Two 15,000 Barrel Spheres (2384 m^3) Involved in the Mexico City LP-Gas Disaster

FIGURE 6.10.3 Fireball Formed in a BLEVE Involving LP-Gas Railroad Tank Cars. The elevated water tank at center is a point of reference in visualizing the dimensions of the fireball.

Protection Against a BLEVE. Protection for an uninsulated liquefied gas container that may be exposed to fire is provided by the application of water so that a film of water coats portions of the container not in internal contact with the liquid. The methods used can range from hose streams to installation of fixed water spray systems.

The preceding data on BLEVE magnitude, time intervals, and protection apply only to unreactive liquefied flammable gases. The additional chemical energy in reactive gases introduces chemical factors not present in the purely physical and combustion phenomena just described, even though the outward appearance and general effects are similar. The hazard can be increased by evolution of internal heat of chemical reaction (which adds to the heat from the exposing fire) and the inability of externally applied cooling water to cool the liquid inside the container.

Prevention of BLEVE. NFPA 58, *Liquefied Petroleum Gas Code,* provides requirements for the installation of propane and

other LP-gas containers. The requirements have evolved over time based on evaluation of BLEVE incidents at propane storage facilities. The incidents had one common feature: the fuel for the fire that caused a BLEVE came from the propane container being threatened or from an adjacent propane container. An example of this type of incident that occurred in Albert City, Iowa, on April 9, 1998.[3] In that incident an 18,000 gallon (68 m^3) propane container exploded following exposure to fire from a broken pipe that fed propane from the tank that ignited and was pointed at the tank following an impact. The tank shutoff valve was located under the tank and was not accessible.

NPFA 58 has been evolving to prevent BLEVEs, using a number of required safety components collectively called *product control.* The key concept of product control is the ability to remotely close container valves in a fire. All larger propane containers are required to have an internal valve, shown in Figure 6.10.4, for all liquid and vapor openings above a minimum size that provide the following safety features:

- *Excess flow valves.* A valve that closes when the flow of liquid or gas exceeds a preset value. Excess flow valves provide a level of safety as they are sized to close upon a clean "guillotine" of a pipe. If a pipe breaks in such a manner that the opening is not round, the area of flow is reduced, and the resulting flow may not be sufficient to operate the excess flow valve. If the ambient temperature is low at the time of a pipe break, the container pressure is reduced and the flow from the container is correspondingly reduced and may not be sufficient to operate the excess flow valve.
- *Remote shutoff.* A remote shutoff can be operated to close the flow of propane from a container to stop fire or the potential of fire either at the valve or between 20 and 100 ft (6 and 30 m) from the valve. Experience has shown that most incidents occur with trained personnel in attendance.

FIGURE 6.10.4 Internal Valve (Source: NFPA 58, *Liquefied Petroleum Gas Code,* 2004 ed., Figure 3.13; Courtesy of Engineered Controls International, Inc.)

All new propane containers have been required to have internal valves since 2001, and all existing propane containers larger than 4000 gal (15 m^3) are required to have internal valves by July 2011.

Combustion Within Containers

Another significant hazard of gas stored in containers is the danger of container failure from overpressure, resulting from combustion of the gas while inside the container. Flammable gas-air or gas-oxygen mixtures are seldom provided in containers intentionally but can be established inadvertently. This type of explosion can occur in industrial and medical gas applications where oxygen or compressed air is often used in conjunction with flammable gases. They can also occur in piping systems delivering both oxygen and a flammable gas, as is common in industrial cutting and welding operations and other applications such as jewelry manufacture. Where such a possibility is inherent in a process, for example, an oxygen-fuel gas metal cutting system, provisions are made to prevent the occurrence of such mixtures in containers by installing special backflow prevention devices. More generally, most explosions can be prevented by education and training in proper container-filling procedures. Consumers of industrial and medical gases seldom have the expertise needed to fill containers safely.

Hazard of Gases Released from Containers

When gases are released from their containers, the hazards vary according to the chemical and physical properties of the gases and the nature of the environment into which the gases are released. All gases, with the exception of air, present a hazard to life if they displace the breathing air. Nitrogen, helium, argon, and other odorless and colorless gases are particularly hazardous because they are not detectable by the human senses. At reduced oxygen concentrations, judgment and coordination are affected.

Toxic or Poisonous Gases. These gases present obvious life hazards. They are especially dangerous when released during a fire because they can impede fire-fighting efforts by either preventing or delaying access to the site by fire fighters.

Oxygen and Other Oxidizing Gases. These gases are nonflammable, but they make combustibles ignite at lower temperatures, accelerate combustion, and start fires by causing flames in fuel-burning appliances to extend beyond their combustion chambers.

Liquefied Gases (Including Cryogenic Gases). Because of their low temperatures, these gases present a hazard to persons and property when they escape as liquids. Contact with cold liquid can cause frostbite, which can be severe if the exposure is prolonged. The properties of many structural materials, particularly carbon steel and plastics, are affected by low temperatures and embrittlement can occur, which could lead to structural failure.

Flammable Gases. Because of their prevalence, the behavior of flammable gases when released from their containers is of

major interest. Released flammable gases present two basic hazards: (1) combustion explosions and (2) fire. Failure to distinguish between the circumstances surrounding these two hazards can result in misapplication of protective measures.

Combustion Explosions

It is useful to consider a flammable gas combustion explosion as occurring in the following sequence:

1. A flammable gas or the liquid phase of a liquefied flammable gas is released from its container, piping, or equipment (including the normal operation of an overpressure relief device). If liquid escapes, it rapidly vaporizes and produces the potentially large quantities of vapor associated with this liquid-to-vapor transition.
2. The gas mixes with the air.
3. With certain proportions of gas and air (in the flammable or combustible range), the mixture is ignitable and will burn (Table 6.10.3).
4. When ignited, the flammable mixture burns rapidly and produces heat rapidly.
5. The heat is absorbed by everything in the vicinity of the flame and by the very hot gaseous combustion products.
6. Nearly all materials expand when they absorb heat. The one material in the vicinity of the flame or hot gaseous combustion products that expands most when it is heated is air. Referring to the gas laws cited earlier in this chapter, it will be noted that air expands to double its original volume for every 459°F (237°C) it is heated.
7. If the heated air is not free to expand (i.e., it is confined in a room), the pressure in the room will rise.
8. If the room structure is not strong enough to withstand the pressure, some part of the room will suddenly and abruptly move and depart from its original position. A bang, woosh, boom, or other noise will be heard.

This sequence of events partly describes an explosion. Because the source of pressure is combustion, this kind of explosion is called a *combustion explosion.* It is also called, less accurately, a room explosion or vapor-air explosion.

A combustion explosion requires that a quantity of flammable gas-air mixture be present in an enclosure. In addition, the quantity/strength-of-enclosure relationship must be such that the strength of some part of the enclosure must be exceeded by the pressure-building potential of the mixture. If the enclosure is strong enough to withstand the pressure, a combustion explosion cannot occur because it is the manner in which the

enclosure performs that basically determines whether such an explosion occurs. However, few enclosures are strong enough to withstand such pressure.

If an enclosure was full of a flammable gas-air mixture at atmospheric pressure, the enclosure would have to withstand about 60 to 110 psi (400 to 750 kPa) in order to remain intact to prevent a combustion explosion. If a reactive flammable gas is involved or oxygen enrichment occurs, even higher pressures are possible. Conventional structures are capable of withstanding pressures only in the order of 0.5 to 1.0 psi (3.5 to 7.0 kPa). This wide pressure disparity shows clearly that conventional structural enclosures are vulnerable even if they are not full of a flammable gas-air mixture. Most combustion explosions of conventional structures typically occur with less than 25 percent of the enclosure occupied by the flammable mixture. This fact should not be overlooked—it is erroneous to assume that a flammable gas-air mixture needs to completely fill a room or building before an explosion can occur.

The mechanics of gas accumulation in a structure are affected by the rate of gas release, whether the gas is in the liquid or gas phase, the density of the gas, and the ventilation in the structure. Classic diffusion laws are of little significance under actual conditions because the combination of extremely slow release rates and airtight structures seldom happens. For this reason, and the fact that most flammable gas-air mixtures are about 90 percent air, the density of the gas itself (i.e., whether it is lighter or heavier than air) is less often a significant factor in gas combustion explosions involving structures than one might expect.

Due to the large and rapid flammable gas-air mixture potential of liquefied gases, codes and standards impose severe limitations on the handling of such gases indoors. Considering the fireball aspect of the BLEVE, it is evident that an indoor fireball behaves similarly to an ignited gas-air mixture accumulation; the results of a BLEVE of a container located indoors can be very similar to a combustion explosion.

Combustion Explosion Safeguards

Basic combustion explosion prevention safeguards are designed to limit the development of a flammable gas-air mixture in a structure. Fundamental safeguards are the use of rugged storage containers and equipment that minimize the chance of leakage, the minimal quantity of gas released by emergency flow control devices, and the use of limiting orifices to minimize the quantity released. Burners are often equipped with flame failure devices that shut off the flow of gas if the flame is extinguished for any reason.

Many gases are colorless and odorless. It is, therefore, common to odorize the more widely used fuel gases to increase chances of leak detection. Odorization of both natural gas and LP-gas is required by codes, standards, and regulations so that these gases can be detected by humans with a normal sense of smell at concentrations in air not exceeding one-fifth of the lower limit of flammability. This is common practice throughout the world today. The odorants are usually volatile organic liquids containing chemically combined sulfur and have a characteristic "gassy" or "rotten egg" odor.

Although it is an effective safeguard, odorization has limitations. The functioning detector, that is, a human's sense of smell, is not always present, such as when the premises are vacant or the occupants are asleep. In addition, all odors deaden the sense of smell if inhaled long enough, and senses of smell vary. Odorants can be scrubbed from the gas by some soils, a factor where leakage stems from underground piping. Mixture accumulations can also be limited by ventilation systems in structures. These systems, however, are usually in industrial operations, and even then only rather nominal release rates can be handled by practical ventilation systems because of the necessity to condition the makeup ventilation air for comfort purposes. Additional information on the odorization of gases can be found in the *National Fuel Gas Code Handbook.*

Control of ignition sources is also fundamental to combustion explosion prevention. This safeguard is limited mainly to industrial operations where the conduct of employees can be controlled. It is impossible to prevent smoking, use of candles, and so on in residential occupancies.

In addition to combustion explosion prevention safeguards, the severity of the explosion can be reduced by special structural design whereby some elements of the structure are designed to dislocate at lower pressures, and other elements are designed to stay in place at the lower pressures that result. This is known as "deflagration venting" and is covered in some detail in NFPA 68, *Standard on Explosion Protection by Deflagration Venting.* Such a building design is not practical for most ordinary buildings, and this practice is applied to industrial structures.

Flammable Gas Fires

The flammable gas fire can be considered as an aborted combustion explosion wherein an explosive quantity of flammable gas-air mixture does not accumulate because the mixture is either ignited too quickly or a confining structure is not present. As would be expected when flammable gas escapes outdoors, fires are more likely than explosions. If a massive release occurs, it is possible for the air or surrounding buildings to comprise enough confinement to lead to a type of combustion explosion known as an open-air explosion or space explosion. Liquefied noncryogenic gases are subject to this phenomenon, as are hydrogen, ethylene, and some reactive gases that have a high flame speed. An example of the intentional provision of prompt ignition to achieve a fire instead of a combustion explosion is the use of pilots in gas-burning equipment, such as range ovens, water heaters, boilers, and furnaces.

Gas fire prevention safeguards include many of the combustion explosion prevention safeguards. Unlike the combustion explosion, the destructive effects of the gas fire can be minimized by control measures applied after the fact.

GAS EMERGENCY CONTROL

Controllable gas emergencies resulting from the escape of gas from containers present the following two basic forms of hazard:

1. Toxic, inert, or oxidizing gases can present hazards to persons or property and unignited flammable gases can be ignited, possibly explosively ("no fire" emergencies).
2. Gas fires can present thermal hazards to persons or property ("fire" emergencies) and, if such fires expose gas

containers, introduce the possibility of container failure and a BLEVE.

A fire in any combustible material also presents the hazard of container failure from fire exposure.

Control of "No Fire" Emergencies

Control consists of directing, diluting, and dispersing the gas to prevent contact with persons, preventing it from infiltrating structures if release is outdoors, and avoiding its contact with ignition sources while, if possible, simultaneously stopping the flow of escaping gas. Gas direction, dilution, and dispersion require the use of a carrier fluid; air, steam, and water have proved to be practical. The use of air, for all practical purposes, is limited to indoor situations and is an extension of the ventilation safeguards against a combustion explosion. Steam has been distributed through systems of fixed nozzles around outdoor ethylene processing equipment and where the large quantities of needed steam are available.

Water in the form of a spray, applied from hoses or monitor nozzles or by fixed water spray systems, is the most common carrier fluid. The use of hose streams is largely a fire department operation because of the personnel requirements. Fixed water spray systems for this purpose are designed differently from the more conventional spray systems used to control fire. To date, such systems have been provided at a few outdoor ethylene and liquefied natural gas (LNG) facilities. When water is used on cryogenic liquid containers, care must be taken to ensure that water does not contact the pressure-relief valve, as it can easily freeze and defeat the operation of this important safety device.

The physical properties of the escaping gas affect control techniques. The density of compressed gases is an important factor. Control tactics for compressed gases that are colorless and odorless can be complicated because instruments are needed to define the extent of the hazardous area.

Liquefied gases possess an inherent visible indicator of their location; the refrigerating effect of their vaporization condenses water vapor from the air that produces a visible fog. The fog roughly defines the gas area, but invisible ignitable gas-air mixtures often extend for several feet (1 ft = 0.3 m) beyond the extremities of the visible fog.

Because noncryogenic liquefied gases contain considerable heat for vaporization (because they are above their atmospheric boiling temperature), they often vaporize so rapidly from contact with the air or ground that they do not exist in the liquid phase once they escape—at least not to the extent that a pool will form. The lower vapor pressure noncryogenic liquefied gases, such as butane and chlorine, are exceptions. Even the higher vapor pressure gases, such as propane, pool when ambient temperatures are well below freezing.

Cryogenic liquefied gases, on the other hand, must obtain nearly all the heat for vaporization from ground or air contact and, therefore, characteristically form a pool if the leak continues for a long enough time. In such cases, application of a carrier fluid increases the vaporization rate if applied to the liquid—an often undesirable effect.

The gas produced near the source of vaporization of a liquefied gas is always heavier than air at normal temperatures because of the low temperature of the gas at that point. This fact, together with the associated water fog, tends to cause even normally tighter-than-air gases to hug the ground for some distance.

The use of foam, particularly high-expansion foam, to control the flow of gas produced by a vaporizing cryogenic gas, which is lighter than air at ambient temperatures, has been investigated to some extent. A sufficiently thick blanket of foam can warm the gas to the point where it will rise above the blanket instead of flowing horizontally near the ground. However, this applies only to established pools of vaporizing liquid and not to the initial high vaporization rate escape phase.

Some gases react chemically with the carrier fluid—particularly if the carrier is steam or water. Chlorine is a notable example—the reaction produces hydrochloric acid. However, the principal problem in this respect is enlargement of the leak as the metal container reacts with the acid.

A special type of "no fire" control for indoor application to flammable gases is the explosion suppression system. Actually, such systems do permit ignition to occur but arrest the combustion of the flammable gas-air mixture before the pressure needed for a combustion explosion is obtained.

Control of "Fire" Emergencies

Control of fire emergencies is generally the control of heat from the fire by the application of water while, if possible, stopping the flow of escaping gas. Many gas fires can be extinguished by conventional extinguishing agents, including carbon dioxide, dry chemical, and the halogenated agents. However, the potential conversion of a gas fire into a combustion explosion if gas continues to escape after extinguishment must be recognized. The generally accepted practice is to limit actual extinguishment by agent application to small leaks that will not present a hazard if they reignite. In addition, the use of halogenated agents is being phased out because of their detrimental effect on the earth's ozone layer. (See Section 17, Chapter 6, "Halon and Halon Replacement Agents and Systems.")

Methods of water application are the same as described for the "no fire" emergencies, that is, hose streams, monitor nozzle streams, and fixed water spray systems, as well as sprinkler systems. The selection of the particular application method, or combination of methods, requires a sound fire protection analysis of the existing conditions. This is particularly true where water is used to prevent a BLEVE because of the limited time available if uninsulated containers are involved. This fact, together with the specialized tactics needed for safety of emergency personnel, has been shown to severely tax the capabilities of hose stream application in many instances. Manual actuation of fixed systems (water spray or sprinkler) that have nozzles and dry piping in the fire area is questionable because the immediate intensity of a gas fire can quickly damage the piping before the water is turned on.

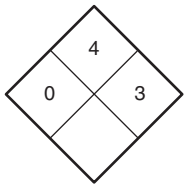
Conventional automatic sprinkler protection is limited to indoor or roofed-over areas. However, sprinklers have been effective in greatly reducing the number of overpressure relief devices on cylinders that operate during a fire. In turn, the number of cylinders that may fail from contact with the burning gas

discharged from pressure relief devices is reduced; sprinkler spacing and water density must be tailored to this hazard.

Foam can control a fire in a pool or tank of cryogenic gas but cannot extinguish it. The degree of control depends on the extent to which the foam can cover the liquid and the length of time the foam application can be maintained.

SPECIFIC GASES

Acetylene



UN 1001

Classifications. Acetylene is classified as reactive, flammable, compressed, and industrial.

Chemical Properties. Acetylene consists of two carbon atoms that are connected to each other by a triple chemical bond and to a hydrogen atom by a single bond. The triple bond, which is easily broken, is responsible for acetylene's reactivity. In the liquid or solid state, or in the gaseous state at moderate or high pressure, acetylene can decompose rapidly with the formation of carbon and hydrogen and the evolution of heat. Decomposition can be initiated by heat. Decomposition of liquid or solid acetylene also can be initiated by mechanical impact. In a confined space, the heated decomposition gases can cause overpressure and container, piping, or equipment failure.

As an indication that a hazardous, heat-producing reaction can occur in the absence of air, an upper flammable limit of 100 percent may sometimes be found in the literature rather than the 81 percent given in Table 6.10.3. This technical misapplication of the flammable range concept has caused confusion.

Acetylene can react with certain metals to produce metallic acetylides, extremely shock-sensitive explosive compounds that, if detonated even in small quantities, can initiate acetylene's decomposition. Copper and some copper alloys are notable in this respect, and their use must be avoided in most acetylene piping and equipment. However, these metals can be used in some components of acetylene systems under conditions that reflect the reaction kinetics involved. Torch tips, for example, fall into this category. Brass containing less than 65 percent copper can be used for acetylene piping systems.

Acetylene is not toxic and many years ago was mixed with oxygen for use as an anesthetic. Pure acetylene is odorless, but acetylene in general use has a characteristic odor due to minor impurities inherent in its generation from calcium carbide or derivation from other hydrocarbons.

Physical Properties—Autoignition Temperature (581°F [305°C]). Although acetylene is considered a compressed gas, the usual acetylene container used in transportation and storage does not exclusively contain acetylene in the gaseous phase and is unique in this respect. To ensure stability under reasonably anticipated shipping and use conditions, acetylene cylinders are filled with a porous-mass carbon or carbon-based packing material containing very small pores or cellular spaces so that any volume of gas therein is correspondingly small. This limits the decomposition energy available and restricts communication between spaces. In addition, the mass is saturated with acetone or dimethylformamide (DMF), a flammable liquid in which acetylene is very soluble. In this manner, acetylene gas can be compressed in solution in a manner similar to that of carbon dioxide in water to produce carbonated water. When the pressure is reduced, for example, by opening a cylinder valve, the gas escapes from solution and thus leaves the container in the gaseous state. Currently, a charging pressure maximum of 250 psig at 70°F (1724 kPa at 21°C) is recognized by DOT and Transport Canada (TC) regulations. The pressure inside an acetylene cylinder will rise or fall 2.5 psig per 1°F of temperature change (9 kPa per 1°C). For each atmosphere (14.7 psi or 101.3 kPa) of pressure, acetone or DMF will dissolve about 25 times its own volume of acetylene so that at 250 psig (1724 kPa) acetone will dissolve about 425 volumes of acetylene. An acetylene cylinder is illustrated in Figure 6.10.5.

Usage. Acetylene is used primarily in chemical processing and as a fuel gas in oxygen-fuel gas cutting and welding operations. Occasionally it is manufactured at the consuming location by reacting calcium carbide (a solid) and water in acetylene generators and piped directly to gas holders or to the point of use.

Hazards Inside Containers. Acetylene is shipped in DOT and TC cylinders as described previously and stored in these or in low-pressure gas holders. It is either handled in hoses or piping systems.

Acetylene cylinders are indirectly protected against overpressure by heat-actuated devices, usually fusible metal plugs of eutectic alloys, which have low melting points similar to those alloys employed in automatic sprinklers. These may be threaded plugs, or the fusible metal can be incorporated into the construction of the cylinder valve. Unlike spring-loaded pressure-relief valves, operation of fusible plugs results in complete reduction to atmospheric pressure because both the compressed gas and acetone or DMF are released at the same time. Due to this mode of overpressure protection, acetylene cylinders are not subject to a BLEVE, which by definition cannot occur if the liquid contents are not above their boiling points at NTP. Under fire exposure conditions and during charging operations in acetylene cylinder charging plants, however, internal decomposition has occurred, which has resulted in BLEVE effects, such as cylinder rupture and propulsion, accompanied by small fireballs.

Because susceptibility to decomposition is directly related to pressure, that is, the higher the pressure, the easier it is to initiate decomposition and the more violent the effects, an acceptable degree of stability in most piping systems containing gaseous acetylene is achieved by limiting or regulating the pressure. In general, this pressure must not exceed 15 psi (103 kPa). In applications requiring higher pressures, particularly in acetylene cylinder charging plants, special piping design features

FIGURE 6.10.5 Cutaway of a Typical Acetylene Cylinder Showing Porous Filler Material. Cylinder valve and packing for well at top of cylinder are not shown.

can be employed to control this hazard. The use of acetylene in either the liquid or solid phases is extremely hazardous and is prohibited by standards and codes covering conventional applications.

Hazards When Released from Containment. When acetylene is released from containment, it presents combustion explosion and fire hazards. Because of its reactivity, it is easier to ignite than most flammable gases and burns more rapidly. The latter effect increases the severity of combustion explosions and increases the difficulty of providing explosion venting. Acetylene is only slightly lighter than air and does not readily dissipate (see Table 6.10.3).

Because of acetylene's reactivity, the design of electrical equipment for use in acetylene atmospheres is unique to this material, and Group A electrical equipment (see NFPA 70, *National Electrical Code®*) is devoted exclusively to acetylene. In practice, electrical equipment is avoided in the more likely acetylene release areas. As a result, available Group A equipment is extremely limited in variety.

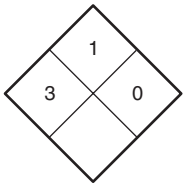
Emergency Control. Because of the limited quantities of acetylene in conventional shipping modes and storage practices, emergencies seldom occur. Fire control measures are similar to those involved with any flammable, nontoxic gas—that is, application of water to containers for cooling and dissipation of leakage and stopping the flow of escaping gas if possible.

Hazards of Acetylene Cylinders Exposed to Fire. Special precautions are needed when acetylene cylinders are exposed to fire. If an acetylene cylinder is exposed to fire, the fusible-metal pressure-relief devices will function when the metal reaches about 212°F (100°C). The nature of acetylene presents hazards that may not be present with other gases. Acetylene will decompose into hydrogen and carbon at temperatures in excess of 570°F (300°C). This property can present a danger when cylinders are involved in fire and heated locally above 570°F (300°C). When this occurs, cylinders can become overpressured and can, in some cases, rupture violently. The decomposition of acetylene can be so rapid that the pressure relief provided by a plug(s) cannot always prevent rupture. Rupture can occur in as soon as a few minutes or up to several hours after exposure.

Acetylene cylinders in the United States and Canada have fusible-metal pressure-relief devices incorporated into the cylinder or cylinder valve. Small cylinders incorporate the fusible metal into the valve. Medium and large cylinders incorporate the fusible metal in a plug(s) in the top head or bottom head. Most acetylene cylinders in Europe and other parts of the world do not have pressure-relief devices and are more susceptible to overpressure and rupture. When part of an acetylene cylinder is exposed to fire and is heated over 570°F (300°C), the acetylene will begin to decompose into carbon and hydrogen. Decomposition is rapid and liberates large quantities of energy. Cylinders exposed to fire should be sprayed with water from a protected location, and persons should not approach an acetylene cylinder that has been exposed to fire. Cylinders exposed to fire can explode even 24 hours after the exposure.

A common hazard of acetylene cylinders happens when a small leak occurs and ignites, resulting in a small flame. This small flame can cause heating of the fusible metal, resulting in the release of a torchlike flame that can be as much as 12 ft (3.6 m) in length. This sudden flame can be a danger to people in the area and to other cylinders.

Anhydrous Ammonia



UN 1005

Classifications. Anhydrous ammonia is classified as flammable, liquefied, and industrial.

Chemical Properties. Anhydrous ammonia is composed of a nitrogen atom bonded to three hydrogen atoms. Although often referred to simply as *ammonia,* this term is more appropriately used to describe a solution of anhydrous (meaning "without water") ammonia in water. The nitrogen component is inert in the combustion reaction and accounts for the somewhat limited flammability of anhydrous ammonia as manifest by its high lower-flammability limit and low heat of combustion (see Table 6.10.3).

Moist ammonia will vigorously attack copper and zinc and many of their brass or bronze alloys, which has caused some problems in agricultural areas where, because of their similar vapor pressures, anhydrous ammonia and propane are often handled in the same storage tanks, transport containers, and associated equipment at different times of the year, with ammonia being used as a fertilizer in the spring and summer, and

propane in the fall and winter as a fuel. LP-gas equipment customarily utilizes brass, bronze, copper, and zinc extensively for valves, gauges, piping, regulators, and so on. This equipment, if converted to anhydrous ammonia service, must be changed to steel. Subsequently, anhydrous ammonia must be carefully purged from a container when it is reconverted to LP-gas service to avoid corrosion of copper and brass components in building piping systems and appliances.

The characteristic pungent odor and irritant properties of anhydrous ammonia serve as warnings for this relatively toxic gas. However, the effectiveness of the warning depends on the rate of release. Large clouds of ammonia gas can be rapidly produced from large liquid leaks, so that people can be trapped and killed before they can evacuate the area. Another important factor is that human sense of smell can become accustomed to the odor of ammonia (and other pungent odors) over time. This is especially important in ammonia production plants and facilities that use large quantities of ammonia, such as many large refrigerated warehouses.

Physical Properties. At its normal boiling point of –28°F (–33°C), anhydrous ammonia has a liquid density of 42.6 lb/ft^3 (682.4 kg/m^3), a gas density of 0.055 lb/ft^3 (0.88 kg/m^3), and a latent heat of vaporization of 589.3 Btu/lb (1371 kJ/kg). At NTP, the gas has a density of about 0.045 lb/ft^3 (0.72 kg/m^3), and vaporization of 1 ft^3 (0.3 m^3) of liquid will produce about 885 ft^3 (25 m^3) of gas.

When vaporized it becomes a colorless gas, with a penetrating suffocating characteristic odor. Liquid released under pressure floats and boils on water.

Usage. Anhydrous ammonia is used primarily as an agricultural fertilizer, as a refrigerant, and as a source of hydrogen for metal heat treating. It is also used to provide special atmospheres in semiconductor manufacturing.

Hazards Inside Containers. Anhydrous ammonia is shipped in DOT and TC cylinders, DOT-specification cargo trucks, railroad tank cars, and barges. It is stored in cylinders, American Society of Mechanical Engineers (ASME) code tanks, and, in cryogenic form, in insulated American Petroleum Institute (API) tanks.

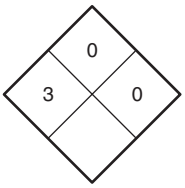
Anhydrous ammonia containers with a capacity of less than 165 lb (79 kg) are not required to be equipped with overpressure protection devices. This reflects the toxicity of the gas and is a safety trade-off between the hazards of container rupture from overpressure and gas release due to operation of an overpressure protective device, especially indoors where the smaller containers are often found. The limited flammability of the gas minimizes the probability of it supplying the exposing fire.

Hazards When Released from Containment. Anhydrous ammonia presents combustion explosion and fire hazards (as well as a toxicity hazard) when released from containment. However, its high lower limit of flammability and low heat of combustion reduce these hazards substantially.

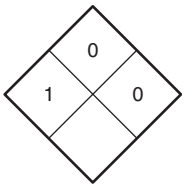
If anhydrous ammonia is released outdoors, it is difficult for it to reach the lower flammability limit concentration except for small zones in the immediate vicinity of the leak. Even where large quantities of liquid are released, ignitable concentrations tend to be in discontinuous pockets and this fact, together with the low heat of combustion, reduces the possibilities of sustained burning. Experience indicates that similar circumstances apply when the release occurs indoors in conventional and reasonably well-ventilated buildings. In unusually tight rooms, such as refrigerated process or storage areas, however, the release of liquid or large quantities of gas can result in the accumulation of sufficient quantities of a flammable mixture to result in a combustion explosion. In such cases, even though the low heat of combustion produces lower pressures than most flammable gases, the pressure is enough to do major structural damage. As a result of these factors, anhydrous ammonia fires are infrequent and, where ignition does occur, a combustion explosion is the likely result.

Emergency Control. At normal temperatures, anhydrous ammonia gas weighs about 0.6 times as much as air. Because of its pronounced solubility in water, the spread of escaping anhydrous ammonia gas can be readily controlled by water spray. If hose streams are used, the toxic and inerting properties of anhydrous ammonia require fire fighters to use protective breathing apparatus. Where liquid contact is likely, full protective clothing should be worn. If release of liquid in cryogenic form occurs, pooling is possible and application of water to pools should be avoided, unless the vapors can be controlled, in order to prevent increasing vaporization rate.

Carbon Dioxide



UN 2187
Cryogenic Liquid



UN 1013
Compressed Gas

Classifications. Carbon dioxide is classified as nonflammable (inert), liquefied, and industrial.

Chemical Properties. Carbon dioxide is composed of a carbon atom bonded to two oxygen atoms. The ability of carbon to chemically link with as much oxygen as possible prohibits its further oxidation (combustion), making it nonflammable. Although nontoxic, carbon dioxide is a "simple asphyxiant," which can cause asphyxiation due to the displacement of air.

Physical Properties. Carbon dioxide exhibits some unique physical properties. At a temperature of –69.9°F (–56.6°C) and a pressure of 60.4 psig (416.4 kPa), it can exist in a container simultaneously as a liquid, solid, and gas (the triple point). At temperatures and pressures above these and below 87.8°F (30.8°C), it exists as both liquid and gas. Above 87.8°F (30.8°C), it exists only in the gaseous phase. At normal temperatures, the gas is about 1½ times heavier than air.

Usage. Carbon dioxide is used primarily to carbonate beverages, to provide an inert atmosphere, and to extinguish fires.

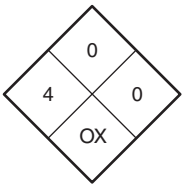
Hazards Inside Containers. Carbon dioxide is shipped in DOT and TC cylinders and insulated DOT-specification cargo trucks and railroad tank cars. It is stored in cylinders at a pressure of about 850 psi at 70°F (5861 kPa at 21°C) or in insulated ASME-code tanks at pressures of about 200 to 312 psi (1380 to 2150 kPa) and temperatures of –20 to 40°F (–28.8 to 4.4°C).

Cylinders are provided with overpressure protection in the form of frangible (bursting) discs. Insulated tanks are equipped with pressure-relief valves. Carbon dioxide cylinders can BLEVE as a result of corrosion with enough energy to nearly demolish small cargo vehicles.

Hazards When Released from Containment. In addition to the hazard of asphyxiation, contact with cold vaporizing carbon dioxide can cause frostbite. For these reasons, actuation of automatic room-flooding extinguishing system applications should incorporate a time delay if personnel occupy the protected area.

Emergency Control. Carbon dioxide emergencies are "no fire" emergencies involving potential asphyxiation hazards. Structure ventilation indoors and water spray control outdoors are applicable. Self-contained breathing apparatus should be used.

Chlorine



UN 1017
Chlorine

Classifications. Chlorine is classified as reactive, nonflammable, liquefied, toxic, and industrial.

Chemical Properties. Chlorine is a basic chemical element. It is a strong oxidizer. Although it is nonflammable, chlorine can react with many organic materials corrosively and, in some instances, explosively, particularly with acetylene, turpentine, ether, gaseous ammonia, hydrocarbons, most fuel gases, and finely divided metals.

The reactivity of chlorine necessitates special attention to the container, piping, and equipment materials of construction. Below 230°F (110°C), steel, copper, iron, and lead are widely used. In contact with water, chlorine forms hypochlorous and hypochloric acids, which are corrosive to most metals.

Physical Properties. The normal boiling point of chlorine is about –30°F (–34.4°C). At 32°F (0°C), the liquid density is 91.7 lb/ft^3 (1468 kg/m^3) and the gas density is 0.2 lb/ft^3 (3.2 kg/m^3). The latent heat of vaporization at the normal boiling point is 123.7 Btu/lb (287.7 kJ/kg). At 32°F (0°C), the vaporization of 1 ft^3 of liquid will produce about 458 ft^3 of gas (1 m^3 of liquid will produce about 458 m^3 of gas). Chlorine has a greenish-yellow color.

Usage. Chlorine is used primarily in chemical processing, bleaching, purification of drinking water and swimming pools, and sanitation of industrial and sewage wastes.

Chlorine has been used in warfare as a poison gas. Liquid chlorine can burn skin. Its sharp odor serves as a warning.

Hazards Inside Containers. Chlorine is shipped in DOT and TC cylinders, in DOT-specification portable tanks (so-called "one-ton containers"), and in insulated railroad tank cars.

Chlorine cylinders and 1-ton (1016-kg) containers are provided with overpressure protection by fusible plugs. Tank cars are protected by pressure-relief valves. Because the operation of fusible plugs results in complete depressurization, the probability of a BLEVE is low.

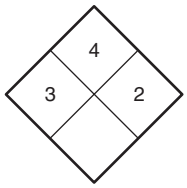
Steel is a suitable material for a chlorine container at normal temperatures; however, it is rapidly attacked at temperatures above approximately 230°F (110°C), and leaks can develop upon fire exposure. For this reason, as well as for BLEVE protection, water should be applied to fire-exposed containers. Application of water directly on a leak should be avoided because it may enlarge the leak from acid corrosion.

Hazards When Released from Containment. Chlorine presents primarily toxicity and corrosion hazards when released from containment. Since chlorine gas is about 2½ times heavier than air, it will hug the ground.

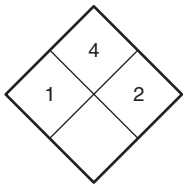
Emergency Control. The gas can be controlled by water spray. If hose streams are used, fire fighters should wear full protective clothing. Water applied to liquid chlorine will accelerate vaporization.

The chlorine industry has developed an extensive leak-control program that includes strategic siting of trained emergency personnel and special equipment kits for stopping the more common leaks in cylinders, ton containers, and tank cars. Information on this program is available from the Chlorine Institute, 1300 Wilson Blvd. Arlington, VA 22209 (http://www.chlorineinstitute.org).

Ethylene



UN 1038
Cryogenic Liquid



UN 1962
Compressed Gas

Classifications. Ethylene is classified as flammable, compressed, cryogenic, and industrial.

Chemical Properties. Ethylene is composed of two carbon atoms connected to each other by a double bond and each connected to two hydrogen atoms. The double chemical bond imparts a degree of reactivity. Except at very high pressures normally encountered only in chemical processing, it is a stable material. It has a wide flammable range (see Table 6.10.3) and

high burning velocity, reflecting its reactivity. Although it is nontoxic, ethylene is an anesthetic and asphyxiant.

Physical Properties. See Table 6.10.1.

Usage. Ethylene is principally used in chemical processing, for example, manufacture of polyethylene plastic. It is also used to ripen fruit.

Hazards Inside Containers. Ethylene is shipped as a compressed gas in DOT and TC cylinders and as a cryogenic gas in insulated cargo trucks and railroad tank cars in accordance with DOT specifications and regulations. It is stored in cylinders or in insulted ASME-code or API tanks.

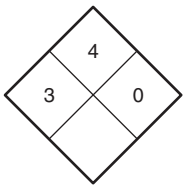
Ethylene cylinders (except for medical cylinders that may have fusible plugs or combination safety devices) are protected against overpressure by frangible (bursting) discs. Insulated truck tanks and tank cars are protected by pressure-relief valves. Cylinders are subject to failure from fire exposure but not to BLEVEs because they do not contain liquid. Insulated containers are subject to BLEVEs, but such incidents are rare.

Hazards When Released from Containment. Ethylene presents combustion explosion and fire hazards when released from containment. A wide flammable range and high burning rate accentuate these hazards. Given a large outdoor release, an open-air or open-space explosion can occur.

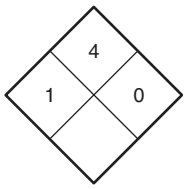
Emergency Control. Escaping ethylene presents both "no fire" and "fire" emergency situations. At normal atmospheric temperatures, ethylene gas is very slightly lighter than air. Ethylene gas vaporizing from the cryogenic liquid near its normal boiling point is heavier than air at 70°F (21°C) and can spread along the ground. Escaping liquid will also pool on the ground. Although the visible fog created is a rough indication of the extent of the hazardous area, the hazard can extend beyond the visible area.

Escaping gas can be controlled by water spray. Contact between water and pooled ethylene should be avoided to prevent increased vaporization, unless the vapors can be controlled. Water should be applied to fire-exposed containers and the flow of escaping gas should be stopped if possible.

Hydrogen



UN 1066
Cryogenic Liquid



UN 1049
Compressed Gas

Classifications. Hydrogen is classified as flammable, compressed, cryogenic, and industrial.

Chemical Properties. Hydrogen is a basic chemical element. Hydrogen has an extremely wide flammable range and the highest burning velocity of any gas. Its ignition temperature is reasonably high, but its ignition energy is very low. Because hydrogen contains no carbon, it burns with a nonluminous flame that is often invisible in daylight. Hydrogen is nontoxic.

Physical Properties. See Table 6.10.3.

Usage. Hydrogen is principally used in chemical processing for hydrogenation of edible oils, in welding and cutting, as a metal heat-treating special atmosphere, as a coolant in large electrical generators, and in the manufacture of semiconductors. It is also being used as a vehicle fuel.

Hazards Inside Containers. Hydrogen is shipped as a compressed gas in uninsulated DOT and TC cylinders, as a cryogenic gas in insulated DOT and TC cylinders, and in insulated cargo trucks and railroad tank cars according to DOT specifications and regulations. It is stored in cylinders or in ASME-code insulated tanks.

Compressed hydrogen cylinders are protected against overpressure by frangible (bursting) discs or such discs in combination with fusible plug devices. Insulated cylinders, trucks and railroad tank cars, and storage tanks are protected by pressure-relief valves and frangible disks. Compressed gas cylinders are subject to failure but not to BLEVEs because they do not contain liquid. Insulated cryogenic containers are theoretically subject to BLEVEs, but the probability is low.

Hydrogen is also shipped as a refrigerated liquid at about its normal atmospheric boiling point of –423°F (–253°C) in insulated containers. These are pressure vessels with reclosing pressure-relief valves, which will open to relieve the pressure that develops when heat leakage into the container results in boiling of some of the stored hydrogen. When this occurs, a visible cloud will develop as the air is cooled. Do not spray water in the vicinity of the discharge point, as it can freeze and block this important safety procedure.

Hazards When Released from Containment. Hydrogen presents both combustion explosion and fire hazards when released from containment. Although its wide flammable range and high burning rate accentuate these hazards, its low ignition energy, low heat of combustion on a volume basis, and its nonluminous (low thermal radiation level) flame exert counteracting influences in many instances.

Because of its low ignition energy, when gaseous hydrogen is released at high pressure, nominally small heat-producing sources, for example, friction and static generation, can result in prompt ignitions. On this basis, hydrogen may be frequently thought of as self-igniting under these circumstances. Typically, in high-pressure applications, fires rather than combustion explosions occur. When hydrogen is released at low pressures, however, self-ignition is unlikely. Rather, hydrogen combustion explosions occur that are characterized by very rapid pressure rises that are extremely difficult to vent effectively. Open-air or open-space explosions can occur from large releases of gaseous hydrogen.

Because of its very low boiling point, contact between liquid hydrogen and air can result in condensation of air and its oxygen and nitrogen components. A mixture of hydrogen and

liquid oxygen is potentially explosive, even though the quantities involved are likely to be small.

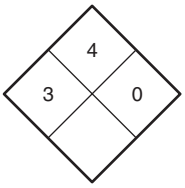
At ordinary temperatures, hydrogen is very light, weighing only about 1/15 as much as air. The accordingly high diffusion rate makes it difficult for hydrogen to accumulate in conventional structures, unless the escape rate is high. This tends to reduce its combustion explosion hazard.

Emergency Control. Escaping gaseous hydrogen seldom presents a "no fire" emergency situation because it either ignites promptly or rises in the atmosphere rapidly. Hydrogen gas vaporizing from the cryogenic liquid near its normal boiling point is slightly heavier than air at 70°F (21°C); this fact, together with the visible fog of condensed water vapor created, causes it to spread along the ground for sizable distances (depending on leak size and meteorological conditions). Because of the low gas density of vapors produced from vaporizing cryogenic hydrogen liquid, impounding or diked areas have not been required.

Ignitable mixtures can extend well beyond the visible cloud. Such escapes can be controlled by water spray. Contact between water and pooled hydrogen should be avoided to prevent increased vaporization, unless the vapor can be controlled.

Water should be applied to fire-exposed containers and the flow of gas stopped, if possible. Because hydrogen burns with a flame that is often invisible in daylight and because its flames produce low levels of thermal radiation, people can walk into its flames unaware. When approaching hydrogen fires, a useful technique is to hold a broom out in front, while progressing slowly and at the same time throwing dirt ahead. The combustibles in the dirt will incandesce and locate the edge of the fire.

Liquefied Natural Gas (LNG)



UN 1972

Classifications. Liquefied natural gas is classified as flammable, cryogenic, and fuel.

Chemical Properties. LNG is a mixture of materials all comprising carbon and hydrogen. The principal component is methane, with lesser amounts of ethane, propane, and butane. The composition will vary, depending principally on whether the source of the natural gas (which has been liquefied) is a transmission pipeline or gas wells. In the former instance, more of the propane and butane is removed prior to introduction into the pipeline (Table 6.10.4). LNG is nontoxic but is a simple asphyxiant, which can cause asphyxiation due to the displacement of air.

Physical Properties. See Table 6.10.4.

Usage. LNG is used as a source of natural gas to augment pipeline supplies during periods of extreme demand (peak shaving), to supply gas distribution systems in areas remote from central distribution systems, and as a basic supply of natural gas. To a small extent, it is used as a vehicle propulsion fuel.

TABLE 6.10.4 Approximate Properties of LNG

Composition	
Methane	83–99%
Ethane	1–13%
Propane	0.1–3.0%
Butane	0.2–1.0%
Physical properties	
Normal boiling point (NBP)	–250 to –260°F (–160 to –164°C)
Density liquid at NBP	3½ to 4 lb per gal (0.42 to 0.48 g/cm^3)
Density vapor at NBP (compared with air at 70°F or 21°C)	1.47
Liquid to vapor expansion	600 to 1
Heat of vaporization	220–248 Btu/lb (512–577 kJ/kg) 770–990 Btu/gal (215–276 mJ/m^3)
Combustion properties	
Flammable range	5–14% (methane at normal temperatures) 6–13% (methane near –260°F or –127°C)
Heat of combustion	22,000 Btu/lb (51.2 mJ/kg)
Burn rate, steady-state pool	0.2–0.6 in. (5 to 15 mm) per min

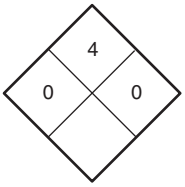
Hazards Inside Containers. LNG is shipped as a cryogenic gas in insulated cargo trucks built to DOT specifications and regulations and in marine vessels under DOT authorization. It is stored in insulated ASME code or API tanks. LNG containers are protected against overpressure by pressure-relief valves. Such containers are theoretically subject to BLEVEs, but the probability is low.

Hazards When Released from Containment. LNG presents both combustion explosion and fire hazards when released from containment. At the present time, LNG is seldom used indoors and when so used the structure is designed for a combustion explosion hazard in accordance with national standards and regulations.

Emergency Control. Escaping LNG presents both "no fire" and "fire" emergency situations. LNG gas vaporizing from the cryogenic liquid near its normal boiling point is about 1½ times heavier than air is at 70°F (21°C) and will spread along the ground accompanied by the visible fog created by condensed water vapor. This distance will depend on the leak size and meteorological conditions and on the geometry of the required liquid-impounding area provided. Ignitable areas are roughly

defined by the visible cloud but can extend beyond the visible area. Such escape can be controlled by water spray. Contact between water and pooled LNG should be avoided to prevent increased vaporization, unless the vapor can be controlled. Water should be applied to fire-exposed containers and the flow of gas stopped, if possible.

Liquefied Petroleum Gases (LP-Gas)



UN 1075

Classifications. Liquefied petroleum gas is classified as flammable, liquefied, and fuel.

Chemical Properties. LP-gas is a mixture of hydrocarbon materials. In commerce, LP-gas is predominantly either propane or normal butane or mixtures of these with smaller amounts of ethane, ethylene, propylene, iso-butane, and butylene (including isomers). Principal variations in composition occur depending on whether the source is gas wells or petroleum refineries. LP-gas is nontoxic but is a simple asphyxiant, which can cause asphyxiation due to the displacement of air.

Physical Properties. See Table 6.10.5.

Usage. LP-gas is used principally as a domestic, commercial, agricultural, and industrial fuel gas in chemical processing and as vehicle fuel. In domestic and recreational applications, it is sometimes known as bottled gas.

Hazards Inside Containers. LP-gas is shipped as a liquefied gas in uninsulated DOT and TC cylinders and in ASME tanks and in DOT-specification cargo trucks, railroad tank cars, and marine vessels. It is also shipped at low temperatures near its normal boiling point of about –40°F (–40°C) at atmospheric pressure in insulated marine vessels. It is stored in cylinders, ASME-code tanks, and insulated API tanks.

LP-gas containers are generally protected against overpressure by pressure-relief valves, although some cylinders are protected by fusible plug devices and, occasionally, by a combination of these. Most containers are subject to BLEVEs.

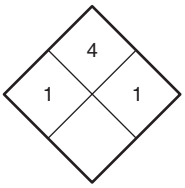
Hazards When Released from Containment. LP-gas presents both combustion explosion and fire hazards when released from containment. This hazard is accentuated when LP-gas is used indoors—reflecting the fact that 1 gal (3.8 L) of liquid propane or butane will produce about 245 to 275 gal (927 to 1041 L) of gas. For this reason, standards and codes severely restrict the uses of liquid-phase LP-gas indoors. Large releases of LP-gas outdoors will most likely result in a deflagration rather than a detonation.

TABLE 6.10.5 Approximate Properties of LP-Gases

	Commercial Propane	*Commercial Butane*
Vapor pressure in psig at		
70°F	127	17
100°F	196	37
105°F	210	41
130°F	287	69
Vapor pressure in kPa at		
20°C	895	103
40°C	1482	285
45°C	1672	345
55°C	1980	462
Specific gravity of liquid at 60°F (15.5°C)	0.509	0.582
Initial boiling point at 14.7 psia	–44°F	15°F
Initial boiling point at 101 kPa	–42°C	–9°C
Weight per gal of liquid at 60°F, lb	4.20	4.81
Weight per m^3 of liquid at 15.5°C, kg	504 kg	582 kg
Specific heat of liquid, Btu/lb 60°F	0.630	0.549
Specific heat of liquid, kJ/kg at 15.5°C	1.46	1.28
ft^3 of vapor per gal at 60°F	36.38	31.26
m^3 of vapor per L at 15.5°C	0.271	0.235
ft^3 of vapor per lb at 60°F	8.66	6.51
m^3 of vapor per kg at 15.5°C	0.534	0.410
Specific gravity of vapor (Air = 1) at 60°F (15.5°C)	1.50	2.01
Ignition temperature in air	920–1120°F (493–549°C)	900–1000°F (482–538°C)
Maximum flame temperature in air	3595°F (1980°C)	3615°F (1990°C)
Limits of flammability in air, percent of vapor in air-gas mixture		
(a) Lower	2.15	1.55
(b) Upper	9.60	8.60
Latent heat of vaporization at boiling point		
(a) Btu/lb	184	167
(b) Btu/gal	773	808
(c) kJ/kg	428	388
(d) kJ/L	216	226
Total heating values after vaporization		
(a) Btu/ft^3	2,488	3,280
(b) Btu/lb	21,548	21,221
(c) Btu/gal	91,547	102,032
(d) kJ/m^3	92,430	121,280
(e) kJ/kg	49,920	49,140
(f) kJ/m^3	25,140	28,100

Emergency Control. Escaping LP-gas presents both "no fire" and "fire" emergency situations. LP-gas vapor is 1½ times heavier than air, and the vapor produced as LP-gas vaporizes from the liquid at its normal boiling point is even heavier. As a heavier-than-air gas, it will tend to spread along the ground but is affected by wind and air currents. When released under pressure, the velocity of a jet release will overcome the weight of the gas. Escaping liquid LP-gas is accompanied by the created visible fog of condensed water vapor. Ignitable mixtures extend beyond the visible area. Such escape can be controlled by water spray. When propane is stored and handled at atmospheric temperatures, it is unlikely to pool, except near the normal boiling point of about –40°F (–40°C). Butane stored and handled at atmospheric temperatures and low-temperature LP-gas are likely to pool at temperatures near the normal boiling point of about 31°F (–0.5°C). Contact between water and pooled LP-gas should be avoided to prevent increased vaporization, unless the vapor can be controlled. Water should be applied to fire-exposed containers and the flow of gas stopped, if possible.

Methylacetylene-Propadiene, Stabilized (MPS)



UN 1060

Classifications. Methylacetylene-propadiene, stabilized (or MPS), is classified as flammable, liquefied, and industrial.

Chemical Properties. Methylacetylene-propadiene, stabilized, is a mixture of materials all composed of carbon and hydrogen. In commerce, and in compliance with standards covering its use as a metal-cutting gas, the composition of MPS is given in Table 6.10.6.

Methylacetylene (also known as "propyne") and propadiene (also known as "allene") contain double and triple chemical bonds and are unstable, reactive materials presenting hazards similar to acetylene. The achievement of an adequate degree of stability for this product depends on the existence of a sufficient quantity of the propane, butane, and iso-butane components of the mixture.

MPS has a degree of chemical reactivity with metals, similar to acetylene—especially as it pertains to the use of copper and copper alloys. (See "Acetylene" in this chapter.)

MPS is nontoxic but has some anesthetic and narcotic effects. It has a strong odor detectable at concentrations as low as 100 ppm in air (Tables 6.10.3 and 6.10.7).

Physical Properties. See Table 6.10.7.

Usage. MPS is principally used as a metal-cutting fuel gas with oxygen.

TABLE 6.10.6 MPS Composition

Methylacetylene-propadiene (in combination with a maximum ratio of 3.0 moles of methylacetylene per mole of propadiene in the initial liquid phase in a storage container)	68 mole percent *maximum*
Propane, butane, isobutane (in combination)	24 mole percent *minimum,* of which at least one-third (8 mole percent of total mixture) shall be butane and/or isobutane
Propylene	10 mole percent *maximum*
Butadiene	2 mole percent *maximum*

Hazards Inside Containers. MPS has physical properties very similar to propane and is shipped as a liquefied gas in uninsulated DOT and TC cylinders and in DOT-specification cargo trucks and tank cars. It is stored in cylinders and ASME-code tanks. Its hazards inside containers are analogous to propane. The pressure of MPS in piping systems is not restricted.

Hazards When Released from Containment. MPS presents combustion explosion and fire hazards when released from containment. It is easier to ignite (due to a lower ignition energy) than propane and burns more rapidly; thus, it is similar to eth-

TABLE 6.10.7 Selected Properties of MPS*

Molecular weight (average-stabilized mixture)	42.3
Heat of vaporization	227 Btu/lb (528 kJ/kg)

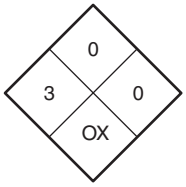
Minimum ignition energy	0.2–0.25 mJ

*MAPP gas (Dow Chemical Company).

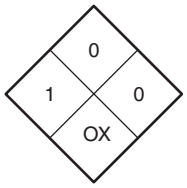
ylene in these respects. MPS is classified as a Group C material for purposes of suitability of electrical equipment installed in classified hazardous areas.

Emergency Control. See "Liquefied Petroleum Gases" in this chapter.

Oxygen



UN 1073
Cryogenic Liquid



UN 1072
Compressed Gas

Classifications. Oxygen is classified as nonflammable (oxidizing), compressed, cryogenic, industrial, and medical.

Chemical Properties. Oxygen is a basic chemical element. It reacts with practically all materials, and the general reaction is known as oxidation. Combustion is a particular type of oxidation reaction. In most combustion reactions, the oxygen is accompanied by nitrogen in a mixture known as air. Nitrogen contributes nothing to the combustion reaction and actually inhibits it. Therefore, concentrations of oxygen in excess of its concentration in air increase most combustion hazards to a degree directly related to the concentration, which affects all basic combustion parameters, except for the heat of combustion. For example, ignition temperatures and energies are lowered, the flammable range is widened, and the burning rate is increased as the oxygen concentration increases—the ultimate effects occurring at an oxygen concentration of 100 percent. In consideration of these properties, the design of systems containing 100 percent oxygen requires particular attention to these factors from a compatibility standpoint.

Physical Properties. See Table 6.10.1.

Usage. Oxygen is primarily used in the production of steel, in metal welding and cutting, in medical applications, in life-support systems, in aeronautic and aerospace applications, and in chemical processing.

Hazards Inside Containers. Oxygen is shipped as a compressed or cryogenic gas in DOT and TC cylinders and in tank cars and trucks in accordance with DOT specifications and regulations. It is stored in DOT-specification cylinders (insulated or uninsulated) or in ASME-code insulated tanks.

Compressed-oxygen cylinders are protected against overpressure by frangible (bursting) discs or a combination of these with fusible plugs. Insulated cryogenic containers are protected with pressure-relief valves. Metals for containers and piping must be carefully selected, depending on service conditions. The various steels are acceptable for many applications, but some service conditions may call for other materials (usually copper or its alloys) because of their greater resistance to ignition and lower rate of combustion.

Similarly, materials that can be ignited in air have lower ignition energies in oxygen. Many such materials may be ignited by friction at a valve seat or stem packing or by adiabatic compression produced when oxygen at high pressure is rapidly introduced into a system initially at low pressure.

Oxygen container failures from fire exposure are rare—probably reflecting standards that require separation of containers from flammable gases and other combustibles. Oxygen system components can fail due to accumulations of grease, oil, and so forth on the surfaces of these components in contact with oxygen, reflecting poor housekeeping practices. Since materials such as grease are easily ignited in air, they are especially ignitable in 100 percent oxygen. Their ignition often results in combustion of system components that are noncombustible in air, including metallic components. Such incidents usually involve only small portions of such components but may occur in a spectacular way, causing property damage and personal injury. They are referred to conventionally as "flashes."

Hazards When Released from Containment. Release of compressed or liquefied oxygen is usually observed by acceleration of the fire in whatever is burning. Release of liquid oxygen in the absence of fire presents an increased possibility that an oxygen-fuel mixture may occur prior to ignition. If ignition delay occurs under these circumstances, an explosion may result. Almost any combination of liquid oxygen and a combustible material is potentially explosive due to the rapid combustion circumstances produced. Some commercial explosives have been derived in this manner. Oxygen is slightly heavier than air at the same temperature, but its density is sufficiently close to that of air that the oxygen will not sink.

Emergency Control. Escaping oxygen presents basically a "no fire" situation but can create a "fire" situation in the vicinity of fired equipment or arcing electrical equipment by causing these to get out of control. For example, metallic components of internal combustion engines have burned in the oxygen-rich atmospheres produced by escaping oxygen. Oxygen gas vaporizing from the cryogenic liquid near its normal boiling point is approximately four times heavier than air is at 70°F (21°C) and will spread along the ground accompanied by the visible fog of condensed water vapor that has been created. Such escape can be controlled by water spray. Contact between water and pooled liquid oxygen should be avoided to prevent increased vaporization, unless the vapor can be controlled. Water should be applied to fire-exposed containers and the flow of gas stopped, if possible.

Liquid oxygen spilled from containers will remain in liquid form for some time while slowly boiling. If it is in contact with any organic material, such as asphalt paving, the combination is shock sensitive and can detonate. The hazard exists only when liquid oxygen is present, and extreme caution is advised.

Utility Gases

Classifications. Utility gases are classified as flammable and fuel.

Chemical Properties. The term *utility gas* applies to any flammable gas distributed by gas utilities as a fuel gas. Natural gas dominates this field today. Some LP-gas is distributed by gas utilities. Many utilities use LP-gas to augment natural gas supplies during short periods of peak demand that occur in unusually cold weather.

The creation of natural gas is the result of decomposition of organic material by heat, pressure, and bacteriological action in the absence of air, usually below ground. As it is evolved underground, natural gas consists of both flammable and nonflammable gases. The flammable gases are composed of carbon and hydrogen and are principally methane and ethane, with some propane, butane, and pentane. The nonflammable gases are principally nitrogen and carbon dioxide. In commerce, most of the nonflammable gases are removed prior to distribution so that the natural gas consists of about 70 to 90 percent methane, with the remainder mostly ethane (see Table 6.10.3).

Natural gas is nontoxic but is a simple asphyxiant. This is in marked contrast to the manufactured gas formerly widely distributed as utility gas and that contained quantities of poisonous carbon monoxide.

Utility natural gas has no odor of its own and is generally odorized as distributed.

Physical Properties. With the exception of liquefied natural gas (LNG), utility natural gas is distributed in piping as a compressed gas at pressures ranging from approximately 0.25 to 1000 psi (1.72 to 6895 kPa) and in cylinders at pressures up to 3600 psi (24.8 MPa). The gas has a density of about ⅔ that of air.

Usage. Utility natural gas supplies about one-fifth to one-fourth of the total fuel energy of the United States for domestic, commercial, and industrial heating and power.[4] It is also being used as a motor fuel and is known as compressed natural gas (CNG). Natural gas (usually supplied from a gas utility distribution piping system) is compressed to 2400 to 3600 psi (16.5 to 24.8 MPa), stored in a fueling station, and dispensed into vehicle containers at the same pressure.

Hazards Inside Containers. Utility natural gas is distributed nearly exclusively by a network of about 1.5 million miles (2.5 million km) of underground pipeline in the United States. It is transported from gas wells in producing areas in large-diameter transmission pipelines at pressures up to approximately 1000 psi (6895 kPa). These pipelines are tapped by utility gas companies, and pressures are reduced for distribution—generally to around 0.25 to 60 psi (1.72 to 414 kPa). Regulators and safety relief devices are used to control pressures.

Steel and cast-iron pipe are used extensively. In recent years, thermoplastic and thermosetting plastic piping have been used extensively in distribution piping at pressures up to approximately 100 psi (689.5 kPa).

SUMMARY

The term *gas* describes the physical state of a substance that has no shape or volume of its own but will take the shape and fill the entire volume of whatever container or other enclosure it occupies. The classfications of gas are flammable, nonflammable, pyrophoric, oxidizing, and toxic.

Gas hazards include both a gas in a container and a gas when it escapes from a container. Hazards within containers include overpressurization, the liquid gas BLEVE, and combustion. Basic combustion explosion prevention safeguards limit flammable gas-air mixture accumulation in a structure.

Medical gases are important from the viewpoint of fire safety not so much because of what they are, but, rather, because of where they are used, namely, in areas where patients are present. Since many patients cannot be readily moved, either because they depend on life-support equipment or because they are not mobile, a fire becomes a more lethal threat than it would be in other environments. The increased use of oxidizers, such as oxygen and nitrous oxide (N_2O), and the increased reliance on potential ignition sources—for example, electrical appliances—places the hospitalized patient at increased risk. This chapter discusses those parts of the health care fire safety problem that are related to the storage and use of medical gases.

Fires directly related to medical gases are fortunately rare; it is primarily the effects of medical gases being near a fire originally caused by other factors that is of greatest concern. The fires most directly associated with medical gases have been related to use of lasers near endotracheal tubing which contains medical gas, with consequent ignition of the gases or tubing, and ignition of catheters (typically for oxygen) because a patient tried to smoke. Some fires are thought to have resulted from ignition of anesthetic waste gases passing through oil-lubricated pumps. Other incidents, injuries, and fatalities associated with medical gases have been the result of construction problems (e.g., failure to test for cross connections in piping systems), cylinder and container misuse (e.g., unsafe handling of cylinders, presence of cylinders filled with the wrong gas, mislabeling, theft), and inadequate training of maintenance personnel.

The safe practices and hazards discussed in this chapter apply to all health care facilities that use medical gases, for example, hospitals, ambulatory health care centers, nursing homes, dental offices, and so on; they also have relevance to the home health care environment. Pertinent information on the problem and hazard of medical gases and equipment can be found in the following chapters: Section 6, Chapter 1, "Fire Hazards of Materials"; Section 6, Chapter 10, "Gases"; Section 6, Chapter 12, "Flammable and Combustible Liquids"; Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 7, Chapter 3, "Storage of Gases"; Section 9, Chapter 12, "Fire Protection of Laboratories Using Chemicals"; and Section 9, Chapter 17, "Oxygen-Enriched Atmospheres."

TYPES AND HAZARDS OF MEDICAL GASES

Types of Medical Gases

In a typical medical facility, there are a variety of gases used for life support, therapy, medical analysis, and mechanical power. These include oxygen, medical air, nitrous oxide, nitrogen, carbon dioxide, blood gas mixtures, helium, and mixtures of these gases. In addition, two vacuum systems are usually present—medical vacuum and waste anesthetic gas disposal (WAGD). The presence of these gas supplies and vacuum systems, combined with the fact that patients may depend on their uninterrupted supply or operation for life support, complicates the fire picture inside any medical facility.

Mark Allen is director of marketing for BeaconMedaes and has been involved in the writing of the medical gas standards in NFPA 99 since the 1983 edition. He has also been involved in the writing of several other industry guidelines, design guides, and technical articles involving medical gas and vacuum piping systems.

Hazards of Medical Gases

Medical gases can present several specific hazards. The first and most significant hazard is the fact that the supply of one or more of these gases may be the only thing keeping a patient alive or ensuring that a treatment or procedure can be successfully completed.

The second hazard is that some of these gases are oxidizers and others are asphyxiants. Oxygen is the most important of these, as a little pure oxygen will increase the intensity of any fire and cause items that are normally considered noncombustible in air to burn very well indeed. Nitrous oxide has a similar character when heated to disassociation—that is, when the nitrogen and oxygen atoms in the N_2O molecule separate, pure oxygen becomes available and the reaction is exothermic, increasing the temperature. Even when not heated to disassociation, nitrous oxide will act as an asphyxiant. Medical air is simply a purified compressed air and will support fire as well as any air, but it is also under pressure. In contrast, nitrogen, helium, and carbon dioxide will slow or stop a fire but at the price of making an anoxic environment, where there is not enough oxygen for breathing and anyone nearby risks asphyxiation.

The third hazard is that these gases are present in cylinders and containers, which, if subjected to overheating from a fire, will vent their contents and, in extreme circumstances, may explode. There are also the simple mechanical hazards of having cylinders fall over, possibly complicating evacuation or presenting the risk of knocking off the cylinder valve and creating a high speed torpedo.

The first way to reduce these hazards is to remove cylinders and containers from the occupied space. This is done simply by locating all the sources remotely and piping the gases and vacuum to the bedside. Centrally piped medical gas systems are found in most hospitals and larger medical facilities. Only in small facilities or facilities that do not use medical gases routinely are there likely to be cylinders at the bedside. An example frequently encountered is nursing homes. However, even in the largest and best-equipped hospital, cylinders for specialized gases will be encountered, most notably in laboratories.

DISTRIBUTION SYSTEMS FOR CENTRALLY PIPED MEDICAL GASES

Components

Distribution systems for medical gases consist of the following components:

- Centrally located supply systems with appropriate controls
- Piping systems, including control valves and alarm
- Terminal units (outlets) in patient care areas and laboratories

The terminal units may be mounted in the wall or in a variety of substructures (manufactured assemblies) located in patient care areas.

Piping System

Each gas and vacuum system will pass through its own dedicated network of copper pipe. All joints, except those at the source of supply, must be brazed or otherwise joined to ensure they can withstand a fire exposure of 1000°F (588°C) or greater. The piping must be pressure tested prior to being filled with the intended gas to ensure there are no leaks and must be tested for purity, cleanliness, and absence of cross connections to other systems before being placed in service, as set forth in detail in NFPA 99, *Standard for Health Care Facilities.*

All piping systems are zoned to allow the gas supply to any specific area to be shut off. In this way, medical gases can be isolated from the piping in a fire area to allow for a "defend in place" fire attack without shutting off the supply of gases or vacuum to patients in other areas who are dependent on these systems (Figure 6.11.1).

Valves

Although zone valves are provided primarily for isolation in case of a fire, extreme care must be exercised before any valve in a medical facility is closed. Valves should only be closed after verifying that all patients are stable and that the supply of gases can be safely cut off. It is also important to note that many valves are poorly labeled and closing one can affect areas not described on the label. Although there are many other valves in a medical gas system, no valve other than the zone valves should be closed by other than facility staff. It is rare to completely evacuate a medical facility and there may be patients in an area not affected by a fire who are still dependent on the medical gases for life.

Station Outlets

Station outlets for medical gas supply systems must be equipped with noninterchangeable fittings that are keyed to the specific gas handled. Station outlets also require a label with the name of the gas supplied to the outlet. It is allowed to connect breathing apparatus, such as supplied air respirators, to medical air systems, but be aware that the connections are often different and not interchangeable. If medical air is intended to be used for these purposes, for instance in the event of a disaster involving chemical or biohazardous agents, ensure that the connections are compatible.

Medical gases are color coded for quick identification. These colors are used throughout the systems from the source to the outlets and even may carry through the equipment that is plugged into the outlets (Table 6.11.1).

Medical Gas Supplies

Cylinder weights, sizes, pressures, and contents are shown in Table 6.11.2, which is taken from NFPA 99. Oxygen is usually supplied from either a bulk oxygen system or a manifold system of cylinders. Safety requirements for both are contained in NFPA 99. Nitrous oxide, carbon dioxide, and nitrogen are commonly supplied through a manifold system of cylinders (Figure 6.11.2). Medical air systems are typically supplied from a compressor, but occasionally a manifold system is used.

Manifold rooms and rooms used to store cylinders should be identified and labeled as containing medical gases. The labeling must indicate if the room contains oxygen or if it contains only asphyxiants. Care should always be exercised when entering a room containing quantities of medical gases.

Medical air compressors and vacuum pumps are typically located in the same mechanical rooms with other equipment. Because these systems can be life supporting, ensure that

patients are under proper alternate care whenever the systems are deactivated.

Specifications for the design, installation, testing, and operation of nonflammable medical piped gas systems for health care facilities are covered in NFPA 99.

OXYGEN AND COMPRESSED AIR

Oxygen and Nitrous Oxide Use

Oxygen is routinely used for many therapeutic purposes. This relates to the simple fact that oxygen is essential to life and getting enough oxygen is the first essential for survival. Thus, recognizing that oxygen-enriched atmospheres are present in various therapeutic applications, fire or explosion prevention in health care facilities must take into account the control of potential fuels and ignition sources.

The problem of oxygen enrichment must be extended to encompass the other commonly used oxidant, nitrous oxide. Since nitrous oxide vigorously supports combustion and also releases heat of decomposition, the fire hazard of N_2O is compounded. The widespread use of oxygen and nitrous oxide in operating rooms, in conjunction with the "wet environment" of the operating room, along with a wide array of potential electrical ignition sources, makes the operating room a particularly hazardous fire location.

Oxygen Compression and Storage

Most oxygen for medical use is prepared by compression and liquefaction of air, followed by fractional distillation. Once purified, it is transported to and stored at the site of consumption as a compressed gas or as a liquid. Because of the economies of scale, almost all medium to large hospitals rely on bulk oxygen storage on site. NFPA 55, *Standard for the Storage, Use, and*

Handling of Compressed Gases and Cryogenic Fluids in Portable and Stationary Containers, Cylinders, and Tanks, includes information on the design and operation of such bulk oxygen storage units.

Oxygen concentrators, which separate air into its major components, nitrogen and oxygen, and then deliver oxygen of purity approaching 90 percent, can also be used. Oxygen concentrators are particularly useful when used on-site in facilities such as mobile military hospitals, hospitals in inaccessible geographic areas, and home health care environments.

Compressed Air

Compressed air has a wide variety of uses in medicine. It can be mixed with oxygen for ventilation of a patient's lungs, thus avoiding the complications of breathing pure oxygen over prolonged periods of time. Compressed air is also used in various laboratory apparatus. NFPA 99 includes provisions for the installation of a central piping system for compressed air for medical purposes.

Atmospheric air compressed to greater than ambient pressure (i.e., greater than 14.7 psi [101 kPa]) constitutes an oxygen-enriched atmosphere. Although not as hazardous as pure oxygen, the ease of ignition of combustible substances is nevertheless increased, and flame spread rate is greater than in air at ambient pressures. The fire hazard created by compressed air is thus significant; fire extinguishment in a compressed air atmosphere is difficult. Fire blankets and dry chemical agents are ineffective, since the burning continues in gas pockets that require the burning material be cooled by water.

If a fire occurs in electrically powered equipment in a compressed air atmosphere, the equipment must first be deenergized. The fire can then be extinguished with water.

Compressed air is supplied from compressors or from manifolded gas cylinders. If a compressor is used to supply a piped medical air system in a health care facility, the compressor must not add impurities, such as hydrocarbons, carbonaceous particulates, or carbon monoxide. To meet these specifications, at minimum, the air intake for the compressor must not take suction from the building in which the compressor is located. In addition, the air supplied by the compressor must be free of any contaminant lubricants or products resulting from the breakdown of lubricants. Some lubricants release contaminants such as carbon monoxide under the pressure and temperature generated in an air compressor, which could be distributed in the compressed air system. In a health care facility using a compressor to furnish air to the operating room and as an adjunct to respiratory therapy, electric power to the compressor must be wired to the critical branch of the essential electrical system of the facility. The specifications for this electric system are set forth in NFPA 99.

If a health care facility is located in an area in which the atmosphere is highly contaminated, it may be desirable to use compressed air from cylinders rather than compressing it on site. Some suppliers of cylinders may not have a pure source of atmospheric air to compress and oxygen-nitrogen mixtures may then be used. This so-called synthetic air is purer than ambient air, because it is made up of pure oxygen and nitrogen and so contains no atmospheric pollutants.

Because of the risks of backfeeding and overdrawing the system, the medical compressed air system should not be used for any nonpatient purpose. Medical air may also be used in hyperbaric chambers.

HELIUM-OXYGEN MIXTURES AND CARBON DIOXIDE

Helium-Oxygen Mixtures

Helium-oxygen mixtures are occasionally used in treating certain forms of respiratory distress and in anesthesia for laser airway surgery. This gas mixture should be treated as an oxygen-enriched atmosphere and precautions noted in the previous section should be followed. It should also be noted that helium delays ignition of combustibles due to its higher thermal conductivity compared to nitrogen. However, if combustion does occur, this higher thermal conductivity creates a more rapid flame spread rate in helium than in nitrogen. In addition, since helium possesses a lower specific heat than that of nitrogen, the flame temperature will be higher in helium dilution than in nitrogen dilution. Thus, although helium can delay ignition, if ignition does occur, the fire in a helium atmosphere is more destructive than in a nitrogen atmosphere.

Carbon Dioxide

Carbon dioxide is seen in more hospitals than previously because the gas is a vital part of "keyhole" surgery, in which it is used to balloon the body (insufflation) to allow space for endoscopes to pass through the body to perform surgery.

VACUUM SYSTEMS

Operation of Medical Vacuum Systems

In addition to centrally piped gas systems for pressurized gases, central vacuum systems are a standard feature in most health care facilities. They will appear the same as the gas systems in most respects, but the flow is into the wall or ceiling rather than out. Station inlets for the vacuum system are commonly installed in emergency rooms, operating rooms, recovery rooms, intensive care units, delivery rooms, nurseries, and patient rooms. Although portable individual vacuum pump units have been used in the past, and are still sometimes available for backup, most large health care facilities use central systems. A central vacuum system requires both collection bottles and trap bottles at the station inlets. The collection bottles collect the fluids. The trap bottles ensure that none of the material so collected enters the suction line. In dealing with vacuum systems, the additional presence of biological contamination must be expected and precautions similar to those employed for blood borne pathogens should be considered.

Vacuum System Uses and Hazards

Medical and surgical vacuum systems are also life supporting. Although it is less likely to be instantly fatal than loss of

oxygen or medical air, loss of vacuum can be deadly to a patient whose condition depends on the vacuum. Medical vacuum systems should be treated with the same precautions as any piped system as regards valve closures or source interruption. A central vacuum system may also be used in laboratories and other hospital facilities. Such systems should not be connected to the medical-surgical vacuum system piping. However, a common receiver tank is permitted.

In the operation of a central vacuum system, it is important to avoid drawing flammable gases or liquids into the system. At the discharge end, the system should avoid contaminants returning into the facility. Requirements for vacuum systems in health care facilities are included in NFPA 99.

Waste Anesthetic Gas Disposal (WAGD) (Scavenging)

Accepted anesthesia practice dictates that waste anesthetic gas disposal (WAGD) be incorporated in anesthetizing locations. Anesthesia techniques can result in a portion of the excess gases being vented to the operating room atmosphere, polluting the operating room and possibly creating an occupational hazard for personnel.

Waste anesthetic gas disposal systems include the collection system for the excess anesthesia gases, the system that transports the gases, and the vacuum producer (typically a pump or blower). The medical vacuum system is permitted to be used for WAGD and if used in this way must have a capacity greater than that for conventional operating room requirements. There have been reports of fires that appear to have resulted from waste anesthetic gases being passed through oil-lubricated pumps; this practice should be discouraged. For more details on WAGD, ANSI Z79.11, *Anesthetic Equipment—Scavenging Systems for Excess Anesthetic Gases,* should be reviewed.

Housekeeping Vacuum Systems

In some health care facilities, a vacuum system for housekeeping purposes may exist. It is used in conjunction with vacuum equipment for cleaning corridors, drapes, and other related housekeeping chores. This system must be separate from the central vacuum system used for medical purposes.

RESPIRATORY THERAPY

Respiratory Therapy Equipment and Uses

Respiratory therapy began with the use of oxygen-enriched atmospheres in oxygen tents. Subsequently, various methods for the use of oxygen in medical care were developed, including oxygen hoods, incubators for newborns, oronasal or nasal masks, nasal catheters, and devices that mechanically assist or control breathing while delivering medical gases via tracheal tubes.

This equipment, which intermittently generates pressure, delivers oxygen, air-oxygen mixtures, or oxygen mixed with therapeutic agents. These devices may be powered by a pressurized oxygen supply or by an electrically operated motor and pump system. Controls for such ventilators are pneumatic, fluidic, or electronic. One type of respiration unit is shown in Figure 6.11.3. The unit shown is connected to the hospital compressed air and oxygen distribution system via quick-connect couplers on hoses at rear. The desired air-oxygen mixture is typically delivered to the patient through a filter and through the attached corrugated tubing. The above-mentioned combination of oxygen-enriched atmosphere and an electrically operated power supply, in addition to the proximity of potential fuels, can contribute to fires in the equipment.

Respiratory Therapy Equipment Hazards

In oxygen-enriched atmospheres, combustible substances possess a lower ignition temperature and burn more rapidly than in air. Flame spread can be extremely rapid, especially if bedding or clothing is saturated with oxygen. The safe practices for the use of respiratory therapy equipment are detailed in NFPA 99.

Handling of Cylinders

Transfilling gas from cylinder to cylinder is a hazardous procedure and should be performed only by qualified personnel. It is

FIGURE 6.11.3 Respirator Typically Used for Intensive-Care Patients

not permitted in patient care areas of health care facilities (see NFPA 99). The Compressed Gas Association publishes safety guides for transfilling cylinders (see Bibliography). In addition to bulk storage of liquid oxygen, liquid oxygen within a medical facility may also be distributed by portable liquid oxygen units.

Oxygen is sometimes used in emergency service vehicles. Generally, small cylinders are employed. The same precautions must be exercised in emergency service vehicles as in a permanent facility.

Medical gases are encountered in home health care usually in the form of smaller containers or concentrators for oxygen. The oxygen is used by the patient for breathing support, sometimes during exercise (a "walker"), or to deliver medications. Fires from smoking around oxygen may occur in these situations.

ANESTHETIC AGENTS

Development of Anesthetic Agents

The introduction of diethyl ether as an anesthetic in 1846 led to dramatic changes in surgical practice. Its benefits were so obvious that general anesthesia rapidly became an accepted technique. Diethyl ether had many drawbacks, however, including flammability, and the search for better methods led to the development and introduction of many other agents, including some that were true gases (e.g., nitrous oxide and cyclopropane). Enrichment of anesthetic atmospheres with oxygen occurred nearly simultaneously with the introduction of nitrous oxide and allowed anesthetists to administer appropriate concentrations of anesthetic to patients while, at the same time, maintaining adequate levels of oxygenation. The practice of using oxygen as a component of inhalation anesthesia persists to this day.

Flammability of Anesthetics

Anesthesiologists have almost completely abandoned the use of flammable anesthetic agents. This includes both ether and cyclopropane. A large number of nonflammable anesthetic agents have replaced them, including halothane, enflurane, isoflurane, desflurane, and sevoflurane. Nitrous oxide continues to be used widely as an adjuvant (i.e., a pharmacological agent added to a drug to increase or aid its effect). Nitrous oxide and oxygen, both oxidants, vigorously support combustion. The oxygen in the nitrous oxide molecule is released under flame conditions, contributing to the oxidation-reduction reaction and the released heat of dissociation contributes to the damage created by the fire.

Anaesthetic agents are considered nonflammable under usual anesthetic conditions of use. However, given that these agents are often mixed with oxygen and nitrous oxide, they can become flammable. Sevoflurane is reported to have a lower flammability limit of 11 percent in oxygen and 10 percent in nitrous oxide. In oxygen, desflurane is reported to have a lower flammability limit of 11 percent and an upper flammability limit of 21 percent. In nitrous oxide, the reported lower flammability limit is 18 percent, and the upper flammability limit is 27 percent.

Safe Practices in Using Anesthetics

A consideration of safe practices in anesthesia begins with understanding the basic chemistry and physics of oxygen and the anesthetic gases, as well as the vapors produced by the volatile liquid agents. Nitrous oxide is stored in cylinders and typically piped through the facility to outlets in all anesthetizing locations. Similarly, oxygen is stored in containers or cylinders and piped to the anesthetizing areas. Medical air is produced on site through compressors and purification apparatus and then piped to the area of use. In contrast, liquid anesthetic agents, such as halothane and isoflurane, are stored as liquids that then volatilize in vaporizers during use. The oxygen, nitrous oxide, and air are carrier gases that transport the vaporized molecules of the volatile anesthetic agent through the anesthesia circuit.

HEALTH CARE FACILITY LABORATORIES

Health care facility laboratories may use a wide variety of gases and gaseous mixtures for chemical analysis, the generation of flames, and other purposes. NFPA 99 sets forth the design features and practices required for the safe operation of such a laboratory.

Gas Sterilization

For many years, sterilization by either dry heat or steam was standard practice for the eradication of bacteria and other pathogens from reusable medical equipment. Ethylene oxide, an extremely volatile liquid that vaporizes readily at room temperatures, was then introduced. It is an effective bactericidal and virucidal agent.

To sterilize objects by this method, the sterilizer chamber is first evacuated of air, then filled with ethylene oxide gas. The gas penetrates the material contained in the chamber and destroys bacteria, viruses, and other pathogenic organisms. Ethylene oxide is highly flammable and chemically reactive. Proper operation of the equipment is required to avoid the danger of unintentional ignition or explosion. The liquid is delivered to the facility in cylinders that must be stored properly, as is the case with any container of flammable liquid or gas. It also can be delivered mixed with other gases to reduce flammability. Ethylene oxide is toxic to humans, and proper venting of the ethylene oxide sterilizer to the outside of the building is mandatory. Ethylene oxide is not considered a medical gas in the sense that oxygen and nitrous oxide are medical gases, and it has no role in patient treatment. This means that it is not covered under the rules that govern the design and installation of medical gases. Safe practices applicable to ethylene oxide storage, handling, and use can be found in NFPA 560, *Standard for the Storage, Handling, and Use of Ethylene Oxide for Sterilization and Fumigation.*

Other Disinfecting Agents

Other chemical sterilizing and disinfecting agents have been used in the past, including chlorine, ozone, sulfur dioxide, and formaldehyde gas. Because of the problems in handling these

agents, their corrosive nature, and the greater efficacy and safety associated with heat and ethylene oxide sterilization, these agents are no longer used for medical sterilization purposes.

FIRE PREVENTION AND FIRE RESPONSE

Fire and Explosion Prevention

Potential ignition sources in hospital oxygen-enriched atmospheres include electrosurgical units, lasers, fiberoptic light sources, heat of adiabatic compression of gases, electric sparks, friction sparks, heated objects (including open flame), static electricity, short circuits, defibrillators, and others. In view of the hazards involved, fire prevention methods generally strive for redundancy to establish built-in safeguards of a multifaceted nature so that an explosion or fire will not occur even if one element of the safety recommendations fails or is omitted.

To prevent dangerous adiabatic compression heating of oxidizing gases, it is recommended that cylinder valves be opened slowly to allow only gradual introduction of the high-pressure gas downstream from the cylinder valve. This allows a slow buildup of pressure and, hence, temperature buildup is minimized, thus allowing the mass of the metal of the regulator or other gas-containing component to dissipate the heat rapidly enough to prevent the buildup of dangerously high temperatures. Under the conditions of oxygen-enrichment and high pressure, certain metals can burn. Aluminum is particularly susceptible to ignition under such conditions. This phenomenon has been held responsible for a number of fires that have occurred in aluminum cylinder regulators used by first responders. Generally, the use of aluminum regulators in this service should be avoided and brass regulators substituted.

The elimination of electric sparks requires the proper design, application, and maintenance of electrical equipment. Specifications for this electrical equipment, as well as for line cords and power supplies, are set forth in NFPA 99. Recommendations for the proper use of this equipment by facility personnel are also spelled out in NFPA 99.

Cylinders, regulators, pipeline systems, and other systems containing compressed air, oxygen, and nitrous oxide must be cleaned specifically for such use and maintained free of hydrocarbon contaminants (solvents, lubricants, etc.) that may act as fuels. Combustion of such fuels contributes to the fire hazard and creates increased pipeline pressure and the release of potentially toxic pyrolysis and combustion products.

Other fuels include mattresses, bed and operating-room table sheets and drapes, patient hair, anesthesia and respiratory care equipment, cleaning and prepping solutions, rubber gloves, oxygen-delivery tubing and masks, gauze pads and sponges, and the intestinal gases hydrogen and methane.

Fire-Fighting Problems

Oxygen-enriched atmospheres are encountered during practically every inhalation anesthetic and respiratory therapy procedure. Nitrous oxide, an anesthetic, is also considered an oxygen-enriched atmosphere. When bedding and clothing become saturated with oxygen and a fire occurs, flame spread will be extremely rapid and large quantities of water are required for extinguishment. Dry chemical fire extinguishers and fire blankets are ineffective. If the fire involves electrical equipment, such equipment must first be deenergized. The fire may then be extinguished with water. Halon and carbon dioxide fire extinguishers are also appropriate. Safe practices for the prevention of fires during the use of respiratory therapy are covered in NFPA 99. Also included is a recommended response in the event of a fire involving respiratory therapy equipment.

Flammable liquids are present in most health care facilities in pharmacy storage, hospital laboratories, housekeeping, and other areas. Special fire problems are created if any of these substances are allowed to enter drains, the central suction system, or ventilation ducts.

Mechanical hazards are created by the potential energy contained in compressed gas cylinders. For some surgical procedures, an operating room meets the definition of a "wet location." Although high-voltage electrical equipment (e.g., radiological) and electronic equipment (e.g., medical monitoring and computer) do not alone usually create a fire hazard, combustibles stored in their vicinity may be involved in a fire. The free use of water is inadvisable because of the electric shock hazard to the fire fighter or damage to the equipment. The presence of radioisotopes may also hamper fire suppression methods. Fire service personnel must be made aware of all special problems created by equipment or supplies in any health care area.

An aid to the identification of hazards associated with medical gases and agents is the NFPA hazards identification symbol system (see NFPA 704, *Standard System for the Identification of the Hazards of Materials for Emergency Response*). This identification scheme, based on the "704 diamond," can visually present information on flammability, health, and self-reactivity (instability) hazards, as well as special information associated with the hazards of the materials being identified. NFPA 99 requires application of the NFPA hazards identification symbols to laboratories. It is also prudent policy to apply the system throughout a facility in such areas as general stores, housekeeping, pharmacy, operating rooms, gas and flammable liquid storage rooms, and any other location where volumes of combustible or flammable materials are stored or used, or where certain special fire-fighting problems exist.

Fire-fighting personnel are trained to recognize and understand the relative hazard potential identified by the 704 diamond. Adoption of the 704 hazard identification system affords enhanced fire protection. Fire personnel are instantly apprised of the hazards they face. In addition, employees are educated about the hazardous nature of the materials they employ daily, enhancing prevention. It is also possible that, in deploying the system, personnel discover hazardous materials no longer in use that should be removed from the hospital premises, thus eliminating potential problems.

HYPERBARIC CHAMBERS

The operation of hyperbaric chambers is another use of an oxygen-enriched atmosphere. Typically, the percentage of oxygen is deliberately increased in the chamber. Some chambers may be small and accommodate only a single patient. Others

may be designed to allow the performance of an operative or other procedure and are thus large enough to accommodate one or more patients and several attendants. Because the pressure of the gas in the chamber is elevated, an increased partial pressure of oxygen results. Safety standards for hyperbaric chambers and facilities are detailed in NFPA 99.

The number of hyperbaric chambers in the United States increased during the latter part of the twentieth century. Most hyperbaric facilities are located in hospitals or other health care facilities and operate under NFPA 99. However, with the recent increase in the number of hyperbaric chambers there has been a corresponding increase in the number of freestanding hyperbaric facilities that operate independently of health care facilities. These independent facilities must also follow safety codes and operational safeguards that are essential with these units.

AMBULATORY CARE FACILITIES

Many requirements for the safe use of oxygen-enriched atmospheres in ambulatory care facilities, dental offices, and other facilities are identical to those for hospitals. Individual vacuum units rather than a central system are commonly used because of the relatively small amount of suction needed in dental offices. In larger dental offices or ambulatory care facilities in which surgery is performed under general anesthesia, it is necessary to incorporate a central vacuum system for the operating rooms and the recovery rooms, as well as for central piping of oxygen and nitrous oxide. Requirements for inhalation anesthesia in such facilities are contained in NFPA 99.

SUMMARY

The storage and use of oxidizing gases in hospitals and other health care facilities represent a unique fire safety problem, since many patients cannot be easily evacuated in a fire emergency. Effective fire prevention measures include minimizing potential ignition sources, such as cigarette smoking and electrical sparks. Cylinders, regulators, pipeline systems, and other systems containing compressed air, oxygen, and nitrous oxide must be cleaned, handled, and maintained properly.

Fire service personnel must be made aware of all special problems created by equipment or supplies in any health care area. An aid to the identification of hazards associated with medical gases and agents is the NFPA hazards identification symbol system, which visually presents information on flammability, health, and self-reactivity (instability) hazards. The use of an oxygen-enriched atmosphere in hyperbaric chambers and the use of inhalation anesthesia in ambulatory care facilities are covered by NFPA 99.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on medical gases discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

Chapter 12

Flammable and Combustible Liquids

Orville M. Slye, Jr.

Chapter Contents

Hazards of Flammable and Combustible Liquids
Classification of Flammable and Combustible Liquids
Physical Properties of Liquids
Physical Characteristics of Flammable and Combustible Liquids
Fire Characteristics of Liquids That Burn
Ignition Temperature (Autoignition Temperature, Autogenous Ignition Temperature)
Burning Characteristics of Liquids That Burn
Fire Prevention Methods

Key Terms

boiling point, combustible liquid, evaporation rate, flammable limit, flammable liquid, flashpoint, ignitable mixture, ignition temperature, specific gravity, vapor density ratio, vapor pressure, viscosity

This chapter focuses on the fire hazards of flammable and combustible liquids and includes a review of the NFPA classification system for these liquids. The physical and fire characteristics of liquids are discussed with a special emphasis on the burning characteristics of these materials. Fire prevention methods for the use, handling, and storage of flammable and combustible liquids complete the chapter.

For more information about flammable and combustible liquids not contained here, see the following chapters: Section 2, Chapter 1, "Physics and Chemistry of Fire"; Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 7, Chapter 4, "Storage and Handling of Chemicals"; Section 8, Chapter 1, "Air-Moving Equipment"; Section 11, Chapter 5, "Control of Electrostatic Ignition Sources"; and Section 17, Chapter 8, "Explosion Prevention and Protection."

Flammable and combustible liquids fires can be controlled and extinguished using foam, dry chemical agents, carbon dioxide, halogenated agents, or water, as covered in the following chapters: Section 16, Chapter 9, "Water Spray Protection"; Section 17, Chapter 1, "Carbon Dioxide and Application Systems"; Section 17, Chapter 2, "Chemical Extinguishing Agents and Application Systems"; Section 17, Chapter 4, "Foam Extinguishing Agents and Systems"; and Section 17, Chapter 6, "Halon and Halon Replacement Agents and Systems."

HAZARDS OF FLAMMABLE AND COMBUSTIBLE LIQUIDS

The fire hazard of a flammable or combustible liquid comes from its vapors, rather than from the liquid itself. When a flammable or combustible liquid is heated, vapors are evolved from the liquid's surface; this is called *evaporation*. If the liquid is heated to its flashpoint, the vapors evolved will be concentrated enough to be ignited and burn. Because, by definition, most flammable liquids are stored and handled above their flashpoint temperature, vapors are continuously released by the liquid resulting in an ignitable mixture of vapor and air over its surface.

Ignitable mixtures occur when concentrations of vapors in air are within a definite percentage range, commonly referred to as the flammable range. The lower limit of the range is known as the lower flammable limit (LFL). The upper limit of the range is known as the upper flammable limit (UFL). For example, the proportions (flammable range) for carbon disulfide are from about 1 to 44 percent carbon disulfide vapors in air by volume; for ethyl alcohol, from about 4 to 19 percent by volume; and for gasoline, from about 1.4 to 7.6 percent by volume. Therefore, storing flammable and combustible liquids in the proper closed containers and minimizing the exposure of the liquid to air while in use are fundamental safety measures.

Accumulations of flammable vapor-air mixtures can occur in a confined space, such as containers, tanks, rooms, or buildings. The violence of a flammable vapor explosion is dependent on the nature of the vapors, the enclosure containing the mixture, the quantity of the mixture, and the concentration of vapor in the mixture with air. Flammable vapor-air mixtures that have vapor

Orville M. Slye, Jr., P.E., is president of Loss Control Associates, Inc., Langhorne, Pennsylvania.

concentrations near the lower or upper limits of the flammable range are less intense than those that occur in a well-mixed "stochiometric" concentration.

Distinct from an explosion of a flammable vapor-air mixture inside a tank or container is overpressuring of a tank or container, which results in a rupture. As with vapor explosions, pressure ruptures vary in intensity. Any closed container may rupture violently when exposed to a severe fire.

Fire and explosion prevention measures are based on one or more of the following techniques or principles: (1) exclusion of sources of ignition, (2) exclusion of air (oxygen), (3) storage of liquids in closed containers or systems, (4) ventilation to prevent the accumulation of vapor within the flammable range, and (5) use of an atmosphere of inert gas instead of air. Extinguishing methods for flammable and combustible liquid fires involve shutting off the fuel supply, excluding air by various means, cooling the liquid to stop evaporation, or a combination thereof.

Gasoline is the most widely used flammable liquid. Gasoline generates flammable vapors at ambient temperatures. However, there are many other volatile flammable products. A comprehensive list of the more commonly used flammable or combustible liquids, including the characteristics of each, appears in NFPA's *Fire Protection Guide to Hazardous Materials,* 13th Edition.

Flashpoint is the most commonly used means to determine the relative hazard of flammable and combustible liquids. Other factors that influence the hazard of a liquid are ignition temperature, flammable range, rate of evaporation, reactivity when contaminated or exposed to heat, density, and rate of diffusion of the vapor. The flashpoint and other factors that determine the relative susceptibility of a flammable or combustible liquid to ignition have minimal influence on the burning characteristics of the liquid once the fire has burned for a short period of time.

Although many flammable and combustible liquids are chemically stable (i.e., their primary fire hazard is that they burn), others introduce the problem of instability or reactivity.

The storage, handling, and use of unstable (reactive) flammable or combustible liquids require special attention. It may be necessary to increase the distances to property lines from storage tanks and between adjacent tanks or to provide extra fire protection. For example, it would be poor practice to locate heat-reactive and water-reactive flammable or combustible liquids tanks adjacent to each other. In the event of a ground fire, water applied to the heat-reactive tank for protection might penetrate the tank of water-reactive liquid and cause a violent reaction.

CLASSIFICATION OF FLAMMABLE AND COMBUSTIBLE LIQUIDS

For fire protection purposes, an arbitrary division between liquids and gases has been established, based on the definition of a flammable liquid found in NFPA 30, *Flammable and Combustible Liquids Code.* Liquids are defined as those fluids with a vapor pressure not exceeding 40 psia (2068 mm Hg) at 100°F (37.8°C). Another arbitrary division also has been established between liquids and solids for the purposes of this classification system. A liquid is additionally defined as one which has a fluidity greater than that of 300 penetration asphalt.

The following classification system for flammable and combustible liquids (from NFPA 30) is based on the division of flammable liquids into three categories. It is anticipated that, in most areas, the indoor temperature could reach 100°F (37.8°C) at some time during the year. Therefore, all liquids with flashpoints below 100°F (37.8°C) are called Class I liquids. In some areas, the ambient temperature could exceed 100°F (37.8°C), requiring only a moderate degree of heating to bring the liquid to its flashpoint. Based on this concept, an arbitrary division of 100 to 140°F (37.8 to 60°C) was established for liquids in this flashpoint range, to be known as Class II liquids. Since liquids with flashpoints higher than 140°F (60°C) would require considerable heating from a source other than ambient temperatures, they have been identified as Class III liquids.

Flammable Liquids

1. Flammable liquids have flashpoints below 100°F (37.8°C) and vapor pressures not exceeding 40 psia at 100°F (2,068 mm Hg at 37.8°C).
2. Class I liquids include those with flashpoints below 100°F (37.8°C) and may be subdivided as follows:
   (a) Class IA liquids includes those with flashpoints below 73°F (22.8°C) and with boiling points below 100°F (37.8°C).
   (b) Class IB liquids includes those with flashpoints below 73°F (22.8°C) and with boiling points at or above 100°F (37.8°C).
   (c) Class IC liquids includes those with flashpoints at or above 73°F (22.8°C) and below 100°F (37.8°C).

Combustible Liquids

Liquids with flashpoints at or above 100°F (37.8°C) are referred to as combustible liquids and may be subdivided as follows:

1. Class II liquids have flashpoints at or above 100°F (37.8°C) and below 140°F (60°C).
2. Class IIIA liquids have flashpoints at or above 140°F (60°C) and below 200°F (93°C).
3. Class IIIB liquids have flashpoints at or above 200°F (93°C).

Other Classification Systems

There are other classification systems for flammable and combustible liquids. In some, the breakpoints between classes of liquids are different, or the open-cup flashpoint tester is used to determine the flashpoint. In some classification systems, the solubility of the liquid with water is considered. Check with local authorities to determine alternative classification systems that might be used.

Solids with Flashpoints

Many combustible chemicals that are solids at 100°F (37.8°C) or above are classified as solids. When heated, the solid becomes

liquid and gives off flammable vapors; flashpoints can then be determined. In their liquid state, these solids should be treated as liquids with similar flashpoints. Some manufactured solids, such as paste waxes or polishes, may contain varying amounts of flammable liquids. The flashpoint and amount of liquid in such manufactured solid materials will indicate the degree of hazard.

PHYSICAL PROPERTIES OF LIQUIDS

In liquids, molecules move freely among themselves, but they do not tend to separate from one another in the way that molecules in gases do. Liquids, unlike gases, are only slightly compressible and are incapable of indefinite expansion. They differ from solids in the ease with which their molecules move against one another, causing them to adapt to the shape of the containing vessel. Some liquids are very viscous (i.e., have a relatively high resistance to flow), however, and no sharp definition can be drawn between these liquids and solids. Neither is there a sharp line of demarcation between liquids and gases. Materials can exist in either state, depending on temperature and pressure conditions. Liquids tend to become gases as their temperatures increase or their pressures decrease. On the other hand, gases tend to become liquids as their temperatures decrease or their pressures increase. However, a material can only exist as a gas, regardless of pressure, if its temperature is above the so-called critical temperature. (The critical temperature is an intrinsic property of a material and is the temperature above which the material can exist only in the gaseous state.) In all cases, the actual state of a liquid is determined by the combination of temperature and pressure.

PHYSICAL CHARACTERISTICS OF FLAMMABLE AND COMBUSTIBLE LIQUIDS

Specific Gravity

Specific gravity is the ratio of the density (weight per unit volume) of a material to that of some reference standard. For liquids, the reference standard is water, which is assigned a specific gravity of 1.0. Because the specific gravity of water equals one, a liquid with a specific gravity of less than one will float on water (unless it is water soluble). A specific gravity greater than one indicates that water will float on the liquid. Because fire-fighting foams are water-based extinguishing agents, this is an important consideration in fighting a flammable or combustible liquids fire.

Vapor Density Ratio

Vapor density is the weight per unit volume of a pure gas or vapor. For fire protection purposes, vapor density is reported in terms of the ratio of the weight of a volume of vapor to the weight of an equal volume of air, under the same conditions of temperature and pressure. In this respect, the vapor density ratio is similar to the specific gravity of a liquid, except that air is used as the reference standard in place of water. Air is taken as unity and the vapor density is reported as a ratio. A vapor density of 3 (i.e., 3:1) indicates that the vapor is three times as dense, or heavy, as air.

$$\text{Vapor density ratio} = \frac{\text{Molecular weight (MW) of the material}}{\text{Composite molecular weight of air}}$$

$$= \frac{\text{MW}}{29}$$

Vapor density ratios are reported at conditions of equal temperature and atmospheric pressure. Unequal or changing conditions will appreciably change the density of any vapor.

Generally, pure vapors are seldom found, except when the liquid is normally stored above its boiling point. For those liquids that are stored or handled below their boiling points, the vapor located above the liquid will be a mixture of vapor and air.

For liquids with boiling points above the prevailing ambient temperature at atmospheric pressure, the vapor density may be a misleading figure. For example, the boiling point of ethyl acetate is 171°F (77°C). At 70°F (21°C) its vapor pressure is about 2.35 psi (16.2 kPa) or 0.16 atm (atmospheres). Thus, an equilibrium mixture of ethyl acetate vapor and air at 70°F (21°C), as might be found in a closed vessel, would have a composition of 16 percent ethyl acetate vapor and 84 percent air. The "theoretical" vapor density of ethyl acetate is 3.0. The "actual" density of the "vapor-air mixture" that is produced by ethyl acetate at 70°F (21°C) and at atmospheric pressure is

$$0.16 \times 3.0 + 0.84 \times 1 = 1.32$$

Vapor densities are ordinarily used as an indication of the settling or rising tendency of a vapor. Thus, a density greater than air indicates that the vapor will accumulate in low areas of a room or outdoor facility. A density less than air indicates that the vapor will rise to the top of an enclosure or is likely to dissipate more readily than heavier vapors. The increased density associated with a substance heavier than air can make vapors released from a spill or similar emergency travel upwind or significant distances to unprotected ignition sources.

Vapor Pressure

The percentage of vapor in the atmosphere of a closed container of liquid can be determined from the vapor pressure of the liquid. The percentage of vapor is directly proportional to the relationship between the vapor pressure of the liquid and the total pressure of the mixture. For example, acetone at a temperature of 100°F (37.8°C) has a vapor pressure of 7.6 psia (52 kPa). Assuming total pressure at 14.7 psia (101 kPa), the proportion of acetone vapor present will be 7.6 divided by 14.7, or 52 percent. Vapor pressures of petroleum liquids usually are determined by the Reid method, as described in ASTM D323, *Standard Test Method for Vapor Pressure of Petroleum Products.*[1] This method gives the vapor pressure in psia (kPa) at 100°F (37.8°C), which differs slightly from the true vapor pressure. Vapor pressure figures for many substances can be found in chemical handbooks. If the closed-cup flashpoint of a liquid and the vapor pressure

at the flashpoint temperature are known, the lower flammable limit for the vapor (at the flashpoint temperature), in percent by volume at normal atmospheric pressure, can be calculated as follows:

$$\text{LFL} = \frac{V}{0.147} \left(\text{in SI: LFL} = \frac{V}{1.01} \right)$$

where LFL is percent vapor by volume at the lower flammable limit, and V is vapor pressure in psia (kPa) at flashpoint temperature. At other pressures,

$$\text{LFL} = \frac{100V}{P}$$

where P is the ambient pressure in psia (kPa).

In a mixture of volatile flammable liquids, the effects of the two vapor pressures, one upon the other, generally depend on whether the two liquids are completely miscible, partly miscible, or completely immiscible. If the two liquids are completely miscible, they lower each other's vapor pressures; if they are nearly completely immiscible, the vapor pressure of the mixture is the sum of the partial pressure of each liquid layer (Dalton's Law of Partial Pressure); if both liquids are partially miscible, the relationships are more complex.

Evaporation Rate

Evaporation rate is the rate at which a liquid is converted to the vapor state at any given temperature and pressure. The differing rates of mixture evaporation is of primary concern in fire protection. In general, as the boiling point decreases, the vapor pressure and the evaporation rate increases.

Viscosity

The viscosity of a liquid is a measure of its resistance to flow resulting from the combined effects of adhesion and cohesion, that is, a measure of internal friction in a fluid. Although there are several recognized devices for determining viscosity, the measurement principles are generally the same. These involve measuring the time required for a predetermined quantity of liquid at a specified temperature to flow into a receiving flask or through an orifice of a prescribed size.

Latent Heat of Vaporization

Latent heat of vaporization is the heat that is absorbed when one pound or gram of liquid is transformed into vapor at the boiling point under one atmosphere pressure and is expressed in Btu per lb or calories per gram (cal/g).

Solubility in Water and Surface Tension

Solubility in water and surface tension are other characteristics of a liquid that concern the fire protection field. Fires in liquids that are water soluble can be extinguished by dilution of the liquid with water, or by use of "alcohol-type" foams for extinguishment. The use of wetting agents affects the surface tension of a liquid and, in some cases, aids in fire extinguishment.

FIRE CHARACTERISTICS OF LIQUIDS THAT BURN

Fire Point

Fire point is related to flashpoint and is defined as the lowest temperature to which a liquid must be heated in order to evolve sufficient vapor to allow sustained burning for at least 5 seconds after application of a test flame.[2] Fire point is the minimum temperature at which the liquid evolves vapor as fast as it is consumed by flame, indicating the temperature for indefinite burning of a pool of liquid. Fire point is at least equal to the flashpoint, but, for high flashpoint liquids, is typically reported as 10°F to 27°F (5°C to 15°C) higher than the flashpoint.[3]

Fire point has application where codes such as NFPA 30 exempt requirements for storage limitations due to liquids having a flashpoint but not being capable of sustained burning. Fire point is typically determined by the Cleveland open-cup apparatus, ASTM D92. The use of an open cup allows liquid, as it is heated slowly, to lose volatile components before the liquid has been heated to the point of ignition. The test therefore may not recognize the ability of large volumes of such mixtures to burn rather than just flash.[4]

Flashpoint

A vapor mixed with air in proportions below the lower limit of flammability may burn at the source of ignition, that is, in the zone immediately surrounding the source of ignition, without propagating (spreading) flame away from the ignition source. The flashpoint of a liquid corresponds roughly to the lowest temperature at which the vapor pressure of the liquid is just sufficient to produce a flammable mixture at the lower limit of flammability. Figure 6.12.1 shows liquid, vapor, and air in equilibrium in a closed container at normal atmospheric pressure.

There are several types of test apparatus used for determining flashpoint (Figure 6.12.2). The material to be tested is slowly heated, and at periodic intervals a test flame is applied to the vapor space. Flashpoint is the temperature at which a

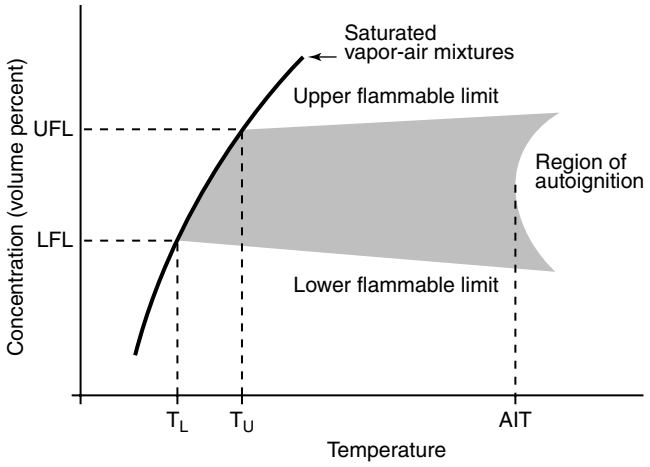

FIGURE 6.12.1 Range of Flammability for a Flammable Vapor

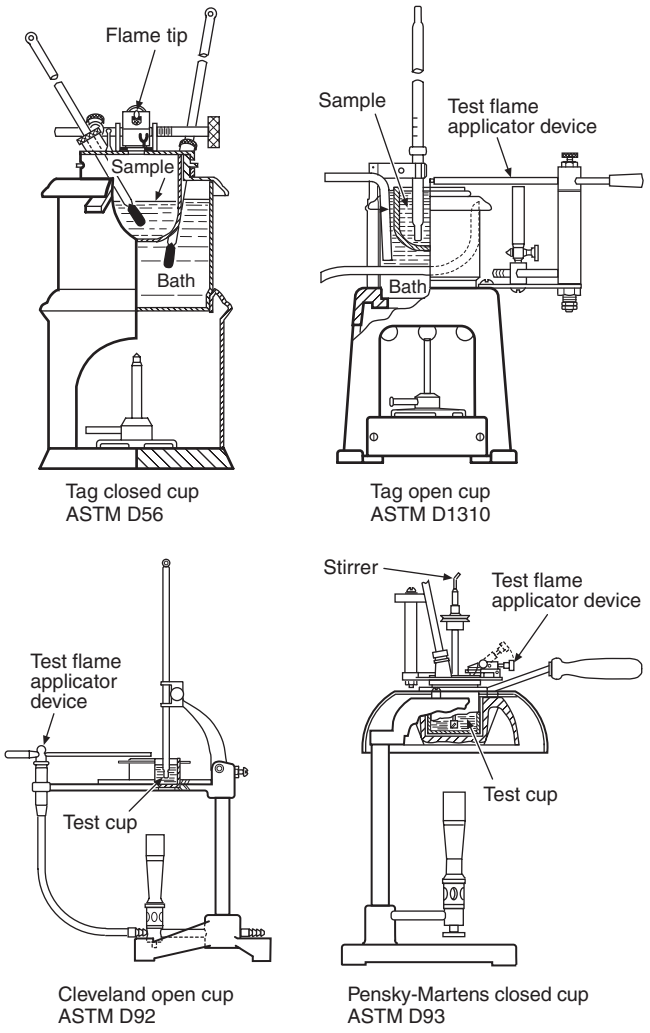

FIGURE 6.12.2 Four of the Commonly Used Testers for Determining Flashpoints of Flammable or Combustible Liquids

flash of fire is seen when the test flame is applied. The full details of conducting tests for each type of testing apparatus are given in the applicable standards of the ASTM or by the manufacturer.

The tag closed tester is described in ASTM D56, *Standard Test Method for Flash Point by Tag Closed-Cup Tester.*[5] The Pensky-Martens closed tester, as described in ASTM D93, *Standard Test Methods for Flash Point by Pensky-Martens Closed-Cup Tester,*[6] is specified for testing liquids with flashpoints above 200°F (93°C) or for certain viscous or film-forming materials.

ASTM D3278, *Standard Test Methods for Flashpoint of Liquids by Small Scale Closed-Cup Apparatus,*[7] is used for testing paints, enamels, lacquers, varnishes, and related products and their components with flashpoints between 32 and 230°F (0 and 18°C).

Open-cup flashpoints are sometimes used in grading flammable liquids in transportation and are determined by ASTM D1310, *Standard Test Method for Flashpoint and Fire Point of Liquids by Tag Open-Cup Apparatus,*[8] or ASTM D92, *Standard Test Method for Flash and Fire Points by Cleveland Open-Cup Tester.*[9] Open-cup flashpoints represent conditions with the liquid in the open and are generally higher than the closed-cup flashpoint figures for the same substances. However, closed-cup flashpoint figures are generally higher than the actual lower temperature limit of flammability (flashpoint) when tested in a vertical tube, using the principle of upward flame propagation.

It is essential to realize that flashpoint varies with pressure and with the oxygen content of the atmosphere, as well as with the purity of the product being tested, the method of test, and the skill of the operator conducting the test. It is quite possible to have a flammable mixture far below the stated flashpoint value if the pressure is considerably less than 1 atm.

IGNITION TEMPERATURE (AUTOIGNITION TEMPERATURE, AUTOGENOUS IGNITION TEMPERATURE)

The autoignition temperature of a liquid is the temperature of the external environment that will initiate combustion without the presence of an obvious ignition source, such as a spark or flame. The autoignition temperature is determined in a closed or nearly closed container that is heated until the vapor in the container spontaneously ignites and burns. Frequently, there is a lag time before ignition occurs. The standard test procedure used to determine autoignition temperature is ASTM E659, *Standard Test Method for Autoignition Temperature of Liquid Chemicals.*[10]

Within a given hydrocarbon series, such as the straight-chain series running from normal methane through normal decane, ignition temperature decreases as molecular weight or carbon chain length increases, all other factors being equal (Figure 6.12.3). Thus, pentane [$CH_3(CH_2)_3CH_3$; molecular weight 72.1] has a higher ignition temperature than hexane [$(CH_3CH_2)_4CH_3$; molecular weight 86.2].

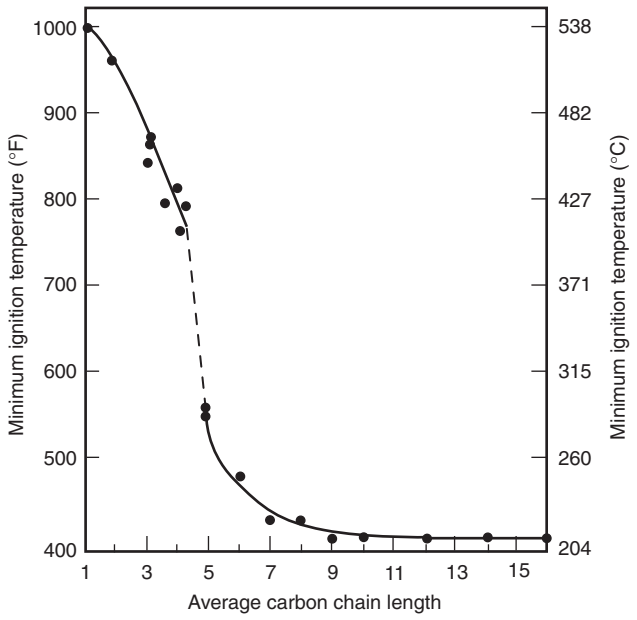

FIGURE 6.12.3 Minimum Ignition Temperatures of Hydrocarbons of Various Carbon Chain Lengths

Boiling Point

The temperature at which the equilibrium vapor pressure of a liquid equals the total pressure on the surface is known as the boiling point. The boiling point is entirely dependent on the total pressure. (Boiling point increases with an increase in pressure.) Theoretically, any liquid may be made to boil at any desired temperature by sufficiently altering the total pressure on its surface. Similarly, unless decomposition takes place, any liquid may be made to boil at any desired pressure by sufficiently changing its temperature.

The temperature at which a liquid boils when under a total pressure of 1 atm (14.7 psia or 101 kPa) is termed the normal boiling point.

This statement applies to pure materials or constant boiling mixtures. Most flammable liquids and gases on the market today are mixtures and do not follow the physical laws governing pure materials. The boiling points of mixtures are reported as distillation curves. The 10 percent point of a distillation performed in accordance with ASTM D86, *Standard Test Method for Distillation of Petroleum Products at Atmospheric Pressure,*[11] is used as the boiling point for most NFPA standards.

Flammable (Explosive) Limits

The term *lower flammable limit* (LFL) describes the minimum concentration of vapor to air below which propagation of a flame will not occur in the presence of an ignition source. The *upper flammable limit* (UFL) is the maximum vapor-to-air concentration above which propagation of flame will not occur. If a vapor-to-air mixture is below the lower flammable limit, it is described as being "too lean" to burn, and if it is above the upper flammable limit, it is "too rich" to burn.

The concept of the flammable range is best illustrated by Figure 6.12.1. This figure illustrates the flammable limits compared with vapor concentration in air and also illustrates the changes to flammable range as temperature increases. Concentrations of vapor that are below the shaded area are less than the LFL line and are, therefore, too lean to be ignited. Conversely, concentrations of vapor above the shaded area are above the UFL line and are too rich to be ignited. The effect of change in temperature is illustrated by the temperature limits T_L and T_U, where T_L is the temperature limit of flammability and T_U corresponds to the upper flammable limit concentration for saturated vapor-air mixtures.

When the vapor-to-air ratio is somewhere between the LFL and UFL, fires and explosions can occur. The mixture is then said to be within its flammable or explosive range. When the mixture happens to be in the intermediate range between the LFL and UFL (synonymous with lower explosive limit [LEL] and upper explosive limit [UEL], respectively), the ignition is more intense and violent than if the mixture were closer to either the upper or lower limits.

Calculating Vapor Volume and Flammable Mixtures

The volume of air necessary to provide sufficient dilution to prevent the formation of an ignitable mixture frequently must be determined when designing ventilation for a drying oven or similar hazard. This can be readily calculated when the quantity of solvent supplied is known or can be reasonably estimated. Examples of such calculations can be found in NFPA 86, *Standard for Ovens and Furnaces*, and in Section 17, Chapter 8, "Explosion Prevention and Protection."

For example, consider a process in which acetone vapor is released. The flammable range for acetone vapor in air is from 2.6 to 12.8 percent by volume. Any mixture containing more air than 100 minus 2.6, or 97.4 percent of air—equivalent to 97.4 divided by 2.6, or approximately 37 volumes of air to 1 volume of vapor—will be too lean to be ignitible. Hence, if the volume of vapor can be estimated, it is a simple matter to determine the required air volume.

The volume of vapor produced from 1 gal of solvent can be calculated from the specific gravity (Sp.G.) of the liquid and the vapor density (V.D.) as follows:

$$\frac{\text{ft}^3 \text{ of vapor from}}{1 \text{ gal of liquid}} = \frac{8.33 \times \text{Sp.G. of liquid } (H_2O = 1)}{0.075 \times \text{V.D. of vapor (air} = 1)}$$

where 8.33 is the weight of 1 gal of water (lb), and 0.075 is the weight of 1 ft^3 of air (lb).

Stated more simply,

$$\text{Vapor equivalent of 1 gal: } 111 \times \frac{\text{Sp.G.}}{\text{V.D.}}$$

If the V.D. is not known, it can readily be calculated from the molecular weight.

Again, taking acetone as an example (Sp.G. = 0.792; V.D. = 2) yields:

$$\text{Vapor equivalent of 1 gal: } 111 \times \frac{0.792}{2} = 44 \text{ ft}^3$$

The volume of air required to dilute vapor from 1 gal of acetone to below the lower flammable limit is

$$44 \times 37 = 1628 \text{ ft}^3$$

If the rate of evaporation of acetone into a given space (oven, etc.) should be 1 gpm, it would require 1628 cfm of uncontaminated ventilating air to keep the vapor concentration below the lower flammable limit.

For SI units, the volume of vapor (m^3) produced by 1 L of solvent can also be calculated from the Sp.G. of the liquid and the vapor density as follows:

The m^3 vapor equivalent of 1 L of liquid is

$$L = 0.83 \times \frac{\text{Sp.G.}}{\text{V.D.}}$$

For acetone, vapor equivalent of 1 L is

$$L = \frac{0.83 \times 0.792}{2} = 0.33 \text{ m}^3$$

In SI units, the volume of air required to dilute 1 L of acetone to below the lower flammability limit is

$$0.33 \times 37 = 12.2 \text{ m}^3$$

Based on the evaporation rate of the flammable liquid, the quantity of air would be proportional. In practice and as a safety

factor, a substantial excess of air ventilation would be applied because of the inevitable lack of uniformity of the atmosphere within the enclosure. Where it is desirable to keep a space "too rich" to be ignitable, a similar procedure (using the UFL) may be used to determine the maximum quantity of air that can be tolerated. This procedure is not, however, recommended, since it is necessary to enter and pass through the flammable range during operation.

Variation in Hazard with Temperature and Pressure

The temperature and pressure to which a particular liquid is subjected must often be considered in the practical application of the flammable limits of that liquid. It can be shown that these factors have a pronounced effect on the fire and explosion hazard and are as important in safe handling as are the flammable limits themselves. A liquid that has a flashpoint above room temperature and, therefore, is not expected to produce flammable vapors, will do so if its temperature is raised to its flashpoint or higher.

The extent of liquid vaporization varies as the pressure in the vapor space over the liquid is increased or lowered. More vapor is released as pressure is lowered and less vapor as pressure is increased. In the same manner, at a higher temperature the liquid will have a higher vapor pressure and will tend to vaporize in greater amounts. When at a given temperature and pressure the liquid has vaporized to the point where no further vaporization will occur unless conditions are changed, a state of equilibrium is said to have been reached. It is evident that equilibrium cannot exist in other than a closed system. In the open air, a vaporizing liquid would continue to vaporize until the supply was exhausted. The pressure-temperature effect, therefore, is applicable only in tanks, pipes, and processing equipment, in which the liquid and vapor-air mixture approach equilibrium.

The lower limits of flammability of vapors are also affected by the temperature. This is a safety factor in installations, such as industrial ovens, where pressure is not a factor, but where temperature needs to be taken into account in hazard evaluation. In such industrial ovens, mechanical or forced ventilation is usually employed to dilute the concentration of the vapors below their lower flammable limits in air and to remove them from the oven. Information on the lower flammable limits of the vapors at elevated temperatures is needed in order to determine the amount of ventilation required for safe operation of an oven[12] (Table 6.12.1). Figures 6.12.4 and 6.12.5 show the effect of temperature and pressure on flammable limits, as determined by Mitchell and Vernon.[13]

Figure 6.12.4 is applicable only to flammable liquids or gases in equilibrium in a closed container. Mixtures of vapor and air will be too "lean" to burn at temperatures below and at pressures above the values shown by the line on the chart for any substance. Conditions represented by points to the left and above

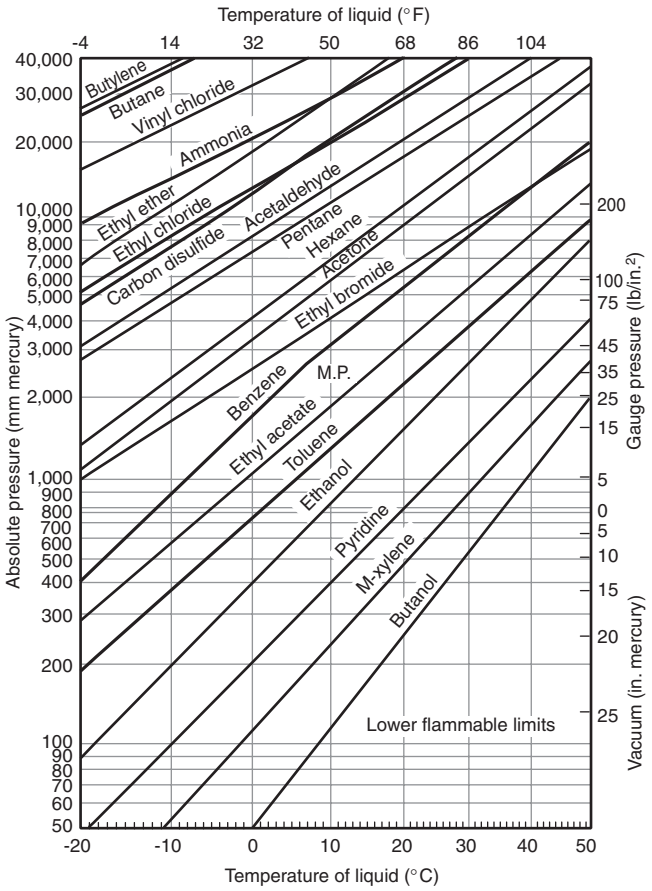

FIGURE 6.12.4 Variation of Lower Flammable Limits with Temperature and Pressure

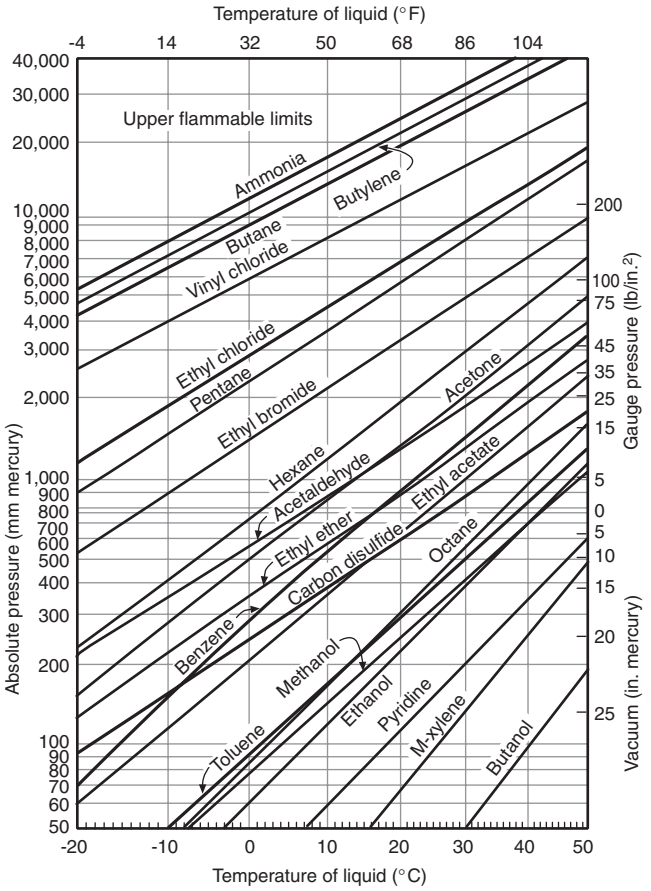

FIGURE 6.12.5 Variation of Upper Flammable Limits with Temperature and Pressure

the respective lines are accordingly nonflammable. Points where the diagonal lines cross the zero gauge pressure line (760 mm of mercury, absolute pressure) indicate flashpoint temperatures at normal atmospheric pressure. Figure 6.12.5 is applicable only to flammable liquids or gases in equilibrium in a closed container. Mixtures of vapor and air will be too "rich" to be flammable at temperatures above and pressures below the values shown by the line on the chart for any substance. Conditions represented by points to the right of and below the respective lines are accordingly nonflammable. In using Figures 6.12.4 and 6.12.5, it should be noted that they represent equilibrium conditions and that, prior to the establishment of equilibrium, values may be different.[13] For example, when a liquid is introduced into a pressure container with air at a temperature such that the resultant vapor-air mixture will be above the UFL (according to the chart), some time will elapse before sufficient evaporation has taken place to reach this condition; meanwhile, the mixture may be flammable or explosive.

It should also be noted that the pressures developed, or the intensity of an explosion, will vary with the initial pressure of the vapor-air mixture. With high initial pressures, the pressures are greater, as in the familiar example of the gasoline engine. With low initial pressures, the pressures are relatively lower.

Energy Required for Ignition of Vapors

The principal sources of ignition of flammable liquids include flames; electrical, static, or frictional sparks; hot surfaces; and adiabatic compression.

Flames. Except for extremely small examples produced under laboratory conditions, flames are unfailing sources of ignition for flammable vapor-air mixtures that are within the flammable range. Flames must be capable of heating the vapor to its ignition temperature in the presence of air in order to be a source of ignition. For some liquids and solids, it will be necessary for the flame to be of sufficient duration and heat to volatilize the fuel and to ignite the released vapors. Once ignited, the radiated heat from the burning vapors perpetuates the burning process.

Electrical, Static, and Frictional Sparks. These sparks must have sufficient energy to ignite flammable vapor-air mixtures. Electrical sparks from most commercial electrical supply installations are above flame temperatures and can ignite flammable mixtures. However, friction sparks might fail to ignite a flammable mixture because the spark may be of such short duration as to fail to heat the vapor to its ignition point. Also, not only

must an electrical spark have sufficient intensity and length, but also some variable conditions must exist within certain limits before ignition will occur. The nature of the ignition points and surfaces, as well as the composition, temperature, and pressure of vapor-air mixtures, are the principal variables in calculating ignition. Most of these same factors and variables also apply to static electrical sparks and frictional sparks as a source of ignition because, in either case, the spark must be of sufficient duration, intensity, or both, to create sufficient heat to cause ignition.

Hot Surfaces. Hot surfaces can be a source of ignition if they are large enough and hot enough. The smaller the heated surface, the hotter it must be to ignite a mixture. The larger the heated surface in relation to the mixture, the more rapidly ignition will take place and the lower the temperature necessary for ignition. A flammable liquid, however, must remain in contact with a hot surface for a sufficient length of time to form a vapor-air mixture within its flammable range. For example, a single drop of a low-viscosity, highly volatile flammable liquid that falls on the surface of an electric hotplate at 2000°F (1093°C) may ignite. A hot exhaust pipe in the open seldom ignites a flammable mixture, even though the surface temperature may be considerably above the environmental ignition temperature test method.

Adiabatic Compression. Adiabatic compression has been the cause of several destructive explosions. When controlled, adiabatic compression is the basis of diesel engine operation. A rapidly compressed flammable mixture will be ignited when the heat generated by the compressing action is sufficient to raise the flammable vapor to its ignition temperature.

Behavior of Mixed Liquids

The behavior of mixed liquids varies considerably, depending on physical characteristics of the liquid and environmental conditions. However, the vapor pressure or evaporation rate of mixed liquids is particularly important in the prevention of fires. These factors are significant when a mixture of liquids is listed as nonflammable or has a high flashpoint but becomes flammable under conditions of use. As a specific example, sufficient carbon tetrachloride can be added to gasoline so that the mixture has no flashpoint. However, while standing in an open container, the carbon tetrachloride will evaporate more rapidly than the gasoline. Over a period of time, therefore, the residual liquid will first show a high flashpoint, then a progressively lower one, until the flashpoint of the final 10 percent of the original sample will approximate that of the higher boiling fractions of gasoline.

To evaluate the fire hazard of such liquid mixtures, fractional evaporation tests can be conducted at room temperature in open vessels. After evaporation of appropriate fractions, such as 10, 20, 40, 60, and 90 percent of the original sample, flashpoint tests can be conducted on the residue. The results of such tests indicate the class into which the liquid should be placed if the conditions of use are such as to make it likely that appreciable evaporation will take place. With other liquid mixtures, the flashpoint may increase as evaporation occurs.

Noncompatible Materials

Noncompatible materials of construction or equipment are those materials with which an unstable flammable liquid or its normal reaction products will combine, or whose products of corrosion are contaminants. For example, if mercury is a harmful contaminant, then mercury thermometers should not be used. If a chlorinated compound slowly releases hydrochloric acid, aluminum should not be used. The aluminum chloride formed by this acid may act as a catalyst. There are many materials that will chemically react with each other; when there is a question, reference should be made to NFPA's *Fire Protection Guide to Hazardous Materials,* 13th edition.

BURNING CHARACTERISTICS OF LIQUIDS THAT BURN

Because it is the vapors from flammable liquids that burn, the ease of ignition as well as the rate of burning can be related to such properties as the vapor pressure, flashpoint, boiling point, and evaporation rate. Liquids with vapors in the flammable range above the liquid surface at the stored temperature will have a rapid rate of flame propagation. Flammable and combustible liquids with flashpoints above temperatures at which they are stored have a slower rate of flame propagation, because it is necessary for the heat of the fire to sufficiently heat the liquid surface and form a flammable vapor-air mixture before the flame will spread through the vapor. There are many variables affecting the rate of flame propagation and burning, including environmental factors, wind velocity, temperature, heat of combustion, latent heat of vaporization, and barometric pressure.

Liquid hydrocarbons normally burn with an orange flame and emit dense clouds of black smoke. Alcohols normally burn with a clean blue flame and produce very little smoke. Certain terpenes and ethers burn with considerable ebullition (boiling) of the liquid surface, making it difficult to extinguish fires involving these substances.

Boilover, Slopover, and Frothover

Three specific conditions—boilover, slopover, and frothover—deserve special mention in regard to fires in open-topped tanks containing various types of oils.

Boilover. Boilover is a phenomenon that may occur spontaneously during a fire in an open-top tank containing certain types of crude oils. This may occur when the roof of a tank is blown off by an explosion, or when a floating roof is sunk to expose the crude. After a long period of quiescent burning, there is a sudden overflow or ejection of some of the residual oil in the tank. It is caused by boiling water that forms a quickly expanding steam-oil froth. The frothing results from the existence of the following three conditions, the absence of any one of which will prevent the occurrence:

1. The tank must contain free water or water-oil emulsion at the tank bottom. This situation will normally prevail in tanks storing crude oil.

2. The oil must contain components having a wide range of boiling points, such that when the lighter components have been distilled off and burned at the surface, the residue, with a temperature of 300°F (149°C) or over, is more dense than the oil immediately below. This residue sinks below the surface and forms a layer of gradually increasing depth which advances downward at a rate substantially faster than the rate of regression of the burning surface. This sets up the so-called heat wave, which is the result of localized settling of a part of the hot surface oil until it reaches the colder oil below. There is no heat conduction from the burning surface downward.
3. Sufficient content of heavier oils are present in the oil to produce a residue that can form a tough persistent froth of oil and steam.

NFPA records indicate the most serious loss-of-life tank fire in history occurred on December 19, 1982, in Tacoa, Venezuela. The storage tank, located a few miles northwest of Caracas in the small seaside village of Tacoa, supplied fuel to an electric generating plant. Two workers died upon ignition of the tank. After 6 hours of intense burning, the contents of the tank erupted into an extremely violent boilover. The final toll—160 people dead, hundreds more injured, others still unaccounted for, and damage estimated at $50 million. Fifty of those who died were fire fighters, which also makes the Tacoa incident the gravest of its kind in terms of loss of life of fire personnel (Figure 6.12.6).

Slopover. Slopover can result when a water stream is applied to the hot surface of a burning oil, provided the oil is viscous and its temperature exceeds the boiling point of water. Since only the surface oil is involved, a slopover is a relatively mild occurrence.

FIGURE 6.12.6 Emergency Personnel on the Scene of Storage Tank Fire Boilover in Tacoa, Venezuela, December 19, 1982. At this moment, the fire had been declared under control. Note the fire fighters on the top of the dike and the other personnel along the roadway fence. The boilover occurred minutes after this photo was taken, and all of the people shown above were reportedly killed.

Frothover. Frothover refers to the overflowing of a container not on fire when water boils under the surface of a viscous hot oil. A typical example would be when hot asphalt is loaded into a tank car containing some water. The first asphalt is cooled by contact with the cold metal, and, at first, nothing may happen. But when the water becomes heated and starts to boil, the asphalt may overflow the tank car.

A similar situation can arise when a tank containing a water bottom or wet emulsion is used for storing oil slops or residium at temperatures below 200°F (93°C), and the tank receives a substantial addition of hot residium at a temperature of 300°F (149°C) or higher. After enough time has elapsed for the effect of the hot oil to reach the water in a tank, a prolonged boiling action can take place, which can remove a tank roof and spread froth over a wide area.

Burning Rates of Liquids That Burn

The burning rate of flammable liquids will vary somewhat similar to the rate of flame propagation. Gasoline, a compound of light and heavy fractions, will burn more rapidly at first while the lighter fractions are burning, whereas the heavier fractions will burn at a rate approaching that of kerosene. The burning rate for gasoline is 6 to 12 in. (150 to 300 mm) of depth per hour, and for kerosene the rate is 5 to 8 in. (130 to 200 mm) of depth per hour. For example, a pool of gasoline ½ in. (12.7 mm) deep could be expected to burn itself out in 2½ to 5 minutes.

In a series of tests conducted at the U.S. Bureau of Mines,[14] the burning rates of several liquids and gases were determined and found to approach "a maximum and constant value with increasing pool diameter. This constant burning rate is proportional to the ratio of the net heat of combustion to the sensible heat of vaporization."[14]

Based on these observed burning rates in petroleum tank fires, an estimate can be made of the extent of area that will be involved in fire from a petroleum spill. When a spill is burning, the fire area will first be small and then spread to a point of equilibrium where it will burn as fast as it is released. At a burning rate of 1 ft/hr (0.3 m/hr), 1 gal/min (3.8 L/min) of spillage will reach an equilibrium burning area of about 8 ft^2 (0.74 m^2). Thus, a 10 gpm (38 L/min) spill rate will be in equilibrium with 80 ft^2 (7.4 m^2) of burning area; 100 gpm at 800 ft^2 (380 L/min at 74 m^2); and so on. For liquids having higher burning rates, the area would be smaller; and for those liquids having lower burning rates, the area would be larger. Also, the terrain will have an influence on the shape of the burning area.

FIRE PREVENTION METHODS

When flammable and combustible liquids are stored or handled, the liquid is usually exposed to the air at some stage in the operation, except where the storage is confined to sealed containers that are not filled or opened on the premises or where handling is in closed systems and vapor losses are recovered. Even when the storage or handling is in a closed system, there is always the possibility of breaks or leaks, which permit the liquid to escape. Therefore, ventilation is of primary importance to prevent the accumulation of flammable vapors. It is also good

practice to eliminate sources of ignition in places where low-flashpoint flammable liquids are stored, handled, or used, even though no vapor may ordinarily be present.

Whenever possible in manufacturing processes involving flammable or combustible liquids, equipment, such as compressors, stills, towers, and pumps, should be located in the open. This will lessen the fire potential created by the escape and accumulation of flammable vapors. Gasoline and almost all other flammable liquids produce heavier-than-air vapors, which tend to settle on the floor or in pits or depressions. Such vapors may flow along the floor or ground for long distances, be ignited at some remote point, and flash back. The removal of such vapors at the floor level (including pits) is usually the proper method of ventilation. Convection currents of heated air or normal vapor diffusion may carry even heavy vapors upward, and, in such instances, ceiling ventilation may also be desirable. Ventilation to eliminate flammable vapors may be either natural or artificial. Although natural ventilation, which depends on temperature and wind conditions, has the advantage of not being dependent on manual starting or on power supply, it is not so easily controlled as is mechanical ventilation. Mechanical ventilation should be used wherever there are extensive indoor operations involving flammable and combustible liquids.

Explosion Venting

In rooms or buildings where possible explosions of flammable vapors may occur, it is recommended that relief through explosion venting be provided for at least Class IA liquids and unstable liquids.

Substitution of Less Combustible Liquids

The hazard created by flammable liquids may be avoided or reduced by the substitution of relatively safer materials. Such materials should be stable, have a low toxicity, and either be nonflammable or have a high flashpoint. For example, trichloroethylene, though higher in price, is nonflammable at ordinary temperatures and may for some uses be substituted for a more hazardous flammable solvent. Tetrachloroethylene (perchloroethylene) is another nonflammable liquid. However, even though these products are less toxic than carbon tetrachloride, they should be used only in well-ventilated areas, with full vapor recovery and controls to prevent release to the atmosphere.

There are several commercial-type stable solvents available that have flashpoints from 140 to 190°F (60 to 88°C) and that have a comparatively low degree of toxicity.

Specially refined petroleum products, first developed as "Stoddard Solvent" but now sold by different companies under a variety of trade names, have solvent properties approximating gasoline, but with fire hazard properties similar to those of kerosene. A danger in their use lies in the possibility that persons believing that they are using a safe solvent without fire hazard may neglect ordinary precautions that would be observed with a liquid such as kerosene. When heated to above their flashpoint [about 100°F (37.8°C)], these solvents produce vapors as flammable as those of gasoline at its flashpoint temperature.

Several other types of commercial solvents which are mixtures of liquids with differing rates of evaporation are available. Some are mixtures of gasoline or one of the various naphthas and a chlorinated solvent having a different and often higher evaporation rate than the flammable solvent which, over a period of time, would leave the original low flashpoint solvent. These mixtures create a toxicity hazard, as well as a fire hazard, and their use in open containers should be discouraged.

Solvents and solvent vapors are toxic in varying degrees, and ventilation is almost always necessary to keep vapor concentration within safe limits.

SUMMARY

The hazards and fire protection of flammable and combustible liquids are a function of the liquids' physical properties and characteristics, as well as fire characteristics (flashpoint, ignition temperature, boiling point, and flammable limits). Effective methods for preventing fires in flammable and combustible liquids include preventing or reducing the accumulation of flammable vapors through ventilation, explosion venting, and substitution of less flammable liquids.

Fighting Fires in Plastics

Key Terms

cellular plastic, cellulose nitrate, elastomer, fire-retardant treatment, flame-retardant treatment, plastic, polymeric material, rubber, rubber (natural), rubber (synthetic), thermoset

Since World War II, the types, variations, and uses of plastics have proliferated at a tremendous rate, producing a family of materials that is extraordinarily complex and varied. Each of the variations can be considered combustible. Some burn very rapidly and under certain conditions present extreme hazards to life and property. When such hazardous characteristics are identified, modifications can be made in manufacture and application that can reduce the hazard to acceptable levels. For example, cellulose nitrate motion picture film presents the hazard of flash burning. This hazard was controlled by phasing out the cellulose nitrate film and replacing it with slow-burning acetate "safety film." More recently, the hazards of cellular plastics, such as polyurethane and polystyrene, which were used for exposed interior finish in buildings, have been controlled by using flame-retardant additives during manufacture combined with thermal barriers installed in the field.

This chapter focuses on the fire behavior of polymeric materials that are used as building materials and on the characteristics of polymers in general. The tests that are used to identify the relative hazards from fire and smoke of plastics used in building applications are also discussed.

Although part of the family of polymers, natural and synthetic rubbers, technically, are not plastics. Yet, because of the many similarities and the formulations that intermix the traditional characteristics of plastics and elastomers, rubbers are included in this chapter. It should be understood, however, that rubber has a whole complex technology of its own—one that predates the modern plastics industry.

For related topics, see Section 6, Chapter 5, "Fibers and Textiles"; and Section 9, Chapter 4, "Plastics Industry and Related Process Hazards." See also Section 6, Chapter 2, "Combustion Products and Their Effects on Life Safety"; and Section 21, Chapter 10, "Marine Vessels."

TERMINOLOGY

The following terms are used in this chapter or are commonly encountered in the application, use, and storage of polymeric products.

Additive: Any material mixed with a resin or compounded with rubber to modify its processing or end-use properties. If the main ingredient is a resin, the resulting mix usually is called a *plastic* to distinguish it from the "resin." Additives may be dyes, pigments, powdered fillers for stiffening, plasticizers for flexibility, fibers to reinforce, antioxidants, lubricants to aid flow into or release from a mold, or flame retardants.

Binders: The resins in a plastic mixture that hold together all of the other ingredients. They are usually a product of polymerization or a naturally occurring substance of high molecular weight.

Blowing Agent: A material that releases gas upon heating so that the plastic in which it is mixed will expand into foam. The gas may result from boiling of a liquid or from decomposition of the blowing agent. (See also "Foaming Agent.")

Copolymers: High-molecular-weight compounds produced when two or more monomers are involved in a polymerization process.

Robert P. Benedetti, P.E., CSP, is principal flammable liquids engineer at NFPA and is responsible for standards development in the area of flammable and combustible liquids.

Guy R. Colonna, P.E., is assistant vice-president for fire protection applications and chemical engineering at NFPA.

Cross-Linking: The process of establishing chemical bonds between adjacent molecules to make a network that will reduce solubility or resist flow on heating. The amount of cross-linking may be enough to render the plastic highly resistant to flow at temperatures up to thermal decomposition, in which case the plastic is said to be a thermoset.

Fillers: Materials that modify the strength and working properties of a plastic. Fillers may be used to increase heat resistance or alter the dielectric strength, for example. A wide variety of products are used, including wood, flour, cotton, sisal, glass, and clay.

Film: A general term for polymeric materials not more than 0.01 in. (0.25 mm) thick, regardless of the process used to make them.

Foam: Any polymeric material having a low-density, cellular structure. The cellular structure can be either open or closed.

Foaming Agent: Synonymous with "Blowing Agent."

Inhibitor: Any material added to prevent or retard an undesired chemical reaction.

Laminate: A composition of two or more layers of polymeric material firmly adhered either by partly melting one or more of the layers, by an adhesive, or by impregnation. High-pressure laminates are rigid stock made in presses at pressures above 400 psi (2760 kPa).

Monomers: The starting molecules, usually gaseous or liquid, used to produce polymer resin.

Plastic (ASTM Definition): A material that contains as an essential ingredient one or more organic polymeric substances of large molecular weight, is solid in its finished state, and at some stage in its manufacture or processing into finished articles can be shaped by flow.

Plasticizers: Organic materials added to plastics to make the finished product more flexible or to facilitate compounding. Some plasticizers increase the combustibility of the plastic whereas others serve as flame retardants.

Polymerization: The process by which molecules of a monomer are made to add to themselves or to other monomers in a repetitive way, forming a much longer chainlike molecule.

Polymers: Large molecules made by combining smaller molecules by chemical reaction.

Reinforced Plastic: A plastic with a filler that significantly increases flexural, impact, or tensile strength. Additives used for reinforcement include glass, asbestos, cotton, or nylon fibers.

Resin (ASTM Definition): A solid or pseudosolid organic material, often of high molecular weight, which exhibits a tendency to flow when subjected to stress, usually has a softening or melting range, and usually fractures conchoidally. *Note:* In a broad sense, the term is used to designate any polymer that is a basic material for plastics.

Sheet: A general term for plastics 0.01 in. (0.25 mm) and thicker, regardless of the method of manufacture.

Stabilizer: A material added to prevent or retard an undesired chemical reaction. When used to prevent polymerization, the preferred term is *inhibitor.* Stabilizers usually comprise less than 1 percent of the total weight. They may be antioxidants, screening agents for ultraviolet radiation, or chemicals to neutralize decomposition products during hot processing.

Thermoforming: The process of stretching or bending a plastic sheet that has been softened by heating.

Thermoplastic (ASTM Definition): A plastic that can be repeatedly softened by heating and hardened by cooling through a temperature range characteristic of the plastic and that in the softened state can be shaped by flow into articles by molding or extrusion.

Thermoset (ASTM Definition): A plastic that, after having been cured by heat or other means, is substantially infusible and insoluble.

THE FAMILY OF POLYMERS

In the classification of engineered materials, polymers are one division under the general category of nonmetals, which also includes ceramics, glasses, and materials such as oils, greases, lubricants, and papers. Polymers are further subdivided into three classes—elastomers, thermosets, and thermoplastics—as shown in Figure 6.13.1. Basically, polymers are characterized by their very large molecules, formed in chemical "polymerization" reactions, which link small molecules into larger molecules. These larger molecules contain repeating structural units of the original molecules. If the linkages result in a rigid "cross-linked" molecular structure, a thermosetting plastic results. If the molecular structure is more flexible, including side chains not rigidly linked to the other molecules, the resulting material is a thermoplastic.

The products known as "plastics" include the common types of thermosetting and thermoplastic polymers included

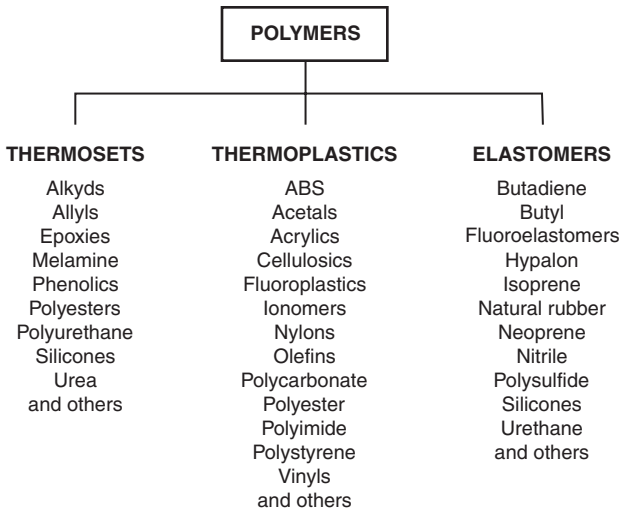

FIGURE 6.13.1 The Family of Polymers

in Figure 6.13.1, plus many more. In addition to the polymer constituent, most finished plastics contain plasticizers, colorants, fillers, stabilizers, reinforcing agents, lubricants, or other special additives. The variation of individual plastics-product formulations runs into the thousands. The ultimate form of each product, whether it appears in solid sections, films and sheets, foams, molded forms, synthetic fibers, pellets, or powders, has a significant effect on its fire properties. Additionally, fire properties are influenced by the environment, and the resultant hazard by the quantity of the product and the conditions of its use. For these reasons, it is important to conduct fire tests of products in their end-use configuration and under conditions that simulate the end-use environment.

Elastomers

Elastomers are commonly referred to as *synthetic rubbers* and are characterized by their elastic or rubberlike properties. As a whole, this class of polymers is intended to reproduce or surpass the best properties of natural rubber for particular applications. The fire characteristics of elastomers are usually similar to those of natural rubber. A discussion of both natural and synthetic rubbers is included in this chapter.

Thermosetting Plastics

Thermosetting plastics, or thermosets, are hardened into a permanent shape in the manufacturing process. These materials cannot usually be softened by heating. For those that can be softened, they cannot be remelted or restored to their original state before they were cured. The components of thermosets can be purchased in liquid form as either monomer/polymer mixtures or as partially polymerized molding compounds. Thermosets are usually formed into their final shape with heat (sometimes under pressure), although some are cured at room temperature.

Thermoplastics

Thermoplastics do not cure or set into a permanent shape under the application of heat, since heat will cause them to soften. They can be softened and rehardened repeatedly, although eventual thermal aging will cause a degradation of the material and limit the number of reheat cycles. When heated to a flowable state, thermoplastics can be transferred to a mold and cooled into the shape of the mold. Thermoplastics can be extruded through dies and solidified around other materials, such as insulation over electrical wiring. Generally, no chemical reaction takes place.

There is some overlap between thermosets and thermoplastics. Thermoplastics, after extrusion, can be cross-linked chemically or by irradiation to produce a thermoset product. The molding techniques typical of thermoplastics have been modified to permit injection molding of thermosets, such as phenolics.

USES OF PLASTICS

Plastics have wide-ranging and continuously expanding applications. In building construction applications, plastics can be found in thermal and acoustical insulation, roofing materials, decorative trims and imitation wood parts, ceiling and wall panels, resilient flooring, light fixture diffusers, electrical conduits, insulation on wiring, water and gas piping, bathtubs and sinks, and heating ducts. Plastics are found in the housings and parts of equipment and appliances. Entire pieces of furniture, seat cushions, mattresses, carpeting, wall coverings, and draperies are often plastics, as are countertops, desktops, and tabletops. Textiles in clothing today often are partially or totally plastics products. Other uses of plastics include major parts, trim, and interiors of automobiles, buses, airplanes, and trains; packaging materials, including plastic wrap; housewares; sports equipment; toys; photographic films; magnetic tapes; phonograph records; and luggage.

Lack of stability under high temperature and inherent combustibility so far have ruled out the use of plastics for applications where fire-resistance ratings are a requirement. One exception is the use of special silicone plastic foams for sealing openings in fire walls; the material retains its sealing and insulating properties while it slowly burns away during fire exposure.

ADDITIVES AND BLENDS

The physical properties of the basic types of polymers can be altered substantially during manufacturing by a variety of techniques. An extraordinary number of combinations of special properties are obtainable through the blending, or alloying, of one polymer with another. Additives, such as carbon black, glass fibers, flame retardants, and fillers ranging from cotton to clay, can alter not only the strength and other properties needed for the finished product but also the response to heat and flame.

Fiberglass and other threads added to plastics (usually, polyethylene) are used in the manufacture of fiber-reinforced plastic (FRP) products, such as boat hulls, motor vehicle body panels, fishing rods, skis, swimming pools, bathtubs, shower enclosures, building panels, and translucent roofing and siding. Although flame retardants can be added to lower the ASTM E84, *Standard Test Method for Surface Burning Characteristics of Building Materials,* flamespread index to a range of 20 to 75, general-purpose FRP panels and other products are likely to have much higher surface flamespread ratings, in the range of 150 to 400.[1]

MAJOR GROUPS OF PLASTICS

The major groups of plastics are briefly described in the following paragraphs. Hundreds of variations are sold under thousands of individual trade names. More detailed information can be obtained from consulting the standard reference works of the industry (see references at the end of this chapter).

Positive identification of the plastic used in a product is often very difficult. Guidelines are available to assist in the identification of the more common types. Braun[2] sets forth simple laboratory tests using heat (pyrolysis), flame, and melting, compiled in a small, easy-to-read reference volume. Saechtling's plastics identification material is included (Figures 6.13.2 through 6.13.5).[2,3] Figure 6.13.6 presents a number of simple

tests that take advantage of the unique characteristics that many common plastics possess.[4]

According to Saechtling,[3] plastics can be divided into four groups that reflect their derivation, method of synthesis, and historical development: (1) plastics from natural products, starting with vulcanized fiber in 1859, celluloid in about 1870, and artificial horn in 1897 as the oldest plastics (Figure 6.13.2); (2) "classical" condensation resins, including thermosets stemming from the discovery of Bakelite in about 1910 (Figure 6.13.3); (3) Staudinger polymerized plastics, deriving from foundations in 1922 for the polymerization of unsaturated monomers into long-chain macromolecules (Figure 6.13.4); and (4) plastics from multifunctional aliphatic and aromatic intermediate products, derived from work since the 1950s in combining various intermediates into a series of general-purpose and specially tailored engineering plastics (Figure 6.13.5).

Commonly accepted abbreviations have been developed for many plastics materials, and some of these have been standardized in ASTM D1600, *Standard Terminology for Abbreviated Terms Relating to Plastics*.[5] Manufacturers are being urged to offer the abbreviation along with trademark names to aid in the rapid identification of the material. This is particularly important for plastics products used in building construction. For the purposes of this text, the abbreviation is noted either in parentheses in the heading or after the name of the plastic in the descriptions that follow.

ABS Plastics: Developed to offset some of the shortcomings of polystyrene, ABS plastics are copolymers of acrylonitrile, butadiene, and styrene monomers in varying proportions. They are balanced for mechanical toughness, good service temperature for other-than-high temperature applications, and ease of fabrication. ABS materials have relatively good electrical insulating properties, good resistance to a wide range of chemicals, and good dimensional stability. Typical applications include automobile dashboards, pump impellers, refrigerator parts, appliance housings, luggage, protective helmets, battery cases, telephones, pipe and fittings, shoe heels, knobs, and tool handles.

Acetals (AR): Acetal resins are made primarily by the polymerization of formaldehyde. Copolymers of acetal are also produced. These materials form one of the strongest and stiffest thermoplastics. The products show good resistance to organic solvents; however, they do react with strong acids or bases. These plastics are widely used for equipment gears, automotive equipment, plumbing parts, and appliances. Two basic types are (1) a homopolymer and (2) a copolymer.

Acrylics: Acrylics are based on any of a number of acrylate and methacrylate monomers. One member of the family, polymethyl methacrylate (PMMA) is known for its excellent clarity, high transparency, good resistance to sharp blows, strength, and rigidity. It is odorless, tasteless, and nontoxic, but the surface scratches easily and contact with grit and harsh scouring agents must be avoided. Because it is a thermoplastic, it loses its shape in boiling water, although some cast acrylics have higher heat resistance. In sheets of varying thickness and color, PMMA is used for glazing, building panels, advertising displays, and protective shields. Solutions and emulsions of PMMA are produced for use as surface coatings, adhesives, and finishes. In rods and tubes, it is used for electric lighting and medical illuminating equipment, which utilize its capacity to transmit light along

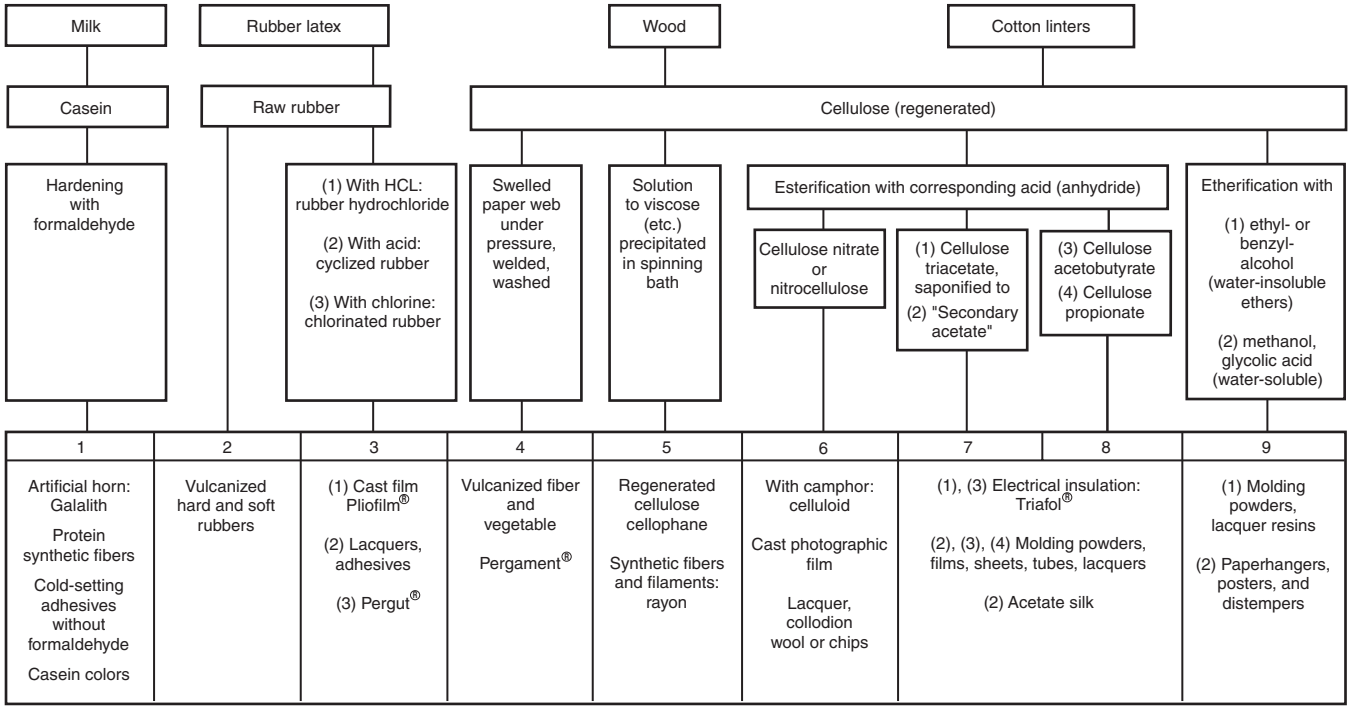

FIGURE 6.13.2 Plastics from Natural Products

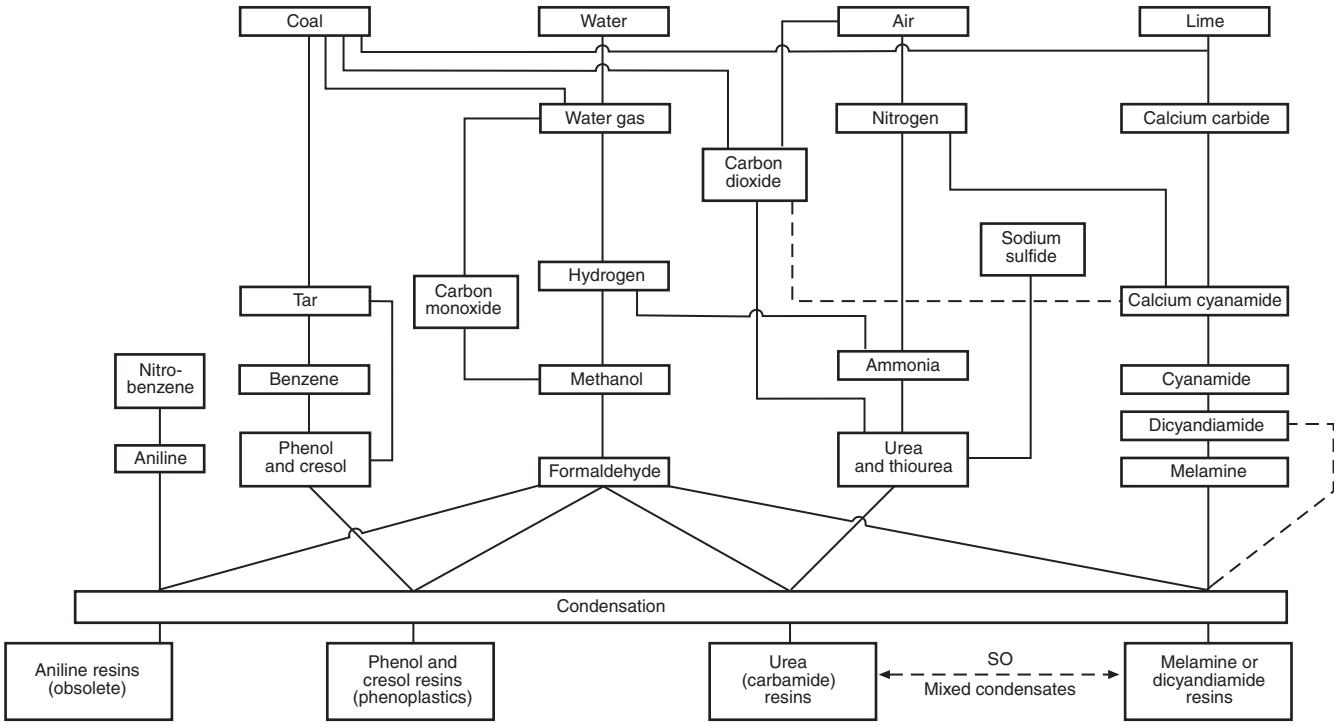

FIGURE 6.13.3 Condensation Resins—Thermosets

its length and around curves. In its molded form, it is used for lenses, dentures, toilet articles, and telephones.

Alkyds: Good insulating properties, excellent moldability, short cure time, and low cost are primary reasons for the use of thermosetting alkyds in electrical materials, such as housings and cases for switchgear, encapsulation of capacitors and resistors, and parts for fuses, light switches, and insulators. Maximum use temperature of the molded parts is 250 to 300°F (120 to 150°C). Liquid resins are used for enamels and lacquers for cars, stoves, and refrigerators.

Allyls (Allylics): Allyl resins and monomers are thermosetting plastics that are commercially available as the diallyl esters of phthalic (DAP) and iso-phthalic (DAIP) acids. Other monomers in this grouping are diallyl maleate (DAM) and diallyl chlorendate (DAC). The latter is used for flame-resistant formulations because of the high chlorine content of the resins. Allyls can be polymerized by raising their temperature or by the use of peroxide initiators. The molding and electrical properties of these materials are excellent. They are primarily used for electrical components, decorative laminates, sealants, and coatings.

Cellulosics: Cellulosic plastics are produced by the chemical modification of cellulose, a natural polymer that is a major constituent of plant life. The primary sources of cellulose for this purpose are cotton linters and wood pulp. The term *cellulosic plastics* applies only to plastics whose resinous content is an ester or ether of cellulose. Included in this group are cellulose acetate, cellulose acetate butyrate, methyl cellulose, cellulose triacetate, cellulose propionate, ethyl cellulose, cellulose nitrate, cellulose films, and fibers.

Cellulose Acetate (CA): A thermoplastic made by treating cellulose with acetic acid and acetic anhydride, with sulfuric acid as a catalyst. It can be formed into molding powder, foamed by rapid evaporation of a solvent, dissolved for lacquers, cast into film, and spun from solution into fibers. It has replaced hazardous cellulose nitrate for photographic use under the name "safety film" (see also cellulose triacetate). Cellulose acetate molding compositions are tough and of good color and gloss; hardness is controlled by varying the ratio of plasticizer and ranges from rigid to flexible. Primary uses are in electronic components, insulation tapes, food packaging, toys, eyeglass frames, and video and sound recording tapes. Rigid cellulose acetate foam is used as the core in sandwich panels and marine floats. Variations in composition include the degree of esterification of cellulose and amount and choice of plasticizer, which is usually a phthalate ester. Molding stocks for general purposes ignite easily, give off burning drips, burn with a dark yellow flame, produce moderate smoke, and have an odor of vinegar unless masked by the odor of the plasticizer. Flame-resistant stocks are widely used for molding.

Cellulose Acetate Butyrate (CAB): A plastic made by treating cellulose with a mixture of acetic and butyric acids and anhydrides in the presence of a catalyst. The ratio of acetic and butyric components can be varied to produce the desired flexibility. CAB absorbs less water than cellulose acetate. Compositions with ultraviolet stabilizers are used for small outdoor and indoor signs. Major uses are for automobile steering wheels and taillights, telephone handsets, toothbrush handles, business machine keys, appliance housings, piping, and tubing.

FIGURE 6.13.4 Double-Bond Polymerization Thermoplastics

Cellulose Propionate (CP): A thermoplastic molding composition made from cellulose and propionic acid. Molding compositions are usually supplied as granules or pellets, and finished articles can be fabricated by injection molding or extrusion. CP has uses similar to those of CA and CAB, but due to better surface hardness than that of CAB and less moisture sensitivity than that of CA, it is also used for mechanical pencils, telephones, and shoe heels.

Cellulose Triacetate (CAT): A thermoplastic made by reacting cellulose with acetic anhydride. It differs from cellulose acetate in chemical structure in that it consists of three acetate

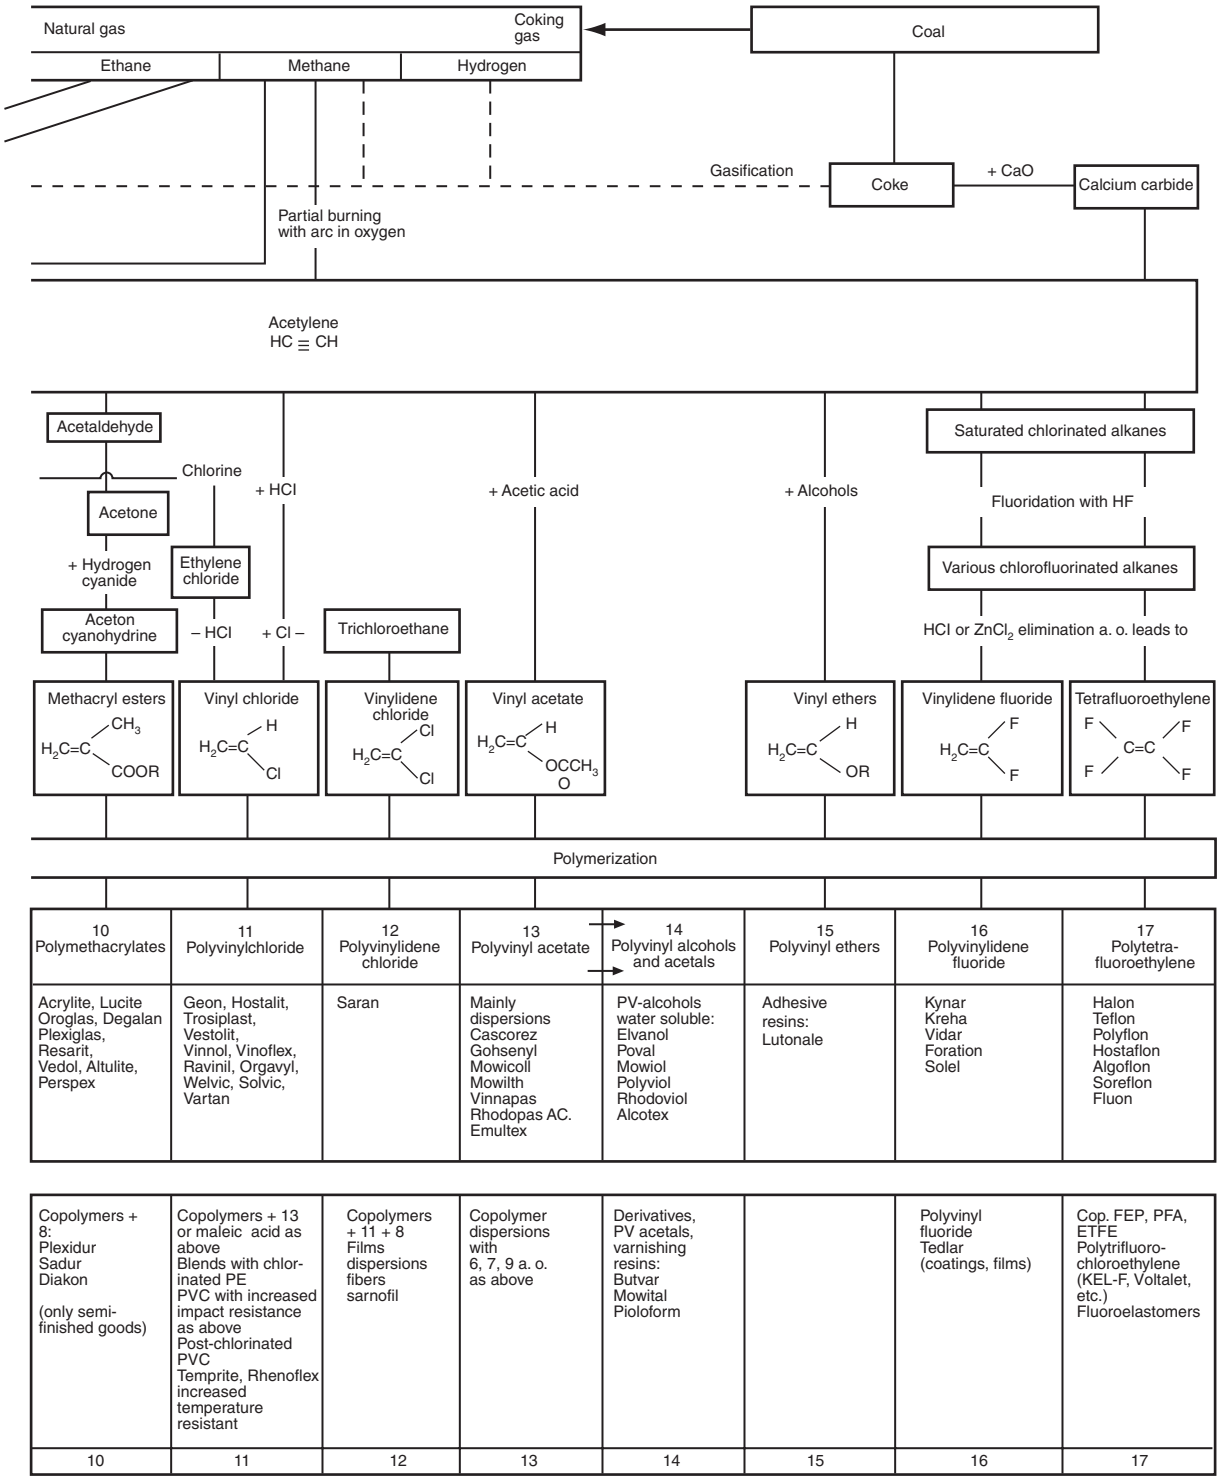

FIGURE 6.13.4 Continued

groups (instead of two) attached to each glucose unit of the cellulose molecule. Because of its high-softening temperature, it is not suitable as molding stock. It has lower water absorption than that of CA and is now the prevalent base for photographic safety film, drawing and printing film, magnetic tape, and transformer and capacitor dielectrics.

Cellulose Nitrate (CN): Because of the extreme fire hazards associated with cellulose nitrate in its processing, use, and storage, this plastic is discussed in detail later in this chapter.

Epoxies (EP): Epoxy resins are primarily produced by the reaction of epichlorohydrin and bisphenol-A in the presence of a

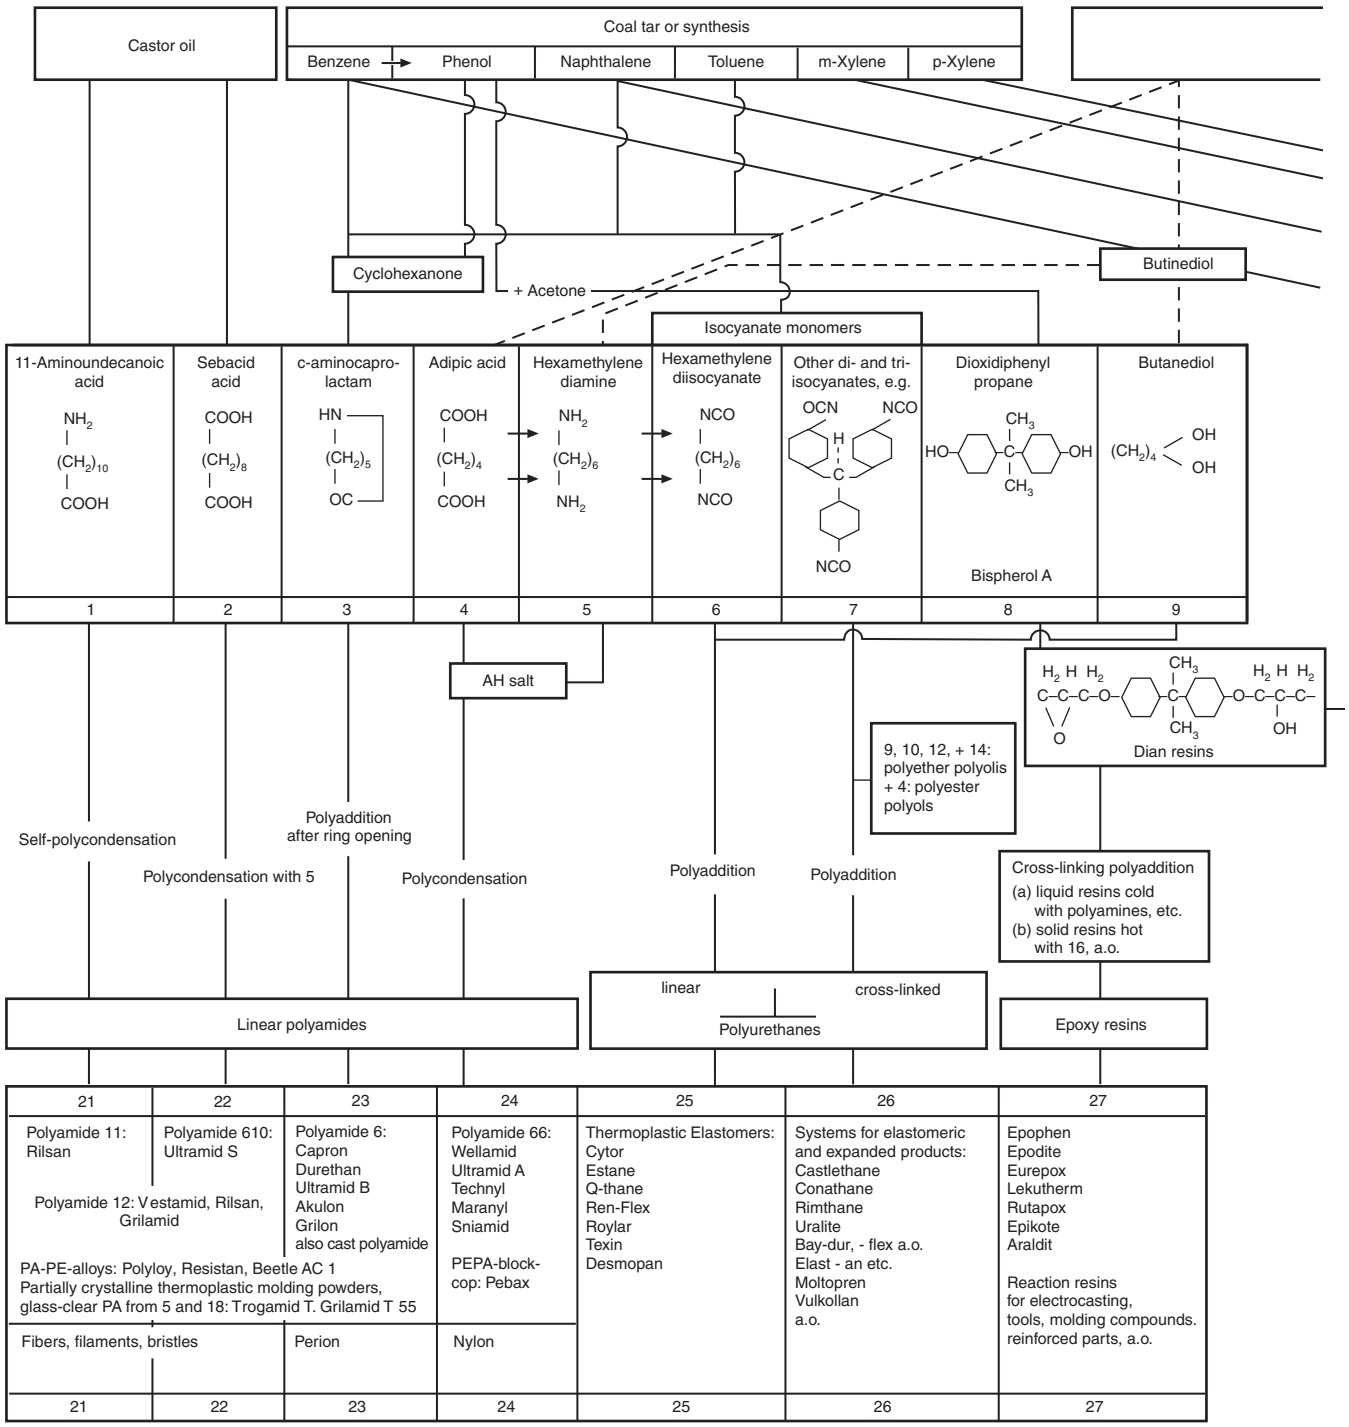

FIGURE 6.13.5 Plastics from Multifunctional Intermediate Products

catalyst. By varying the ratio of the ingredients, the resultant product may be a low-viscosity fluid or a high-melting solid. Two primary classes are available: (1) the liquid resins that are combined with curing agents for adhesives, potting, and tooling compounds, and (2) the solid resins that are modified with other resins to make coating materials. Epoxy resins also are used as "body solders" for automobile repair, as dies for forming sheet metal, as piping and tubing, and as foamed blocks for construction insulation.

Fluoroplastics: Fluoroplastics or fluorocarbons are commercially available in several major groups under the headings polyethylene-tetrafluoroethylene (ETFE), polyethylene-chlorotrifluoroethylene (E-CTFE), polytetrafluoroethylene (TFE), polyfluoroethylene-propylene (FEP), polychlorotrifluoroethylene (CTFE), polyvinyl fluoride (PVF), and polyvinylidene fluoride (PVF_2). All of these resins are characterized by resistance to solvents and chemical at-

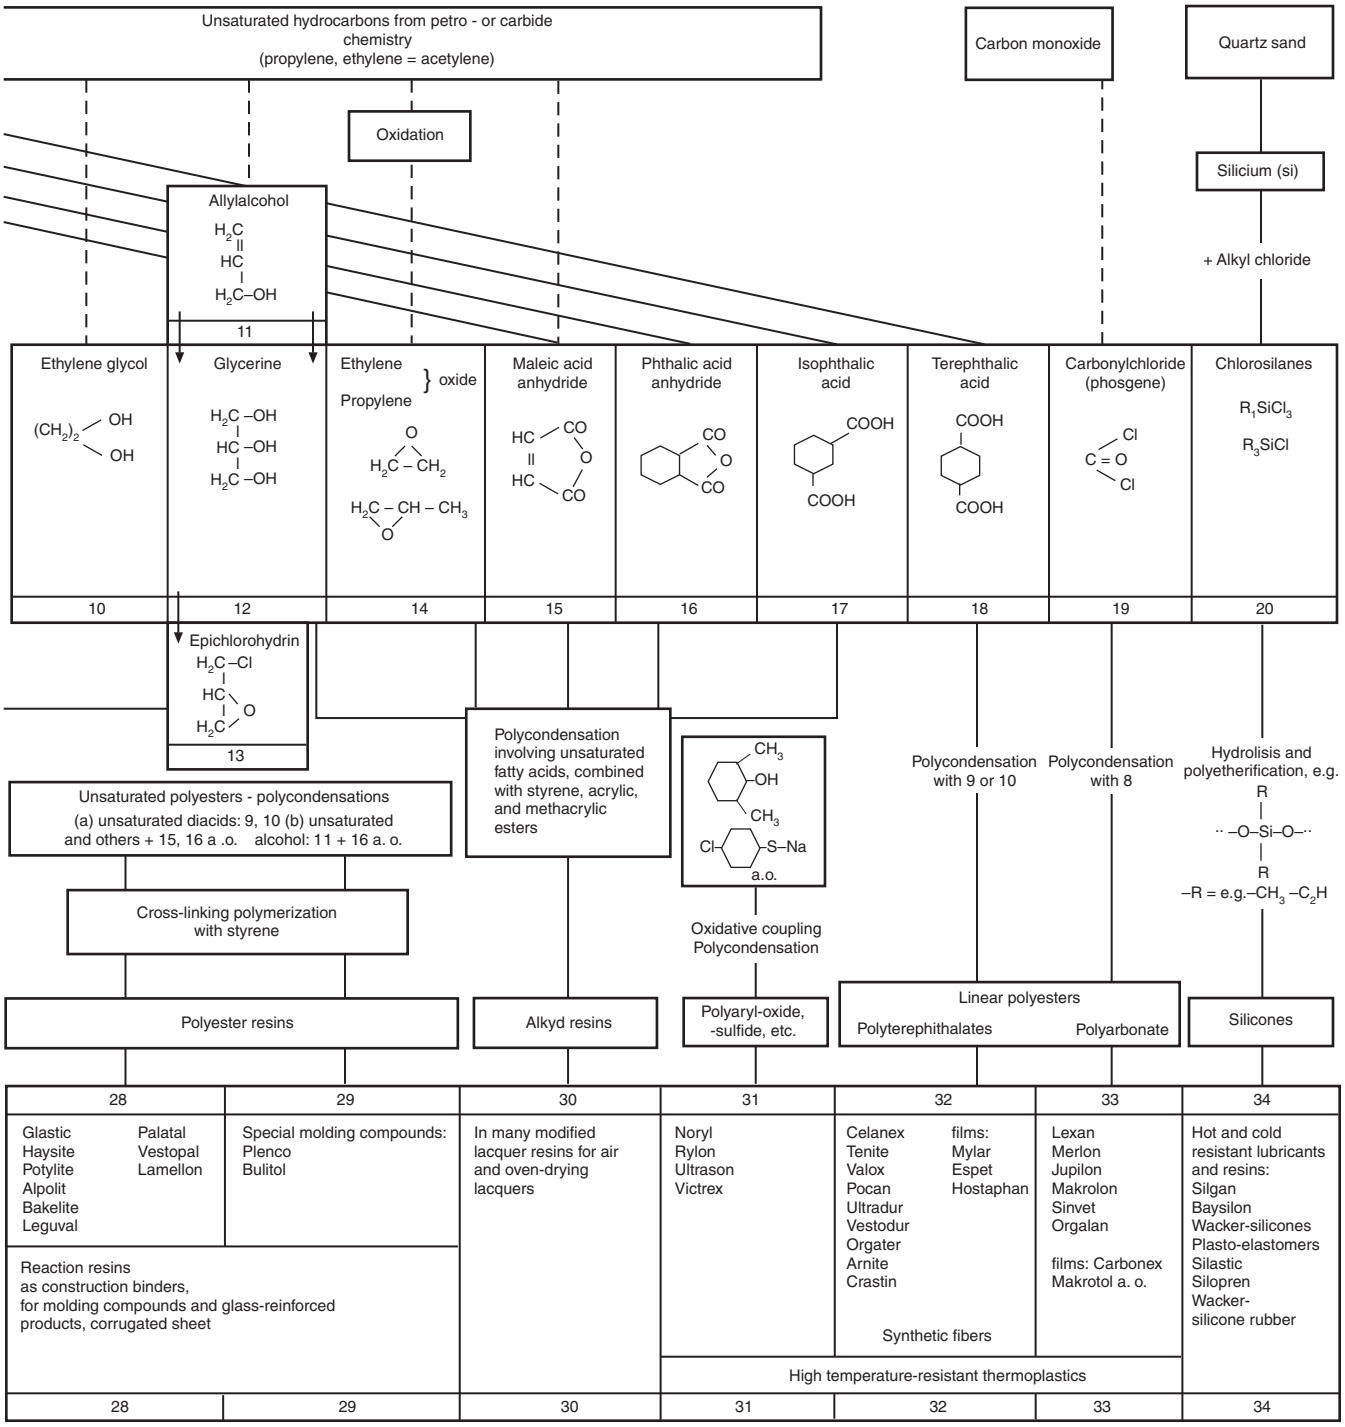

FIGURE 6.13.5 Continued

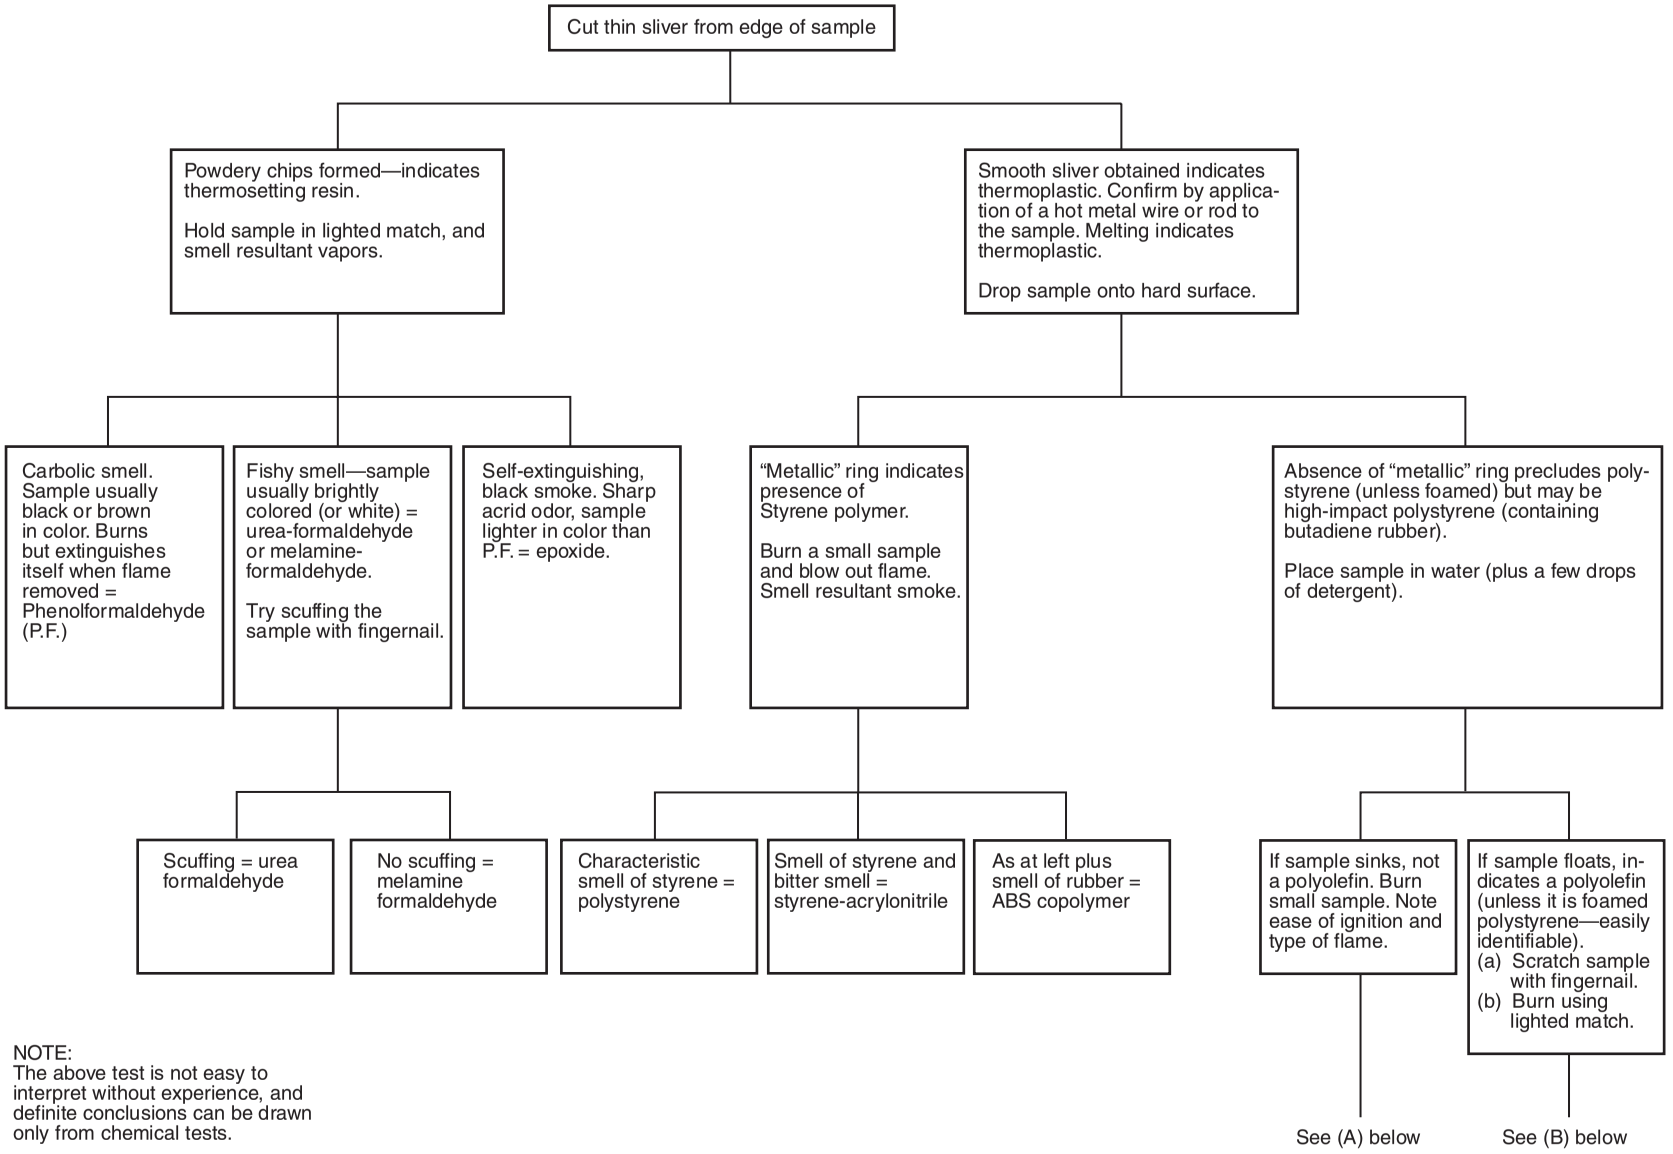
tack and good-to-excellent weatherability. Six are described below.

Polytetrafluoroethylene (PTFE): A representative of a group of completely fluorinated resins. It is handled as general-purpose molding powders, fine granules, and aqueous dispersions. The methods of processing include compression molding, extruding, dip coating, and film casting. PTFE has a very extended range of serviceable temperatures, from –450 to 500°F (–265 to 260°C). It is used as chemical gasketing, high-frequency and high-temperature electrical insulation, lubricants, and on molded bearings and coated cookware.

Polyfluoroethylene-propylene (FEP): A copolymer of tetrafluoroethylene and hexafluoropropylene. FEP can be handled through the melt-flow processes involved in extrusion and



NOTE:
The above test is not easy to interpret without experience, and definite conclusions can be drawn only from chemical tests.

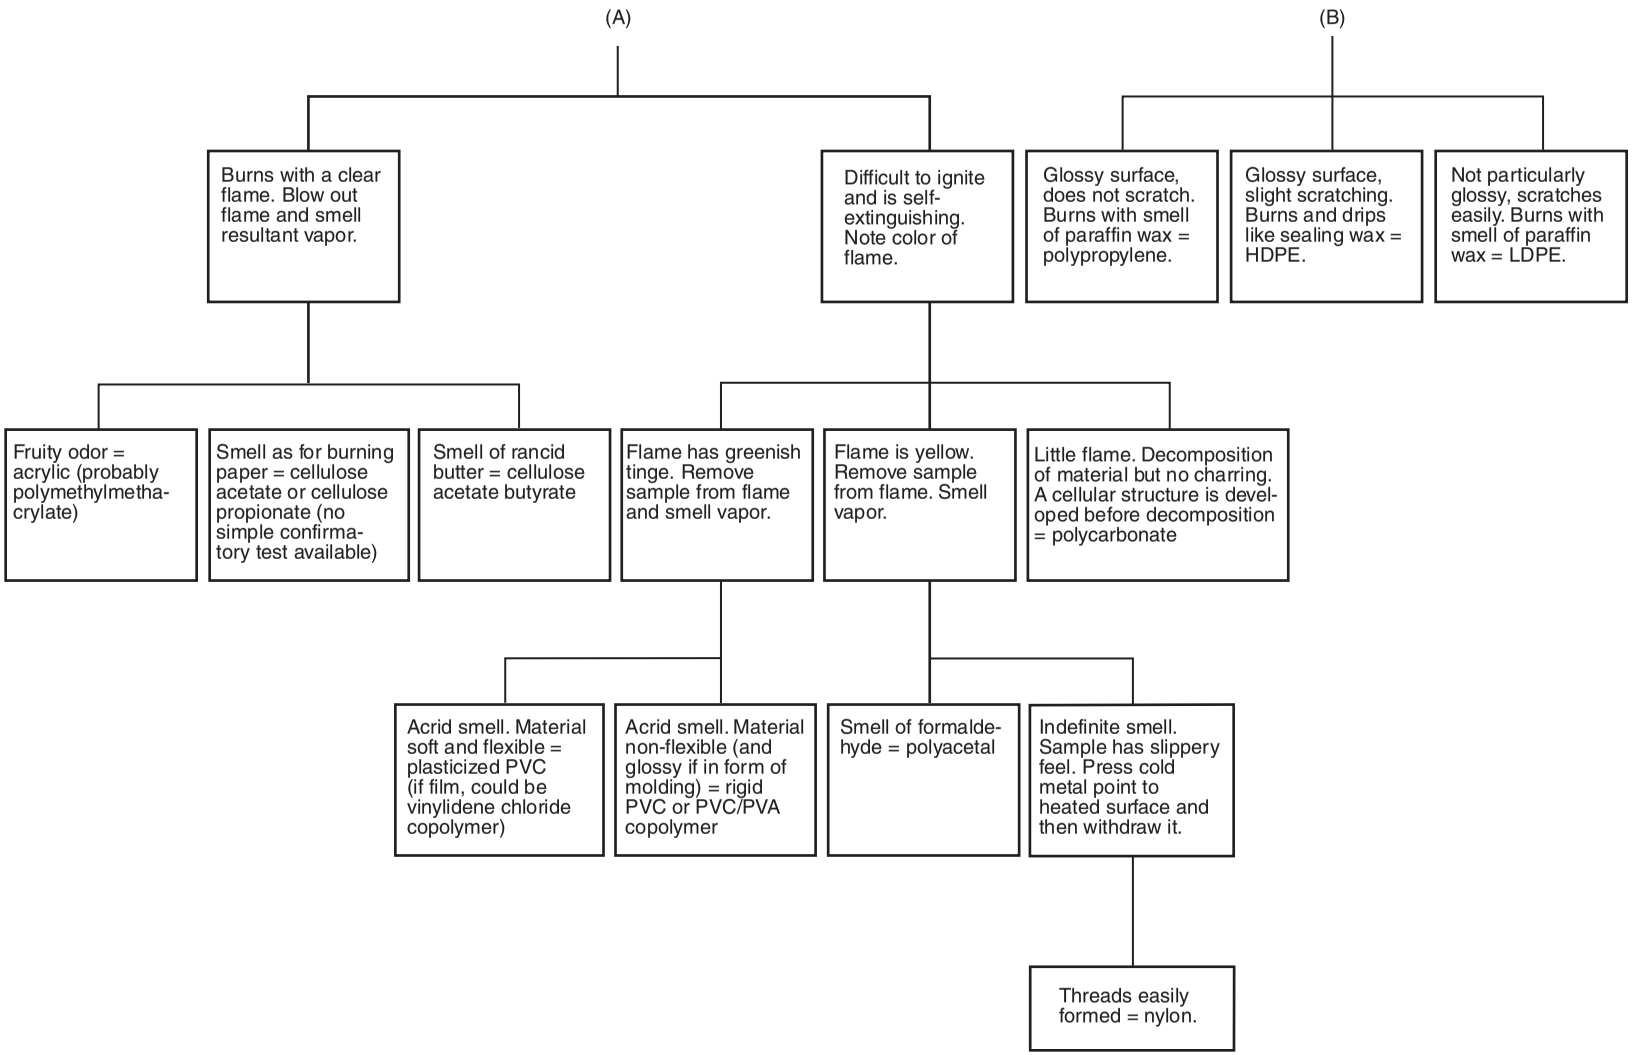


FIGURE 6.13.6 Simple Tests for Identifying the More Common Plastics

injection molding. It is widely used in industrial applications, particularly as insulation for process industries involving heat and corrosive atmospheres. It is also used as a lining for vessels, pipes, valves, and fittings handling corrosive fluids.

Polyethylene-tetrafluoroethylene (ETFE): A copolymer of ethylene and tetrafluoroethylene. It is processed by the conventional method of extrusion and injection molding. Its applications include use as gears, pump components, automotive parts, labware, valve linings, electrical connectors, and wire coatings. ETFE can be reinforced with glass fiber.

Polychlorotrifluoroethylene (CTFE): A thermoplastic resin produced in various formulations of fluoroplastics. It differs from the usual fluoroplastic in that its molecular structure contains chlorine. It flows like FEP for injection molding or extrusion, but is less thermally stable. It is chemically resistant to many corrosive liquids. Its serviceable temperatures range from –400 to 390°F (–240 to 200°C). Its electrical and thermal properties make it valuable for insulation, cable assemblies, printed circuits, and electronic components. It is also used in the chemical process industries in valves, fittings, and gaskets.

Polyethylene-chlorotrifluoroethylene (E-CTFE): A 1:1 copolymer of ethylene and chlorotrifluoroethylene. E-CTFE is processed by extrusion, molding, rotocast, and powder coating techniques. Applications include chemically resistant linings, coatings, containers, labware, moldings, wire coatings, fibers, and films.

Polyvinyl fluoride (PVF): A plastic produced through the polymerization of vinyl fluoride. Films are cast from selected hot solvents, and the major use is as a weather-resistant surface on building siding made of aluminum, wood, composite boards, or polyester glass fiber laminates.

Ionomers: The term *ionomer* is used to describe the class of thermoplastic polymers in which ionized carboxyl groups create ionic crosslinks in the intermolecular structure. Ionomer resin formulations are available in a wide variety of compositions. They are outstanding plastics, with regard to toughness, transparency, and solvent resistance, and they resist impact at temperatures as low as –160°F (–107°C). Articles made from these plastics include housewares, toys, containers, safety shields, tool handles, electrical insulation, and packaging. These plastics are also used in the lamination of various building construction materials.

Melamines (MF): Melamine, one of the members of the amino family, is a thermosetting plastic noted for its extreme hardness, permanent colors, and good electrical insulating characteristics. Alpha-cellulose filled, general-purpose grades are used for dishes and kitchenware, where their lack of taste and odor and resistance to food stains make them particularly desirable. Mineral-filled grades are used in electrical applications. The resin may be bonded with fabrics, paper, wood veneers, etc., to produce laminates for building applications.

Nylon: See polyamides.

Olefins: See polybutylene, polyethylene, polyallomers, and polypropylene.

Phenolics (PF): The discovery of phenol formaldehyde plastics (Bakelite™) in about 1910 marked the beginning of the plastics industry. Many varieties are now available, marked by low cost and good mechanical, electrical, and thermal properties. General-purpose, wood-filled grade phenolics are suitable for use up to about 300°F (150°C), but glass- or mineral-filled compounds have long-term retention of properties up to approximately 500°F (260°C). Some special, heat-resistant types are usable for up to 1 hour at temperatures as high as 1000°F (540°C).

Paper or fabric impregnated with phenolic resin in a water or organic solvent can be wound into tube form or pressed into flat sheets to make tough thermoset "laminates" with low water absorption and high service temperature capabilities. Laminates are used for electrical insulation and bearings for marine propellers and heavy rolling mills. Similar compositions are used as laminating adhesives for exterior-grade plywood and as impervious surfacing materials. Paper impregnated with phenolic resin and printed with wood grain is frequently the top surface for wall panels or furniture, with backing of other phenolic laminates or plywood. Phenolics are standard binders for brake shoes, sandpaper, grinding wheels, sand-casting foundry molds, and wood chip particleboard.

Two types of phenolic foam—reaction foam and syntactic foam—are used in construction or for thermal insulation. Reaction foam is made by curing the phenolic resin with agitation so rapid that water is produced as a byproduct, and is vaporized and trapped to make the voids in the foam. Syntactic foam is made from hollow spheres of phenolic resin with a phenolic or other resin binder. Each type is used for cores in sandwich panels and as buoyancy or a stiffening means in marine and aircraft structures. Cast phenolic resin is largely used for decorative applications.

Polyallomers: Polyallomers are made by polymerizing two monomers with catalysts so that blocks of each polymer are formed in the polymer chain. The most common polyallomer contains ethylene and propylene. Applications for polyallomers include films, bottles, appliance parts, automotive parts, toys, and closures.

Polyamides: Two aliphatic polyamides—nylon-6,6 and nylon-6—find their greatest uses in home furnishings and apparel, and account for most of the production in this family of polymers. The manufacture of nylon-6,6 started in 1938, and nylon-6 in 1939. The first major application was in the hosiery market. Nylon has become one of the leading polymers due to its high-impact strength, versatility, and ease of processing. Other forms of nylons are also commercially available and find application in ropes, fishlines, cable jacketing, gears, slide fasteners, boat propellers, and appliance parts.

Aromatic polyamides are more heat resistant. Their commercial production started in 1961 with Nomex™ and, more recently, Kevlar™ fiber. Nomex™ is found in items such as fire fighter's protective clothing, whereas Kevlar™ is ideally suited for tires and ballistic vests because of its strength. Kevlar™, together with graphite, is finding a use in superior composite materials, such as fiber-reinforced plastics (FRP). Polyamide imides and polyimides are other members of this grouping, typically used for heat-resistant electrical wire and cable insulation.

Polybutylene (PB): Polybutylene is flexible, has excellent creep resistance at room and elevated temperatures, and has higher long-term temperature resistance than other polyolefins. Other advantages include good toughness, high tear strength, and good moisture barrier and electrical insulation characteristics. Applications include film and sheeting, hot-melt coatings and adhesives, flexible pipe and tubing, and shrink film.

Polycarbonates (PC): Polycarbonates are thermoplastic polyesters of carbonic acid. The resin is available in several different forms, including pellets, powder, film, sheet, rod, plate, and tubing. High-impact strength, good electrical properties, clarity, and resistance to creep have caused this material to find many applications, such as in appliances, electrical and electronics equipment, food-handling systems, and sporting goods. Its transparency makes it useful for lenses, safety shields, and glazing.

Polyester, High-Temperature Aromatic: Important characteristics of this material are its dimensional stability at high temperatures (over 600°F [315°C]), self-lubricating properties, good stiffness, electrical insulating properties, and solvent resistance. It decomposes rapidly at approximately 1000°F (540°C). An unusual aspect of this thermoplastic is its very high thermal conductivity, which makes the material useful in applications, such as bearings and electrical insulation, where failure from localized hot spots is a problem with most plastics. Stick-free coatings for frying pans and encapsulation of electronic parts are among its other uses.

Polyesters, Thermoplastic: Unsaturated polyesters show good weathering resistance, light stability, and heat resistance. Their primary application is in the production of reinforced plastics. They are used to fabricate structures ranging in size from electrical components to large boat hulls. Saturated polyesters do not have the double bond that would permit further polymerization by treatment with initiators, such as organic peroxides. Saturated polyesters of high molecular weight, such as ethylene glycol terephthalate, are used principally in fiber and film production, for example, magnetic recording tapes, tough or boil-in-bag food packaging, and satellite balloons. They can be backplated with metals for decorative films and nameplates. The low-molecular-weight esters are used as plasticizers for vinyl and acrylic resins.

Thermoplastic polyester molding compositions are available. Besides poly (ethylene-terephthalate)—PET, there are poly (1,4-butylene-terephthalate)—PBT, poly (tetramethylene-terephthalate)—PTMT, and poly (cyclohexylenedimethylene-terephthalate-isophthalate)—PCDT. PBT and PTMT are the same chemically. Thermoplastic polyesters have engineering applications, including automotive parts, appliance parts, business machine parts, electrical and electronic parts, gears, bearings, pulleys, and pump components. The polyester PET, discovered in Britain during World War II, can be spun into a fiber that is commonly used in textiles.

Polyethylene (PE): Three major types of polyethylene are marketed: the low-, medium-, and high-density products. In addition, copolymers of ethylene-ethyl acrylate, ethylene-vinyl acetate, and ethylene-butylene are produced. The three density ranges are 56.8 to 57.7, 57.8 to 58.7, and 58.8 to 60.2 lb/ft^3 (90.9 to 92.4 kg/m^3, 92.5 to 94.0 kg/m^3, and 94.1 to 96.4 kg/m^3).

Low-density stocks are waxy, relatively limp, and are the toughest of the polyethylenes, with an upper service temperature of approximately 160°F (70°C). As density increases, so does surface hardness, stiffness, resistance to permeation by oils and water, and softening temperature. For polyethylenes of the highest density, the upper service temperature is 240°F (115°C) under no-load conditions.

The outstanding properties of polyethylenes are (1) good moldability, (2) good mechanical properties, (3) excellent electrical resistance, (4) low moisture vapor transmission, (5) resistance to solvents and chemicals, and (6) lightness in weight. Polyethylene is widely used for film, sheeting, plastic bottles, piping, tubing, dish pans, garbage containers, laundry baskets, electronic components, insulation, and textiles. Boat and motor vehicle fuel tanks are a recent application for high-density polyethylene. Polyethylene can be crosslinked chemically or by irradiation to form a thermoset with high heat resistance.

Polyphenylene Oxide (PPO): Polyphenylene oxide is a thermoplastic resin formed by the catalyzed oxidation of 2,6-xylenol. It is a specialized, highly engineered plastic with a wide temperature range, good mechanical and electrical properties, and resistance to corrosive materials. It has many electrical and electronic applications, and is used for packaging frozen foods and as a replacement for glass and stainless steel in hospital utensils and medical instruments.

Polyphenylene Sulfide (PPS): Excellent chemical resistance and high stiffness at elevated temperatures make polyphenylene sulfide useful as a coating for various metals, including aluminum, steel, cast iron, and brass, and in the petroleum and chemical processing industries. Other uses include cookware, pump impellers, pumps, conveyor rollers, and machine parts.

Polypropylene (PP): Polypropylene possesses the lowest density of the commercially available thermoplastics. In addition, it exhibits good rigidity, high yield strength, good surface hardness, exceptional flexural properties, resistance to chemicals, and excellent dielectric properties. Like all olefins, it has excellent resistance to water solutions that are highly damaging to many metals.

Primary areas of use include the usual categories of molding, as well as in film and piping. It is used for luggage, housewares, automobile and aviation components, and appliance parts. Because of its superior insulating properties, it is also used to make electronic components. Carpeting made of polypropylene fibers also is available. Polypropylene filled with asbestos offers high-impact strength, stiffness (up to 250°F [120°C]), and low friction.

Polystyrene (PS): A glassy transparent thermoplastic, primary characteristics of polystyrene are hardness, rigidity, clarity, and heat and dimensional stability. By varying the polymerization reaction, polystyrenes have been developed with higher heat distortion temperatures. Styrene polymers are marketed in granular and powder form for extrusion or molding. Beads of polystyrene that contain the flammable gas pentane as a blowing agent are sold for the production of polystyrene foam.

General-purpose and impact grades of polystyrene are used for refrigerator liners, appliance housings, automotive applications, films for wrapping, sporting goods, toys, and novelties. Heat-resistant polystyrene is used for television sets, radios, and illuminated signs. Glass-filled polystyrene is used for business machines, electronic equipment, and military hardware. Polystyrene foam is used to make toys, insulation, displays, shipping containers, and molded furniture. Construction panels, consisting of cores of polystyrene foam between sheets of plywood, plastic, or aluminum, and foamed-in-place polystyrene insulation are used in the building industry.

Polysulfone (PSU): Polysulfone is a thermoplastic resin that contains a diphenylene group. This group imparts certain desirable characteristics to the polymer, including thermal stability (over 300°F [150°C]), oxidation resistance, and rigidity. Glass fibers may be added for improved environmental stress crack resistance. Commercial applications include electronic units, electrical circuit breaker parts, automobile engine parts, aircraft interiors, kitchen range hardware, electroplating equipment, and appliance hardware.

Polyurethane (PUR): Polyurethanes consist of a group of polymers that are produced in the following two general forms: (1) foams, for example, flexible, semiflexible, and rigid; and (2) elastomers, for example, casting compounds and elastoplastic resins, adhesives, coatings, and spandex fiber. The basic reaction used to produce the urethane polymers involves isocyanates and reactive hydrogen-bearing materials, such as polyethers, castor oils, amines, carboxylic acid, and water. By varying the number of branchings, it is possible to make polyurethanes that are thermoplastic or thermosetting.

Polyurethane foams are widely used in the production of upholstered furniture, bedding, sponges, toys, wearing apparel, and medical dressings. Rigid urethane foams are used for insulation in building construction. Substantial quantities of the polyurethanes are used to produce coatings and adhesives. Their rubberlike qualities aid in the production of specialty fillers and elastomers. Gears, sprockets, and rolls are produced from urethanes. Very thin films are used to produce containers impermeable to gas and moisture.

Silicones (SI): Silicone resins comprise a large group of polymers consisting of chains of alternating silicone and oxygen atoms with organic groups, for example, methyl groups attached to the silicone atoms. They are stable at high and low temperatures, have good dielectric properties, resist weathering, do not react with most chemicals, and repel water.

Silicone emulsions are used as mold-release agents, defoamers, and waterproofing materials. A compound of liquid silicone and finely divided filler produces a grease suitable for high-temperature lubrication applications. Silicone paints, varnishes, and enamels have many uses, including cloth and wire coating. With inorganic fillers, such as glass or asbestos, silicones are molded into such products as connector plugs, coil bobbins, insulators on induction furnaces, and heat barriers in jet engine afterburners. Silicone glass laminate applications include rigid hot air ducts for aircraft, terminal boards, and transformer spools and spacers. Rigid silicone foams can be preformed or foamed in place. High-temperature insulation is the principal use of rigid silicone foams.

Styrene Acrylonitrile (SAN): Produced through the copolymerization of styrene and acrylonitrile, styrene acrylonitrile is a transparent thermoplastic with improved heat resistance, stiffness, and scratch and impact resistance. It finds application in decorative panels, food packages, "dishwasher-safe" housewares, battery cases, lenses, glasses, appliance parts, and automobile components.

Ureas (UF): Urea formaldehyde, as a thermosetting plastic, is especially suitable for any application that must resist heat. The material has excellent resistance to oils and greases, but is not recommended for high-humidity environments. Because urea formaldehyde is hard, strong, odorless, and tasteless, it has been frequently used in tableware, crockery, and decorative articles for the home. Other uses are for electrical parts, such as switches and outlet covers, bottle tops, toys, and as a laminate in building panels.

Vinyls: The vinyl resins are thermoplastics that exist in a wide variety of polymers and copolymers. Commercial production of the vinyl chloride monomer starts with acetylene or ethylene. Most vinyl plants use an oxychlorination process with ethylene to produce vinyl chloride. Copolymers of vinyl chloride and vinyl acetate account for a large part of vinyl production.

The major applications for flexible and rigid vinyls include automobile seat covers, floor mats, and moldings; shower curtains; window shades; wrappings; bottles; adhesives; flooring; siding; piping; wiring; swimming pools; records; and medical appliances.

Polyvinyl Chloride (PVC): This type of plastic is made as a rigid product for a number of building components and as a flexible plasticized stock for upholstery and wearing apparel. It exists in hundreds of individual formulations. It has good abrasion resistance. The unplasticized PVC softens as it burns, producing white smoke and acrid fumes, which can be corrosive. Most of the chlorine content of PVC is released as hydrogen chloride. The fire properties of plasticized PVC are determined to a large extent by the nature of the plasticizer. Building products should be tested individually.

Vinyl Chloride—Vinyl Acetate Copolymers (Polyvinyl Acetate) (PVAC): These contain from 5 to 20 percent vinyl acetate in the polymer. They are used for more flexible stocks than is PVC and are more readily softened by plasticizers. Their properties are essentially those of PVC.

Polyvinyl Dichloride (PVDC): Because this plastic is made by chlorinating PVC, its properties are essentially those of rigid PVC. It is used most where more toughness, stiffness, and heat resistance are needed than are offered by PVC.

Vinyl Acetate Polymer (VAC): Vinyl acetate polymer is a thermoplastic that is used in coatings, as a wood primer, and as an adhesive in a milky aqueous dispersion. It is not used as a molding or sheet plastic, as its upper service temperature is below 120°F (50°C).

Vinyl Alcohol Resins (PVA): Because they are made by hydrolysis of polyvinyl acetate, PVA products swell or dissolve completely in water. They are highly impervious to oils and many lacquer solvents. They are used in hoses for spray painting and as water-soluble film for dose-packaging detergents, and so on.

Polyvinyl Butyral (PVB): Polyvinyl butyral is produced by condensing butyraldehyde with polyvinyl alcohol. It has remarkable adhesive qualities and is primarily used as plasticized film for laminating automotive safety glass.

Polyvinyl Formal (PVFM): Polyvinyl formal is produced by condensing formaldehyde with polyvinyl alcohol to make a hard resin. Polyvinyl formal is then mixed with small amounts of phenolic resin to improve the bond and reduce creep. It is not to be confused with polyvinyl fluoride (see fluoroplastics). Its principal use is as standard insulation enamel for magnet wire in small motors and electronic equipment.

Vinylidene Chloride Polymer: This is a thermoplastic that as a film has low permeability to water vapor. A principal use is as a coating on cellophane. Filaments are used for webbing on garden furniture and for window screening.

Vinylidene Chloride-Vinyl Chloride Copolymer: This plastic is less rigid than PVC and flows more readily in extrusion and molding. Its major use is as a coating for metals and molded electrical parts.

NATURAL AND SYNTHETIC RUBBER

Like plastics, rubber appears in many shapes and forms, from very soft and pliable products to hard rubber that looks and feels like a molded plastic. Many polymers can be manufactured in elastomeric grades and are classified in that form as synthetic rubbers. Crepe soles fall in that category.

Natural Rubber (NR): Natural rubber is a constituent of latex, the white milky sap collected from the rubber tree. The processed rubber may be used in sheet form for items like shoe soles, extruded into products like inner tubes, or compression molded with heat to make items like tires and hot-water bottles. Liquid latex has a variety of applications. It is often coated on fabrics for waterproofing, mixed with cement for superior bonding qualities, included in water-based paints to produce a cohesive film after the paint dries, and expanded into the familiar foam latex, or foam rubber. The density of the foam is controlled by varying the ratio of foam to air and the size of the cavities.

Vulcanization is a curing process that causes rubber to crosslink. Rubber that has been vulcanized cannot be reshaped or remolded when reheated. By prolonging the vulcanization process, the degree of hardness can be varied, eventually resulting in "hard rubber" (known as ebonite or vulcanite in England). Hard-rubber tubes and rods have been popular products, valued for their resiliency, electrical insulating quality, and chemical inertness. Other common products have included automobile battery cases, combs, telephone receivers, castors, wheels, and bushings. In many of these applications, synthetics have replaced natural rubber.

Synthetic Rubber (SR): These materials are intended to imitate the elasticity of natural rubber and they can be vulcanized. They have similar long-chain molecular structures, built up from copolymerized synthetic monomers, such as butadiene with styrene, or butadiene with acrylonitrile. The former method produces styrene-butadiene rubber (SBR); styrene-butadiene rubber is used extensively in automobile tires. Nitrile rubber (NBS) is the product of the butadiene-acrylonitrile reaction, whereas butyl rubber is produced from an isobutylene-isoprene copolymer. Neoprene (GR) is a very strong and durable synthetic made from chloroprene.

Synthetic foam rubber usually means a soft flexible product of the polyurethane type and is either polyester (AU) or polyether (EU). However, new types are continually being developed, including ethylene-propylene rubber (EPR), polybutadiene (BR), and polyisoprene, the synthetic equivalent of natural rubber.

Silicone rubber (SI) incorporates the inorganic, inert element silicone, which gives it a number of unique properties. It is the only satisfactory soft material for human implants, and it is commonly used for breast implants and many other implants, including artificial ears, skull plates, and jawbones. In building applications, self-curing, water-repellent silicone rubber is used as a sealant, and it finds many applications where a nonstick surface is desired. Some formulations have been used successfully as firestops and to seal openings in fire walls, where its flexibility gives performance superior to grout or plaster.

Additional information sources on synthetic rubbers are *Plastics: Design and Materials,*[6] *Introduction to Industrial Polymers,*[7] and *Rubber Technology Handbook.*[8]

CELLULOSE NITRATE (CN)

Cellulose nitrate (also referred to as nitrocellulose and pyroxylin) is made by the action of nitric and sulfuric acids on cellulose materials, such as cotton. Pyroxylin plastic comprises the lower nitrated products and contains from 11 to 12 percent nitrogen. Cellulose nitrate material that has been subjected to heat, such as that salvaged from a fire, may be so altered in composition that it is subject to spontaneous ignition.

When cellulose nitrate products are heated to temperatures above 300°F (150°C), decomposition starts, which generates further heat and soon raises the material to its ignition temperature. Decomposition of cellulose nitrate generates heat and does not depend on an external air supply.

Cellulose nitrate, when in solution in acetone or any of the various solvents, has no greater hazard than that of the solvent. If the solvent is lost, the hazard reverts to that of cellulose nitrate.

Most articles formerly made of cellulose nitrate are now made from less hazardous plastics, but it is still used to some extent in industrial applications, for items such as shoe heels, some housewares, and as a pigment in lacquers.

Processing Cellulose Nitrate

Fire safety in plants processing cellulose nitrate plastic consists essentially of four parts: (1) segregation of hazards, (2) elimination of ignition sources, (3) good housekeeping, and (4) strong

fire control facilities. In some plants, finished cellulose nitrate plastic parts may be assembled with other articles that do not involve any special fire hazard, for example, toilet seats. In such cases, the hazard and necessary protection depend on the quantity of cellulose nitrate used. If the quantities used are large, the same safeguards should be followed as for plants in which the product is made entirely from cellulose nitrate.

Cellulose Nitrate Storage

Storage of cellulose nitrate plastics requires special facilities. Depending on the quantity to be stored, these facilities may be cabinets, vaults, storage rooms, or isolated storage buildings. Storage facilities are described in detail in two NFPA standards: NFPA 40, *Standard for the Storage and Handling of Cellulose Nitrate Film*, and NFPA 42, *Code for the Storage of Pyroxylin Plastic*.

Cellulose Nitrate Photographic Film

All photographic film made in the United States and Canada since 1952 is the safety-base type, usually cellulose acetate or triacetate or polyester. An engraving process used in some printing plants engraves on cellulose nitrate plates.

There is comparatively little storage of cellulose nitrate X-ray film, although some hospitals may still store X-rays made on cellulose nitrate film many years ago. However, appreciable quantities of old nitrate motion picture and aero film still exist. Small amounts of portrait, industrial, and amateur nitrate film probably exist, but the usual storage of this material (in paper envelopes) poses no serious hazard. Nitrate-based film manufactured in other countries may occasionally be found.

The existence of old nitrate motion picture and aero film does present a hazard, since persons handling this material may not be familiar with its serious hazards and the elaborate precautions necessary to handle it safely. Although it is unlikely that nitrate film will be projected in a theater handling present-day motion pictures, such material may be shown in small art or film society theaters. Unfortunately, projectionists may not be aware of the fact that a nitrate print is to be shown. For this reason, theater projection standards for nitrate film should still be kept in effect. Storage of nitrate film should be in accordance with NFPA 40.

The amounts of scrap-nitrate motion picture film have greatly decreased, and most of the agencies that formerly handled this material are no longer in existence. This has given rise to the possibility that scrap could accumulate in dangerous quantities. Prior to environmental concern with air pollutants from outdoor burning, the best procedure for disposing of scrap nitrate film was to burn it at a remote location in the open, with all personnel at a safe distance upwind (because toxic oxides of nitrogen are among the products of combustion of this film). If accumulations of scrap-nitrate film are a problem, the best course to follow would be to check with environmental authorities to learn if such open burning is permitted locally.

Transportation of Cellulose Nitrate

The U.S. Department of Transportation (DOT) regulates the interstate transportation of cellulose nitrate plastic by rail, land, or water. These regulations permit dry shipment of cellulose nitrate (pyroxylin) scrap when specially packaged, but if there is evidence or the possibility of decomposition, the cellulose nitrate must be packaged under water. Shipment of cellulose nitrate sheets, rolls, rods, and tubes is not subject to special DOT regulation, except when shipped by rail express or water.

Articles manufactured entirely of or containing cellulose nitrate plastic do not require special packaging when shipped by land, rail, or water. Special shipping regulations apply to cellulose nitrate wet with alcohol, solvent, or water.

Shipments of cellulose nitrate motion picture and X-ray films are permitted when certain packaging requirements are met, including inside containers made of light metal, cardboard, or fiberboard for individual reels of film. NFPA 40 places restrictions on the transportation of nitrate film in public vehicles so as to protect the public against the consequences of a possible fire involving the film.

Air transportation of cellulose nitrate plastic scrap is not permitted by regulations of the International Air Transport Association. Cellulose nitrate plastic rods, sheets, rolls, tubes, manufactured articles, and motion picture and X-ray films are permitted only when specially packaged.

Extinguishing Cellulose Nitrate Fires

Large volumes of water are required to extinguish cellulose nitrate fires. Automatic sprinklers constitute the best general protection for areas where cellulose nitrate materials are stored or handled. Water supplies should be particularly strong. Closer sprinkler spacing than for ordinary occupancies is required in order to supply sufficient water to absorb the heat. The water from sprinklers, in addition to its extinguishing and cooling effects, tends to absorb the poisonous oxides of nitrogen fumes but has no effect on carbon monoxide.

If hose streams are required, the objective should be to get large quantities of water on the fire as soon as possible. Fire fighters should be located upwind or protected by self-contained breathing apparatus (SCBA) to prevent inhalation of the products of combustion.

FIRE BEHAVIOR OF PLASTICS

Although there is no special fire hazard for most accepted usages of plastics, some exhibit burning characteristics that are considerably different from those encountered with the more traditional cellulosic building materials. Different fire conditions cause significantly different burning characteristics that pose unusual hazards to life and property, including the following.

Ignitability and Rate of Burning. Although plastics tend to have a higher ignition temperature than wood and other cellulosic products, some are easily ignited with a small flame and burn vigorously. Very high surface flame spread rates are possible—up to approximately 2 ft/sec (0.6 m/sec), or 10 times the rate of flame spread across most wood surfaces.

Smoke Produced. The burning of some plastics is characterized by the rapid generation of large amounts of very dense,

sooty, black smoke. Chemicals added to inhibit flammability may increase smoke production.

Toxic Gases. Any fire will generate lethal products of combustion, principally carbon monoxide. Depending on the plastic and the particular fire conditions, gases with much higher toxic potency, such as hydrogen cyanide and hydrogen chloride, may also evolve (see Section 6, Chapter 2, "Combustion Products and Their Effects on Life Safety").

Flaming Drips. Thermoplastic articles tend to melt and flow when heated. In a fire, this characteristic may cause the material to melt away from the flame front and inhibit further burning, or it may produce flaming and tar-like dripping, which is difficult to extinguish and may start secondary fires.

Deviation from Test Results. Small-scale "Bunsen burner" tests are used for product development and laboratory control purposes. In the past they were used to indicate that certain plastics were "self-extinguishing" or "nonburning" and, presumably, safe for use. Unfortunately, in real-life situations the same materials can show flash burning characteristics.

Corrosion. Severe corrosion damage to sensitive electronic equipment and to metal surfaces can occur following fires involving such plastics as polyvinyl chloride.

Smoke Generation

Smoke generation from a given polymer may vary widely, depending on the nature of the polymer, the additives present, whether fire exposure was flaming or smoldering, and the type of ventilation that was present. The following comments from Gaskill's[9] comprehensive study on smoke density are especially pertinent:

1. Woods and most polymeric material pyrolytically degrade, yielding smokes that are dense to very dense. Ventilation tends to clear the smoke, but in most cases it does not reduce the intensity to the point of satisfactory visibility. With fire retardants incorporated into the polymer (at least in the case of solid materials), heat and flame generally produce very dense smokes, and this occurs rapidly.

2. Woods and those polymeric materials that burn cleanly will yield smokes, under conditions of heat and flame, of somewhat less density.

3. Urethane foams under flaming or nonflaming exposures generally yield dense smokes, and, with few exceptions, obscuration occurs in a fraction of a minute. Flaming exposure usually causes the smokes to be generated in less than 15 seconds, and the intensities in this case are usually higher than in the nonflaming case.

Cellular Plastics

Cellular plastics (or foamed or expanded plastics) have been in widespread use since the 1960s. The low resistance of cellular plastics to excessive heat and their ease of ignition contrast sharply with their most valuable property in building construction—their excellent resistance to heat transfer. In a 1969 study of the flammability of cellular plastics,[10] Underwriters Laboratories Inc. (UL) reported on an analysis of 34 fires where rigid cellular plastics had been used as building materials. The report indicated the following:

1. The fire performance of cellular plastics can vary considerably depending on whether they are exposed or protected and/or flame resistant, along with the degree of flame resistance. But the reduction in flammability through the use of inhibitors or protective coverings is not conclusively demonstrated by the study.

2. In 8 of 21 fires, a high rate of flame spread was reported and appeared to be especially typical of sprayed-on polyurethane and rigid polyurethane boards. Flame spread ratings from NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials,* tunnel tests of some of the materials ranged from 5 to 1375 (red oak, 100).

3. The fire behavior of cellular plastics appears to be affected by the extent of foam application, that is, whether the foam is applied to the walls and ceiling or only to the walls.

4. The fire behavior of the flexible foam plastics appears to be similar to that of the rigid plastic foams. (Peculiar to the flexible foams, though, is the pool of liquid product that can be generated in a fire in the bulk storage of the foam "buns." The liquefied plastic burns like a high flashpoint flammable liquid.)

Whereas untreated rigid polyurethane burns rapidly and is readily ignited by common ignition sources found in the environment, fire-retardant grades have substantial resistance to localized, temporary ignition sources under most fire environments. Sustained application of heat and flame causes such foam to burn, but the burning rate tends to be retarded. Often, burning will cease entirely when the external flame source is removed. The production of dense smoke is a characteristic of both treated and untreated urethane.

Untreated rigid polystyrene foam, likewise, ignites easily and burns vigorously with the production of dense, black smoke and a very black, viscous melt product which can burn with the intensity of a flammable liquid. Fire-retardant treatments inhibit ignition; the plastic tends to shrink away from fixed heat sources without igniting. The heat of combustion of styrene is about 50 percent higher than that of urethane foam (18,000 Btu/lb versus 12,000 Btu/lb [42 mJ/kg versus 28 mJ/kg]).

At times, cellular plastics that exhibit good resistance to burning under most exposure conditions have shown a markedly different behavior when surfaces of the exposed plastic are arranged to cause a feedback of radiant heat between the surfaces.[11] The combination of low thermal conductivity, high rate of heat release, and rapid degradation under heat exposure appears to be responsible for a rapid upward propagation of the flame front occurring in a room corner configuration. When the ceiling is also insulated with the exposed foamed plastic, the corner configuration encourages rapid extension of the fire across the underside of the ceiling. This phenomenon has occurred even with ignition sources as small as a wastebasket fire. The laboratories of FM Global Research (formerly Factory Mutual

Research Corporation) devised the "corner test" to simulate this exposure condition.

Rubber

Burning rubber is notable for its smell and dense smoke. The material, as generally used, is not easily ignited and does not burn with unusual rapidity.

The bulk storage of rubber items, particularly rubber tires, is subject to hot, difficult-to-control, and very smoky fires. Surface application of water may be only marginally effective because the fire can easily burrow into the material. Special automatic sprinkler protection is required to help ensure control if the storage is more than 5 ft (1.52 m) high (see NFPA 13, *Standard for the Installation of Sprinkler Systems*).

Rubber or plastic jacketing on grouped electrical cables has provided the fuel for fires in the electrical and communications industries. Considerable work has been done to raise the operating temperature limits and ignition temperatures of insulation for electric power and control cables. An applicable standard is IEEE 383, *Standard for Type Test of Class IE Electric Cables, Field Splices, and Connections for Nuclear Power Generating Stations.* Butyl/neoprene and neoprene rubber insulation, for example, tend to burn readily and fail such small-scale tests.

No significant differences appear to exist in the ignition or combustion characteristics of natural rubber and the various synthetics. Silicone rubbers can be formulated to reduce combustibility to a minimum under ordinary conditions, but not all silicone rubbers have that quality: the material failed the requirement of no flashover in a quarter-scale room fire test conducted at the National Bureau of Standards.[12]

Test Results

The variation of the fire behavior of plastics when compared to that of other building materials was further demonstrated in tests conducted at Underwriters Laboratories Inc.[13] Thirty-one materials were subjected to the Steiner tunnel test (NFPA 255; ASTM E84, *Standard Test Method for Surface Burning Characteristics of Building Materials;* and UL 723, *Standard for Safety Test for Surface Burning Characteristics of Building Materials*) to establish flame spread and smoke-developed classifications. These materials were also subjected to a 20 lb (9.1 kg) wood crib exposure fire in a full-size corner configuration. Testing established that the 20 lb (9.1 kg) wood crib presented fire severity conditions about equal to the 5000 Btu/min (88 kW) burner in the tunnel test, generating a heat flux of about 0.97 Btu/sec·ft^2 (1.1 W/cm^2). Four materials in the test series achieved an identical flame-spread classification of 18 (cement asbestos, 0; red oak, 100), but the smoke that developed and the extent of burning were markedly higher for the flame-retardant grade of plastic foam (Table 6.13.1).

These four building materials were also subjected to exposures in the heat-release rate calorimeter test developed by NIST (National Bureau of Standards).[14] As reported by UL[13] in the document on the 1973–74 test series, the first three specimens, code letters E, I, and T, yielded identical heat release rates of 0.26 Btu/sec·ft^2 (0.3 W/cm^2) at an exposure energy level of 2.6 Btu/sec·ft^2 (3 W/cm^2). However, a heat release rate 25 times higher [6.6 Btu/sec·ft^2 (7.5 W/cm^2)] was recorded for the flame-retardant plastic, code letter Z.

TABLE 6.13.1 Test Results (Cellular Plastics) for a 20 lb (9.1 kg) Wood Crib Fire Test

Code Letter	*Material*	*FSC*[a]	*SDC*[b]	*Affected Area*[c]
E	3½-in. (89-mm) thick glass fiber blanket insulation, 6% resin by weight, unfaced, 0.65 pcf (10.4 kg/m^3) density	18	3	24%
I	½-in. (12.7-mm) thick wood fiberboard acoustic ceiling panels, integrally flame retardant treated, decorative finished, 18.8 pcf (301.2 kg/m^3) density	18	4	37%
T	½-in. (12.7-mm) thick wood particleboard, integrally flame retardant treated	18	37	25%
Z	2-in. (51-mm) polyurethane spray cellular plastic on ¼-in. (6-mm) asbestos cement board; 2.2 pcf (35.2 kg/m^3) density, flame retardant	18	935	85%

[a]Flame spread classification, tunnel test result.
[b]Smoke developed classification, tunnel test result.
[c]Percentage of 192 ft^2 (17.8 m^2) total wall and ceiling area affected in full-scale corner test (7 percent affected in control fires).

Another cellular plastic, 2 in. (51 mm) extruded polystyrene cellular plastic boardstock (1.8 lb/ft^3 [0.03 g/cm^3] density, flame retardant), obtained a flame spread classification of 3 in the tunnel test, but its smoke developed classification was 785 (red oak, 100), and 146 ft^2 (13.6 m^2), or 76 percent, of the wall-ceiling area of the corner test structure was adversely affected by the burning.

The fire problem associated with plastics was studied by the Products Research Committee (PRC), formed to administer a trust fund established by a number of companies engaged in the manufacture and sale of cellular plastics and their ingredients. The PRC issued its final report[15] in 1980 after a five-year effort, which included sponsoring a number of research programs. Highlights of conclusions reached by the PRC included the following:

1. Building codes today appropriately require that foam plastic insulation not be installed exposed within buildings unless covered by a 15 minute thermal barrier or unless the

insulation has met the provisions of the NFPA 286, *Standard Methods of Fire Tests for Evaluating Contribution of Wall and Ceiling Interior Finish to Room Fire Growth,* room corner test.

2. Properly designed interlayers between furniture fabric and padding are one means of reducing the fire risk of upholstered furniture.
3. The use of results of many different small-scale fire tests to obtain an estimate of behavior of a material in fire is appropriate; however, the present state of the art does not allow regulatory decisions to be made without considerable expert judgment and, preferably, data from full-scale fire tests in which the most probable fire scenarios are simulated.

FIRE TESTS FOR PLASTICS

Combustibility characteristics and suitability for use should be determined for any material or assembly on the basis of tests that simulate the end-use condition as realistically as possible. The tests should be designed to show how the product will perform when it is subjected to the type of fire exposure that can be anticipated under the conditions of use. The most desirable tests, from the standpoint of fire protection, engineering, and codes, are those that are suitable for all products for a particular application and that treat all products equally. Separate tests for plastics, or any other group of materials, that do not allow comparison of the fire behavior under like test conditions are undesirable.

As explained previously, small-scale tests, such as the oxygen index test (ASTM D2863) and the UL 94, are now used mostly for product development and production control. Such tests, where the ignition source is small and of low intensity, are unsuitable for evaluating the fire characteristics of materials under room fire or other full-scale fire conditions.

Greater fire intensity exposures are produced by standard fire tests, such as the Steiner tunnel test (ASTM E84/NFPA 255). The tests need to be selected in a manner that is suitable for the application in which the material or product is intended to be used. Examples of such tests include NFPA 286, ISO 9705, and the FM Global Research corner test, and other specialized tests designed specifically for the application. Guidance on selection of large-scale tests for realistic applications is found in ASTM E603 and ASTM E2067.

Other tests that may be required by the authority having jurisdiction (AHJ) are used to determine, separately, ignition temperature, surface flame spread index, and the rate of smoke production. Potential heat (caloric value) of the plastic material may have to be determined, but this parameter is of little significance in fire protection engineering; more important is the rate at which heat is liberated and contributes to the intensity of the fire. A multiplicity of tests to qualify plastics, or any other material, for end-use applications may not be required in the future. Test apparatus that measure heat release and smoke development rates at varying radiant heat flux exposures provide more realistic assessments of probable fire response under real-life situations than some of the older test methods. The first standardized test for this analysis is ASTM E906, *Standard Test Method for Heat and Visible Smoke Release Rates for Materials and Products,* for use with the Ohio State University (OSU) heat and smoke release-rate apparatus (Figure 6.13.7). Typical of the curves generated by the OSU heat and smoke release rate apparatus shown in Figure 6.13.7 are (a) heat release rates for several specimens at an exposure level of 2.6 Btu/sec·ft^2 and

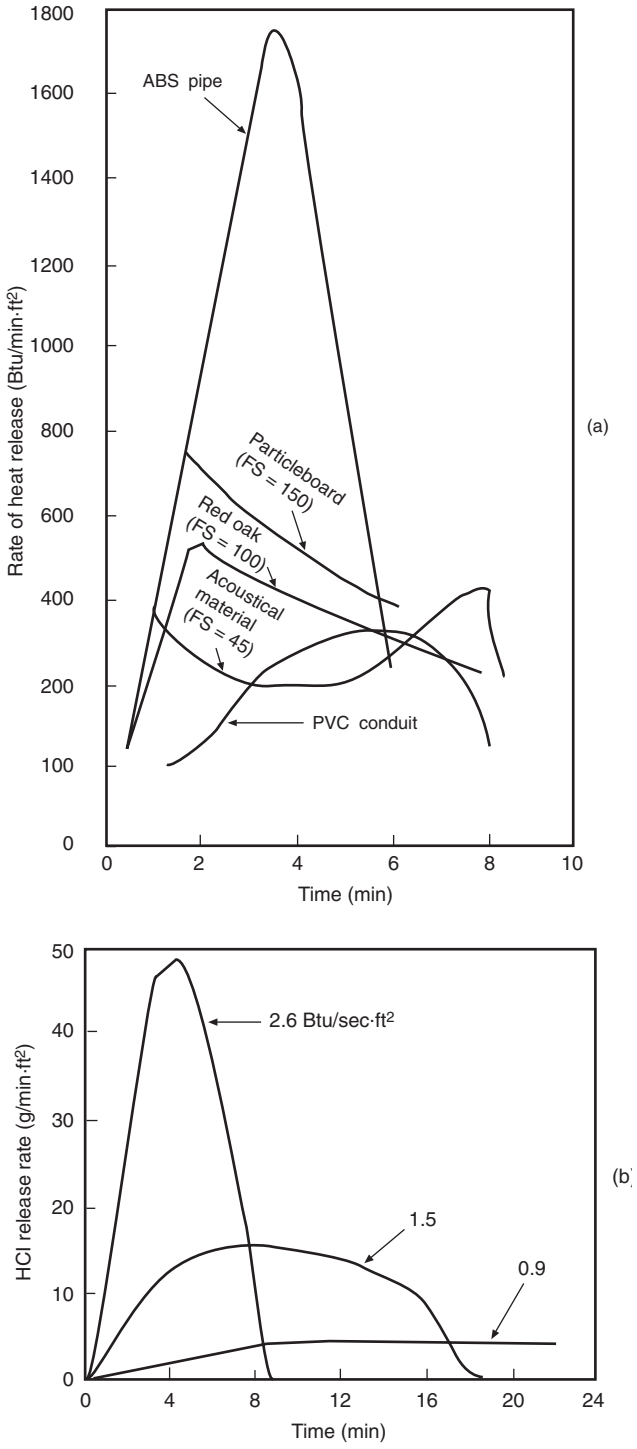

FIGURE 6.13.7 Curves Generated by the OSU Heat and Smoke Release Rate Apparatus (FS = flame spread rating, ASTM E84 [1 Btu/sec·ft^2 = 0.053 W/m^2])

(b) hydrogen chloride release rates from a sample of conduit at different exposure levels. Measurements include heat and smoke particles released by the test specimen per unit time and total during the test, toxic gases given off, ease of ignition, and flame spread rate. Procedures for similar analyses using an oxygen-consumption cone calorimeter developed at National Institute of Science and Technology (NIST) are standardized in ASTM E1354, *Standard Test Method for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter,* and NFPA 271, *Standard Method of Test for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter.* FM Global Research also developed a small-scale calorimeter, which has since been standardized for use with materials in clean rooms (NFPA 287, *Standard Test Methods for Measurement of Flammability of Materials in Cleanrooms Using a Fire Propagation Apparatus (FPA),* and ASTM E2058, *Standard Test Methods for Measurement of Synthetic Polymer Material Flammability Using a Fire Propagation Apparatus (FPA).*

In addition to the fire test methods for building construction materials and assemblies in general (i.e., not product related), a number of test methods have been developed to analyze flammability and other fire response characteristics of plastics, specifically. Almost all are small-scale tests intended primarily for research, product development, and manufacturing quality control. They are not intended for, and should not be used for, building or room fire hazard assessments, unless their scope is so noted. A number of such test methods have been issued by the American Society for Testing and Materials (ASTM); descriptions can be found in ASTM D3814, *Standard Guide for Locating Combustion Test Methods for Plastics.* Underwriters Laboratories Inc. (UL) has several standards for measuring ease of ignition and other characteristics of plastics that are used in products that have been tested and listed or classified by UL. One common test is UL 94, *Standard for Safety Tests for Flammability of Plastic Materials for Parts in Devices and Appliances* (Figure 6.13.8), which includes procedures for hot-wire and arc ignition and for rates of burning while the sample is positioned horizontally and vertically. Results of this test, like the ASTM plastics flammability tests, cannot be compared to the fire behavior of the materials under full-scale fire exposures.

A number of organizations have cooperated in producing test methods for evaluating the hazard of plastics and textiles in specific applications. Working with the U.S. Consumer Product Safety Commission, the Upholstered Furniture Action Council, NIST, and others, NFPA has prepared test methods NFPA 260, *Standard Methods of Tests and Classification System for Cigarette Ignition Resistance of Components of Upholstered Furniture,* and NFPA 261, *Standard Method of Test for Determining Resistance of Mock-Up Upholstered Furniture Material Assemblies to Ignition by Smoldering Cigarettes,* for determining the resistance to cigarette ignitions in upholstered furniture. Similarly, ASTM E1590, *Standard Test Method for Fire Testing of Mattresses,* covers the fire response of mattresses and bedding exposed to flaming ignition. NFPA 262, *Standard Method of Test for Flame Travel and Smoke of Wires and Cables for Use in Air-Handling Spaces,* used for determining fire and smoke characteristics of plastic and other insulations on wires and cables, was derived from one of the UL tests. NFPA 272, *Standard Method of Test for Heat and Visible Smoke Release Rates for Upholstered Furniture Components or Composites and Mattresses Using an Oxygen Consumption Calorimeter,* addresses fire characteristics of upholstered furniture, mattresses, and bedding when material samples are tested in the cone calorimeter.

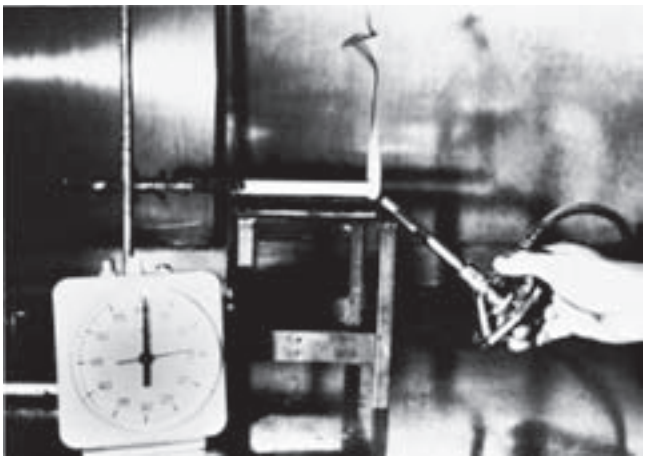

FIGURE 6.13.8 Specimen Being Tested Under the Horizontal Burning Test of UL 94 for Flammability of Plastics (Source: Underwriters Laboratories Inc.)

Some U.S. government agencies have promulgated regulations to control the flammability of plastics and textiles in certain applications. Under MVSS-302, the DOT regulates interior materials for automobiles, using a test for burning rate in the horizontal mode. The U.S. Coast Guard, under 46 CFR, Subchapter T, regulates materials used as resins for hulls in boats-for-hire carrying more than six passengers. The U.S. Coast Guard also uses a modified version of ASTM E136, *Standard Test Method for Behavior of Materials in a Vertical Tube Furnace at 750°C,* to establish the "noncombustibility" of materials used in the interior of passenger-carrying ships. More detailed information on applications for marine vessels can be found in Section 21, Chapter 10, "Marine Vessels." Guidelines for the flammability of carpets, rugs, children's sleepwear, mattresses, and mattress pads are issued by the U.S. Consumer Product Safety Commission. CPSC has been involved since the 1990s in the development of potential test methods for upholstered furniture and mattresses. The U.S. Nuclear Regulatory Commission has issued guidelines for the ignitability and flammability of plastics used in the insulation of electrical cables requiring qualification under test procedures in IEEE 383, *Standard for Type Test of Class IE Electric Cables, Field Splices, and Connections for Nuclear Power Generating Stations.*

INSTALLATION SAFEGUARDS

In the current state of the art, large areas of cellular plastics left exposed in interior building construction or decoration must be considered to be extremely hazardous. Exposed foam on ceilings or walls, in air-handling plenums, in shafts, in other

flue-like vertical spaces inside walls, or above hung ceilings should be avoided. A low flame-spread classification (e.g., 25 or less) does not ensure that a product has limited combustibility under such conditions, nor can it be assumed that automatic sprinklers will control the hazard. Coating such surfaces with a fire-retardant paint, intumescent or otherwise, is not likely to produce satisfactory results.

Model building codes require that foamed plastic used as interior wall insulation be covered with a thermal barrier, such as ½ in. (12.5 mm) thick ordinary gypsum board, or another method that reduces the risk of ignition and the subsequent flash-fire propensity. The use of foamed plastics in the cavities of hollow masonry walls, such as perimeter insulation around the foundation of a building, insulation below concrete slabs on the ground, and for roof insulation under certain conditions, is generally accepted without thermal barrier protection. All such plastics in the thickness and density used must have a smoke-developed rating no greater than 450 and a flame-spread rating no greater than 75, under ASTM E84 (NFPA 255) tunnel test conditions.

In other than noncombustible or fire-resistant building types, foamed-plastic insulated steel or aluminum exterior building panels are permitted by the model building codes, provided the foam core has a flame-spread classification of 25 or less and the space is protected by automatic sprinklers.

When used as interior wall and ceiling finish, plastic materials other than foamed plastic generally are not subject to any special requirements. As for any other materials, plastics are subject to limitations on surface flame spread and often on the smoke generated, as measured by standard test procedures, such as the Steiner tunnel test or radiant panel test. These or other special limitations may be applied to plastics used as diffusers in lighting fixtures, where it is often acceptable to have a plastic that deforms and drops out of the fixture at an elevated temperature still well below its ignition point. Special limitations may also be set forth by building codes for the use of plastic glazing instead of glass in exterior walls of buildings, where the normal requirement for conformance to the limitations for interior finish may be waived.

Plastic laminates for countertops, kitchen cabinets, tabletops, and so on, are not usually included in the definition of interior finish, as regulated by building codes. Even when it is not regulated by local code, the flammability level should be limited to that encountered when natural products are used in these applications. Plastic laminates are commonly available with low surface flame-spread classifications, in the range of 25 to 75.

Further guidelines for the installation of plastics in various applications can be found in publications of the Society of the Plastics Industry[16] and FM Global Research.[17]

The packaging, storage, and shipping precautions that are customarily observed for ordinary combustible materials apply generally to most plastics. No special shipping requirements for plastics (other than cellulose nitrate) have been adopted by the DOT.

FIRE- AND FLAME-RETARDANT TREATMENTS

All organic and some inorganic materials burn under proper conditions. Fire and flame retardants can make a given material more difficult to ignite, and when ignited, cause it to burn more slowly. Retardants can be very effective in preventing ignition from low-level, short-duration flame and heat exposures. Even under moderate exposures, the burning characteristics can be greatly improved by fire retardants, depending on the product and the additive used. For severe exposures, such as from a fully developed room fire, treated and untreated plastics typically show similar fire behavior.

Fire- and flame-retardant chemicals are added to plastics during the manufacturing process. Because of the widely varying properties of plastics, no single, universal additive is available, nor is there only one effective mechanism for imparting flame resistance. Fire- and flame-retardant additives may be blended into the polymer mix during processing, or they may be reactants that change the molecular structure of the polymer. The additives can be chemically reacted throughout the polymer substrate or on the surface of finished or semifinished products. Surface treatments added after the manufacturing process, such as fire-retardant paints or coatings, are unreliable without test data to prove the effectiveness of the combination.

Additives blended into the mix may be organic or inorganic materials. Organic additives typically are chlorinated and brominated hydrocarbons or halogenated and nonhalogenated organophosphorous compounds. Among the inorganic flame retardants are the salts of antimony, zinc, molybdenum, and aluminum. Those classed as reactants include brominated aromatics, brominated aliphatic polyols, and phosphorous-containing polyols.

Phosphorous additives appear to improve flame resistance by (1) promoting formation of char to reduce concentration of carbon-containing gases; (2) forming a glassy, insulating layer; and (3) either entering into chemical reactions that remove heat from the combustion system, or chemically inhibiting the combustion process, or both. Compounds containing halogens, such as chlorine and bromine, tend to inhibit burning in the gas phase by interrupting chain reactions needed for continuous burning. Other flame retardants involve heat absorption reactions, for example, by providing a heat sink through evaporation of water of hydration.[18]

A complicating aspect of treating plastics and other materials is that a fire-retardant chemical that works on one substrate system will not necessarily work on other substrates. Thus, fire-retardant chemicals for polystyrene will not necessarily work on polyethylene, nylon, wood, or cotton. Fire-retardant chemicals often impair some other material properties. For example, fire-retardant treatments for cotton fabrics generally reduce fabric strength and wear life. Fire retardants in plastics may reduce allowable processing temperatures and impair physical properties. Costs are generally increased.

Smoldering, rather than free-burning, combustion is likely to increase the amount of total smoke produced, while reducing the rate of smoke production per unit time, and there tends to be more smoke when fire retardants are added to polymers, but this is not true in all cases. Comparisons were made among five different types of products in fire-retardant and non-fire-retardant versions in a series of tests sponsored by the Fire Retardant Chemicals Association at the National Institute of Science and Technology.[19] Included were polystyrene TV cabinets, polyphenylene oxide business machine housings, polyurethane

foam-padded chairs, electrical cable with polyethylene insulation and rubber jacketing, and polyester/glass electric circuit boards. Heat release, spread of flames, and the propensity for flashover were reduced when the fire-retardant products were tested. Smoke yields generally were similar, but fire-retardant TV cabinets produced twice the amount of total smoke than the non-fire-retardant versions. Potential escape times for occupants were reported to be 15 times greater when the fire-retardant products were used in the tests.

FIGHTING FIRES IN PLASTICS

Plastics other than cellulose nitrate are classified as ordinary combustibles. Consequently, extinguishing methods suitable for fires involving wood and other ordinary combustibles (Class A fires) should be used to extinguish a burning plastic. Some plastics, for example, flexible polyurethane, may form a pool of burning liquid during a fire, similar to a high-flashpoint combustible liquid (Class B) fire. Water from automatic sprinklers or spray nozzles on hoselines can be used for fire control, although the extent of a pool fire is likely to be overshadowed by the more generalized fire in the area.

Storage with a preponderance of plastics products or materials can develop into fires with extremely high temperatures that tremendously magnify the normal problem of radiant heat, structural damage, and exposure.[19] Rapid fire spread, high burning rates, and thick, dense smoke in heavy clouds can be anticipated. FM Global Research recommends a two-fold attack: (1) properly designed sprinkler protection, and (2) appropriate manual fire-fighting techniques. Large-orifice (17⁄32 in.) sprinklers have been found to be substantially better in controlling fires in plastics, and large-drop and early suppression fast response (ESFR) sprinklers were developed at FM Global Research specifically to address the high-challenge plastics fire.

The physical form of plastics will greatly influence their fire behavior. Molding pellets, which are shipped in bags, drums, or large cartons, provide little surface for access to air. These same plastics in such shapes as flashlight cases will have much more access to air and may burn vigorously until heat causes the shapes to melt, thereby reducing the surface area exposed to air. Melting may be a hazard if it causes burning drips to carry flame to a lower floor or spreads fuel for later ignition.

Although fire may develop more slowly in the more dense, unexpanded form than in foamed products, once established, the burning rate is comparable. For fires that have become well established in a large quantity of plastics products in a sprinklered warehouse, "buttoning up" the building to limit combustion air and letting the sprinklers do the work of fire control, for hours if necessary, before moving in for final mop-up by conventional means, is an approach recommended by FM Global Research.[19] Shutting off sprinklers to allow the smoke to rise and vent the building is dangerous because the high combustibility of the storage can cause the blaze to rapidly flash out of control.

Toxicity

Possibly because of the long chemical names of some plastics, combustion and thermal decomposition products of plastics have been a cause for concern among fire fighters. For plastics now in commercial use, the hazard of carbon monoxide from partial combustion greatly outweighs the toxic effects of other fire gases, both as to nature and amount.

On burning, some plastics, for example, polyvinyl chloride or ethylene sulfide rubbery caulking materials, generate hydrogen chloride or sulfur dioxide. Because these are strongly irritating, they ordinarily force evacuation long before their toxic effects become dangerous. These gases also are corrosive to metals and electrical equipment; therefore, such equipment should be ventilated, rinsed, or treated with dilute ammonia, and rinsed as soon as possible after exposure.

The need for a standard method for the development of data that could be used in toxic hazard modeling prompted the NFPA Technical Committee on Fire Tests to develop NFPA 269, *Standard Test Method for Developing Toxic Potency Data for Use in Fire Hazard Modeling.*

SUMMARY

Plastics and rubber belong to the varied and complex family of polymers, and all types are combustible to varying degrees. Special fire behavior problems associated with plastics include the emission of dense, sooty smoke and toxic gases. In building construction, plastics can be found in many applications, including thermal and acoustical insulation, roofing materials, decorative trims and imitation wood parts, ceiling and wall panels, resilient flooring, light fixture diffusers, electrical conduits, insulation on wiring, water and gas piping, bathtubs and sinks, and heating ducts. Combustibility characteristics and suitability for use should be determined for any material or assembly on the basis of tests that simulate the end-use condition as realistically as possible. Modifications can be made in the manufacture and application of plastics that can reduce hazards to acceptable levels, for example, by treating with fire- or flame-retardant additives. Large-orifice sprinklers and large-drop and early suppression fast response (ESFR) sprinklers have been found to be effective means of suppressing plastics fire.

Chapter 14

Pesticides in the Workplace

Revised by
Fred Whitford

Chapter Contents

Regulations and Guidelines
Hazard Identification and Labeling
Facility Planning for Risk Reduction
Emergency Plans
Security

Key Terms

emergency action plan, flammable liquid, hazardous material, pesticide, security, toxicity

FIFRA, the Federal Insecticide, Fungicide, and Rodenticide Act, defines a pesticide as a chemical or mixture of chemicals or substances used to repel or combat an animal or plant pest including insects, spiders, and other invertebrate organisms; vertebrate pests, such as rodents and birds; weeds; plant diseases; and microorganisms. Household germicides and plant growth regulators are also examples of chemicals that fall under FIFRA's definition of a pesticide. *Pesticides* is a general term that encompasses products that control pests and are subdivided into groups, depending on the pests being controlled. For instance, insecticides control insects, fungicides control plant diseases, bactericides control bacteria, herbicides control unwanted weeds, and rodenticides control mice and rats.

Pesticide products are diverse in chemical composition, formulation, and hazard. There are literally thousands of different pesticide products that reflect the enormous diversity of insect, weed, disease, rodent, bird, and other pests that they are intended to control. There are also many federal and state agencies that regulate their transportation, storage, use, and disposal. In some cases, local jurisdictions have established their own sets of standards for storage, handling, and use. Pesticide products are widely distributed through retail and wholesale outlets. Some communities are host to manufacturing operations and warehouses where large amounts of these products are stored awaiting shipment to regional distributors and retailers. A variety of state and county agencies store pesticides, including state and county parks, highway departments, and mosquito control units. Finally, there is a large number of service-oriented businesses (e.g., lawn care, pest control, right-of-way maintenance) and farms that store pesticides on-site.

In addition to being stored at manufacturing facilities, large volumes of pesticides are stored at farm supply stores, company-owned distribution warehouses, commercial (public) warehouses, and agricultural chemical warehouses. Fire protection education and safeguards have traditionally focused on pesticides stored in warehouses such as those just described, but it is important to be aware of hazards presented by the presence of pesticides in other locations. On the retail front, lesser amounts of pesticide products can be expected to be found at nurseries, supermarkets, discount stores, hardware stores, and other retail outlets. In transportation, expect them to be shipped in solid, liquid, and in a few cases, gaseous form. Emergency responders should always be prepared to deal with pesticides when responding to problems involving fires at these facilities or when reacting to a transportation accident.

This chapter provides an overview of the requirements and practices that reflect state-of-the-art philosophies in location, construction, and administration of facilities that handle pesticide products, from manufacturing facilities, to local businesses and farms. However, local, state, and federal laws need to be reviewed to determine specific measures that will have to be implemented.

For additional information relevant to the hazards of the storage and use of pesticides, see Section 3, Chapter 7, "Fire Hazard Analysis Techniques"; Section 3, Chapter 8, "Fire Risk Analysis"; Section 6, Chapter 1, "Fire Hazards of Materials"; Section 6, Chapter 12, "Flammable and Combustible Liquids"; Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 7, Chapter 3, "Storage of Gases"; Section 7, Chapter 4, "Storage and Handling of Chemicals";

Fred Whitford is the coordinator of Purdue Pesticide Programs of the Purdue University Cooperative Extension Service. He has written three books and has authored more than 200 research, extension, and regulatory publications. Dr. Whitford's prior professional activities include lab and field research, extension outreach, regulatory oversight, and commercial pesticide application.

Section 7, Chapter 5, "Hazardous Waste Control"; Section 11, Chapter 4, "Fire Hazards of Construction, Alteration, and Demolition of Buildings"; Section 12, Chapter 8, "Effect of Building Construction and Fire Protection Systems on Fire Fighter Safety"; and Section 20, Chapter 16, "Storage Occupancies."

REGULATIONS AND GUIDELINES

Reducing Exposure of Personnel

Pesticide products are governed by numerous "standard of care" regulations and guidelines that address proper transportation, storage, handling, use, and disposal. These regulations and guidelines also address the need to reduce exposure to workers, emergency responders, the general public, and pesticide applicators, as well as the need to prevent release to the environment that might cause water contamination or wildlife injury. For example, state and federal governments have enacted laws that address concerns over the transportation and storage of pesticides through (1) formal, comprehensive planning for product management, as outlined by Occupational Safety and Health Administration (OSHA) regulations; (2) employee training documentation of competency; (3) planning for pesticide emergencies and sharing those plans with local and state authorities; (4) reporting inventories to local and state officials; and (5) management of transportation through safe driver training, proper inspection of trucks and trailers, and proper placarding. Figures 6.14.1 and 6.14.2 show emergency plans being put into action. Figure 6.14.1 shows local responders and medical personnel practicing procedures at a mock pesticide spill and mock injury on a farm. In Figure 6.14.2, a medical helicopter staff are attending a field day to explain their procedures for handling accident victims.

Preventing Release

Most modern regulations focus on what can be done to prevent the release of pesticides at the facilities that handle such products or from the vehicles that transport them. Secondarily, the regulations enforce training to deal with pesticide releases into the environment in the event of an accident. Much of this change by government at all levels has been supported by both the pesticide-use industry and the farming community. Everyone seems more aware today of the dangers and costs associated with the escape of a pesticide into the environment. Any release of pesticide product due to fire, natural disaster, or deliberate act can have consequent costs associated with the cleanup and remediation of the site where the release occurs and could conceivably include dealing with contamination of groundwater or surface water that renders a public drinking water supply unfit for use. Ground spills can lead to substantial costs associated with removing contaminated soil to an approved landfill that can accept such waste. Personal injuries can result that often lead to a decade or more of legal action. Even the cost of replacing the protective gear of emergency responders or the decontamination of ambulances and hospital rooms can reach thousands of dollars. All of these factors have added to a change in philosophy in which strategies and regulations that focus on prevention and communication have surpassed reaction measures.

Compliance with Regulations

Business owners must invest time and effort in training employees to deliver products and services in a safe, effective, professional manner. Managing a business now means more than just managing the bottom line and attracting new customers. Today's businesses must also comply with numerous regulations that deal with all aspects of licensing and hiring, pesticide storage, transportation, and use. Employee training is a part of nearly every federal and state pesticide regulation. Table 6.14.1 is a checklist that provides a starting point in maintaining compliance with federal and state regulations as it relates to the safe handling of pesticide products.

General Guidelines

Concise guidance is provided to facility managers and risk planners by the following documents:

1. *The Crop Protection Handbook.* This document has an excellent comprehensive and detailed checklist for agricultural chemicals stored in warehouses. (See http://www.greenbook.net.)

2. *SARA Title III, List of Lists.*[1] This document presents a consolidated list of chemicals regulated by the Environmental Protection Agency (EPA) under the Comprehensive Environmental Response, Compensation, and Liability Act (otherwise known as "Superfund"), the Superfund Amendments and Reauthorization Act (SARA Title III), the Emergency Planning and Community Right-to-Know Act (EPCRA), and the Clean Water Act. It provides a chemical list of materials that are required to be reported when the facility's storage exceeds the published threshold quantities. In addition, this document provides the

threshold for chemicals that need to be federally reported during a spill.

3. *Survey Form for Public Warehousing of Crop Protection Products.* Mid America CropLife Association identifies eight key elements of facility location, structures, and management. It provides a series of questions that helps the manager to evaluate the relative risk of chemical accidents at a specific facility.[2]

National Fire Protection Guidelines

The introduction to this chapter lists chapters in this handbook that contain additional information on the hazards of storage and use of pesticides.

Purdue University Cooperative Extension Service Pesticide Programs Publications

The Purdue Pesticide Program publishes an extensive series of publications on storage and transportation of pesticide products and their regulation. Within this chapter, publications identified as PPP are those from Purdue Pesticide Programs. Information about each publication can be found at the following website: http://www.btny.purdue.edu/ppp. Extension pesticide specialists can be reached at each state's land grant university (see http://www.aapse.org) in order to determine the availability of state-specific printed and web-based safety and regulatory publications.

HAZARD IDENTIFICATION AND LABELING

Data Sheets

The hazards of any particular pesticide product can originate from the active ingredients, that is, the components that provide the pesticidal activity, or the inert ingredients used as the carrier, or both. (See the following Purdue Pesticide Program publication: PPP-31, *Pesticides and Formulation Technology.*) It can also be a flammable or combustible liquid solvent or a flammable gas. Obviously, the best method of determining the hazards of the active and inert materials is to access the product's material safety data sheet (MSDS). (See PPP-37, *Pesticide and Material Safety Data Sheets.*)

MSDSs should be available for reference in all emergencies. They provide quick access to information on the product, how to deal with the emergency, and access through the emergency phone number to other professionals who can help supply valuable information. Additional and current sets of the MSDS should be available in an easily reached off-site location. The MSDS should be made available to the fire department, local hospitals, and other associated parties. Figure 6.14.3 shows an emergency response information mailbox containing site maps, product inventories, contact numbers, and MSDSs.

The pesticide facility should also maintain an up-to-date site plan that shows the general classification and approximate quantities of products within the various storage areas. This site plan should also be available during an emergency and preferably given to the local emergency response services. Approved "lock boxes" and outside plastic tubes that can be mounted on a building exterior are available in sizes that accommodate MSDS binders, contract numbers, and site plans. These boxes limit access to all but authorized personnel and can protect against tampering when connected to security systems.

FIGURE 6.14.3 Emergency Response Information Mailbox

The intrinsic toxicity of the active ingredient in pesticides varies considerably. When considering together the hazards presented by the components of the pesticide formulation, including its active ingredients, carriers, and adjuvants, pesticides can be corrosive, reactive, flammable or combustible, or relatively benign. In a fire situation, however, products of combustion may present a significant health hazard to responding fire departments or to occupants of neighboring properties. MSDSs and all of the hazards used to identify single products are of little use when multiple products are engulfed in a fire. Incident commanders and fire fighters need to take extreme care when responding to a facility, farm, or transport vehicle where pesticides are involved in the accident.

Flammable and Combustible Liquids and Solids

Liquids. The majority of pesticide products stored in large volumes are in liquid form. Some of these formulations are considered flammable or combustible liquids by the U.S. Department of Transportation (DOT), and the outer packaging holding individual containers or the intermediate bulk container will have the appropriate transportation label. The pesticide products pictured in Figure 6.14.4, for example, are categorized as flammable liquids and are appropriately marked with DOT labels. The hazards of flammable or combustible liquids when released from containers can range from a manageable spill fire to near-explosive ignition of ignitable vapors in a confined area. Like all other products used in commerce, each pesticide must be reviewed individually to access what its flammable, combustible, and health risks are to the emergency responder, community, and employees.

FIGURE 6.14.4 DOT Marking on Cardboard Box Containing Pesticides

Solids. Solids are usually stored and handled as granules, dusts, and powders. The DOT marking on the package shown in Figure 6.14.5 indicates that it contains a solid pesticide product with its specific Class 6 hazard. If combustible, solids can present a dust explosion hazard when dispersed into the air. Most pesticide solids, however, are specific formulations absorbed into an inert material, such as clay. Hazards of "inerts" used in pesticide formulations need to be evaluated on a case-by-case basis during a release incident. Once again, inerts are not specifically identified on the product label or on its MSDS. However, some MSDSs will list the hazards of the inerts, which can provide valuable guidelines in dealing with a spill or other accident. A list of pesticides that should be kept away from ignition sources is provided in the Crop Protection Handbook at http://www.greenbook.net.

FIGURE 6.14.5 DOT Marking When Required Identifies the Hazards of a Pesticide Product

Labeling

The labels on packaged pesticides can provide emergency responders with quick, useful information. Labeling of pesticides reflects the fact that they are grouped according to their level of toxicity for humans. On the front panel of each product label are signal words that infer the level of acute toxicity of the material in the container or bag. These signal words are "Danger," Warning," and "Caution" in descending order of toxicity. (Figure 6.14.6 shows a signal word contained on a product label.) Normally, products labeled with the "Danger" identifier have more and stricter requirements for personal protective equipment.

Pesticides are grouped by the hazard they pose to the applicator and/or to the environment. Products that carry additional risks to human health, water, and wildlife are categorized as restricted-use pesticides. They are easily identifiable from the product label. Above the brand name of the product, a restricted-use pesticide will have a rectangle at the top of the container or bag that contains the restricted-use statement.

Pesticide labels are regulated by the EPA and provide specific directions and precautions directed to the end user (see PPP-24, *Pesticides and the Label,* and PPP-36, *Pesticides and the Law.)* Hazard information dealing with short-term effects provided on pesticide labels (e.g., signal word) is based on the combination of active ingredient and the inerts. The label in many aspects provides little information to the emergency responder for the community or the company. The label also does not typically address fire or reactivity hazards of the complete formulation as a whole, nor does it provide the details needed to respond to an emergency beyond very general statements for small spills. Information on the synergistic effects due to fire

FIGURE 6.14.6 Signal Word Warning Clearly Marked at the Lower-Left Edge of the Container

or due to releases involving a mixture of pesticide materials is not available from any source. This lack of information should cause emergency responders to consider in great detail their initial approach to a fire, the equipment worn, and the potential for evacuating the surrounding population. In many respects, the MSDS is the key source of information on how to deal with any emergency involving pesticides. Concentrations of active ingredients will vary widely in the various formulations. Table 6.14.2 lists the current EPA-required warning systems for labeling pesticide containers.

FACILITY PLANNING FOR RISK REDUCTION

Handling and Storing Pesticides

It is important to realize that most state and federal laws do not dictate how pesticides must be stored. There are laws that regulate how large volumes should be diked and bermed, but these laws basically focus on warehouses and large agricultural facilities. Most industries such as lawn care, golf course, pest control, and right-of-way that use pesticides as part of their service do, however, follow industry-specific best management practices when it comes to how products are stored on-site. Therefore, emergency responders should do on-site visits to determine the volume of material stored, when those quantities are at their highest inventories, and the manner in which they are stored.

In addition to routine housekeeping, special attention should be paid to accumulations of combustible materials in areas where pesticide products are stored and to the handling, storage, and prompt management of spills, leaks, and damaged and returned goods. NFPA 434, *Code for the Storage of Pesticides,* NFPA 30, *Flammable and Combustible Liquids Code,* and NFPA 13, *Standard for the Installation of Sprinkler Systems,* provide information relative to aisle space in the storage area. Other relevant NFPA standards should also be consulted as to pile size and storage height limitations for chemicals of other hazard classes. Storage area personnel and retail stock personnel should know the class and hazards of each product stored and displayed. Pesticide products should never be stacked to heights that exceed the structural strength of the packaging or the shelving units.

Flammable and restricted-use pesticides should be stored and displayed separately from other products. A system that recognizes not only the chemical hazard classes of the materials involved but also the potential loss to the facility should a fire or release occur must be used. Stored substances must be segregated according to accepted codes, standards, and industry best management practices. DOT tables for coshipment of incompatible materials in highway cargo vans can be used as an initial guide.

TABLE 6.14.2 EPA Toxicity Categories

Category 1: POISON/DANGER

All pesticide products meeting the following criteria:
- Oral LD_{50} up to and including 50 mg/kg
- Inhalation LD_{50} up to and including 0.2 mg/liter
- Dermal LD_{50} up to and including 200 mg/kg
- Eye effects—corneal opacity not reversible within 7 days, and skin effects corrosive.

Must bear on the front panel the signal word "Danger." In addition, if the product was assigned to Category 1 on the basis of its oral, inhalation, or dermal toxicity (as distinct from skin and eye local effects), the word "Poison" must appear in red on a background of distinctly contrasting color, and the skull and crossbones must appear in immediate proximity to the word "Poison."

Category 2: WARNING

All pesticide products meeting the following criteria:
- Oral LD_{50} from 50 through 500 mg/kg
- Inhalation LD_{50} from 0.2 through 2.0 mg/liter
- Dermal LD_{50} from 200 through 2000 mg/kg
- Eye effects—corneal opacity reversible within 7 days (irritation persisting for 7 days)
- Skin effects—severe irritation at 72 hr

Must bear on the front panel the signal word "Warning."

Categories 3 and 4: CAUTION

All pesticide products meeting the following criteria:
- Oral LD_{50} greater than 500 mg/kg
- Inhalation LD_{50} greater than 2.0 mg/liter
- Dermal LD_{50} greater than 2000 mg/kg
- Eye effects—no corneal opacity
- Skin effects—moderate irritation at 72 hr

Must bear on the front panel the signal word "Caution."

Facility Planning and Construction

Farms and businesses that do not warehouse pesticides should conduct their own environmental site assessments to determine how safe pesticides are being stored, used, and transported. (See PPP-42, *Pesticides and Environmental Site Assessments*.) The following criteria represent ideal storage facility conditions for pesticide products with significant hazards.

Location and Site Factors for New Construction

If siting a new building, this might be the most important decision that a business or farm can undertake. Often a well-positioned building can eliminate much of the risk to the surrounding environment. There are many factors that can affect the location of a business or warehouse that will store pesticides. Obviously, such a facility should be located in an area where exposure and risk are minimal should a fire or other disaster such as a tornado or flood occur. The first concern is what types of commercial, residential, and public buildings are located near the site under consideration. It is preferred that new construction be placed on the property as far away as possible from schools, hospitals, retirement homes, places of assembly, day care centers, or other buildings where large numbers of people congregate or are housed. In many cases, county zoning is quite helpful in that the building of a pesticide warehouse or service business

storing pesticides will be limited to certain areas. In older areas, buildings storing pesticides do pose a problem for emergency responders. In an emergency at these facilities, the occupants of such public and private buildings may have to be evacuated, thereby increasing the complexity of dealing with a pesticide emergency.

State and federal laws may require specific separation or set-back distances that will have to be followed. Guidance can be provided by the architect who will design the building and by local building and fire prevention officials. In some cases, actual separation distances can be determined by a realistic process hazards analysis developed on a site-specific basis.

Preferably, facilities storing large quantities of pesticides will be located in an area where the probability of a natural disaster, such as flood, earthquake, tornado, or hurricane, is low. When this is not the case, the design of the building and its contents needs to address the specific risk issues faced. The proposed site should be easily accessible to emergency responders. It is important to discuss this situation with local emergency responders to gather their recommendations about what can be done to address any concerns about the facility.

Easy access to and easy movement within the facility by the responding fire department is essential in the event of a fire or chemical release. The site plan should be devised to ensure that all areas of the facility can be easily reached.

Consideration should be given to providing multiple entry points to facilitate a safe, upwind approach to the facility for emergency response in the case of hazardous materials release. Separate storage areas for products with widely different hazards or characteristics may need to be considered. For example, products that are not chemically compatible with each other should be stored in separate rooms or buildings. Consideration may need to be given to separating flammable materials without a significant toxicity hazard from those materials that are flammable and have a significant health hazard, such as those that produce toxic products of combustion, are skin-contact poisons, or represent significant environmental hazards. Nonflammable materials that have a health hazard rating of "3" or "4" according to NFPA 704, *Standard System for the Identification of the Hazards of Materials for Emergency Response,* should also be isolated from other materials. Generally speaking, however, small businesses do not segregate their products in inventory due to space limitations.

Facility Construction

The pesticide storage building will have to comply with local and state building codes. Very few jurisdictions beyond the building codes dictate how buildings that store pesticides are to be designed and constructed. The following are suggestions that might improve the safe storage of pesticides at facilities and farms that are smaller than warehouses:

- Single-story facilities without basements are preferred.
- Noncombustible construction is preferred when the choice of building materials presents itself. NFPA 220, *Standard on Types of Building Construction,* provides details for approved noncombustible or limited-combustible materials.
- Insulation, when required, should not be of a type that will contribute fuel to a fire; insulation should serve to contain a fire.
- Floors should be constructed of materials that are easy to clean and maintain. Floor sealers that can resist pesticides, solvents, and fuels should be considered, but they require considerable maintenance.
- Buildings should be well lighted to prevent accidents. A guideline is that lighting levels should be sufficient for personnel to read written materials without the need of an additional lighting source.
- Storage areas might need to have interior fire walls to prevent a fire from spreading from one area to another. These walls should be standard 4-hour-rated fire walls that extend 3 ft (0.9 m) above the roofline. They should also be liquid-tight with floor ramps or raised sills at openings.
- Fire doors should be appropriately rated for the opening protected and arranged to close automatically in the event of a fire. See NFPA 80, *Standard for Fire Doors and Other Opening Protectives,* for criteria and installation requirements for fire doors.
- The use of noncombustible walls or partitions should be considered where there needs to be an effective means of segregating incompatible materials within a building.
- All electric service should be in compliance with NFPA 70, *National Electrical Code®*.
- Heating appliances should be segregated from the storage areas.
- Ventilation is an essential component to safe storage. Ventilation system design should consider the handling of both materials and containers and the potential effects of odors from solvents and pesticide products, which can build up to irritating, if not unhealthy, levels. Professional guidance will be needed to specify proper design of the ventilation system, including flow rates, make-up air, location of vents, and so forth. Automatic systems that are preset for temperatures are preferred over the standard wall on-off switch.
- The floor of the pesticide storage area should be sloped into a "blind" drain to allow for easy cleanup in the event of a spill. All drains leaving the building should be temporarily or permanently sealed to prevent a spill from entering the sewer or septic system. All water sources entering the building should have air gaps or antisiphon devices to prevent the movement of pesticides into private or public wells.
- Storage in smaller businesses and farms should be located within a specifically designated area that will provide emergency responders with many options in dealing with a fire. In Figure 6.14.7, for example, pesticides are stored in a predesignated area within a barn.

Conventional precautions for fire protection of pesticide facilities and farms must be balanced with concerns for off-site exposures due to evolution of products of combustion during a fire situation and the potential for environmental damage due to fire water runoff. (See following subsection entitled "Environmental Impact and Containment.") The instructions printed next to a drain shown in Figure 6.14.8 show that local officials are concerned about waste entering drains.

FIGURE 6.14.7 Storage of Pesticides in Predesignated Area

FIGURE 6.14.8 Community Concern Demonstrated by Warning Against Dumping Products in Storm Drains

A pesticide facility should ideally have 100 percent sprinkler coverage, where needed, a sufficient number of fire extinguishers for preliminary response by employees, and a fire detection system that includes smoke and heat detectors. NFPA standards are referenced at the end of this chapter. See also appropriate chapters of this handbook as indicated at the start of the chapter.

Environmental Impact and Containment

In the event of atmospheric release of pesticide products or smoke and products of combustion from a fire, it is important to assess and plan for the effect on sensitive areas downwind. The facility should have the capability to contain any spills and water runoff within the facility boundary by means of a secondary containment system. It is important to note that most pesticides that will be encountered are not required to be placarded, nor are they found in the Emergency Response Guidebook. Response policies and previous experiences all help to shape what action is undertaken to bring the situation under control. One excellent source of information is the emergency phone number found on the product's MSDS. Often the persons answering the phone can provide quick and reliable information on what needs to be done in the specific example. With so few examples in which pesticides have been involved, getting personnel within a company to share their experiences and what ought to be done is a critical first step. The MSDS is the key to accessing such persons.

Internal Containment. If the nature of the material being contained permits, internal containment by means of curbs and sloped ramps at door openings provides a limited alternative to traditional methods of conducting spillage and runoff to an exterior impounding area. Advantages to internal containment include (1) greater control over the materials if spilled, (2) security against vandalism, (3) localized storage, and (4) prevention of rainwater from contacting any spilled material. Drawbacks to internal containment are (1) potential workplace exposure to the contaminants remaining in the building, (2) the presence of released chemicals that may pose the threat of flash fire, (3) potential for vapor explosion or other unacceptable occurrence, and (4) hindrance to emergency responders whose work will be made more difficult by the retention of large quantities of spilled materials. Although there are drawbacks, secondary containment in most cases offers too many advantages to be ignored. Secondary containment is required by state or federal law only when specific quantities of pesticides trigger containment.

External Containment. In some cases, especially in agriculture, pesticides may be contained outdoors in large tanks designed to contain concentrated pesticide products. Exterior containment areas should be secured from access and located away from important valves, building exits, incompatible materials, or environmentally sensitive areas. If exterior containment areas are not roofed, they should be adequately sized to contain additional volumes of rain.

Calculating Containment Volume. Adequate containment volume should be calculated, at a minimum, to include a reasonable and credible worst-case scenario release from (1) a single tank or vessel, and (2) potentially contaminated water from fire-fighting runoff and/or sprinkler operation. In many cases, the state Department of Agriculture has already mandated how much secondary containment is required for the volume being stored. Water utilized during fire control operations may dissolve chemicals, resulting in contaminated runoff from the fire scene. The volume of fire-fighting water runoff to be contained should be determined by the authority having jurisdiction. Overflow from secondary containment must not pose an immediate threat to people, property, or the environment.

Additional Tips. The following tips can help to reduce the threat of a fire or the negative consequences arising from a fire or transportation accident:

- Store all chemicals in one location, away from wells, ditches, animals, and equipment.
- Store chemicals in the smallest quantities possible.

- Use returnable/refillable containers or dry formulations with low use rates.
- Plan ahead. Develop a safety and environmental contingency plan. Share this with local authorities and emergency response services.
- Post emergency phone numbers throughout the facility.
- Post emergency phone numbers at the building entryway where they are easily visible to emergency response personnel.
- For remotely located facilities, such as farms, place large, reflective 9-1-1 numbers on the mailbox to help responders identify and reach the site in an emergency.
- Have emergency responders tour the facility on a regular basis.
- Put backflow preventers on all wells and other water sources.
- Never pump water directly from a well into spray equipment.
- Perform a walkaround inspection of all vehicles to check for potential problems.

Figure 6.14.9 shows a mailbox containing a site map and summary information that fire fighters can use during an emergency. The mailbox pictured in Figure 6.14.10 marks the entry to a county road and posts the number 7865, which is the emergency property identification number assigned by the county to help fire fighters quickly locate a fire or spill.

Additional recommendations for farms and businesses can be found in the following publications: PPP-50, *Managing Farm Chemicals;* PPP-57, *Managing Farm Emergencies;* PPP-58, *Pesticides and Fleet Vehicles: Transporting Pesticides Safely;* and PPP-61, *Pesticide Safety Tips for the Workplace and Farm.*

Detection and Extinguishment

Facility management, assisted by safety and supervisory personnel, should develop and implement a routine system for safety, health, and environment inspection of the facility. This creates a consistent system for maintenance, safe and compatible product storage, management of damaged and returned goods, and overall safe operation of the facility. Inspection tours should be supported by documentation. The aerial photo shown in Figure 6.14.11 is an example of documentation that fire fighters could use to gain a quick visual understanding of a site plan.

Detection System. If fire protection is to be provided by a sprinkler system, a detection system should also be installed to alert facility personnel of incipient fires, thus allowing time for response that may control the incident before sprinkler discharge is triggered. Consideration should be given to both automatic and manual alarm systems that can provide rapid notification of incipient fires or other emergency conditions to personnel. If the facility is not occupied on a 24 hour basis, supervision of these systems should be provided.

FIGURE 6.14.10 Glow-in-the-Dark County-Assigned Number Posted on a Mailbox

FIGURE 6.14.9 Fire Emergency Mailbox Containing Emergency Information

FIGURE 6.14.11 An Aerial Map Downloaded from the Internet Can Provide Important Layout Information

Inspection, Testing, and Warnings. Routine inspections and tests should be conducted to ensure fire protection systems are operable. The inspections and tests should cover sprinkler systems, valves, fire pumps, extinguishers, hose systems, fire doors, runoff containment structures and vessels, and runoff treatment systems, if any. A "no-smoking" policy is mandatory for any area where flammable and combustible materials are stored.

Indentification. Hazard warning signs using the NFPA 704 system should be posted on all structures and fixed tanks that house or store hazardous materials. The use of the NFPA 704 placards should be coordinated with the servicing fire jurisdiction.

Application of Water. The application of water to a building containing pesticides can lead to significant contamination of the property and of the environment if the pesticide-contaminated runoff is not controlled and contained. Given the right set of circumstances, contaminated runoff can kill large numbers of fish and other aquatic animals or can severely contaminate a drinking water supply. Matters are somewhat complicated in that many businesses and farms that store pesticides also store large amounts of fuels and anhydrous ammonia and other fertilizers. In some cases, facility operators should consider posting the W signal (Figure 6.14.12) (from NFPA 704) to warn emergency responders not to use water. The W signal should, of course, only be posted after consultation with the local authorities and with the insurance companies of facilities or farms.

Farmers are sometimes creative and generous in allowing responders to use their irrigation systems for fire emergencies. Figure 6.14.13 shows an irrigation system that has been modified by a farmer to enable fire departments from three districts with three different fitting sizes to connect to his irrigation system.

Alternative Means of Extinguishment. Due to the potential for spread of contamination via runoff from sprinkler systems or the water reactivity of some materials (e.g., fumigants), consideration should be given to alternative means of fire extinguishment and control. Dry chemical, carbon dioxide, or other extinguishing agents and systems may be effective means of fire protection in some pesticide facilities. However, compatibility of the products with these alternative fire extinguishing agents should be given careful consideration. It is important to have the local fire department review the products in storage to determine if appropriate extinguishing materials are on hand at the business, farm, or emergency response organization. In some cases, business owners may need to purchase the appropriate agents if the local emergency services do not have or lack the funds to purchase them. Figure 6.14.14 shows a trailer equipped by business owners with emergency response equipment and supplies.

FIGURE 6.14.12 The W Signal Posted on the Side of a Building

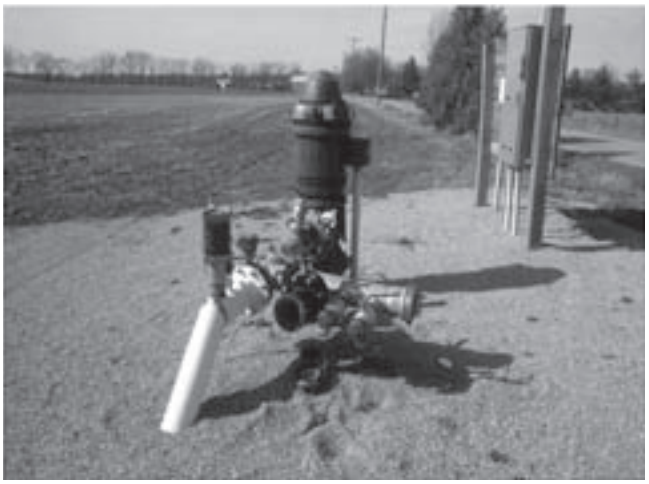

FIGURE 6.14.13 Irrigation System Modified to Accept Fire Department Hose Fittings

Training

Employee Training. Managers and supervisors of pesticide products facilities must be safety conscious and constantly on the lookout for means to reduce spills and injuries resulting from

FIGURE 6.14.14 A Pesticide Application Business Equipped with Emergency Response Supplies

the misuse or careless storage of pesticides. All facility personnel should be able to demonstrate a thorough knowledge of the regulations that are imposed on the facility and themselves, including training of employees under DOT, EPA, OSHA, and state agencies. The safety at the facility or on the farm will only be as good as the routine safety performance of the employees. Copies of relevant regulations, standards, and permits should be available at each facility. Initial and periodic refresher training should be provided as needed and all training and educational programs documented.

All facility personnel should be properly trained, on an annual basis, in the use of the fire extinguishers available at their location. It is recommended that training sessions be conducted with local fire and emergency services. This training should include identification and location of sprinkler control valves, so that emergency responders can control fire spread from the area of origin into adjoining areas of the facility, while allowing them to stop the discharge of water onto released chemicals. The training should also include procedures for notifying both fellow rescuers and personnel at the facility where the emergency occurs. Contact names of fire fighters and business owners should be listed in a hierarchy that enables callers to try one name after another on lists until they reach appropriate responders.

Management of Training for Emergency Response. Management must create, review, deliver, and keep records of effective training programs in all aspects of operations. OSHA's *Hazardous Waste Operations and Emergency Response Standard* (HAZWOPER, 29 CFR 1910.120) and PPP-44, *Pesticides and Planning for Emergencies,* provide detailed guidance for the management of training and specify the degree to which participants can respond to a spill. Participation in outside trade councils may be another important source of effective training materials. Training program documentation must include comprehensive initial technical as well as safety/health training, refresher programs, on-the-job training, and drills and exercises with local responders.

EMERGENCY PLANS

Regulations, Records, and Reports

Under SARA Title III/EPCRA and many other federal and state regulations, facilities may be required to prepare emergency plans. Detailed guidance for such plans is available in NFPA 434, *Code for the Storage of Pesticides,* and NFPA 471, *Recommended Practice for Responding to Hazardous Materials Incidents,* as well as in other documents such as PPP-44, *Pesticides and Planning for Emergencies: Prevention, Reaction, and Response.* Because there are many regulations scattered across the Environmental Protection Agency, the Department of Transportation, the Department of the Interior, and the Department of Labor, the agencies agreed to a single, consolidated plan: The National Response Team's Integrated Contingency Plan. This consolidation allowed businesses that store pesticides to focus on a single plan. That plan can be found in the Federal Register, Volume 61, No. 109, Page 28642, and in PPP-44.

It is critical that the chemicals stored on-site be reviewed against the products on the SARA Title III/EPCRA listing of reportable products. If the pesticide is on that list and is stored above its reportable quantity, then the facility is required to report to local fire departments, the appropriate state emergency response commission (SERC), and any local emergency planning commissions (LEPC). Management at chemical storage and retail facilities should (1) have a thorough knowledge and understanding of the requirements, (2) file all necessary reports, (3) complete an effective emergency response preplan in concert with local fire authorities, and (4) be active in the local emergency planning committee (PPP-32, *Pesticides and Community Right-to-Know*).

Developing and Implementing Emergency Plans

Preplanning. Effective risk management for general operations and for emergency response is a joint responsibility of the facility owner/operator and the emergency response organizations serving the facility. Adequate preplanning requires evaluation of material safety data sheets (MSDSs) for each formulation. As is the case with all chemicals, the emergency response organization must have MSDSs available to them and must be capable of interpreting how the physical and chemical characteristics of the pesticide products in storage change or modify its approach to responding, reacting, and containing an emergency.

Developing the Plan. The plan should address product spills, medical emergencies, and other types of disasters that may occur at the facility. The plan should be prepared with the cooperation and consultation of local, state, and federal emergency response agencies and with their assistance, if possible. The emergency response plan should be viewed as an integral component of an overall chemical management plan for the facility. Once the plan has been completed, the various positions identified as participating actively in response (e.g., incident commander, technician, and specialist) must be trained to meet the requirements of the OSHA HAZWOPER regulations. NFPA 472, *Standard for*

Professional Competence of Responders to Hazardous Materials Incidents, provides competency standards for such training.

As part of emergency planning, facility management, the fire department, and other involved agencies should identify under which scenarios a fire will be fought versus letting it burn. Factors to be evaluated when making this determination by the responders should include (1) the presence of combustible loading in the form of flammable products, (2) combustible packaging materials, (3) the stage (intensity) of the fire at the time emergency responders arrive, (4) combustible construction, (5) the toxicity of the products involved, (6) the expected toxicity of smoke and products of combustion, (7) the direction of the smoke, (8) the surrounding population, (9) impact of fire water runoff on the environment, and (10) the location of drinking water sources. Other factors include the ability to contain fire-fighting water runoff and the proximity of people, property, or sensitive environmental areas to the products of pesticide combustion.

Insurance Coverage. Many insurance policies held by commercial businesses and farms have insurance clauses that exclude pollution remediation from the policy (see PPP-49, *The Insurance Policy*). A Let-It-Burn Policy is found in PPP-44, *Pesticides and Planning for Emergencies.* Before instigating such a policy, it is advisable to check with the insurance carrier and attorney to see what other legal ramifications are involved with taking such a position. No matter what an insurance policy for a facility stipulates, it is always the fire responders' responsibility to determine if the public is better protected by letting the fire burn or extinguishing it.

Figure 6.14.15 shows a barn being allowed to burn because of pesticides stored inside.

FIGURE 6.14.15 Letting a Barn Burn Due to Pesticide Storage

Implementing the Plan. The emergency plan should be exercised and reviewed annually to reflect changes in products handled, quantities handled, and operating methods, and this process should be documented. The plan should also be reviewed with local fire departments. To handle emergencies, it is important to have on hand a complete list of emergency contacts and phone numbers. These phone numbers should include both mandatory regulatory notification numbers as well as contacts for technical assistance and cleanup services. Examples of necessary phone numbers include those of the facility emergency coordinator, fire department, police, emergency medical transport and hospitals, CHEMTREC, and chemical suppliers, among others. This phone list should be updated whenever changes in contacts and personnel are made, and the list should be verified at least twice a year. (For a prototype list, see PPP-45, *The Quick Emergency Response Plan*, and PPP-28, *Pesticides and Spill Management.*)

SECURITY

Today security has become a serious issue that each farm and business must address. There are many types of threats that can have serious repercussions, not only to a facility's operations but to the community as well. Threats can come from a mischief-maker, trespasser, thief, narcotics entrepreneur, disgruntled employee, computer hacker, homegrown extremist, or terrorist. It is very important for those planning security to determine which one is a realistic threat and, then, to implement measures to deter their unwelcome work. This means deterring, detecting, and delaying the wrongdoer. Security issues are addressed in great detail in PPP-64, *Rural Security Planning: Protecting Family, Friends, and Farm.*

A pesticide facility should have good exterior lighting. Fencing and gates, as shown in Figure 6.14.16, can be effective deterrents to security breaches. Security alarms are also an effective method to deter unauthorized entry. Inbound and outbound shipments should be handled in a designated area. Patrolling the facility affords additional security with the benefit of providing early identification of chemical releases. Access to all hazardous pesticide storage areas must be controlled. In some cases in which there have already been problems, electronic security measures, such as alarms, access control, and video surveillance, might be warranted. Figure 6.14.17 shows electronic devices a farmer has installed on his grain bin. Facil-

FIGURE 6.14.16 Fencing Around a Commercial Agricultural Facility

FIGURE 6.14.17 A Farmer's Grain Bin Protected from Vandalism by Electronic Devices

ity managers can always turn to local police when they feel that increased surveillance is called for.

It is important to hire employees who are not only well qualified for the work but who have also been screened to identify those who might pose a security risk. In many companies, routine drug and alcohol testing as well as background checks are job requirements for drivers and warehouse employees (PPP-69, *The Hiring Process*).

Routine inventories reduce pilferage and help identify problems early. Inventories must be thorough with special attention given to visual inspection of each unit. In many cases, employees cannot access the pesticide products without first contacting a supervisor who actually handles the transfer of product to the employee.

SUMMARY

Pesticides are important products that produce tangible benefits to the public. However, like most technologies, the benefits come with some level of risk when the products are stored on site in large quantities or are transported on highways. The storage, transportation, and use of pesticides are controlled by state and federal regulations and locally through building codes and zoning. Business owners and farm managers must not only comply with these standards but also follow additional industry guidelines. It is important that emergency responders take the initiative to work closely with business owners and farm managers. By visiting facilities where pesticides are stored, emergency responders can become familiar with sites ahead of time and review emergency plans with owners. The goal is to put into practice measures that prevent the release of pesticides into the environment, whether through an accidental release, a fire, natural disaster, vandalism, or terrorism. Site-specific practices must be developed to ensure that the risks posed to employees, neighbors, community, and environment are minimized and controlled.

Overview
Nature of Explosive Materials
Types of Explosive Materials
Classes of Explosives
Manufacture of Explosive Materials
Transportation of Explosive Materials
Storage of Explosive Materials
Fire Protection for and Safety and Security Issues Involving Explosive Materials

Key Terms

blasting agent, explosive, low explosive, nuclear explosive, permissible explosive, primary explosive, propellant, secondary high explosive, storage magazine, two-component explosive

This chapter describes explosives and explosive materials, with emphasis on their fire and explosion hazards. Additional important data concerning the manufacture, transportation, storage, and use of explosive materials can be found in NFPA 495, *Explosive Materials Code,* and in other referenced material. NFPA 495 is a current and comprehensive code that should be studied by all who work with explosives.

See also Section 2, Chapter 8, "Explosions"; and Section 17, Chapter 8, "Explosion Prevention and Protection."

OVERVIEW

Hazard of Explosives

NFPA 495 provides a rule that must always be obeyed: *Do not fight fires involving explosive materials.* Always look for signs demarcating explosives storage. Never fight a fire that involves explosives; evacuate the area instead. In 1988, six fire fighters were killed in Kansas City, Missouri, fighting a fire in an ammonium-nitrate-based blasting agent storage facility.[1]

The hazardous nature of explosives has long been recognized, and their production and use throughout the United States and around the world make it necessary to point out those properties that contribute most to the inherent dangers of these very important industrial and military products. In the industrial field alone, over 7 billion pounds (3.2 million metric tons) of explosives and blasting agents were used in 2005. As shown in Figure 6.15.1, commercial explosives consumption has steadily increased in the last half century. Of these totals, approximately 90 percent were used in mining and the remainder principally in construction operations.[2]

History

An explosive is any chemical compound, mixture, or device, the primary or common purpose of which is to function by explosion. Black powder was the first explosive known, although fireworks and pyrotechnics were known and used many centuries earlier.[3] Roger Bacon described the preparation and properties of black powder in the thirteenth century, and it was first used for military purposes in the fourteenth century. The first use of black powder for mining operations occurred in the latter part of the seventeenth century, and it remained the dominant commercial explosive until the latter part of the nineteenth century. In 1846, the compound nitroglycerin was first prepared and its explosive properties studied. The extremely hazardous nature of this compound prevented its wide use until 1867, when Alfred Nobel made the discovery that nitroglycerin absorbed in an inert material, such as diatomaceous earth, produced a mixture that was relatively safe to handle. The best-known form of this mixture is dynamite. This explosive mixture, with many modifications and improvements, remained the predominant commercial explosive until the introduction of modern blasting agents in the mid-1950s. Meanwhile, the use of black powder decreased to an insignificant

Lon D. Santis is manager of technical services for the Institute of Makers of Explosives. He is a member of NFPA's Technical Committee on Explosives.

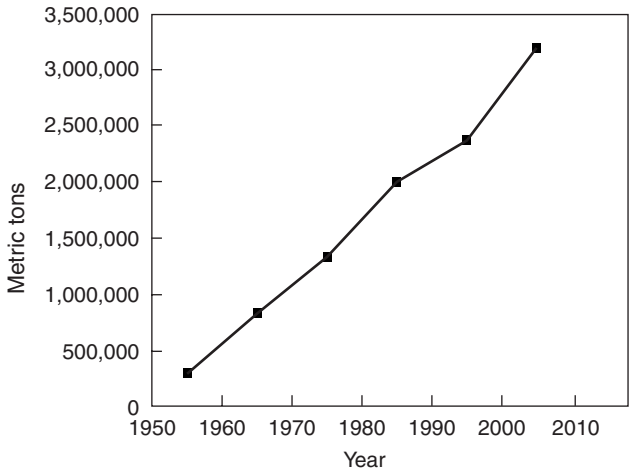

FIGURE 6.15.1 U.S. Commercial Explosives Consumption

quantity, largely because of its sensitivity to heat and flame. In the last 50 years, blasting agents composed principally of ammonium nitrate (AN) have taken over approximately 99 percent of the market.[2] Today, over 90 percent of blasting agents are delivered to the worksite in bulk. These changes are based largely on (1) economic considerations and (2) the greatly improved safety of water-based explosive materials.

NATURE OF EXPLOSIVE MATERIALS

Terminology

An understanding of the nature of explosive materials is essential before one can understand the fire and explosion potential of these hazardous products. A few general terms are defined to provide a background for future discussions.

Blasting Agents (Division 1.5 Materials): Materials that have been classified according to tests specified in Title 49 of the U.S. *Code of Federal Regulations,* Parts 170–189,[4] and found to be so insensitive that there is very little probability of accidental initiation to explosion or of transition from deflagration to detonation. Blasting agents cannot be detonated in the standard blasting cap sensitivity test.

Detonator: Any device containing an initiating or primary explosive that is used for initiating detonation. A detonator is not permitted to contain more than 154 grains (10 g) of explosive material per unit, excluding ignition or delay charges. The term includes, but is not limited to, electric detonators of the instantaneous and delay types, detonators for use with safety fuses, detonating cord delay connectors, and nonelectric detonators of the instantaneous and delay types that consist of a detonating cord, a shock tube, or any other replacement for electric leg wires.

Explosion: A chemical reaction involving an extremely rapid expansion of gases usually associated with the liberation of heat.

Explosive: Any chemical compound, mixture, or device, the primary or common purpose of which is to function by explosion. The term includes, but is not limited to, dynamite, black powder, pellet powder, initiating explosives, detonators, safety fuses, squibs, detonating cord, igniter cord, and igniters. The term includes any material determined to be within the scope of Title 18, United States Code, Chapter 40, "Importation, Manufacture, Distribution and Storage of Explosive Materials," and also includes any material classified as an explosive by the U.S. Department of Transportation, "Hazardous Materials Regulations," 49 CFR, Parts 100–199.

Explosive Material: Includes explosives, blasting agents, water gels (slurries), and detonators. A list of explosive materials is published annually by the Bureau of Alcohol, Tobacco, and Firearms (ATF) in the Federal Register.

Propellant: An explosive that normally functions by deflagration and is used for propulsion purposes. It is classified by the U.S. Department of Transportation, "Hazardous Materials Regulations" as Division 1.1 or 1.3, depending on its susceptibility to detonation.

Fires and Explosions

A distinction must be made between controlled and unwanted fires and explosions. Controlled combustion reactions are basic to the production of power and necessary for an industrial economy. Likewise, detonation reactions are essential for use by the mining and construction industries. On the other hand, the loss of life and natural resources from unwanted fires and explosions is a matter of international concern. Since fire is a major hazard associated with the utilization of explosives and blasting agents, this chapter discusses the basic nature of these materials and methods for reducing the loss from uncontrolled reactions in these materials.

TYPES OF EXPLOSIVE MATERIALS

This chapter mainly addresses commercial explosives, but some of the similarities and differences between commercial and military explosives are mentioned. Most military explosives have high shattering power and relatively high detonation velocities. Military explosives are often kept in storage for relatively long periods of time and therefore must have extremely good long-term stability. It is essential that these explosives detonate reliably even after storage in a wide variety of conditions. Although there are no truly military explosives equivalent to the blasting agents used in commercial operations, the military uses commercial-type explosives and blasting agents for operations such as road building, airstrip preparations, and a wide variety of similar operations.

Commercial explosives are designed to have a wide range of properties to meet the diverse needs of users. Explosives users consider factors such as water resistance, fume production, sensitivity, energy, shelf life, and ruggedness when choosing the right product for their application. For example, explosives used in underground operations should have relatively good postdet-

onation fume characteristics to minimize production of toxic gases that might adversely affect personnel.

Explosive materials can be divided into a number of specific types according to their characteristic properties.[4] The following types are generally recognized in industry.

Primary or Initiating High Explosives

Primary explosives are sensitive explosives that nearly always detonate by simple means such as spark, flame, impact, friction, or other primary heat sources of appropriate magnitude. These materials are quite hazardous, but they play a very important role in the utilization of explosive materials. Typical explosives of this type are mercury fulminate, lead styphnate, and lead azide. Because of their high sensitivity they are seldom, if ever, used alone, and their principal function is to initiate detonation in less-sensitive explosives. They are used almost exclusively as the initiating agent in detonators, and are classified by the Department of Transportation (DOT) as Division 1.1A materials. Unless shipped as a component of a manufactured article, initiating explosives normally must be wetted (desensitized) with water or alcohol for shipment.

Secondary High Explosives

These are materials that are relatively insensitive to mechanical shock and heat and yet are readily detonated by the shock from a primary explosive. They can be used for both military purposes and in commercial blasting operations. Secondary high explosives include such products as TNT, RDX, dynamite, nitroglycerin, and pentaerythrital tetranitrate (PETN). Because of nitroglycerin's sensitivity, it is normally not used alone. Secondary high explosives are generally detonator-sensitive, which distinguishes them from blasting agents, and are classified by DOT as Division 1.1D materials.

Low Explosives or Propellants

These are used primarily for propulsion purposes. They normally function by deflagration (rapid burning) rather than detonation, although some propellants are susceptible to detonation when confined. Black powder, smokeless powder, and solid rocket fuels fall into this category. Fire constitutes the greatest hazard in the handling and use of propellant explosives. Propellants can be Division 1.1 or 1.3 materials (Class A or Class B explosives).

Blasting Agents

The most commonly used explosive is a fuel/oxidizer system that consists primarily of ammonium nitrate and a fuel, such as No. 2 diesel fuel. The formulation is termed ANFO and is sold under a variety of trade names. The addition of approximately 6 percent fuel oil to specially prepared AN prills produces a very efficient blasting material. This combination has the advantages of low cost, high energy, satisfactory fume characteristics, and greatly increased safety over nitroglycerin dynamites. Although blasting agents and secondary explosives should simply burn in a fire, confinement may allow the burning to transition into a detonation. ANFO's use in wet conditions is limited, and ANFO does not have relatively strong shattering power. Therefore, many variations of the basic ANFO formulation have been developed and successfully used. Powdered aluminum or other fuels can be added to increase the energy and blasting efficiency of the basic ANFO formulation. AN solutions can be emulsified or slurried with other ingredients to make a semisolid type of blasting agent and mixed with AN or ANFO.

Water Gels, Slurries, and Emulsions

Operations where a very water-resistant explosive material is a necessity and where a higher shock energy than can be obtained with ANFO is desirable, have led to the development of water gels, slurries, and emulsions. These may be classed as either 1.5 (blasting agents) or 1.1 explosives, depending on their formulation and sensitivity. Ammonium nitrate is usually the basic oxidizer in this type of explosive, and it may be sensitized by a variety of materials, including paint-grade aluminum, monomethylamine nitrate (MMAN), TNT, and various gelling agents and emulsifiers. Water gels, slurries, and emulsions usually contain between 10 and 25 percent water.

Nuclear Explosives

Nuclear explosives are used for military purposes only.

CLASSES OF EXPLOSIVES

In 1991 the Department of Transportation (DOT) issued regulations for the transportation of hazardous materials based on the *United Nations Recommendations on the Transportation of Dangerous Goods*.[5] Use of the classification system previously in place (Class A, B, and C) is no longer permitted by DOT.

UN Recommendations for Classification

Under the United Nations recommendations, hazardous materials are assigned to a class according to their specific characteristics. Explosives are assigned to Class 1, and the explosives in Class 1 are divided into six divisions, as shown in Table 6.15.1. Class 1 divisions are further divided into compatibility groups.

Where the classification system in effect prior to January 1, 1991, is referenced in state or local laws, ordinances, or regulations not pertaining to the transportation of hazardous materials, Table 6.15.2 can be used to compare old and new hazard class names.

Other Classification Systems

The Department of Justice's ATF bureau has a classification system based on the type of explosive material involved. In their system, explosive materials are classified as high explosives, low explosives, and blasting agents. This classification is employed in the enforcement of Title 11, "Regulation of Explosives," of the *Organized Crime Control Act of 1970* (18 U.S.C., Chapter 40), which is intended to provide for the secure and safe storage of explosive materials.

TABLE 6.15.1 UN Recommendations for Classification of Explosives

Class 1 Division	*DOT Package Label*
Division 1.1. Consists of explosives that have a mass explosion hazard. A mass explosion is one that affects almost the entire load instantaneously. Division 1.2. Consists of explosives that have a projection hazard but not a mass explosion hazard. Division 1.3. Consists of explosives that have a fire hazard and either a minor blast hazard or a minor projection hazard, or both, but not a mass explosion hazard.	
Division 1.4. Consists of explosives that present a minor explosion hazard. The explosive effects are largely confined to the package, and no projection of fragments of appreciable size or range is to be expected. An external fire must not cause virtually instantaneous explosion of almost the entire content of the package.	
Division 1.5. Consists of very insensitive explosives. This division comprises substances that have a mass explosion hazard but are so insensitive that there is very little probability of initiation or of transition from burning to detonation under normal conditions of transport.	
Division 1.6. Consists of extremely insensitive articles that do not have a mass explosion hazard. This division comprises articles that contain only extremely insensitive detonating substances and that demonstrate a negligible probability of accidental initiation or propagation.	

Notes:
The "**" on the DOT package label must be replaced with the appropriate division number and compatibility group letter.
The "*" on the DOT package label must be replaced with the appropriate compatibility group.

Permissible Explosives

The term *permissible explosive* is used to describe a type of explosive that has been tested and approved by the Department of Labor's Mine Safety and Health Administration as meeting the minimum safety requirements for use in underground coal mines.[6] These materials are modified dynamites, water gels, or emulsions that exhibit reduced tendencies to ignite flammable gas-air and gas-air-coal dust mixtures.

TABLE 6.15.2 Comparison of Old and New Hazard Class Names as of January 1, 1991

Current Classification	*Class Name Prior to January 1, 1991*
Division 1.1	Class A explosives
Division 1.2	Class A or B explosives
Division 1.3	Class B explosives
Division 1.4	Class C explosives
Division 1.5	Blasting agents
Division 1.6	No applicable hazard class

Two-Component Explosives

Two-component, or binary, explosives consist of two or more unmixed, commercially manufactured, prepackaged chemicals, including oxidizing chemicals, flammable liquids, or solids that are not independently classified as explosives. When mixed, the chemicals exhibit explosive properties and must be stored, transported, and handled as explosives.

MANUFACTURE OF EXPLOSIVE MATERIALS

All manufacturers of explosive materials in the United States must obtain a license from ATF and must follow the ATF regulations as specified in Title 27 of the U.S. *Code of Federal Regulations,* Part 555. Additionally, state and local regulatory agencies may also have rules covering the manufacture of explosive materials and may license manufacturers.

Cartridged or packaged explosive materials are manufactured at fixed plant sites and are transported to the point of use or are shipped to storage/distribution facilities generally located in or near explosive-consuming areas. The production of explosive materials at fixed plant sites must be under the close super-

vision of qualified personnel. The safety record at such plants should be extremely good. Hazards should be well recognized and operating procedures designed to keep potential hazards to a minimum. Fire is the chief concern during manufacture, and plant layout should keep this hazard within reasonable limits. Smoking should never be allowed near the explosive operations, and use of flame-producing equipment must occur only in specific areas under strict safety procedures.

The use of bulk explosives dominates large mining, quarrying, and construction blasting operations. Bulk explosives are Division 1.5 materials (blasting agents) and can consist of ANFO, water gels, slurries, or emulsions, or blends of these materials. Bulk explosives can be plant-mixed and delivered to the blast site by bulk trucks or they can be mixed at the blast site in a bulk truck. Bulk explosives are normally moved by auger or pumped from the bulk truck directly into the blastholes.

Fire is a safety concern in the operation of any type of bulk truck, and the driver/operator must be thoroughly trained in the operation of the mixing, pumping, and/or augering equipment. Bulk transfer operations involving pumps should follow industry standards.[7] Equally important are the characteristics, safe handling, and emergency procedures for the explosive materials being handled. The driver/operator must have a DOT commercial driver's license (CDL), with a hazardous materials (H) endorsement.

TRANSPORTATION OF EXPLOSIVE MATERIALS

The DOT regulates the transportation of all explosive materials in accordance with regulations set forth in U.S. *Code of Federal Regulations,* Title 49, Chapter I, "Transportation," Parts 100–199.[8] Copies of these regulations can be obtained from the U.S. Government Printing Office in their bookstores or on the Internet at http://www.gpoaccess.gov.

DOT must approve and classify an explosive before it can be transported. Most commercial explosives are transported over public highways by truck. Military explosives are transported both by rail and by truck. Fire is the greatest concern in the transportation by motor vehicle over public highways. Although tire fires are less common since the introduction of tubeless tires, they are still a concern and represent a hazard that is difficult to control because the driver of a truck may be unaware of the fire until it has gained considerable headway. Detonators may be transported in limited quantities on the same vehicle with explosives and blasting agents, provided DOT regulations concerning quantity and type of container are observed.

Truck and rail transportation exposes the public to fire and explosion hazards. Unfortunately, fires and other types of accident situations can draw spectators, which increases the danger of casualties.

The DOT publishes an *Emergency Response Guidebook* (ERG),[9] which covers emergency response procedures for transportation incidents involving explosives or other hazardous materials. The publication is widely distributed and is normally carried on all hazardous materials transport vehicles and by emergency responders such as fire and police departments. Copies of the ERG can be purchased from the U.S. Government Printing Office in their bookstores. Electronic copies of the ERG and other ERG resources are available on the Internet at http://hazmat.dot.gov/pubs/erg/gydebook.htm.

Safe havens and interchange lots provide parking and interchange facilities for vehicles transporting explosives. Some explosives interchange lots also provide temporary holding facilities for less-than-truckload quantities of explosives. These terminals should be well controlled and are operated under strict safety regulations. Regulations for these terminals are contained in NFPA 498, *Standard for Safe Havens and Interchange Lots for Vehicles Transporting Explosives.*

STORAGE OF EXPLOSIVE MATERIALS

Objectives

A primary objective for the storage of most nonexplosive industrial materials is to provide protection for such materials from their surroundings. Because of the hazardous nature of explosive materials, the reverse must be considered. Safety to the industrial workers involved and to the general public in the vicinity of such storage must be of primary importance. Since most explosive materials are used by the mining and construction industries, these industries should train their employees to provide the maximum attainable safety. Employees of explosives manufacturing firms must be well aware of the hazards of their occupation and have safety be an integral part of their work.

Commercial explosives are usually consumed quickly, but occasionally, old or abandoned explosives are encountered in questionable condition. Commercial explosives can have shelf lives ranging from a few weeks to indefinite and can become unstable or even inert. Consult the manufacturer or local bomb squad if any uncertainty exists.

Storage Magazines

To provide proper storage for the wide variety of explosive materials now being produced, five different types of magazines are recognized. The requirements for these five types of magazines are given in the regulations developed by the ATF.[10] The specifications for these magazines and types of materials to be put in them can be obtained from ATF or can be found in NFPA 495.

The probability of unintentional initiation of an explosive while in an approved storage location is very small. To safeguard the general public, the *American Table of Distances for Storage of Explosive Materials* (ATD) has been prepared to indicate the isolation distances for stores of explosives from points of contact with the public[11] (Table 6.15.3). The Institute of Makers of Explosives periodically revises this table. Although Division 1.5 materials (blasting agents) are appreciably less sensitive than Division 1.1 materials, once they are initiated to detonation, the damage produced by such an accident is comparable, and the ATD is used to determine the safe distances of stores of Division 1.5 materials from inhabited buildings, public highways, and passenger railways. However, because of the lower sensitivity of Division 1.5 materials, the separation distances between stores

Explanatory Notes Essential to the Application of the American Table of Distances for Storage of Explosives

[a] 1 ft = 0.305 m.

[b] "Explosive materials" means explosives, blasting agents, and detonators. "Explosives" means any chemical compound, mixture, or device, the primary or common purpose of which is to function by explosion. A list of explosives determined to be within the coverage of Title 18, United States Code, Chapter 40, "Importation, Manufacture, Distribution and Storage of Explosive Materials," is issued at least annually by the Director of the Bureau of Alcohol, Tobacco, and Firearms of the Department of the Treasury. For quantity and distance purposes, detonating cord of 50 grains per foot should be calculated as equivalent to 8 lb (3.7 kg) of high explosives per 1000 ft (305 m). Heavier or lighter core loads should be rated proportionately. "Blasting agents" means any material or mixture consisting of fuel and oxidizer, intended for blasting, and not otherwise defined as an explosive, provided that the finished product, as mixed for use or shipment, cannot be detonated by means of a No. 8 test blasting cap where unconfined. "Detonator" means any device containing any initiating or primary explosive that is used for initiating detonation. A detonator may not be permitted to contain more than 154 grains (10 g) of total explosives by weight, excluding ignition or delay charges. The term includes, but is not limited to, electric blasting caps of instantaneous and delay types, blasting caps for use with safety fuses, detonating cord delay connectors, and nonelectric instantaneous and delay blasting caps that use detonating cord, shock tube, or any other replacement for electric leg wires. All types of detonators in strengths through No. 8 cap should be rated at 1½ lb (0.7 kg) of explosives per 1000 caps. For strengths higher than No. 8 cap, the manufacturer should be consulted.

[c] "Inhabited building" means a building regularly occupied in whole or part as a habitation for human beings, or any church, schoolhouse, railroad station, store, or other structure where people are accustomed to assemble, but does not include any building or structure occupied in connection with the manufacture, transportation, storage, or use of explosive materials.

[d] "Highway" means any public street, public alley, or public road.

[e] "Railway" means any steam, electric, or other railroad or railway that carries passengers for hire.

[f] "Magazine" means any building, structure, or container, other than an explosives manufacturing building, approved for the storage of explosive materials. Where two or more storage magazines are located on the same property, each magazine shall comply with the minimum distances specified from inhabited buildings, railways, and highways, and, in addition, they should be separated from each other by not less than the distances shown for "separation of magazines," except that the quantity of explosive materials contained in detonator magazines shall govern with regard to the spacing of said detonator magazines from magazines containing other explosive materials. If any two or more magazines are separated from each other by less than the specified "separation of magazines" distances, such magazines, as a group, shall be considered as one magazine, and the total quantity of explosive materials stored in such group shall be treated as if stored in a single magazine located on the site of any magazine of the group, and shall comply with the minimum specified distances from other magazines, inhabited buildings, railways, and highways.

[g] 1 lb = 0.454 kg.

[h] "Natural barricade" means natural features of the ground, such as hills, or timber of sufficient density that the surrounding exposures that need protection cannot be seen from the magazine when the trees are bare of leaves. "Artificial barricade" means an artificial mound or revetted wall of earth of a minimum thickness of 3 ft (0.9 m). "Barricaded" means the effective screening of a building containing explosive materials from the magazine or another building, a railway, or a highway by a natural or an artificial barrier. A straight line from the top of any sidewall of the building containing explosive materials to the eave line of any magazine or other building or to a point 12 ft (3.7 m) above the center of a railway or highway shall pass through such barrier.

[i] Storage in excess of 300,000 lb (136,200 kg) of explosive materials in one magazine generally is not necessary for commercial enterprises.

[j] This table applies only to the manufacture and permanent storage of commercial explosive materials. It is not applicable to the transportation of explosives or any handling or temporary storage necessary or incident thereto. It is not intended to apply to bombs, projectiles, or other heavily encased explosives.

[k] Where a manufacturing building on an explosive materials plant site is designed to contain explosive materials, the building shall be located at a distance from inhabited buildings, public highways, and passenger railways in accordance with the American Table of Distances based on the maximum quantity of explosive materials permitted to be in the building at one time.

Source: The American Table of Distances is reprinted from IME Safety Library Publication No. 2 with permission of the Institute of Makers of Explosives, as revised in June 1991.

of Division 1.1 materials and stores of Division 1.5 materials, or between stores of Division 1.5 materials, need not be as great as that required between stores of Division 1.1 materials (Table 6.15.4).

The ATD applies to the manufacture and storage of *commercial* explosive materials. The distances specified are those measured from the explosive materials storage facility to the inhabited building, highway, or passenger railway, irrespective of property lines.

The ATD covers all commercial explosive materials, including, but not limited to, high explosives, blasting agents, detonators, initiating systems, and explosive materials in process. The ATD is not designed to be altered or adjusted to accommodate varying explosive characteristics such as blast effect, weight strength, density, bulk strength, and detonation velocity.

The ATD should not be used to determine safe distances for blasting work, the firing of explosive charges for testing or quality control work, or the open detonation of waste explosive materials. It may, however, be used as a guide for developing distances for the unconfined, open burning of waste explosive materials where the probability of transition from burning to high-order detonation is unlikely.

Table 6.15.4 shows the recommended separation distances and the thickness of artificial barricades for the separation of Division 1.1 from Division 1.5 materials and AN. When barricades are *not* provided, the recommended distances must be increased by a factor of six, as shown in Table 6.15.4 (Note 2).

FIRE PROTECTION FOR AND SAFETY AND SECURITY ISSUES INVOLVING EXPLOSIVE MATERIALS

Fire is a principal cause of accidents involving explosive materials. Although explosives may vary in their sensitivity to fire, they always have the potential to produce a disastrous explosion when subjected to fire. The only effective method for fire protection with explosive materials is to eliminate the source of fire. This involves meticulous housekeeping standards. It is often a small fire in oily rags or wastepaper that triggers a major catastrophe. Smoking or the use of any fire-producing equipment should not be permitted where explosive materials are produced, handled, stored, or used. Because of the relative insensitivity of 1.5 materials (blasting agents), there is always a danger that personnel will become careless around these materials. A fire and subsequent explosion in a blasting agent mixing house near Norton, Virginia, illustrates the potential hazard from the careless use of heat-producing equipment.[12] Another fire and explosion in a blasting agent storage facility in Kansas City, Missouri, killed six fire fighters who were fighting the fire.[1]

Some of the materials used in making explosives and blasting agents may also be hazardous. Materials likely to be found include nitric acid, aluminum powder, AN, ammonium perchlorate, sodium nitrate, fuel oil, and corrosive gas. NFPA codes and standards should be consulted for proper storage and protection of these materials.

For all explosive materials, whether in manufacture, storage, transportation, or use, housekeeping should be of the highest order.

Fighting Fires Involving Explosives and Blasting Agents

No attempt should be made to fight a fire involving explosive materials. The area should be evacuated to a distance of at least 2000 ft (610 m).

Truck fires involving explosive materials pose a special threat to the public because of the potential for large numbers of occupants of other vehicles to be within the radius of effects of any blast. A study of DOT data showed there were 10 truck fires involving Class 1 materials in the six-year period from 1993 to 1998.[13] Although none of these incidents resulted in a mass detonation, the possibility always exists. To prevent loss of life, all sources of ignition should be controlled until the cargo can be transported away. Immediate evacuation in the event of a fire is imperative because although the possibility of a detonation always exists, DOT regulations should prevent it from occurring for some time.

Security

Long before the current threats existed, the element of security was integral to commercial explosives operations. Although commercial explosives are usually not the choice of terrorists or other criminals, nonetheless the public must be protected from the illicit use of commercial explosives. Security-related regulations of the DOT, ATF, and Department of Homeland Security (DHS) should be thoroughly understood and complied with. Copies of these regulations can be obtained from the U.S. Government Printing Office in their bookstores or on the Internet at http://www.gpoaccess.gov. Industry standards should be consulted for ways to increase security beyond the level that the regulations require or address.[14]

Destruction of Explosive Materials

At times it may be necessary to destroy commercial explosive materials. These may consist of explosives or blasting agents from containers that have been broken during transportation, or may be materials that have exceeded their recommended shelf life, are believed to be overage, or are no longer needed.

Before destroying any explosives product, one must be familiar with the regulatory requirements and properties of the product. The member companies of the Institute of Makers of Explosives have agreed to supply advice and assistance in destroying explosives. Assistance should be sought from the manufacturer, if known. If the manufacturer is not known, a member company of the Institute of Makers of Explosives may provide advice or assistance.

When improvised explosive devices or bombs, military ordnance, military explosives, or homemade or illegal explosive materials are involved, disposal should be under the supervision of trained bomb disposal experts from a governmental regulatory agency.

SUMMARY

Generally speaking, the greatest threat to unintentional initiation of explosives is fire. Every effort should be made to prevent

TABLE 6.15.4 Table of Recommended Separation Distances of Ammonium Nitrate and Blasting Agents from Explosives or Blasting Agents[a,b,h]

Donor Weight		Minimum Separation Distance of Acceptor when Barricaded[a] (ft)[c]

80,000	90,000	30	108	40
90,000	100,000	32	115	40
100,000	120,000	34	122	50
120,000	140,000	37	133	50
140,000	160,000	40	144	50
160,000	180,000	44	158	50
180,000	200,000	48	173	50
200,000	220,000	52	187	60
220,000	250,000	56	202	60
250,000	275,000	60	216	60
275,000	300,000	64	230	60

[a]Where the ammonium nitrate or blasting agent, or both, is not barricaded, the distances shown in Table 6.15.4 must be multiplied by 6. These distances allow for the possibility of high-velocity metal fragments from mixers, hoppers, truck bodies, sheet-metal structures, metal containers, and the like that could enclose the donor. Where storage is in bullet-resistant magazines recommended for explosives or where the storage is protected by a bullet-resistant wall, distances and barricade thicknesses in excess of those prescribed in the American Table of Distances (see Table 6.15.3) are not required. Recommended separation distances are to prevent explosion of ammonium nitrate and ammonium-nitrate-based blasting agents by propagation from nearby stores of high explosives or blasting agents referred to in the table as the "donor." Ammonium nitrate, by itself, is not considered to be a donor where applying this table. Ammonium nitrate, ammonium nitrate-fuel oil, or combinations thereof are acceptors. If stores of ammonium nitrate are located within the sympathetic detonation distance of explosives or blasting agents, half the mass of the ammonium nitrate shall be included in the mass of the donor.

[b]These distances apply to blasting agents that pass the insensitivity test prescribed in regulations of the U.S. Department of Transportation and the U.S. Department of the Treasury, Bureau of Alcohol, Tobacco, and Firearms.

[c]1 ft = 0.305 m.

[d]1 lb = 0.454 kg.

[e]The distances in the table apply to ammonium nitrate and ammonium nitrate–based materials that show "negative" (–) result in the UN Test Series 2 Gap Test and show "positive" (+) result in the UN Test Series 1 Gap Test. Ammonium nitrate and ammonium–nitrate–based materials that are DOT hazard Class 1–sensitive shall be stored at separation distances determined by the American Table of Distances (see Table 6.15.3).

[f]Earth, sand dikes, or enclosures filled with the prescribed minimum thickness of earth or sand shall be permitted to be used as artificial barricades. Natural barricades, such as hills or timber of sufficient density that the surrounding exposures that need protection cannot be seen from the donor when the trees are bare of leaves, also shall be permitted to be used.

[g]1 in. = 2.54 cm.

[h]For determining the distances to be maintained from inhabited buildings, passenger railways, and public highways, Table 6.15.3, the American Table of Distances for Storage of Explosives, shall be used.

the start of fire near explosives. Equipment should be on hand to control fires and prevent them from involving the explosives in the fire. *If the explosives become involved in the fire, all fire fighting must stop and people must be removed to a distance of at least 2000 ft (610 m).*

Chapter 16

Manufacture and Storage of Aerosol Products

David L. Fredrickson

Chapter Contents

The Aerosol Product
Classification and Fire Behavior of Aerosols
Aerosol Filling Plants
Product Storage

Key Terms

aerosol, aerosol (hazard classification), propellant, warehouse

A wide variety of products are packaged as aerosols for consumer and industrial uses. Applications of this packaging technique include lubricants, cleaning agents, personal care products, pharmaceuticals, food products, paints, and pesticides.

Prior to the issuance of the first edition of NFPA 30B, *Code for the Manufacture and Storage of Aerosol Products,* in 1990, fire protection of aerosol products was governed by NFPA 30, *Flammable and Combustible Liquids Code.* Under NFPA 30, aerosol products were considered to be equivalent to Class IA flammable liquids. This classification often led to fire protection strategies, particularly in aerosol storage facilities, that were considered by many users to be excessive.

Fire testing conducted in the early to mid-1980s by a consortium of aerosol product manufacturers, industry suppliers, distributors, and interested insurance companies indicated that the fire characteristics of aerosol products were more complicated than provided for under NFPA 30. Some products presented severe fire hazards, whereas others presented a much lower fire challenge than a Class IA flammable liquid, leading not only to the development of an aerosol product fire hazard classification system but to improved fire protection strategies for aerosol storage facilities and, later, to the development of NFPA 30B. Additional research in the late 1980s and early 1990s led to improved understanding and clearer identification of the three levels of aerosol products and their protection criteria.

This chapter reviews the components and manufacture of aerosol products, the fire hazard classification system associated with aerosol products, the fire behavior of aerosol products, and fire protection strategies for manufacturing and storage occupancies.

See also Section 6, Chapter 1, "Fire Hazards of Materials"; and Section 6, Chapter 2, "Combustion Products and Their Effects on Life Safety."

THE AEROSOL PRODUCT

Containers

The most common aerosol containers are high-strength metal units with capacities ranging from 10 milliliters (less than one-half fluid ounce) up to a liter (about one quart). The top and base of the container are generally domed to provide strength. Unit working pressure ranges between 965 to 1241 kPa (140 to 180 psi).

A finished aerosol product typically consists of the basic elements shown in Figure 6.16.1. A base product is dispensed into the aerosol container, an actuator assembly is fitted to the container body, and the container is pressurized with propellant. If a nozzle or tip assembly is not part of the previously installed actuator assembly, one is installed. Depending on actuator design, a protective outer cap (not shown in Figure 6.16.1) may be provided to prevent damage to the nozzle or premature discharge of product.

David L. Fredrickson, Fredrickson & Associates, LLC, is a fire protection engineering and code consultant specializing in aerosol products. Formerly with S. C. Johnson & Son, he is a member of the NFPA Committee on Aerosol Products.

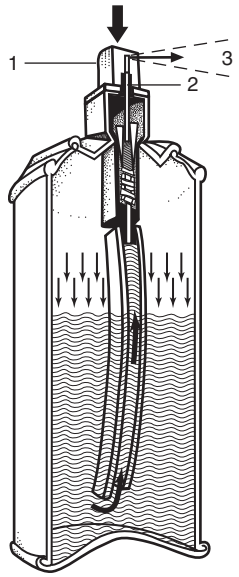

FIGURE 6.16.1 Aerosol Can (Cutaway View). When the plunger (1) is pressed, a hole in the valve (2) allows a pressurized mixture of product and propellant (3) to flow through the plunger's exit orifice.

Propellants

A variety of liquefied gas and compressed gas propellants are available to aerosol formulators. Hydrocarbon propellants are most widely used for a number of reasons, including their ability to maintain relatively constant pressure and resultant spray patterns throughout the life of the product. Characteristics of concern to formulators include odor, purity, stability, and toxicity. Often, to satisfy performance needs, blends of liquefied gases are selected. Although compressed gases are not often used, they do fill certain needs for the formulator. The compressed gases used include carbon dioxide, nitrous oxide, nitrogen, and air.

Liquefied gas propellants are typically blends of propane and butane. Specific blends of these gases are provided to aerosol fillers by propellant suppliers and are marketed as "aerosol"-grade gases. As with most consumer and industrial products, these gas blends are sold under specific manufacturer's product names.

Liquefied gas propellants are gaseous at ambient temperatures and pressures. They will condense to liquid form under moderate pressure or at low temperature. They maintain constant pressure within the aerosol container, at a given temperature, throughout the life of the unit.

Table 6.16.1 contains a summary of the fire hazard properties of the common liquefied propellant gases. The vapor pressure of these materials and the large quantities of gas they produce when vaporized makes them suitable propellants.

A particular gas or gas blend can be denoted by its vapor pressure at 70°F (21°C). For example, A-31 refers to aerosol-grade isobutane, which has a vapor pressure of 31 psig (214 kPa). A-108 refers to propane, with a vapor pressure of 108 psig (745 kPa). A particular desired vapor pressure can be achieved by blending gases.

Base Products

The material other than propellant dispensed from the aerosol container is referred to as the "base product" or the "concentrate." These base products run the full range of consumer and industrial products. The fire hazards of these materials can be minimal (e.g., a water-based liquid), to highly flammable, such as with many lubricants or coatings. An understanding of the physical properties and fire hazards of these materials is important. Each plays an important role in developing the proper fire plans for facilities that manufacture or store aerosol products.

CLASSIFICATION AND FIRE BEHAVIOR OF AEROSOLS

Classification

In order to determine appropriate fire protection measures for use with aerosol products, aerosol products are classified by NFPA 30B into one of three levels. The 1994 edition of the

TABLE 6.16.1 Fire Hazard Properties of Liquefied Gas Propellants

	Flammable Limits*		Flashpoint		Autoignition Temperature	
	Lower	*Upper*	°F	°C	°F	°C
Propane	2.1	9.5	–156	–104	940	504
Isobutane	1.8	8.4	–117	–83	890	477
n-Butane	1.8	8.4	–101	–74	806	430

*Present in air by volume.

standard first recognized a revised approach to aerosol hazard classification developed by Factory Mutual Research Corporation (FMRC).

This new classification method is based on the chemical heats of combustion of the aerosol products. The chemical heats of combustion calculation method accounts for the chemical heats of combustion of the propellant and the base product.

Based on the aerosol product's aggregate chemical heat of combustion, the following hazard levels have been established:

- *Level 1.* Those aerosol products with total chemical heat of combustion equal to or less than 8600 Btu/lb (20 kJ/g)
- *Level 2.* Those aerosol products with total chemical heat of combustion greater than 8600 Btu/lb (20 kJ/g) but less than or equal to 13,000 Btu/lb (30 kJ/g)
- *Level 3.* Those aerosol products with total chemical heat of combustion greater than 13,000 Btu/lb (30 kJ/g)

The 1998 edition first recognized a second classification method with fire testing of a 12-pallet test array.

Proper fire hazard classification of aerosol products is particularly important in storage areas used for aerosol products. The expected fire behavior and associated protection requirements will vary greatly with the level of aerosol product.

Fire Behavior

Fire tests of large amounts of aerosol products have demonstrated the importance of proper sprinkler protection of these products. In an out-of-control situation, Level 2 and Level 3 aerosol products can produce intense heat; rocketing of ruptured containers can make manual fire fighting extremely difficult. These tests have also shown that Level 1 aerosol products, even though they may contain flammable gas propellants, can be very easy to protect. Level 1 aerosol products can be protected in the same manner as Class III commodities, as defined by and in accordance with NFPA 13, *Standard for the Installation of Sprinkler Systems.*

Level 2 aerosol products are typically alcohol-based products, which means most of the base product is water soluble. Although they can produce a very intense fire, they are easier to protect than are Level 3 aerosol products due to the lower heat output of the burning ingredients and solubility in water of the base product.

Level 3 aerosol products are typically petroleum solvent–based products. The higher heat output and lack of water solubility produce an extremely intense fire when sprinkler protection is not adequate.

Both Level 2 and Level 3 aerosol products in warehouse settings have been shown to require rapid sprinkler response. Quick-response sprinklers, such as early suppression fast-response (ESFR) sprinklers or in-rack sprinklers, which are close to the product, demonstrate excellent protection for stored aerosol products, since they generally respond to the carton fire before the aerosol products themselves become involved. Fires involving properly protected Level 2 and Level 3 aerosol products are quite often extinguished by the sprinklers. They do not produce rocketing containers and, where manual fire fighting is required, it can be readily accomplished.

Annex B in NFPA 30B describes many of the small and full-scale tests run with aerosol products. Some full-scale tests had up to 64 pallets of product in the arrays.

Warehouse Fires Involving Aerosols

Prior to the research programs and development of NFPA 30B, aerosol products were involved in several large-scale and costly warehouse fires. One of the most notable fires involving aerosol products destroyed a 27 acre (10.9 ha) distribution center operated by the Kmart Corporation in Falls Township, Pennsylvania, in 1982.[1] A fire in palletized storage of Level 3 aerosol products overwhelmed the automatic sprinkler protection. The fire quickly spread beyond the aerosol storage area. The large volume of fire and failure of the automatic sprinkler protection led to the loss of structural integrity within the building. The loss, expressed in 1982 dollars, was estimated to be in excess of $100 million (Figure 6.16.2).

Aerosol products also were present in a fire that resulted in the loss of a large storage facility in Elizabeth, New Jersey, in 1985, and the loss of a coatings product distribution facility in Dayton, Ohio, in 1987.[2] These and similar incidents indicate that aerosol products storage arrangements should be maintained in configurations that are within the capability of the level of fire protection provided.

AEROSOL FILLING PLANTS

Fire and explosion hazards within aerosol product filling operations are controlled using a number of layers of protection. These layers are (1) incident prevention, (2) fire/explosion suppression, and (3) incident magnitude mitigation. Where not properly protected by these layers, aerosol filling operations have suffered explosions that destroyed facilities and injured employees. Some instances have even resulted in single or multiple deaths. Proper controls, interlocks, and safeguards are needed to prevent catastrophic scenarios.

FIGURE 6.16.2 Aerosol Cans Located in the Area of Fire Origin of the Kmart Fire

Incident Prevention

Aerosol product filling facilities, properly designed to minimize fire and explosion hazards, are subdivided into several areas. Propellant gases are stored in remotely located bulk storage facilities. Further subdivisions can occur in multiple-line filling operations and filling components, such as propellant pumps.

Charging of aerosol cans with propellant must take place in an area separated from the main manufacturing area. Many modern designs use a propellant charging house that is physically separate from the main aerosol production building.

Empty aerosol cans are placed on a conveyor and run through a product filling station where the base product is metered into the can. The actuator assembly is placed into the can and prepared for propellant charging. The actuator assembly may or may not be sealed to the can, depending on which of two methods is used to charge the propellant.

The through-the-valve pressure filling method involves sealing the actuator assembly to the can before the can enters the propellant charging station. There, the propellant is injected into the can through the stem of the actuator assembly, essentially in the reverse manner in which the aerosol product is used. Figure 6.16.3 shows a propellant-charging machine of this type. Figure 6.16.4 is a diagram of one of the charging heads.

In the undercup filling method, the aerosol can is conveyed to the propellant charging station with the actuator assembly in place but *not* sealed to body of the can. In the charging station, the aerosol can is mated to a filler head that lifts the actuator assembly, charges the propellant, then replaces and seals the actuator assembly. Figure 6.16.5 shows an under cup propellant charging machine. Figure 6.16.6 is a diagram of one of the charging heads.

As filled aerosol cans are returned from the filling area to the main production area, quality testing is performed. Cans are conveyed through hot water test baths and defective units removed to disposal containers. Reject-can containers should be provided with active ventilation to remove propellant gas and/or base-product vapors. Finished cans are cartoned and placed in storage.

The initial preparatory steps within the general manufacturing area typically present no unusual fire hazards. Combustibles in the area might include packaging materials, such as cardboard and plastic wrap. The area will also customarily include large quantities of metal containers.

Within the charging facility, several severe fire hazards might exist. The aerosol base product will be present. This material might be a combustible or flammable liquid. Most importantly, propellant gas will be present in the area. Small quantities of propellant might be lost to the atmosphere during charging operations. The propellant gas losses and any vapor evolved from the base product must be controlled by a properly maintained, dedicated ventilation system.

Several active prevention and protection systems should be provided. For prevention purposes, a flammable gas detection system should be installed and interlocked to the charging area's ventilation system, equipment controls, and alarm system.

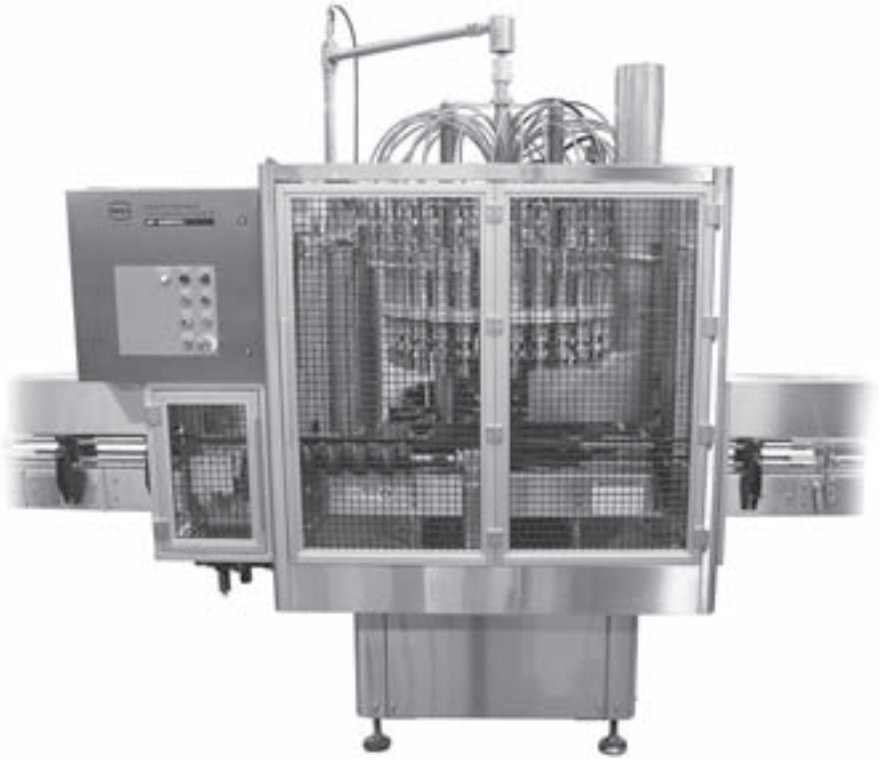

FIGURE 6.16.3 Through-the-Valve Propellant Pressure Filler (Courtesy Packaging Technologies, Inc., Davenport, IA)

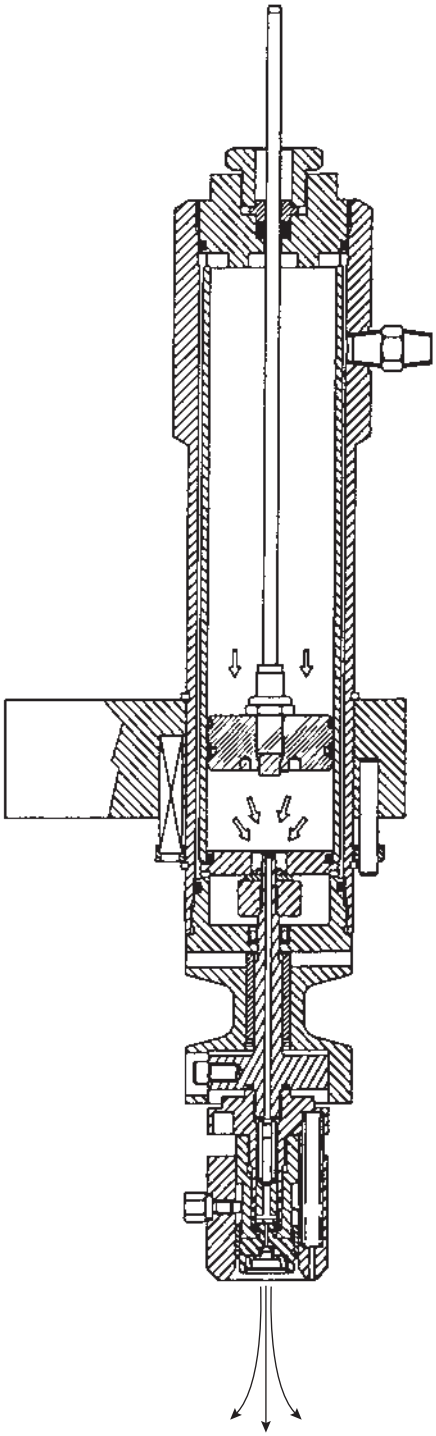

FIGURE 6.16.4 Detail of Through-the-Valve Propellant Pressure Filler Head (Courtesy Packaging Technologies, Inc., Davenport, IA)

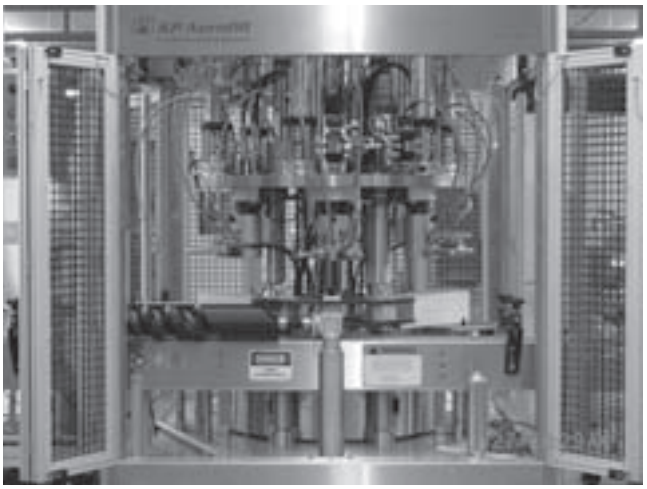

FIGURE 6.16.5 Undercup Propellant Filler (Courtesy Packaging Technologies, Inc., Davenport, IA)

The charging area ventilation system should be designed by experienced professionals and should account for anticipated propellant losses during filling operations. Furthermore, it must have the capability to provide high-volume air removal under emergency operations. When the combustible gas detection system senses conditions above 20 percent of the propellant's lower explosive limit (LEL), the ventilation rate in the charging area should be increased to at least 150 percent of the design airflow or two air changes per minute, whichever is greater. Audible and visual alarms should be activated to alert operators to the condition.

Automatic equipment controls should also be provided. When the gas detection system senses 40 percent of the propellant LEL, the aerosol line and the main propellant supply line should be shut down automatically. Audible and visual alarms should be activated to alert operators to the condition.

Fire/Explosion Suppression

In the event that prevention measures fail, an explosion suppression system should also be provided. Such a system will respond quickly to suppress an explosion in its earliest stages. Wet-pipe automatic sprinkler protection should also be provided in the area. All protective systems should be interlocked to aerosol production equipment, so that equipment is shut down in the event of protective system activation.

Mitigation

In the event that both prevention and suppression measures fail, the design of the charging facility should provide for relief of deflagrations. Structural elements in the charging area, located adjacent to major buildings or assets, should be designed to withstand the anticipated overpressure of a deflagration. Deflagration vents, directed away from buildings and personnel, should be provided at the charging area exterior walls.

PRODUCT STORAGE

Storage arrangements for aerosol products depend to a great degree on the amount of material stored by the manufacturer or distributor. NFPA 30B provides guidance for the storage of

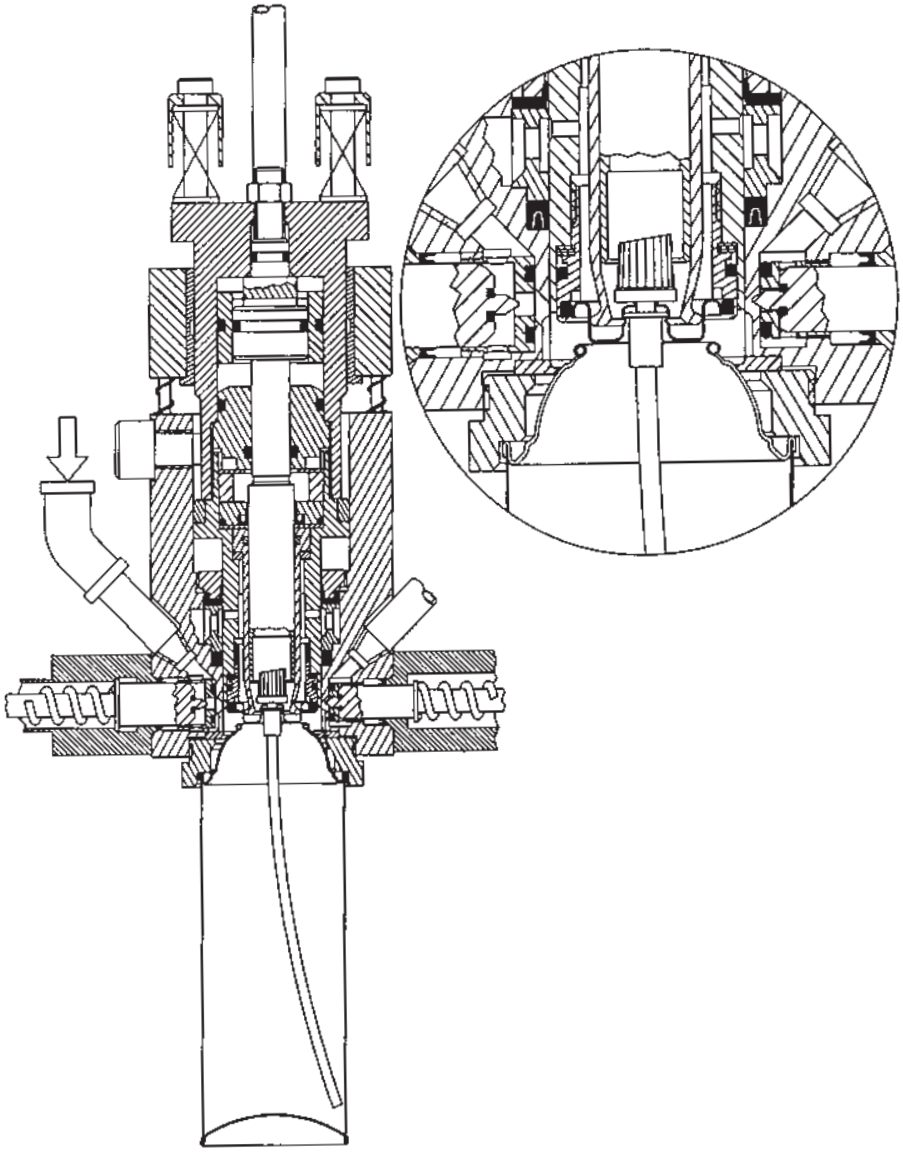

FIGURE 6.16.6 Detail of Undercup Propellant Filler Head (Courtesy Packaging Technologies, Inc., Davenport, IA)

limited amounts of aerosol products in assembly, business, educational, industrial, or institutional occupancies. Storage in a single fire area within these occupancies for Level 2 and Level 3 aerosol products should be limited to 1000 lb (454 kg) and 500 lb (227 kg), respectively. If larger amounts are required, storage should be in separate inside storage areas or flammable liquid cabinets.

NFPA 30B includes design criteria for sprinkler protection of palletized (solid pile) storage and rack storage of both cartoned and uncartoned aerosol products. The tables for uncartoned aerosols were developed based on research done by a consortium of aerosol manufacturers, suppliers, and insurance companies in the late 1990s. The ceiling sprinkler design criteria specify the sprinkler type and nominal orifice size, the sprinkler's response/nominal temperature rating, and the design density in terms of the number of sprinklers operating at a specified discharge pressure. For in-rack sprinkler protection, the appropriate tables also specify the sprinkler type and nominal orifice size, the sprinkler's response/nominal temperature rating, and the required discharge pressure. To assist the user, the tables are presented in pairs, one table in SI (metric) units and a corresponding table in English customary units.

The following tables are reproduced from the 2006 edition of NFPA 30B. Tables 6.16.2 and 6.16.3 show the sprinkler system design criteria for palletized storage of cartoned aerosol products. Tables 6.16.4 and 6.16.5 show the sprinkler system design criteria for rack storage of cartoned Level 2 aerosol products. Note that the figures referenced for in-rack sprinkler

layout are NOT reproduced, due to space limitations. In general-purpose warehouses, Level 2 and Level 3 aerosol products must be segregated as described in NFPA 30B. Very large quantities should be stored in an aerosol warehouse that requires separation from other occupancies by either fire-rated assemblies or by distance.

Wet-pipe automatic sprinkler protection is required for Level 2 and Level 3 aerosol product storage. Live fire testing

has produced a substantial knowledge of appropriate sprinkler design and storage arrangements. It is very important that Level 2 and Level 3 aerosol products be arranged and protected according to the storage tables provided.

For the design and evaluation of sprinkler protection, Level 1 aerosol products are considered to be a Class III commodity, as defined by NFPA 13. Protective criteria for these commodities can be drawn from the standard appropriate for the storage configuration.

SUMMARY

The manufacture and storage of aerosol products involve fire hazards present throughout the process, including the usage of containers, propellants, base products, and the aerosol products themselves. Effective fire prevention includes proper handling and storage procedures, the installation of fire detectors such as gas detection systems, and the installation of audible and visual alarms. For fire protection purposes, aerosol products have been divided into three levels, based on the aggregate chemical heat of combustion. An appropriate fire suppression system depends on the level of aerosol product and the type of facility. For example, alcohol-based and petroleum solvent–based aerosol products in a warehouse setting are best protected by a quick-response sprinkler system.

As with other NFPA codes and standards, the experts on the technical committee are constantly working to update this code to the most up-to-date and safest practices known.

Heats of Combustion: The heat of combustion is, by definition, the enthalpy of reaction when fuel and oxidant at standard conditions are reacted and form products at standard conditions. A unique value for the heat of combustion is possible only if these conditions are fully specified.[1,2] In normal combustion work the standard conditions are taken as follows:

1. Fuel and oxidant enter at 1 atmosphere pressure and 25°C (298 K) temperature. An amount of heat, which is equal to the heat of combustion, is extracted, so that the products are also at 25°C and 1 atmosphere.
2. The oxidant is gaseous oxygen.
3. The main products consist of liquid H_2O, gaseous CO_2, and gaseous N_2. There is no CO formed.
4. For fuels containing sulfur, the standard products include liquid $H_2SO_4 \cdot 115H_2O$. For chlorine-containing fuels reference states consisting of either liquid HCl in water solution or gaseous Cl_2 have been used.
5. In the combustion of silicones, the silicon goes to amorphous silica, SiO_2.

The state of the fuel—gaseous, liquid, or solid—is not standardized and must be specified. The heat of combustion as defined above is termed the gross or upper value and is customarily determined in an oxygen bomb calorimeter.[3] For common materials the value is a negative number; however, customarily a minus sign is included in the definition to make heat of combustion a positive value.[4] Heat of combustion, enthalpy of combustion, calorific value, and heating value are synonyms, the latter two being used more commonly in the heating industry.

In many cases the products are not cooled down to 25°C. For modest temperature differences the change in the effective value could be taken as $C_p(T - 25°)$, where C_p is the constant pressure heat capacity of the products. For this relationship to hold, the enthalpy curve has to be smooth and cannot include condensation. Thus it often becomes convenient to define a lower, or net, heat of combustion where the products are as before except that H_2O stays in gaseous form (and sulfur, if any, goes into gaseous SO_2). The relationship between the values for simple fuels can be expressed as:

$$\Delta h_c^l = \Delta h_c^u - 0.2183\ [\%H]$$

where

Δh_c^l = lower heat of combustion (MJ/kg)

Δh_c^u = upper heat of combustion (MJ/kg)

[%H] = percent, by mass, of hydrogen in fuel

In practice, combustion is rarely complete. For example, some carbon often goes to CO instead of CO_2. Reactions with fuels containing sulfur, or chlorine or other halogens can go into

Vytenis Babrauskas, Ph.D., is president of Fire Science and Technology, Inc., Issaquah, Washington.

Note: Nomenclature Description
- Abbrev.: abbreviation
- Recycling symbol
- CAS No.: unique identifier set by the American Chemical Society
- Unit composition
- MW: molecular weight
- Gross Δh_c^u: gross heat of combustion
- Net Δh_c^l: net heat of combustion
- $\Delta h_c^l/r$: oxygen consumption constant
- r_o: oxygen/fuel mass ratio
- Δh_m: enthalpy of melting (kJ/mol)
- C_{ps}: heat capacity (solid) (kJ/kg·°C)
- T_g: glass transition temperature
- T_{soft}: softening temperature
- T_m: melting temperature

a variety of products, depending on exact reaction conditions. Incomplete combustion acts to lower the heat of combustion. There are no simple general rules to aid in determining the degree of incomplete combustion. Also explosive and propellant materials rarely exhibit reactions where H_2O and CO_2 are the main products; thus, their heats of explosion or reaction will tend to be substantially different from the heat of combustion.

Even though the state of reactants is not described in the definition, most commonly it is taken as the natural state at ambient pressure and temperature. In some references, however, the gaseous state of fuels such as benzene or methanol is assumed, even though they would be normally considered as liquid fuels. The heat of combustion of fuels from the gaseous state is higher than from the liquid state by an amount equal to the fuel's heat of vaporization at 25°C. For combustion of plastic fuels, the most convenient reference state is the solid phase. In such cases, to compute the heat liberated in a given application, it is not necessary to subtract the heat of gasification from the heat of combustion.

Heats of combustion (per kg of fuel) are listed in Tables 6.17.1 through 6.17.4. Also listed in Tables 6.17.1 and 6.17.2 is r_o, the stoichiometric oxygen-fuel mass ratio. The heats can be seen to vary quite a bit for different fuels. Recently, however, increasing engineering use is made of the observation that the heat of combustion per kg of oxygen consumed is nearly constant for most organic fuels. It can be shown that a value of $\Delta h_c^l r_o$ = 13.1 MJ/kg O_2 is near-constant.[56] An assumption of constant heat of combustion per kg of oxygen is useful in heat release rate measurements and for air-limited combustion problems.

For certain fuels it is more convenient to express heats of combustion by use of equations or charts, rather than tables. Two such instances are woods and certain petroleum products. The gross heat of combustion for dry woods is typically in the vicinity of 18–21 MJ/kg. This value varies, however, according to the species and according to the part of the plant. Furthermore, when wood normally burns, pyrolysates are first released and burned, which are lower in calorific value, followed by burning of the remaining char, which has a higher value. The following empirical correlation can be derived, applicable to all species of dry woods, provided the percent carbon, by weight is known.[57]

$$\Delta h_c^u = 0.433\ [\%C] - 1.527$$

where Δh_c^u is the gross heat of combustion for dry wood (MJ/kg) and [C] is the percent of carbon, by weight. This correlation is equally applicable to charred wood and to wood pyrolysates, provided their ultimate analysis is known. For wet fuels, an additional correction should be made:

$$\Delta h_{c,eff}^u = \Delta h_c(1 - M/100) - 0.0257M$$

where M is the percent water in the fuel. Lower heats of combustion, if needed, can then be determined as noted above.

For petroleum products a series of empirical rules is available for estimating thermochemical properties, based on specific gravity or on API degrees[58] (see Table 6.17.10). A determination of the exact heat of combustion by calorimetry is usually not required for typical petroleum products, which include crude oils, fuel oils, kerosenes, and volatile products. These empirical rules are as follows:

Heat of combustion

$$\Delta h_c^u = 52.12 - 8.79d^2 - 0.14d\ \text{(MJ/kg)}$$

Percent hydrogen

$$[\%H] = 26 - 15d$$

Heat of vaporization, at 25°C

$$\Delta h_v = \frac{240}{d}\ \text{(kJ/kg)}$$

Specific heat at 25°C, liquid

$$C_{pl} = \frac{1770}{\sqrt{d}}\ \text{(J/kg°C)}$$

Specific heat at 25°C, vapor

$$C_{pv} = C_{pl} - \frac{380}{d}\ \text{(J/kg°C)}$$

In all the above relationships, d = specific gravity at 15.6°C (60°F). For conversion from degrees API, see Table 6.17.10. The relationship for [%H] can be used to obtain net heat of combustion, according to the general equation given earlier. A more detailed method, requiring additionally the determination

TABLE 6.17.5 Heats of Combustion of Selected Metal Alloys

Material	Δh_c *(MJ/kg)*
Copper alloys	
Bronze (88 Cu/10 Sb/2 Zn)	2.64
Red brass (85 Cu/15 Zn)	2.89
Cartridge brass (70 Cu/30 Zn)	3.33
Yellow brass (60 Cu/40 Zn)	3.62

of percent aromatics, volatility, and sulfur content, is available as an ASTM method.[65]

In some cases the combustion properties, including heat of combustion, are desired for burning metals. The specified combustion product in each case is a stable metal oxide in crystalline form. Tables 6.17.4 and 6.17.5 list the heats of combustion of selected metals, metal alloys, and nonmetallic elements. For further discussion consult the references.[59,62]

Also listed in the tables, where available, are T_b, the boiling point; the heat capacities C_{pl}, C_{pv}, and C_{ps}, of the liquid, vapor, and solid phases respectively, taken at constant pressure at T_b; and Δh_v, the latent heat of vaporization at T_b. For purposes where the total heat of vaporization (i.e., heat to bring a liquid at 25°C up to a gas at T_b) is desired, an estimate can be made by adding to Δh_v the quantity $C_{pl} \cdot (T_b - 25)$. More precise values can be obtained by using enthalpy tables.[8,60]

In some common applications, especially for building materials, a laboratory technique for assessing the possible effect

TABLE 6.17.6 Oxygen Index Values

Material	*Oxygen Index Value**	*Material*	*Oxygen Index Value**
methanol	11–12	nylon	20.1–26.0
benzene	13–16	birch wood	20.5
sulfur	13.6	polyester fibers	20.6
polyacetal	14.9	phenolic resin	21.0
polyoxymethylene	15.7	phenolic-paper laminate	21.7
acetone	16.0	polyvinyl alcohol	22.5
kitchen candle	16.0	polycarbonate	22.5–28.0
cotton	16.0–18.5	polyvinyl fluoride	22.6
mineral oil	16.1	red oak	23.0
polyurethane foam, typical	16.5	wool	23.8
cellulose acetate	16.8	neoprene rubber	26.3–40.0
styrene-butadiene-rubber foam	16.9	Nomex fibers	26.7–28.5
polybutadiene foam	17.1	modacrylic fibers	26.8
natural rubber foam	17.2	polyphenylene oxide	29.0
polymethylmethacrylate	17.3	silicone rubber	30.0
polyethylene	17.4	polysulfone	30–32
polypropylene	17.4	leather	34.8
polystyrene	17.6–18.3	carbon powder	35.0
polyacrylonitrile	18.0	phenol-formaldehyde resin	35.0
paper, cellulose filter	18.2	polyimide	36.5
polybutadiene	18.3	polyvinyl chloride	37.1–49
ABS	18.3–18.8	Kynol fibers	38.0
cellulose triacetate	18.4	polybenzimidazole	40.6–41.5
polyisoprene rubber	18.5	polyvinylidene fluoride	43.7
rayon	18.7–18.9	polyvinyl chloride, chlorinated	45–60
polymethylsiloxane (silicone fluid)	18.9	carbon black	56–63
cellulose	19.0	polyvinylidene chloride	60.0
cellulose acetate-butyrate	19.6	polychlorotrifluoroethylene	95.0
epoxy resin	19.8	polytetrafluoroethylene	95.0
polyethylene terephthalate	20.0		

*The values in the table above were determined using the ASTM Oxygen Test (D2863) and represent typical values for materials without added fire retardants. Adding fire retardants to polymers can increase substantially the measured oxygen index value.

multiply by 4.184×10^{-3}

to convert kcal/mol to MJ/kg multiply by $4.184/W$

where W = molecular weight (g/mol)

to convert kJ/mol to MJ/kg multiply by $1/W$

to convert Btu/lb to MJ/kg multiply by 2.322×10^{-3}

NOTES TO TABLE 6.17.7

In recent years measurement data have started to be tabulated on the engineering performance of plastics. These data are usually measured in heat release rate calorimeters on a bench scale (specimens typically 0.1 m dimension). A number of these data are summarized in Table 6.17.7. In many cases wide variations for a property are shown. These can be attributed to (a) specimen size differences, (b) specimen orientation differences, (c) air flow rate differences, (d) heating flux (irradiance) differences, and (e) specimen composition differences. The data for the plastics listed do not represent pure polymers, but rather engineering plastics, which vary in additives, degree of polymerization, and so on. When only a single number is indicated, this should be taken as reflecting a paucity of data, rather than a high precision of measurement.

The minimum flux needed for ignition has sometimes been considered to be a constant. Table 6.17.7 shows that it varies

39	1.3679	11.39			

This table has been adopted by the U.S. National Bureau of Standards from the formula:

Liquids heavier than water, degrees Baumé $= 145 - \frac{145}{R}$

Liquids lighter than water, degrees Baumé $= \frac{140}{R} - 130$

where R is the ratio of the density of a liquid to that of distilled water, both densities being taken at 60°F (15.5°C).

Note: Degrees API, used to measure the density of petroleum oils, differ slightly from the Baumé scale for liquids lighter than water. API specific gravity is determined by a similar formula, using the figures 141.5 and 131.5 instead of 140 and 130.

*One lb per gallon equals 119.8 kg/m^3.

[a]The specific gravity of gasoline and other petroleum products is commonly given in Degrees API (American Petroleum Institute). The API degree is based on the following formula:

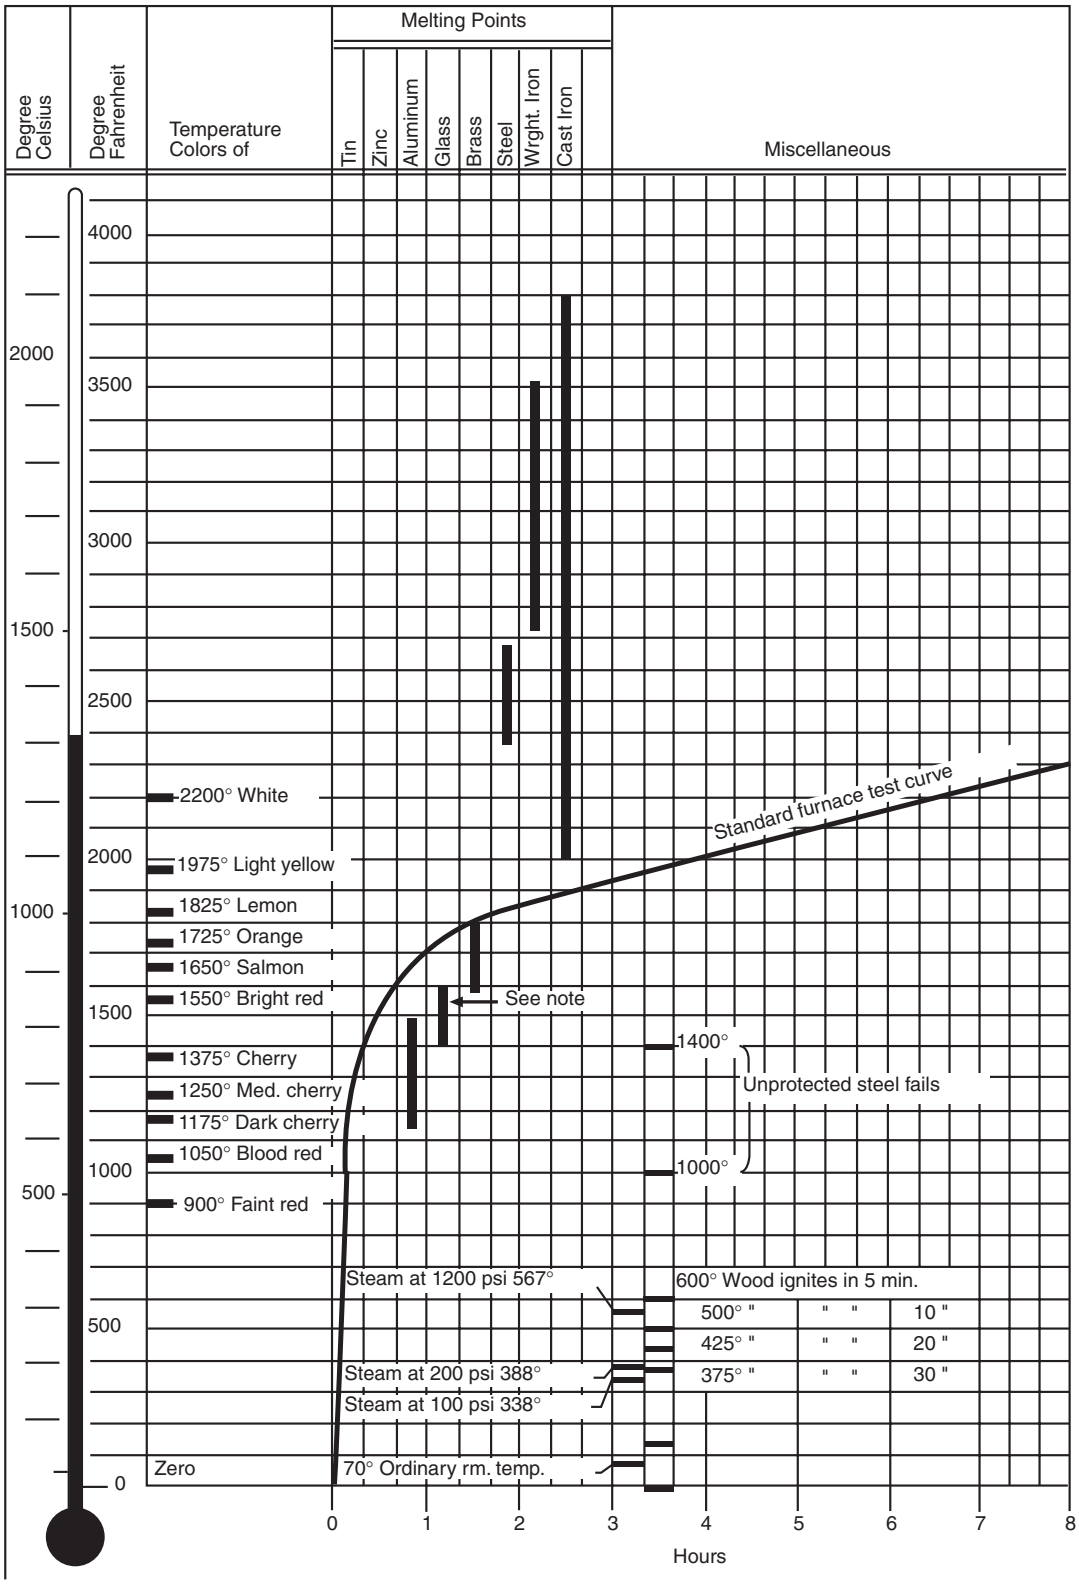
$$\text{Degrees API} = \frac{141.5}{\text{Specific gravity}} - 131.5$$

The standard method of test for gravity of petroleum and petroleum products by means of a hydrometer specifies 60°F as the test temperature, and the formula is based on the specific gravity of the liquid tested at 60°F as compared with water at 60°F.

[b]"Apparent weight," or weight when weighed in air. True weight corrected for weight of air, differs by less than 1 /10 of 1 percent. One lb per gallon equals 119.8 kg/m^3. 60°F equals 15.55°C.

among materials, but only over a range of about 2:1. Ignition temperatures are seen to vary little for common plastics. The total absorbed energy (kJ/m^2) required for ignition has more recently been considered a measure of ignitability.

The effective heat of gasification is a parameter intended to represent the ease of achieving a given heat release rate. The tabulated values, however, do not show the wide range of heat release rate behaviors seen with commercial products. This is



NOTE: Glass has no definite melting point but softens between 1400 and 1600°F (750 and 850°C)

FIGURE 6.17.1 Temperature Colors, Melting Points of Various Substances, and Data on the Behavior of Some Materials at Elevated Temperatures and Pressures

TABLE 6.17.11 Materials Subject to Spontaneous Heating

Name	*Tendency to Spontaneous Heating*	*Usual Shipping Container or Storage Method*	*Precautions Against Spontaneous Heating*	*Remarks*
Alfalfa meal	High	Bags, bulk	Avoid moisture extremes. Tight cars for transportation are essential.	Many fires attributed to spontaneous heating probably caused by sparks, burning embers, or particles of hot metal picked up by the meal during processing. Test fires caused in this manner have smoldered for 72 hours before becoming noticeable.
Burlap bags "used"	Possible	Bales	Keep cool and dry.	Tendency to heat dependent on previous use of bags. If oily would be dangerous.
Castor oil	Very slight	Metal barrels, metal cans in wooden boxes	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Possible heating of saturated fabrics in badly ventilated piles.
Charcoal	High	Bulk, bags	Keep dry. Supply ventilation.	Hardwood charcoal must be carefully prepared and aged. Avoid wetting and subsequent drying.
Coal, bituminous	Moderate	Bulk	Store in small piles. Avoid high temperatures.	Tendency to heat depends upon origin and nature of coals. High volatile coals are particularly liable to heat.
Cocoa bean shell tankage	Moderate	Burlap bags, bulk	Observe extreme caution to maintain safe moisture limits.	This material is very hygroscopic and is liable to heating if moisture content is excessive. Precaution should be observed to maintain dry storage, etc.
Coconut oil	Very slight	Drums, cans, glass	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Only dangerous if fabrics, etc. are impregnated.
Cod liver oil	High	Drums, cans, glass	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Impregnated organic materials are extremely dangerous.
Colors in oil	High	Drums, cans, glass	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	May be very dangerous if fabrics, etc. are impregnated.
Copra	Slight	Bulk	Keep cool and dry.	Heating possible if wet and hot.
Corn-meal feeds	High	Burlap bags, paper bags, bulk	Process material carefully to maintain safe moisture content and to cure before storage.	Usually contains an appreciable quantity of oil which has rather severe tendency to heat.
Corn oil	Moderate	Barrels, tank cars	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Dangerous heating of meals, etc. unlikely unless stored in large piles while hot.
Cottonseed	Low	Bags, bulk	Keep cool and dry.	Heating possible if piled wet and hot.
Cottonseed oil	Moderate	Barrels, tank cars	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	May cause heating of saturated material in badly ventilated piles.
Distillers' dried grains with oil content (brewers' grains)	Moderate	Bulk	Maintain moisture 7 percent to 10 percent. Cool below 100°F (38°C) before storage.	Very dangerous if moisture content is 5 percent or lower.
No oil content	Moderate	Bulk	Maintain moisture 7 percent to 10 percent. Cool below 100°F (38°C) before storage.	Very dangerous if moisture content is 5 percent or lower.

TABLE 6.17.11 Continued

Name	*Tendency to Spontaneous Heating*	*Usual Shipping Container or Storage Method*	*Precautions Against Spontaneous Heating*	*Remarks*
Feeds, various	Moderate	Bulk, bags	Avoid extremely low or high moisture content.	Ground feeds must be carefully processed. Avoid loading or storing unless cooled.
Fertilizers				
Organic, inorganic, combination of both mixed	Moderate	Bulk, bags	Avoid extremely low or high moisture content.	Organic fertilizers containing nitrates must be carefully prepared to avoid combinations that might initiate heating.
Synthetic, containing nitrates and organic matter	Moderate	Bulk, bags	Avoid free acid in preparation.	Insure ventilation in curing process by small piles or artificial drafts. If stored or loaded in bags, provide ventilation space between bags.
Fish meal	High	Bags, bulk	Keep moisture 6 percent to 12 percent. Avoid exposure to heat.	Dangerous if overdried or packaged over 100°F (38°C).
Fish oil	High	Barrels, drums, tank cars	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Impregnated porous or fibrous materials are extremely dangerous. Tendency of various fish oils to heat varies with origin.
Fish scrap	High	Bulk, bags	Avoid moisture extremes.	Scrap loaded or stored before cooling is extremely liable to heat.
Foam rubber in consumer products	Moderate		Where possible remove foam rubber pads, etc. from garments to be dried in dryers or over heaters. If garments containing foam rubber parts have been artificially dried, they should be thoroughly cooled before being piled, bundled, or put away. Keep heating pads, hair dryers, other heat sources from contact with foam rubber pillows, etc.	Foam rubber may continue to heat spontaneously after being subjected to forced drying as in home or commercial dryers, and after contact with heating pads and other heat sources. Natural drying does not cause spontaneous heating.
Grain (various kinds)	Very slight	Bulk, bags	Avoid moisture extremes.	Ground grains may heat if wet and warm.
Hay	Moderate	Bulk, bales	Keep dry and cool.	Wet or improperly cured hay is almost certain to heat in hot weather. Baled hay seldom heats dangerously.
Hides	Very slight	Bales	Keep dry and cool.	Bacteria in untreated hides may initiate heating.
Iron pyrites	Moderate	Bulk	Avoid large piles. Keep dry and cool.	Moisture accelerates oxidation of finely divided pyrites.
Istle	Very slight	Bulk, bales	Keep cool and dry.	Heating possible in wet material. Unlikely under ordinary conditions. Partially burned or charred fiber is dangerous.
Jute	Very slight	Bulk	Keep cool and dry.	Avoid storing or loading in hot wet piles. Partially burned or charred material is dangerous.
Lamp black	Very slight	Wooden cases	Keep cool and dry.	Fires most likely to result from sparks or included embers, etc., rather than spontaneous heating.
Lanolin	Negligible	Glass, cans, metal drums, barrels	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Heating possible on contaminated fibrous matter.

(continued)

TABLE 6.17.11 Continued

Name	*Tendency to Spontaneous Heating*	*Usual Shipping Container or Storage Method*	*Precautions Against Spontaneous Heating*	*Remarks*
Lard oil	Slight	Wooden barrels	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Dangerous on fibrous combustible substances.
Lime, unslaked (calcium oxide, pebble lime, quicklime)	Moderate	Paper bags, wooden barrels, bulk	Keep dry. Avoid hot loading.	Wetted lime may heat sufficiently to ignite wood containers, etc.
Linseed	Very slight	Bulk	Keep cool and dry.	Tendency to heat dependent on moisture and oil content.
Linseed oil	High	Tank cars, drums, cans, glass	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Rags or fabrics impregnated with this oil are extremely dangerous. Avoid piles, etc. Store in closed containers, preferably metal.
Manure	Moderate	Bulk	Avoid extremes of low or high moisture contents. Ventilate the piles.	Avoid storing or loading uncooled manures.
Menhaden oil	Moderate to high	Barrels, drums, tank cars	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Dangerous on fibrous product.
Metal powders*	Moderate	Drums, etc.	Keep in closed containers.	Moisture accelerates oxidation of most metal powders.
Metal turnings*	Practically none	Bulk	Not likely to heat spontaneously.	Avoid exposure to sparks.
Mineral wool	None	Pasteboard boxes, paper bags	Noncombustible. If loaded hot may ignite containers and other combustible surroundings.	This material is mentioned in this table only because of general impression that it heats spontaneously.
Mustard oil, black	Low	Barrels	Avoid contact of leakage with rags, cotton, or other fibrous combustible materials.	Avoid contamination of fibrous combustible materials.
Oiled clothing	High	Fiber boxes	Dry thoroughly before packaging.	Dangerous if wet material is stored in piles without ventilation.
Oiled fabrics	High	Rolls	Keep ventilated. Dry thoroughly before packing.	Improperly dried fabrics extremely dangerous. Tight rolls are comparatively safe.
Oiled rags	High	Bales	Avoid storing in bulk in open.	Dangerous if wet with drying oil.
Oiled silk	High	Fiber boxes, rolls	Supply sufficient ventilation.	Improperly dried material is dangerous in form of piece goods. Rolls relatively safe.
Oleic acid	Very slight	Glass bottles, wooden barrels	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Impregnated fibrous materials may heat unless ventilated.
Oleo oil	Very slight	Wooden barrels	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	May heat on impregnated fibrous combustible matter.
Olive oil	Moderate to low	Tank cars, drums, cans, glass	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Impregnated fibrous materials may heat unless ventilated. Tendency varies with origin of oil.

TABLE 6.17.11 Continued

Name	*Tendency to Spontaneous Heating*	*Usual Shipping Container or Storage Method*	*Precautions Against Spontaneous Heating*	*Remarks*
Paint containing drying oil	Moderate	Drums, cans, glass	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Fabrics, rags, etc. impregnated with paints that contain drying oils and driers are extremely dangerous. Store in closed containers, preferably metal.
Paint scrapings	Moderate	Barrels, drums	Avoid large unventilated piles.	Tendency to heat depends on state of dryness of the scrapings.
Palm oil	Low	Wooden barrels	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Impregnated fibrous materials may heat unless ventilated. Tendency varies with origin of oil.
Peanut oil	Low	Wooden barrels, tin cans	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Impregnated fibrous materials may heat unless ventilated. Tendency varies with origin of oil.
Peanuts, "red skin"	High	Paper bags, cans, fiber board boxes, burlap bags	Avoid badly ventilated storage.	This is the part of peanut between outer shell and peanut itself. Provide well ventilated storage.
Peanuts, shelled	Very slight or negligible	Paper bags, cans, fiber board boxes, burlap bags	Keep cool and dry.	Avoid contamination of rags, etc. with oil.
Perilla oil	Moderate to high	Tin cans, barrels	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Impregnated fibrous materials may heat unless ventilated. Tendency varies with origin of oil.
Pine oil	Moderate	Glass, drums	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Impregnated fibrous materials may heat unless ventilated. Tendency varies with origin of oil.
Powdered eggs	Very slight	Wooden barrels	Avoid conditions that promote bacterial growth. Inhibit against decay. Keep cool.	Possible heating of decaying powder in storage.
Powdered milk	Very slight	Wooden and fiber boxes, metal cans	Avoid conditions that promote bacterial growth. Inhibit against decay. Keep cool.	Possible heating by decay or fermentation.
Rags	Variable	Bales	Avoid contamination with drying oils. Avoid charring. Keep cool and dry.	Tendency depends on previous use of rags. Partially burned or charred rags are dangerous.
Red oil	Moderate	Glass bottles, wooden barrels	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Impregnated porous or fibrous materials are extremely dangerous. Tendency varies with origin of oil.
Roofing felts and papers	Moderate	Rolls, bales, crates	Avoid over-drying the material. Supply ventilation.	Felts, etc. should have controlled moisture content. Packaging or rolling uncooled felts is dangerous.
Sawdust	Possible	Bulk	Avoid contact with drying oils. Avoid hot, humid storage.	Partially burned or charred sawdust may be dangerous.
Scrap film (nitrate)	Very slight	Drums and lined boxes	Film must be properly stabilized against decomposition.	Nitrocellulose film ignites at low temperature. External ignition more likely than spontaneous heating. Avoid exposure to sparks, etc.
Scrap leather	Very slight	Bales, bulk	Avoid contamination with drying oils.	Oil-treated leather scraps may heat.

(continued)

TABLE 6.17.11 Continued

Name	*Tendency to Spontaneous Heating*	*Usual Shipping Container or Storage Method*	*Precautions Against Spontaneous Heating*	*Remarks*
Scrap rubber or buffings	Moderate	Bulk, drums	Buffings of high rubber content should be shipped and stored in tight containers.	Sheets, slabs, etc. are comparatively safe unless loaded or stored before cooling thoroughly.
Sisal	Very slight	Bulk, bales	Keep cool and dry.	Partially burned or charred material is particularly liable to ignite spontaneously.
Soybean oil	Moderate	Tin cans, barrels, tank cars	Avoid contact with rags, cotton, or fibrous materials.	Impregnated fibrous materials may heat unless well ventilated.
Sperm oil—see whale oil				
Tankage	Variable	Bulk	Avoid extremes of moisture contents. Avoid loading or storing while hot.	Very dry or moist tankages often heat. Tendency more pronounced if loaded or stored before cooling.
Tung nut meals	High	Paper bags, bulk	Material must be very carefully processed and cooled thoroughly before storage.	These meals contain residual oil which has high tendency to heat. Material also susceptible to heating if over-dried.
Tung oil	Moderate	Tin cans, barrels, tank cars	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Impregnated fibrous materials may heat unless ventilated. Tendency varies with origin of oil.
Turpentine	Low	Tin, glass, barrels	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Has some tendency to heat but less so than the drying oils. Chemically active with chlorine compounds and may cause fire.
Varnished fabrics	High	Boxes	Process carefully. Keep cool and ventilated.	Thoroughly dried varnished fabrics are comparatively safe.
Wallboard	Slight	Wrapped bundles, pasteboard boxes	Maintain safe moisture content. Cool thoroughly before storage.	This material is entirely safe from spontaneous heating if properly processed.
Waste paper	Moderate	Bales	Keep dry and ventilated.	Wet paper occasionally heats in storage in warm locations.
Whale oil	Moderate	Barrels and tank cars	Avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials.	Impregnated fibrous materials may heat unless ventilated. Tendency varies with origin of oil.
Wool wastes	Moderate	Bulk, bales, etc.	Keep cool and ventilated or store in closed containers. Avoid high moisture.	Most wool wastes contain oil, etc. from the weaving and spinning and are liable to heat in storage. Wet wool wastes are very liable to spontaneous heating and possible ignition.

Note: Originally prepared by the NFPA Committee on Spontaneous Heating and Ignition, which has been discontinued. Omission of any material does not necessarily indicate that it is not subject to spontaneous heating. Newer information is available in Babrauskas, V., *Ignition Handbook,* Fire Science Publishers/Society of Fire Protection Engineers, Issaquah, WA, 2003.

*Refers to iron, steel, brass, aluminum, and other common metals.

partly because for most materials the heat release progress is highly transient, whereas the definition of the effective heat of gasification (average energy required to gasify a unit mass of material) requires assuming steady-state conditions.

Smoke properties can be measured in two ways: (1) Optically, by determining the obscuration along a light beam. This can be expressed as smoke specific extinction area per unit specimen mass (m^2/kg). The unit system implied here is natural-log (Base-e). (2) Gravimetrically, by determining the soot mass evolved, per unit specimen mass.

SECTION 7

Storage and Handling of Materials

L. Jeffrey Mattern

7.1 Storage and Handling of Solid Fuels
7.2 Storage of Flammable and Combustible Liquids
7.3 Storage of Gases
7.4 Storage and Handling of Chemicals
7.5 Hazardous Waste Control

The proper methods for storage and handling of materials, along with the control of ignition sources, are the keys to minimizing the potential for fires in occupancies where such materials are found. Proper separation of volatile materials limits the possibility of a fire spreading from areas where these materials are stored and handled to their adjacent areas. The type of materials discussed in the chapters within this section are often easily ignited and lead to rapid fire growth. Thus, it is essential that such materials be properly stored and handled, and that ignition sources be properly controlled. As a last resort, adequate fire protection concepts are important to mitigate the effects of a fire, should one occur.

The purpose of this section is threefold: (1) to discuss the common arrangements of storage found for the specific materials, (2) to identify the fire hazards associated with the specific materials, and (3) to provide methods by which the fire hazard of the specific materials is reduced and mitigated.

Chapter 1, "Storage and Handling of Solid Fuels," discusses the bulk storage of materials such as coal used in the utility industry, or large manufacturing plants that have power generation such as pulp and paper mills, and storage of wood products in the form of logs, chips, sawdust, and related by-products. The proper storage arrangements, fire prevention concepts, and fire control methods are introduced.

Chapter 2, "Storage of Flammable and Combustible Liquids," thoroughly discusses the storage of combustible and flammable materials in their extensive array of storage arrangements, from large holding tanks to small containers. The chapter discusses the fundamentals of the design and construction of large tanks, their proper venting, emergency containment, and fire suppression concepts. The chapter also discusses the use of small container storage and provides a brief discussion on transportation of these materials.

Chapter 3, "Storage of Gases," provides background on the construction of gas cylinders and tanks, as well as their associated safeguards and control of ignition sources. Chapter 4, "Storage and Handling of Chemicals," provides a tutorial on the hazards of various commonly used chemicals, along with their fire control methods. Lastly, Chapter 5, "Hazardous Waste Control," explains the control of hazardous waste, including its source, characteristics, collection, handling, storage, recovery, and disposal.

L. Jeffrey Mattern is retired from FM Global in Philadelphia, where his most recent positions were senior account engineer and chief engineer of mid-Atlantic operations. He has served on various NFPA technical committees and the NFPA Standards Council since 1968.

Fire Protection for Wood Fuels
Solid Waste as Fuel

Key Terms

coal fuel, dust, explosion, solid fuel, spontaneous heating, wood, wood-derived materials

Solid fuels are used commercially for the generation of heat for steam, electrical power, or process needs. This chapter addresses the major solid fuel sources of coal, wood, and wood by-products. The hazards and safe practices in the storage and handling of these fuels are discussed.

The actual combustion of these fuels in boilers and furnaces is covered in Section 10, Chapter 6, "Boiler Furnaces"; on the hazards of dust, see Section 6, Chapter 8, "Dusts." Incinerators are addressed in Section 11, Chapter 1, "Waste Handling and Control."

COAL AS A FUEL

Coal is an abundant fuel source in many parts of the world. It is the predominant fuel for boilers that generate hot water and steam for process use, heating, and the generation of electricity. As of the year 2000, 57 percent of the electricity in the United States was supplied by coal-burning power plants.[1] Coal is also a key ingredient in the making of steel. Since coal, by and large, fueled the industrial revolution, its properties and uses have been studied for more than a century.

The hazards of the storage and handling of coal include fires, flash fires, and dust explosions. An important cause of coal fires in storage piles, bins, hoppers, and other containers is spontaneous heating. Coal, when heated, can release gases, some from entrained volatile hydrocarbons and some from oxidation (e.g., carbon monoxide). This chapter covers the hazards of the storage and handling of coal and outlines methods of reducing the likelihood and consequences of fire and explosions in this operation.

Ranking of Coals

ASTM D388, *Standard Classification of Coals by Rank,* is used to rank coals. The ranking provides useful data on the behavior of the coal and the equipment necessary to handle and burn it. Table 7.1.1 lists the rankings by class and group of coals. Through most of the twentieth century, Class II or bituminous coal was the staple of coal-fired boilers. These coals, mined in places like Tennessee, Kentucky, Ohio, West Virginia, and Illinois, offer high heat values, usually above 15,000 Btu/lb (34.9 MJ/kg), but are soft enough to grind or pulverize for combustion. Unfortunately, these coals also contain sulfur in the form of pyrites, which cause SO_2 emissions, a prime cause of acid rain. To meet SO_2 emission restrictions without costly scrubbers, more power boilers started burning Class III or subbituminous coal, which typically contains significantly less sulfur but also has lower heat values. These are often referred to as western coals, because they are mined in places like Montana and Wyoming. One of the more common sources of these coals is the Powder River Basin deposits, or PRB as it is sometimes called. The ranking of the coal can give some indication of its propensity for spontaneous heating and also its dust explosion hazards.

Spontaneous Heating of Coals

One major hazard of the storage and handling of coal is spontaneous heating. Spontaneous heating occurs from a slow oxidation reaction within the coal pile causing heat to build up to the point

Kenneth W. Dungan, P.E., is a principal of Risk Technologies, Knoxville, Tennessee. He has more than 35 years of experience in industrial fire protection. He is a fellow and past president of SFPE and a former chair of the NFPA committee on electrical generation stations.

TABLE 7.1.1 Classification of Coals by Rank (ASTM D388)

Class	*Group*
I. Anthracitic	1. Meta-anthracite 2. Anthracite 3. Semianthracite
II. Bituminous	1. Low volatile bituminous coal 2. Medium volatile bituminous coal 3. High volatile *A* bituminous coal 4. High volatile *B* bituminous coal 5. High volatile *C* bituminous coal
III. Subbituminous	1. Subbituminous *A* coal 2. Subbituminous *B* coal 3. Subbituminous *C* coal
IV. Lignitic	1. Lignite A 2. Lignite B

of igniting the coal. This phenomenon is a problem displayed by bituminous and lignite coals. For this oxidation to reach an ignition potential, heat of oxidation must build up faster than it dissipates. The chemical and physical makeup of the coal greatly affects the potential for spontaneous heating. Principal conditions affecting coal's susceptibility to spontaneous heating include the following:

1. Susceptibility of the coal to breakage (friability) and the fineness of the particles produced
2. Ability of the coal particles to absorb oxygen, as well as the percentage of actual oxygen content
3. Amount of moisture trapped and confined in the coal (moisture assists oxidation)
4. Chemical composition of the coal, especially of impurities (generally, the lower the grade of coal, the greater the possibility of spontaneous heating)
5. Extent of air trapped in the voids of the coal pile
6. Presence of sulfur in the form of pyrites or marcasites (in general, an increase of sulfur content results in increased friability of coal; the brittle coal breaks more easily, thus exposing more surface area for oxidation)
7. Free gases trapped in the coal pile
8. Amount of foreign substances in the pile such as wood, sticks, timber, leaves, and grass
9. Method and depth of the coal pile
10. Temperature of the surrounding area (the oxidation reaction increases with temperature)
11. Type and amount of ventilation allowed in the coal pile

STORAGE PRACTICES FOR COAL

The methods used to build outside storage piles and to fill silos, bins, and bunkers have a significant effect on the oxidation hazard of coal. The spontaneous heating problem is controlled either by compacting to reduce the air movement or by minimizing the coal storage time by keeping it moving to the boiler. Coal is usually stored either in an uncompacted (50 to 55 lb/ft^3 [801 to 881 kg/m^3]) or compacted (70 to 75 lb/ft^3 [1121 to 1201 kg/m^3]) form. When coal is not compacted, air occupies approximately 35 percent of the volume of the pile, so it is relatively easy for air to move through the pile. Coal is at this density when it is handled on conveyors or placed in trucks, railroad cars, bunkers, silos, or in any form of "live" pile. Coal is uncompacted whenever it is moved and falls on itself. Table 7.1.2 shows the range of densities of coal.

Compacted Coal Storage

Generally, when coal is compacted, it is placed in relatively thin layers from 6 to 12 in. (150 to 300 mm) thick. Each layer is then rolled over with a device that has a relatively high loading in lb/ft^2 (kg/m^2) of surface area (1 lb/ft^2 equals 4.9 kg/m^2). Rubber-tired carryalls are normally used for this purpose, since they compact the coal while they convey the coal to the desired location.

A coal pile should be compacted on all sides to eliminate any low-density areas. When coal is compacted, it has a density of about 70 to 75 lb/ft^3 (1100 to 1200 kg/m^3) and air occupies only 12 percent of the pile. This makes it far less likely that there would be appreciable air movement through the pile. Virtually all types of coal have been stored successfully in this manner, including piles exceeding 1 million tons (1 ton equals 1016 kg) and at depths approaching 100 ft (30 m).

Large users of coal (e.g., utilities and large industries) will generally have compacted permanent storage piles and uncompacted "live" storage piles, whereas the smaller users (e.g., small industry, commercial, and residential) normally have uncompacted storage. All coal users have some form of uncom-

TABLE 7.1.2 General Ranges of Densities of Coal

Physical Description of Coal	*Range of Density lb/ft^3 (kg/m^3)*	*Approximate Percentage of Coal Pile Occupied by Air*
Coal in the seam before mining	80–85 (12.8–13.6)	0%
Coal size 2" × 0 normal shipping size as loaded in RR car, truck, etc., no compaction	50–55 (8–8.8)	36%
Coal size 2" × 0 compacted with track-mounted dozers	60–65 (9.6–10.4)	24%
Coal size 2" × 0 compacted with rubber-tired carryall or sheepsfoot roller	70–75 (11.2–12)	12%

pacted storage and this form of storage might require special fire protection considerations.

Uncompacted Coal Storage

Ideally, all uncompacted coal is stored in properly designed bunkers, silos, bins, and even outside piles so all of the coal moves through the storage system with no dead or unmoving portion of the coal pile. Although the coal is still subject to slow oxidation, it will move through the system before any appreciable heating can occur. Many new bunkers, silos, and bins are designed for mass flow of coal and heating problems have been minimized. Coal piles can be worked in such a manner that the piles are rotated and the first coal in is the first coal out. This achieves the same results as the mass flow conditions in bins where none of the coal remains for prolonged periods of time.

When bunkers, silos, or bins have not been, or cannot be, designed to achieve mass flow, heating of the coal might occur and create problems. As much as practical, sealing off the bottom of the storage system can minimize the airflow through the coal; however, space above the coal in the storage system should not be sealed. This will prevent the accumulation of gases that can become liberated from freshly mined or crushed coal. In these cases, the area above the coal should be ventilated to carry off any accumulation of gases. Some storage systems, particularly ones where pulverized coal is stored, are designed to prevent the formation of a hazardous mixture of gases and coal dust with air.

It might be necessary to routinely draw down the storage system and clean the static deposits of coal from the bunker to minimize problems. Because cleaning bunkers, silos, or bins can be hazardous, special safety precautions should be taken.

If heating occurs in a bunker, silo, or bin, it is generally in an area where static deposits of coal have remained for a period of time. Once spontaneous heating develops to the fire stage, it becomes very difficult to extinguish the fire, short of emptying the bin, bunker, or silo. Therefore, provisions for emptying the bunker should be provided. Fire fighting in coal silos is a difficult, long-duration activity, and can take several days to completely extinguish the fire. NFPA 850, *Recommended Practice for Fire Protection for Electric Generating Plants and High Voltage Direct Current Converter Stations,* provides excellent guidance on how to combat these types of fires.

Carbon dioxide vapor has proved to be an effective fire-suppression agent when forced through the coal by pressure injection in the upper and lower parts of the silo. The rate of application should be sufficient to compensate for absorption by the coal. Inerting can normally be accomplished within an 8 hour shift, if an adequate supply of carbon dioxide is available.

Since carbon dioxide is stored as a liquid, it must be vaporized before injection into the silo. This is accomplished using an external, in-line vaporizer sized such that the anticipated application rate can be increased if the maximum anticipated leakage rate is exceeded.

Normal inerting procedure involves starting the carbon dioxide flow at a preset volume from the flow-control valve. Initially, the carbon dioxide vapor should be injected into the top of the silo, into the space above the coal, to mitigate the potential of developing an explosive atmosphere. Once this inerting is established, the flow can be reduced and the primary flow directed into the bottom (while continuing trickle injection into the top) of the silo. Silo geometry creates a chimney effect, which will prevent the carbon dioxide from settling throughout the silo. Therefore, it is necessary to add injection points near the bottom. In addition, high-expansion foam can be added to the top.

Carbon dioxide inerting is generally considered successful when the carbon dioxide concentration reaches 65 percent. However, the logistics of injecting carbon dioxide might result in almost 100 percent saturation throughout most of the silo in order to achieve at least 65 percent concentration in all portions of the silo. Since leakage in the silo is inevitable, it will be necessary to anticipate using a large quantity of carbon dioxide. It is advisable to order a quantity of carbon dioxide equivalent to about three times the gross volume of the silo when using a low-pressure system.

When carbon dioxide is used, there is a risk of oxygen depletion in the area above, around, or below a silo, bin, or bunker. Areas where gas could collect and deplete oxygen should be identified with appropriate barriers and warning signs.

Nitrogen has been used successfully to inert silo fires. It is applied in a manner very similar to carbon dioxide. A notable difference is that nitrogen has about the same density as air (whereas carbon dioxide is significantly more dense). Therefore, it must be applied at numerous injection points around the silo to ensure that it displaces available oxygen. This results in the need for more injection equipment and a larger quantity of agent.

Another method is the use of Class A foams and penetrants. These agents have found some success, but it is difficult to predict the resources required for successful fire control. The agents generally require mixing with water prior to application, usually in the range of 1 percent by volume. The typical application of Class A foam is 1 percent to fight wetland fires. However, coal plants have reported success with using Class A foams at 0.1 percent. This causes the agent to act as a surfacant. Higher percentages have caused excessive bubble accumulation, which impedes penetration into the coal.

Water and steam are not recommended, because the potential for explosion exists when water reaches the hot spot and the expansion of the steam is trapped by the water. The introduction of steam can actually increase spontaneous heating because of the introduction of additional heat and moisture.

Suppression activities can be enhanced by using portable infrared heat detectors to search for hot spots, either on the sides or top of the silo, to facilitate injection of the agent as close as possible to the fire area. The infrared imagery can be used to evaluate performance and monitor progress of the attack. The agent solution must penetrate to the seat of combustion to be effective. This can be affected by the degree of compaction, voids, rate of application, evaporation rate, and so on. Runoff must be drained through feeder pipes and will require collection, cleanup, and disposal.

Detection and location of hot spots can be achieved by using CO gas monitors, portable infrared heat detection, or thermography. A long thermocouple (10 ft [3.1 m]) connected

to a portable instantaneous readout monitor can be employed. Pushing the thermocouple into the coal storage can detect developing hot areas or strata at different depths. Periodic monitoring of temperature change in these areas will help predict spontaneous combustion development and aid in response preplanning.

Regardless of the type of suppression approach selected, prefire planning is an important element of successful fire control and extinguishment. If all necessary fire-fighting resources are not stockpiled on site, suppliers should be contacted in advance to ensure that equipment and supplies are available on relatively short notice.

Personnel requirements for this fire-fighting activity should be identified in advance. Personnel should be trained and qualified for fire fighting in the hot, smoky environment that might accompany a silo fire. This includes the use of self-contained breathing apparatus (SCBA) and personal protective equipment. Personnel engaged in this activity should be minimally trained and equipped to the structural fire brigade level, as defined in NFPA 600, *Standard on Industrial Fire Brigades.* See also NFPA 1081, *Standard for Industrial Fire Brigade Member Professional Qualifications.*

Selecting an Outside Storage Site

Many plants have uncompacted storage piles on the ground and some precautions must be taken in selecting and preparing a storage site. First, it should be determined that the proposed site is not over open sewers or other devices that might bring air into the base of the pile. Neither should the site contain any steam lines or systems that could raise the temperature of a portion of the pile beyond normal ambient temperatures.

Once selected, the site should be cleaned of all vegetation and foreign materials, particularly materials that could have heating tendencies. Then it should be graded smoothly and contoured so that water will not drain into the base of the pile. The periphery of a pile should be given special attention in the grading process to make sure that all of the water draining from the pile will be carried away.

Recognizing that uncompacted piles tend to heat, a good practice is to size and/or shape a pile for easy access to areas that have heat so that they can then be handled appropriately. It is also good practice to limit the height of an uncompacted pile to approximately 15 ft (4.6 m) if the coal is known to have high heating tendencies. Greater pile heights can be tolerated if the coal has low heating characteristics and if the pile can be rotated with ease.

Weatherproofing of Coal Piles

In very special cases (e.g., when coal piles are to be retained for long periods or coking properties are of special importance) the exclusion of air can be further improved by covering the completed pile with road tar in the same manner as dressing is applied to roads. Road tar is an efficient and economical method and, in addition, can be used on heated heaps that, in the complete absence of air, would then stop oxidizing and cool off. The sealing of a coal pile has some added advantages, such as protection against wind loss and reduction of channeling due to heavy rain. A secondary effect, therefore, is reduction of atmospheric and river pollution.

Special Storage Precautions

It is beneficial to handle coal going to storage in a manner that prevents segregation of coarse coal from the fines. Segregation occurs when coal is placed in a conical pile; the coarse coal runs to the edge and outside of the pile, and the fines collect in the center. The air can then move readily through the coarse coal to the fines containing the large surface area, greatly encouraging heating of the pile.

Placing coal in storage near a vertical wall presents special problems, because coal tends to be less compacted when it is placed near these vertical surfaces unless special precautions are taken. Preferably, coal should not be stored around supporting beams or similar members. Less dense coal provides a natural flue for air ventilation. When vertical walls or surfaces of any kind cannot be avoided, the coal should be stored along the wall or parallel to the wall, as opposed to pushing the coal up to the vertical surface.

Selecting Storage Method for Coal

Commercial and domestic users select the size of coal best suited for their burning equipment, and, in most cases, it is usually a double-screened coal with a 1¼ in. (32 mm) top size, a ¼ in. (6 mm) bottom size, and a relatively small percentage of fines. This size coal, if handled reasonably well, will not segregate and a pile can be considered fully ventilated. There will be a minimum tendency of heating because of fewer fines and because any heat generated will be readily removed from the pile.

Industries and utilities normally use a coal with a larger percentage of fines, and it is advantageous to use a coal that can be handled and stored with ease. Normally, a good shipping size is 2 in. (50 mm) top size or less, but if a larger size is used, extra care should be exercised to minimize segregation and oxidation in storage.

GAS GENERATION AND EXPLOSIONS WITH COAL

Methane and other gases can be liberated from freshly mined and freshly crushed coal. An accumulation of a dangerous proportion of gas from this source is rare, but when explosions do occur, severe and fatal losses can result. Spontaneous heating can cause the generation of carbon monoxide, which is both a health and explosion hazard.

Dangerous accumulations of gas can occur over the tops of bins, silos, and bunkers and in underground coal reclaiming facilities. Adequate ventilation is the best solution to prevent dangerous accumulation. The ventilation system should sweep airflow across the tops of bins, silos, and bunkers and through the conveyor gallery of underground reclaiming systems. Care should be taken in the design and operation of the storage system to minimize any airflow through the stored coal, thus preventing spontaneous heating. In addition, any airflow through

the pile should be in a direction that will minimize any dangerous accumulations of gas.

If there is any suspicion of gas accumulations, gas monitors can be permanently installed, and portable detectors can be used by personnel working in these areas. The areas should be monitored both for CO and for methane.

COAL HANDLING AND COAL DUST EXPLOSIONS

Coal handling facilities include receiving operation, crushers, and conveyors. A major hazard common to all these facilities is the potential for coal dust explosions. (General information on the hazards of dust is discussed in Section 6, Chapter 8, "Dusts.") Finely divided particles of coal can produce violent explosions under conditions favorable for such explosions. The minimum explosive concentration for coal dust in air required for an explosion has been determined to be 0.035–0.050 oz/ft^3 (35–50 g/m^3). The explosion pressures developed by a coal dust explosion may vary from 5 to 100 psi (34.5 to 690 kPa). The principal factors influencing the violence of a dust explosion are the specific chemical structure of the coal dust, concentration of material, particle size, source of ignition, oxygen concentration, enclosure type and size, turbulence of mixture, and effectiveness of vent closure. The effect of moisture on coal dust explosibility is negligible below about 10 percent.

The principal dust-producing mechanisms in coal handling processes include transfer points, screens, pneumatic cleaning equipment, crushers, and conveyors. Each of these items of equipment can create and/or distribute combustible dust-air mixtures that might be explosive. These mechanisms can also provide the means of ignition unless properly designed, constructed, and maintained. Crushing or pulverizing equipment and frictional sparks or sparks from tramp metal are major causes for fire risk and dust explosion losses.

Dust Collection Systems

Because of coal dust explosibility, minimizing the production and emission of coal dust is essential in the design of any coal handling facility. Where coal dust production is unavoidable, dust collection systems might be required. Care should be taken to size the dust collection equipment appropriately to ensure that the coal dust will be controlled as rapidly as it is formed. All dust collection systems should be located outdoors. Fans for dust collectors should, if possible, be installed downstream of collectors so that they handle only clean air. Under special circumstances, where located inside buildings, explosion-relieving panels should be vented to the outside. Explosion protection should be provided for all dust collection systems in the form of explosion-relief vents. The vents should be sized in accordance with NFPA 68, *Standard on Explosion Protection by Deflagration Venting.* Residual coal dust contributes to the risk of dust explosion propagation. Often, in dust explosions, the initial "puff" creates a secondary explosion caused by disturbing the built-up layer of dust. Good housekeeping to minimize residual dust is paramount to controlling the hazard. Vacuum cleaning is the best way to clean up the dust without creating a potential cloud.

Vacuum cleaner tools should be made of nonsparking, electrically conductive materials. The piping and suction hose should be permanently grounded to prevent static sparks.

Coal Conveyors

Coal conveyors provide a vital link between receiving, storage, and processing equipment. In addition to the dust explosion hazard discussed earlier, the combustibility of coal creates another major fire hazard for conveying systems. Burning coal could be transported throughout the plant causing widespread damage. Belt material itself might also be combustible. Belts constructed of fabric-reinforced rubber or synthetics can burn with an intensity that produces high heat release rates and dense smoke. Materials meeting fire resistance standards of the Mine Safety and Health Administration are more difficult to ignite than noncompliant, typically older materials. Selection of the proper belt materials can reduce the probability of conveyor fires. This selection does not obviate the need for adequate protection. Even the best belts can get coated with lubricants or coal residues after use and can present increased fire hazards.

The most common ignition source in conveyor fires is friction between belts and rollers. This can be caused by either a driver or a stuck idler. Misalignment or misadjustment of belts can cause a heat buildup capable of igniting belts or coal. One successful control of friction ignition sources from drivers is "zero speed" or slippage switches. These devices shut down the power to the drivers if the belt speed drops to below a safe threshold. Poor preventive maintenance can result in rollers sticking, which can also cause friction between belts and rollers. These hot idler–caused fires usually show up after the shutdown of a transfer operation, when the still belt stays in contact with the hot idler.

The selection of fixed fire protection for use on coal conveyors depends largely on the construction of the conveyor housing. Open, uncovered conveyors that can be reached with hose streams can be adequately protected with manual fire suppression. More common are the light noncombustible construction enclosures protecting coal conveyors from the weather. These types of conveyors as well as underground conveyors make manual fire suppression extremely difficult.

Since manual fire fighting is both difficult and slow, detection systems and automatic suppression systems might be desirable. Two basic approaches have been effectively applied successfully for the suppression of coal conveyor fires. If conveyors are not shut down upon the detection of a fire, an open-head deluge system operation of the length of the belts must be applied to control and extinguish the possible moving fire on the belt. This might not be a very effective approach and could result in chasing a "moving" fire and operating many adjacent systems. The second method of suppressing coal conveyor fires is to use thermal detectors to shut down the conveyors combined with a typical closed-head automatic sprinkler, which will operate only in the zone affected by the fire. Because of freezing problems in cold climates, this closed-head system is frequently combined with a preaction valve, which will open on the same detection signal that shuts down the conveyor. Because of the concerns discussed earlier, the best approach, whether using

deluge or closed-head systems, is to stop the belts on a "fire" signal and to tie this to the interlocks referenced previously.

The design of automatic sprinkler and water spray systems will depend on the physical arrangement of the conveyors. Where multilevel conveyors are used and where potential for coal accumulation beneath belts exists, suppression system coverage should be extended to both above and below conveyor belts. Guidance on the protection of coal conveyors appears in NFPA 850.

WOOD AS A FUEL

Wood is becoming widely used because of the cost and because of improved technology for whole tree chipping on site. Maine, New Hampshire, Vermont, and other northern tier states that have reasonably abundant supplies of wood are continuing to research how wood can be converted into usable form to produce energy for heat and power generation. The U.S. Department of Energy reported an electricity-generating capacity of 5886 MW from wood and forest products as of 2002. The capacity curve has been relatively flat in the last decade.

The increasing use of wood as an energy source competes with the use of wood as raw material for pulp, paper, and building products. Consequently, much of the research into wood use today is concentrated on the less commercially useful wood species and on wood waste from the forest products industry. The emphasis is on total use of the tree, either in the production of the product or of the waste as fuel. Environmental regulations on the disposal of wood wastes have provided additional encouragement for their use as fuel.

HAZARDS OF WOOD FUELS

Given a source of ignition, wood in all its forms will burn. As the tree is cut and processed into its eventual use, the hazard of fire increases from two directions: (1) reduction of moisture content from air drying, and (2) reduction of the wood particle size from the standing tree to finished lumber, to chips for fuel and chemical pulp, and to waste wood particles the size of finely divided dust and flour. As the drying and reduction process proceeds from the relatively large particles down to the dust/flour stage, the hazard changes from that of a Class A combustible material subject to typical burning characteristics to one of such rapid combustion that it is termed an explosion. In considering the storage of wood as a fuel, the hazards encountered will range from those for solid wood to those for wood dust/flour.

Solid Wood

The hazard for solid wood is Class A combustible material not readily ignited but capable of generating a large amount of heat if allowed to burn unimpeded. The rapidity with which fire will spread depends on pile configuration, moisture of the wood and surrounding atmosphere, physical characteristics of the wood (i.e., size of individual pieces), whether wood is peeled or with bark, and species of wood. Pile size and configuration will determine the amount of radiant heat released.

Chips

This form of wood is being used on an ever-increasing scale as fuel for heat and power generation because it can be mechanized on the scale needed. The hazard is again one of a Class A combustible and, because of its small size (⅝ to 1¼ in. [16 to 32 mm]), fires in piles tend to be surface type with no more than about 50 mm or more (few inches) of fire penetration into the pile itself. Internal fires do occur from spontaneous heating as a result of excessive internal heat buildup. These fires are usually from fines that cause too much compaction or humus material within the pile, which is subject to more rapid oxidation than clean wood chips.

The chip fines can present a flash fire or explosion hazard if handled inside and dispersed in a manner that allows the wood dust to collect on structural members or to be suspended in air at concentrations above the minimum explosive concentration (MEC).

Sawdust and Shavings

Sawdust and shavings, by-products of lumber mills and wood processing plants, are generally used as a fuel on site. If strategically located, the usable material, along with other waste wood, might be shipped to other locations for use in manufacturing pulp, particleboard, or pellet fuel. The hazards are Class A combustible material and possible explosion in storage and handling from wood dust buildup.

Other Wood Waste

Wood scrap and edgings are another waste by-product, particularly of lumber mills and furniture manufacturing plants. This material is generally put through a hog to reduce the size for conveying or blowing to storage bins and boiler rooms for fuel. If the larger pieces of scrap are recoverable for use as chips in pulp manufacturing, they are conveyed to a chipper and pneumatically blown to a loading station for transfer into rail cars or tractor trailers for shipment. The hazards are similar to those for chips and sawdust. The larger wood particles are readily ignited, whereas the fines generated by the sawing, planing, and chipping processes can contain particles small enough to be an explosion hazard.

Pellets

The process uses pulverized wood waste from the forest products industry, which is formed under high temperature and pressure into pellets approximately ¼ in. by ¾ in. (6 mm by 19 mm). The finished pellets are stored in bulk form inside to keep them dry; the raw stock of wood waste is stored outside. The finished pellet storage presents little dust hazard but will burn as a Class A combustible material.

Bark

Bark is generated at pulp mills, sawmills, and chip plants as a waste material and used to a limited extent as a soil conditioner and as fuel for limited-size boilers (when mixed with other wood

scrap from the process), or it is simply disposed of by burning in teepee-type bark burners. Until recent years, bark was basically a disposal problem. Some pulp mills, however, generated too much bark over the years to be disposed of by the preceding means and it was simply piled at a detached site convenient to the plant. Over many years of operation, these piles have grown into miniature mountains. The sheer height and bulk of the piles have created a fire hazard from internal heating leading to spontaneous ignition and from external sparks from heavy equipment used to build the pile, particularly during dry periods.

A method has been outlined for eliminating fires in wood bark piles by controlling the flow of air (oxygen) horizontally into the pile. Oxygen control is achieved by sloping the pile at a 30 to 40 degree angle from the horizontal. In Figure 7.1.1 dimension A is the depth at which pressure and moisture allow the chemical reaction to generate enough heat and volatile material to provide two sides of the fire triangle (i.e., heat and fuel). Dimension B is the distance air (oxygen) must travel to complete the fire triangle and is approximately three times greater, with a 30 degree slope than with a 60 degree slope. The upward flow of heated gases within the pile prevents oxygen from reaching the point of combustion except from the nearly horizontal direction, which means the resistance to oxygen flow increases as dimension B increases. Where increasing the slope is not practical, sealing the slope to air penetration is an alternative.

What was formerly a waste disposal problem has become a valuable commodity as the price of fuel oil has gone up and the technology for burning bark on a large scale has improved. For those with such piles, they can be reclaimed as fuel for relatively large bark boilers. The reclaimed bark is mixed with the bark generated daily in the pulp manufacturing process.

STORAGE PRACTICES FOR WOOD FUELS

Logs that are to be brought to the site of use for industrial and commercial conversion to chips for fuel should be stored in ranked piles (i.e., piled in parallel form), because such piles are lower in height with less volume and less radiant heat exposure than stacked piles (i.e., large, circular, "matchstick" piles). The use of long logs, which is likely, will dictate the ranking method of storage. The piles should be 100 ft (30 m), but preferably more, from the nearest important building. The length and width of piles and pile height should be kept as small as practical to make fire fighting easier and to limit the amount of wood subject to a fire. The storage area should be clean and on solid ground with good access for fire-fighting purposes.

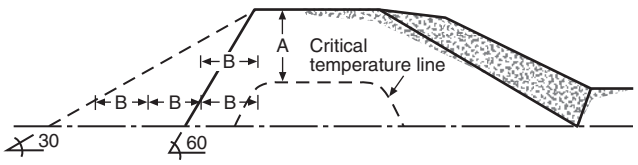

FIGURE 7.1.1 Method for Eliminating Fires in Wood Bark Piles by Controlling the Flow of Oxygen Horizontally into the Pile

Residential use of cordwood and long logs is generally in the 5- to 15-cord range and presents a relatively light hazard. Common sense dictates maintaining as much clear space as possible between the rough storage and dwelling. After cutting and splitting for use, the wood often is moved into the basement or garage for seasoning where there can be a fire potential from heating appliances, electrical wiring, and smoking. Care should be taken to store the wood away from the furnace in which it is to be burned, electrical switchboxes, and wiring. A better method is to store the wood in a pile detached from the residence and bring in a week's supply as needed.

The use of wood chips for a residential fuel is still in the developmental stage. Furnaces and the means of automatically stoking them with the chips as well as chip storage are being developed and marketed. Wood chips for fuel, often mixed with other biomass, have forged ahead in industrial and independent energy projects as illustrated by the numerous wood-to-energy projects proposed in the state of Maine.

Where chips for fuel are used on a large scale, it likely will be in a relatively isolated area close to the source of the wood and, unfortunately, away from municipal fire protection facilities and water supplies. Only the larger operations under these conditions can economically justify an independent water supply distribution system and it will be doubly important to limit outdoor chip pile size and height to dimensions less than those recommended in NFPA 1, *Uniform Fire Code*™. The plant should be located, if possible, near a pond or stream so water is available for hose streams. Any outside storage should be well isolated from processing buildings and surrounding forests.

Storage of chips, sawdust, shavings, and sander wood waste in silos, bins, and buildings can present fire and explosion hazards. Therefore, storage should be arranged to minimize these hazards by proper location, preferably outside the buildings, and by physical construction of the bin or silo and associated ducts with explosion-relief venting and explosion-isolating chokes.

Large-scale bark-burning boilers require a continuous supply of fuel to avoid fluctuations in steam output or the need to fire oil burners to take up the slack. Consequently, it is common practice to provide an enclosed surge storage area capable of providing a one- or two-day supply of fuel. One design used for such a storage building is the "A" frame style with storage capacities up to 2000 tons (1800 metric tons) at 50 to 60 percent moisture. These storage buildings should be designed to minimize the possibility of wood dust buildup on structural building members by minimizing surface areas on which the wood dust can collect. If possible, the walls should be sloped at angles approaching 60 degrees. Structural members that cannot be sloped should be covered with sheet metal designed to eliminate flat surfaces on which the dust can settle.

HANDLING WOOD FUELS

Logs, either tree length or cordwood, are loaded and piled using mechanical equipment mounted either on the log truck or on a separate vehicle. Logs present minimal fire hazard exposure to the wood-handling operation.

Wood chips and wood waste material are generally transferred either pneumatically or by belt conveyor from one place to another. The fans, ducts, cyclones, and collectors associated with air movement of wood fuel constitute a fire and explosion hazard to the process of which they are a part; therefore, they should be located so as to minimize this exposure, preferably outside the buildings whenever possible.

Magnetic separators should be provided to reduce the possibility of a spark igniting the dust. The fans should be downstream of the collectors, if possible, to prevent passage of the wood fuel through the fan.

Belt conveyors present a fire hazard from the belt material as well as from the wood material being conveyed. Sources of ignition are frictional heat from belt slippage, cutting and welding, smoking, and overheated bearings. Belt conveyor fires are sometimes complicated by the need to run the belts overhead, particularly in large bark-burning boilers. Overhead conveyors present an access problem for hose stream use.

Screw conveyors and rotary air locks should be utilized to provide chokes for fire and explosion isolation where the wood material being handled is fine enough to present an explosion hazard. It is necessary to remove a revolution (helix) of the screw in order to provide the choke. Backdraft dampers can also be used in high-velocity systems (Figure 7.1.2).

FIRE PREVENTION FOR WOOD FUELS

Where there is outside bulk storage of wood for fuel in any form, the first line of defense should be to limit the pile size to the absolute minimum required for economical operation. The homeowner and small commercial stick wood consumer will likely limit inventory to one or possibly two years' supply, whereas the larger commercial and industrial users who consume wood fuel to generate heat and power will likely restrict inventory to one day or even hours because, in many cases, they are consuming the wood waste as it is generated in the process.

Logs should be ranked rather than stacked. If large chip piles are necessary, they should be arranged as outlined in NFPA 1. Two or more smaller piles are better than one large pile.

There is indication that foreign material in piles of chips or bark accelerates the buildup of heat, possibly from chemical reaction or simply the increased porosity that allows freer movement of air through the pile. Keeping the piles free of contamination is effective fire prevention.

Pile site selection, whether for chips or bark, should take into consideration the topography of the ground, which should be clean and free of combustibles. Clearance from surrounding forest, brush, or grass should be adequate to prevent an exposure fire from reaching the storage pile. Piles should be detached from buildings and located sufficiently apart from each other to allow fire-fighting efforts to control an exposing fire.

Bark piles stored outside, whether rough or hogged bark, create heat that can lead to spontaneous ignition under certain conditions. The piles should be limited in height and contoured to restrict the flow of air (oxygen) through the pile. Heat that is generated within the pile rises to the surface and is dissipated to the surrounding air, which tends to keep the internal temperature below the spontaneous ignition point. However, in northern climates, a blanket of ice and snow can impede heat release to the extent that combustion does occur. Thus, restricting the pile height to limit heat from pressure and restricting airflow through the side of the pile become doubly important under these conditions (see Figure 7.1.1).

Storage bins, silos, and vaults for waste wood fine enough to be an explosion hazard should be outside plant buildings, if possible, or, if inside, should be arranged to vent explosions to the outside. For further details, see NFPA 664, *Standard for the Prevention of Fires and Explosions in Wood Processing and Woodworking Facilities.*

The need to control moisture content of wood waste fuel for more efficient combustion might require use of lightly constructed metal buildings on a concrete slab to protect the fuel from the weather. Such buildings should be designed to minimize dust buildup on structural members. Lighting, if required, should conform to applicable provisions of NFPA 70, *National Electrical Code®*.

If the wood waste being stored contains a considerable amount of fines in the dust/flour range (such as sander fines), it might be necessary to incorporate explosion relief in the building design. A partially open structure may be a feasible design.

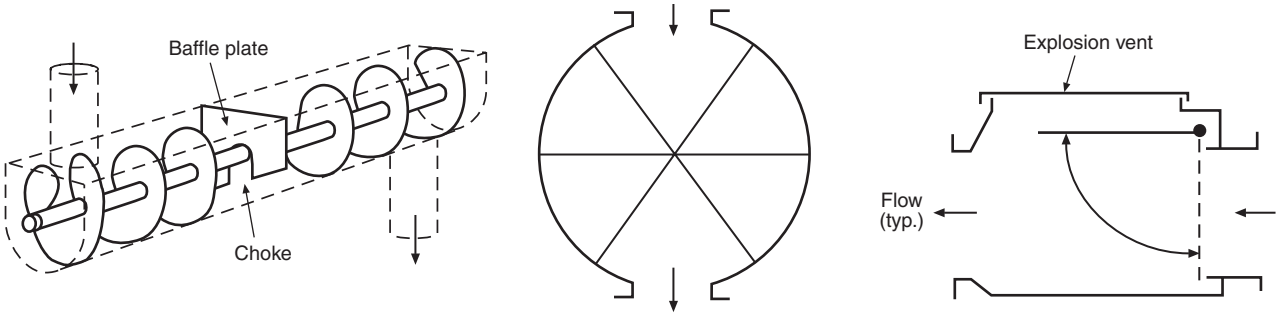

FIGURE 7.1.2 Types of Chokes Used to Isolate Fire and Explosion When Wood Material Is Fine Enough to Explode

FIRE PROTECTION FOR WOOD FUELS

The bins, silos, or vaults in which chips and other wood waste are collected should be constructed of metal and located outside the boiler building, if possible. Collector and storage units handling fines that present an explosion hazard should be constructed with explosion-relief venting arranged to operate well below the design strength of the equipment. If bulk storage must be in or adjacent to the boiler building, it should be cut off with a fire-rated masonry wall.

Ranked log piles, arranged as previously described, should be protected with a yard hydrant system suitable for the storage arrangement and size, as defined in NFPA 1. If the plant location and size preclude having an adequate water supply and a plant fire brigade, smaller, more segregated piles will be necessary with greater clear space between the wood storage and plant.

Chip and bark piles also require large amounts of water to control and extinguish fires. Although it is likely that storage piles of chips and bark to be used as fuel would not be the same size as piles of these materials at pulp mills, conscious effort should be made to keep the piles limited in size in order to reduce the volume of water and the fire-fighting effort needed to combat a fire. (See NFPA 1 for details of yard fire protection.)

Automatic sprinkler or water spray protection should be provided in the collecting, conveying, and storage areas. Where fuel storage buildings are utilized in the system, they should be provided with automatic sprinkler protection in accordance with NFPA 13, *Standard for the Installation of Sprinkler Systems;* NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection;* and NFPA 850.

Where bark or chips are transported from the outside storage pile or silo to an inside bin for feeding to the boiler by enclosed conveyors, the structure should be noncombustible and arranged to meet applicable safety codes. Regardless of the system type used, the conveyor should be interlocked to shut down on actuation of the sprinkler or detection system. As a result of the increased interest in resource recovery and the expansion of independent, nonutility power generation, the use of nontraditional (alternative) solid fuels has become common.

SOLID WASTE AS FUEL

Each year in the United States more than 200 million tons of solid waste are generated in municipal waste facilities. Approximately one-third of these wastes are used productively to generate electricity or through recycling. The rest are destined for landfills. As landfill space and waste transportation become more limited, incineration of these wastes will increase. Incinerators are addressed in Section 11, Chapter 1, "Waste Handling and Control." However, larger facilities where waste is transported to centralized facilities are discussed here.

According to USDOE statistics, more that 3300 MW of electric-generating capacity exists in the United States as of 2002. Solid waste or refuse is also used for steam and hot water production. The processing of municipal solid waste (MSW) varies according to the furnaces used to combust the waste.

Storage of Waste

MSW is usually delivered to the plant by truck and dumped on the tripper floor or into waste pits. Facilities that dump MSW on tripper floors use this area as a first sorting site to remove noncombustibles, recyclables, and other undesirables from the waste stream. In facilities where this sorting is done in pits or prior to delivery to the site, the tripper floor should be relatively free of residual combustibles. Housekeeping is important in this area because of the potential ignition sources from delivery trucks. MSW should not be allowed to accumulate. MSW stored in pits should be monitored by cameras or plant personnel to ensure that fires and unsafe conditions are detected. If the tripper floor is enclosed (walls and roof), it should be provided with automatic sprinkler protection or the structure should be built of fire-resistive construction. Building codes would limit the area for Type V construction (i.e., unprotected structural steel) to no more than 8500 ft^2 (Figure 7.1.3).

Processing of MSW

Some facilities burn the MSW with a minimum of processing. These are often referred to as mass burn plants. More frequently,

FIGURE 7.1.3 Fire Fighters Spraying Water on Full Engulfed Fire at Nashville Thermal Plant (Source: *The Tennessean*)

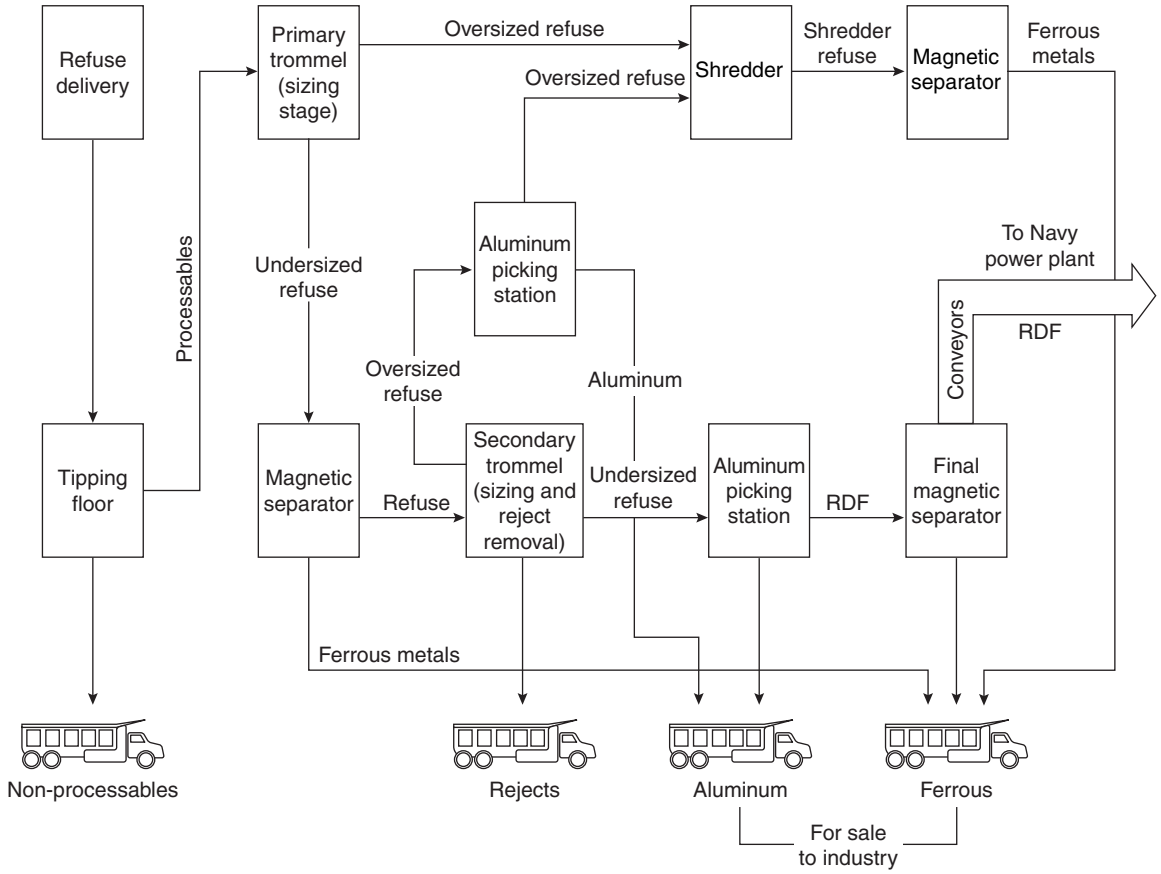

FIGURE 7.1.4 MSW Processing That Converts Waste into Fuel (Source: Courtesy of Southeastern Public Service Authority)

to improve combustion efficiency, the MSW is processed. These processes include size reduction and drying. The subsequent treated fuel is referred to as refuse derived fuel (RDF). Figure 7.1.4 shows one such processing plant, which sizes and separates as the first step, followed by shredding. In this plant the shredded fuel is conveyed to the boiler.

Shredders introduce the risk of explosions, usually from dusts generated by the shredding. The most common ignition source is "tramp" metal that fails to get separated. Magnetic separators are provided to reduce the likelihood of ferrous metals being carried into the shredder. To reduce the damage to plant and personnel in the event of an explosion, venting in combination with resistant construction should be provided.

Some RDF facilities further process the MSW by drying and by pelletizing. The resulting fuel can be consumed at the site or can be shipped to other facilities to fuel boilers. Figure 7.1.5 shows an example of a pellet extrusion process. The pellets can be stored in bins or silos at the power plant. The fuel is transferred to the boiler by either belt conveyors, chain conveyors, or screw conveyors. The pellets can also be a source of dust. Housekeeping and dust collection systems are necessary to prevent the accumulation of dust to dangerous levels.

Chapter 9 of NFPA 850 provides fire protection recommendations for these and other alternative solid fuels.

SUMMARY

Safe practices are required for the storage and handling of solid fuels, which are used to generate heat for steam, electrical power, or process needs. Major sources of solid fuel are coal, wood, wood by-products, and solid waste, which need to be stored and handled properly in order to minimize hazards. Coal is susceptible to such hazards as fire, flash fire, and dust explosion, and wood in all its forms burns if ignited. Storage and handling factors that need to be properly implemented and maintained include storage facilities and practices, housekeeping, conveyance materials, fire suppression methods, and prefire planning.

Chapter 2

Storage of Flammable and Combustible Liquids

Anthony M. Ordile

Chapter Contents

Tank Storage
Other Storage of Flammable Liquids
Handling of Flammable and Combustible Liquids
Transportation of Flammable and Combustible Liquids

Key Terms

combustible liquid, container storage, flame arrester, flammable liquid, hazardous materials storage locker, lower explosive limit (LEL), lower flammable limit (LFL), pressure relief valve, pressure vessel, safety can, storage tank (aboveground), storage tank (underground), tank, tank vehicle, vent valve

The first requirement for the storage of flammable and combustible liquids is properly designed containers that are liquid-tight and from which release of vapors, if required, is carefully controlled. The containers range from large, vertical, outdoor storage tanks of thousands of gallons capacity (264,200 gal = 1000 m^3) down through drums to small containers that hold a few ounces of liquid.

This chapter discusses the various types of containers used in the storage and transportation of flammable and combustible liquids and the precautions that should be observed in handling the liquids as they are loaded, unloaded, or dispensed.

Additional information relevant to the storage of flammable and combustible liquids can be found in Section 2, Chapter 8, "Explosions"; Section 6, Chapter 1, "Fire Hazards of Materials"; Section 11, Chapter 5, "Control of Electrostatic Ignition Sources"; Section 14, Chapter 8, "Gas and Vapor Detection Systems and Monitors"; Section 15, "Water Supplies for Fixed Fire Suppression"; Section 16, "Water-Based Fire Suppression Equipment"; and Section 17, "Fire Suppression Systems and Portable Extinguishers."

TANK STORAGE

Tanks can be installed aboveground, underground, or, under certain conditions, inside buildings. Openings and connections to tanks, for venting, gauging, filling, and withdrawing, can present hazards if they are not properly safeguarded.

Given substantially constructed, properly installed, and well-maintained tanks, storage of flammable and combustible liquids should be less dangerous than transferring these liquids because storage does not involve any active steps where human error can lead to spills and where distance from ignition sources may be less consistently achieveable. The severity of the storage hazard might seem to depend on the quantity stored. As a practical matter, however, the size of the tank or the number of tanks is less important than such factors as the characteristics of the liquid stored, the design of the tank and its foundation and supports, the size and location of vents, and the piping and its connections.

Flammable liquids expand when heated. Gasolines expand about 0.07 percent in volume for each 10°F (6°C) increase in temperature within ordinary atmospheric temperature ranges. The effect of temperature increase on the volume of acetone, ethyl ether, and certain other flammable liquids with higher coefficients of expansion is greater than in the case of gasolines. To avoid danger of overflow, tanks should not be filled completely, particularly where cool liquid is placed in a tank in a warm atmosphere—for example, when filling a gasoline can from an underground tank at a service station on a warm day.

Several methods are used to prevent storage evaporation loss and loss of vapors as the tank is filled. Underground tanks reduce evaporation losses because there is less fluctuation of temperature. Aboveground tanks often are painted with aluminum or white paint to reflect heat, thus decreasing the temperature rise of liquid contents and slowing evaporation of tank contents. Floating roof tanks

Anthony M. Ordile, P.E., is a consulting engineer employed by Loss Control Associates, Inc., a fire protection and process safety consulting firm in Langhorne, Pennsylvania. He is a member of the NFPA Technical Committee on Flammable and Combustible Liquids.

minimize vapor loss and tend to reduce the fire hazard. Storage in pressurized tanks reduces the loss of vapor. In some cases, vapors are conserved by the use of lifter roof or vapor dome tanks, or the vents from several cone roofed tanks might be connected through manifolds to a vapor dome or pressure-type tank.

The vapor space in tanks storing flammable liquids with vapor pressures above an absolute pressure of 28 kPa (4 psia), such as gasoline, is normally too rich to burn. The ratio of vapor to air is above the upper flammable (explosive) limit (UFL). However, if the temperature of the liquid gasoline is in the range of –10 to –50°F (–23 to –46°C), the vapor space might be within the flammable range. When a tank is being off-loaded or when there is a sudden cooling rainstorm on a hot day, a portion of the tank vapor spaceway might be within flammable limits, resulting from introduction of air. This condition might remain for several hours or even days, due to stratification of the vapors.

The vapor space in tanks storing low vapor pressure liquids (below approximately 2 psia or 14 kPa), such as kerosene, is normally too lean to burn. The ratio of vapor to air is below the lower flammable (explosive) limit (LFL). However, if the entire body of liquid is heated to its flashpoint, as can happen during refining processes or by exposure to fire, the vapor space might enter the flammable range. It should be noted that it is the temperature of the liquid and not the temperature of the vapor space that determines the presence of a flammable vapor–air mixture. The vapors driven off by the heated air in the vapor space are condensed back to liquid by the cooler body of liquid in the tank. Therefore, the vapors are only flammable for a very short distance above the liquid surface despite the fact that the air within the tank might be considerably above the flashpoint temperature.

Tank storage of ethyl and methyl alcohol, JP-4 or Jet B turbine fuel, and other liquids of similar vapor pressure (approximately 2 to 4 psia at 100°F or 14 to 28 kPa at 38°C) presents an unusual hazard, since the vapors are normally in the flammable range. Storage in floating roof or similar tanks or the addition of inert gas in the vapor space is desirable to reduce the possibility of an explosion in the vapor-air mixture in the tank. Floating roof tanks, cone roof tanks with internal floating roofs, lifter roof tanks, and vapor dome tanks are also used for vapor conservation purposes for Class I liquids.

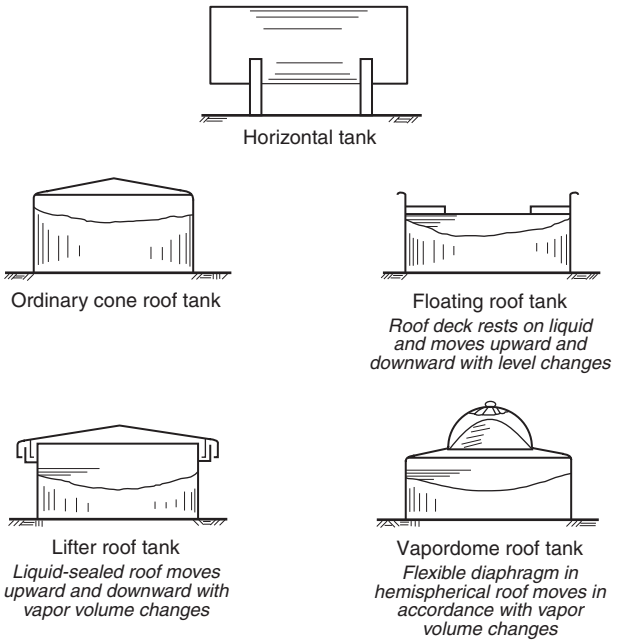

FIGURE 7.2.1 Common Types of Atmospheric Storage Tanks

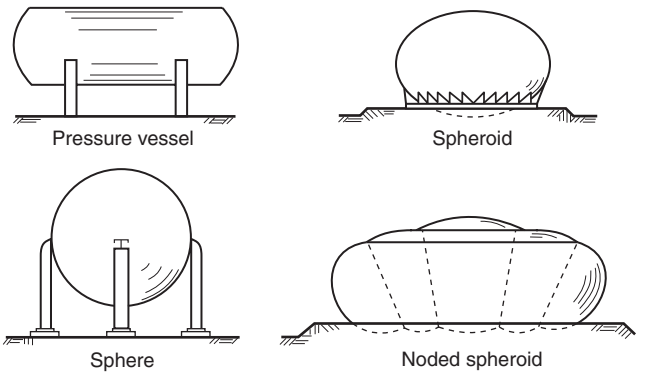

FIGURE 7.2.2 Common Types of Low-Pressure Tanks or Pressure Vessels

Aboveground Storage Tanks

Storage tanks come in a variety of design and construction types. They are divided into three general categories of pressure design: (1) atmospheric tanks, for pressures of 0 to 1.0 psig (0 to 6.9 kPa); (2) low-pressure storage tanks, for pressures from 1.0 to 15 psig (6.9 to 103 kPa); and (3) pressure vessels, for pressures above 15 psig (103 kPa). Some of the more common types of aboveground storage tanks are shown in Figures 7.2.1 and 7.2.2. Pressure tanks and pressure vessels normally are used for vapor conservation purposes, particularly for liquids with high vapor pressures.

In recent years, aboveground secondary containment-type tanks have become increasingly more popular for atmospheric storage of flammable and combustible liquids. The popularity of these tanks has been aided by federal regulations now imposed on underground tanks. Various types of aboveground secondary containment tanks are manufactured and approved for use. Figures 7.2.3 and 7.2.4 show typical aboveground secondary containment tanks. These tanks incorporate a primary steel tank that is either completely encased by another steel or fiberglass tank or a geomembrane shell so that any leakage from the primary tank is contained by the outer tank or shell. For protection against exposure fires and vandalism, many aboveground secondary containment tanks are encased with 6 in. (152 mm) of reinforced concrete, thus also providing fire resistance. Requirements covering size limitations, pipe connections, and overfill protection are contained in NFPA 30, *Flammable and Combustible Liquids Code*. Figure 7.2.5 shows the various construction and protection requirements provided on secondary containment tanks listed by Underwriters Laboratories Inc. (UL).

FIGURE 7.2.3 Common Type of Rectangular Aboveground Secondary Containment Tank (Source: Courtesy of Highland Tank & Manufacturing Company, Inc.)

Construction. All aboveground storage tanks should be built of steel or concrete, unless the character of the liquid necessitates the use of other materials. Both steel and concrete tanks resist heat from exposure fires. Tanks built of materials less resistant to heat (e.g., low melting point materials) might result in tank failure and fire spread.

The thickness of the metal used in tank construction is based not only on the strength required to hold the weight of the liquid but also on an added allowance for corrosion. When intended for storing corrosive liquids, the specifications for the thickness of the tank shell are increased to provide additional metal and allow for the expected service life of the tank. In some cases, special tank linings are used to reduce corrosion. Periodic inspection should be made to ascertain metal thickness of the tank, establish safe operating limits, and avoid overstressing the tank. The inspection of tanks for corrosion can be through the use of visual, magnetic particle, ultrasonic, and radiographic methods, or by experience gained from the storage of similar materials. Ultrasonic devices operate on a principle of the length of time it takes for sound waves to reflect from a surface. Any difference in metal thickness is quickly disclosed by these instruments, which are particularly effective when large areas with many potential corrosion spots are involved.

For atmospheric, vertical, cylindrical, and aboveground welded tanks, API Standard 650, *Welded Steel Tanks for Oil Storage,*[1] may be used in calculating the minimum thickness of shell plates. The required nominal thickness of shell plates must be the greater of the design shell thickness, including any corrosion allowance, or the hydrostatic test shell thickness, but in no case less than the values given in Table 7.2.1.

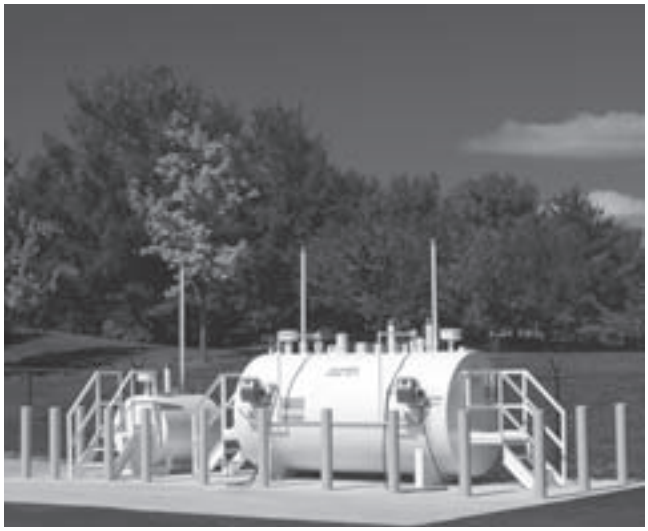

FIGURE 7.2.4 Common Type of Cylindrical Aboveground Secondary Containment Tank (Source: Courtesy of Highland Tank & Manufacturing Company, Inc.)

TABLE 7.2.1 Shell Plate Thickness

Nominal Tank Diameter (ft)	*Nominal Thickness (in.)*
Smaller than 50	3/16
50 to, but not including, 120	1/4
120 to 200, inclusive	5/16
Over 200	3/8

For SI units: 1 ft = 0.304 m; 1 in. = 25.4 mm.

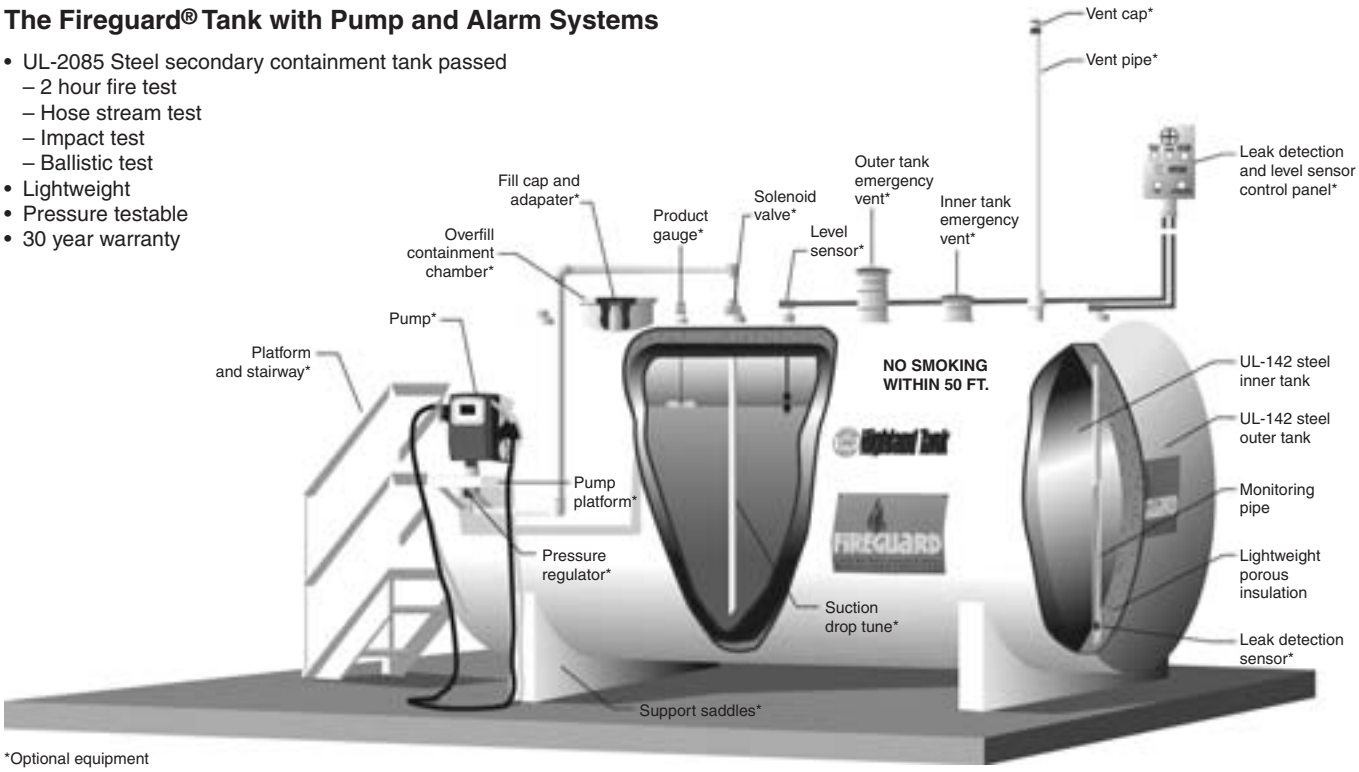

FIGURE 7.2.5 Typical Construction and Protection Features Required of Aboveground Secondary Containment Tanks (Source: Courtesy of Highland Tank & Manufacturing Company, Inc.)

Those tanks listed by UL and other testing organizations or built in accordance with American Petroleum Institute (API) standards meet the required construction specifications.

Concrete tanks require special engineering. Unlined concrete tanks should be used only for the storage of liquids with a specific gravity of 40 degrees API or heavier. Concrete tanks with special linings are permitted for other services, provided the design is in accordance with appropriate engineering practices. Tanks built of material other than steel should be designed to specifications embodying equivalent steel safety factors.

Installation. Aboveground tanks should be installed in accordance with NFPA 30, which specifies distances from tanks to property lines that can be built on and to public ways or important buildings. These distances will vary depending on whether the pressures in the tanks, including those attained during fire exposure, can be under or over 2.5 psig (17 kPa), as well as whether the contents are stable or unstable liquids, or liquids having boil-over characteristics. Other factors affecting distances are the size and design of the tank, protection for exposures, fire-extinguishing or control systems provided, and other protection features. The spacing between tanks is also specified in NFPA 30.

When a tank is located in an area that is subject to flooding, applicable provisions in NFPA 30 should be followed.

Venting and Flame Arresters. An appropriate vent must be provided for normal operation of any tank to permit filling and emptying and for the maximum expansion or contraction of the tank contents with changes in temperature. API Standard 2000, *Venting Atmospheric and Low-Pressure Storage Tanks,*[2] provides the design bases for sizing vents for product movement and breathing. Alternatively, the normal vent should be at least as large as the largest filling or withdrawal connection, but in no case should it be less than 1.25 in. (32 mm) nominal inside diameter. Clogged or inadequately sized vents can result in the rupture of tanks from internal pressure or collapse due to internal vacuum. During the filling operation, the vents discharge flammable vapors. If the mixture is sufficiently rich or if the vent location is such that the released vapor is a hazard, the vapors should be piped to a safe outside location at least 12 ft (3.7 m) above grade. The vapor release should not occur under eaves or close to doors, windows, or possible sources of ignition.

Some venting devices are normally closed when the tank is not under pressure or vacuum and this is required by NFPA 30 for Class IA liquids (flashpoint below 73°F [28°C]; boiling point below 100°F [38°C]). Devices installed on vent pipes can be approved pressure-vacuum conservation (breather) vent valves or flame arresters to prevent flashback into tanks (Figures 7.2.6 and 7.2.7). These devices are required when a flammable mixture is present and for the storage of all Class I liquids. Arresters constructed of banks of parallel metal plates or tubes having a large surface of metal to dissipate heat are more effective than screens for larger openings and are less subject to clogging and

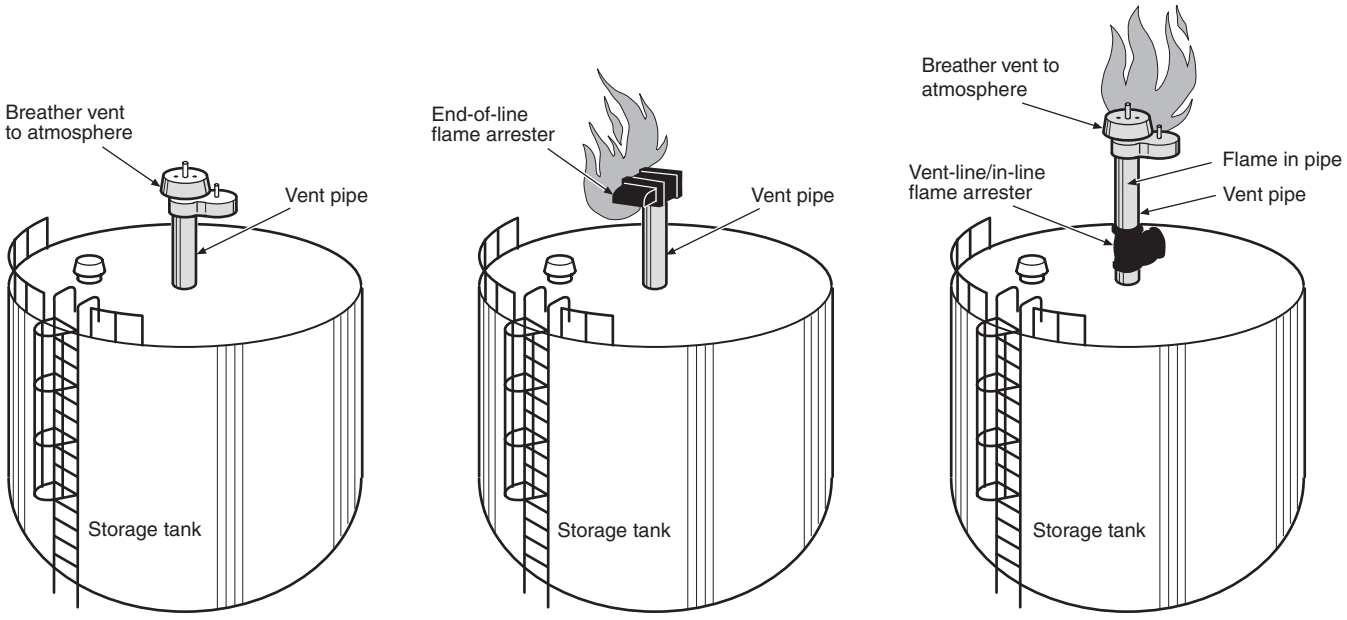

FIGURE 7.2.6 Typical Arrangement of Pressure-Vacuum Conservation (Breather) Vent Valves and Flame Arresters

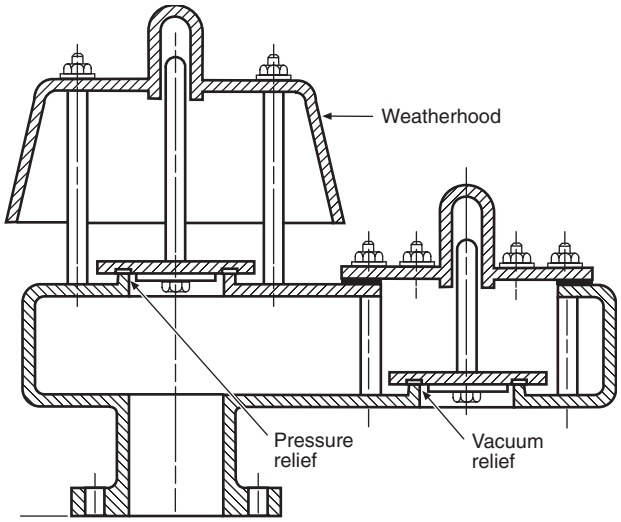

FIGURE 7.2.7 Typical Pressure-Vacuum Conservation (Breather) Vent

corrosion. Heat from exterior flames is absorbed by the plates or tubes, thus quenching the flames and preventing ignition of vapors inside the tank. However, if the flame arrester is exposed to long burning periods, the metal plates can become sufficiently hot on the bottom side to ignite any flammable vapor-air mixtures in the tank. Approved flame arresters are cellular arresters that include perforated-plate arresters, parallel-plate arresters, crimped-metal-ribbon arresters, and sintered metal arresters. The two critical parameters that govern the effectiveness of cellular arresters are (1) diameter or width and (2) length of the flame passages.

Vent design should be suitable for venting tank vapor space in accordance with API 2000[2] and NFPA 30 and should not restrict vapor relief under design conditions.

Where the liquids stored have flashpoints in the range of normal summer temperatures, the vapor space above the liquid in the tank will normally contain vapors in the flammable range. Flame arresters have their most important application on such tanks. However, condensation and crystallization of certain liquids and freezing of moisture in winter might make conservation vents and flame arresters impractical. Steam tracing (steam heating) is provided in some cases to prevent freezing or crystallization of contents.

Although a wire screen of 40 mesh* ordinarily will prevent the passage of flame through small openings, it cannot be relied on as an effective flame arrester because of possible physical damage to the wires or clogging of the mesh by dirt or other residues.

Pressure-Relief Devices. Appropriate venting of aboveground tanks and pressure vessels can also be achieved by the use of pressure-relief devices. These devices are actuated by inlet static pressure and are designed to open during an emergency or abnormal conditions to prevent a rise of internal pressure in excess of a specified value within the tank or vessel.

*A woven wire fabric in which there are 40 wires per in. (25.4 mm) in each direction and 1600 interstices per in.^{2} (645 mm^2). The size of the openings depends on the diameter of the wires and on the mesh of the screens, but the size of wire is approximately uniform for any given mesh, and specifying a screen in terms of its mesh determines the size of the openings with sufficient accuracy for practical purposes. The individual opening in a 40-mesh screen has an area of about 0.00022 in.^{2} (0.14 mm^2).

Pressure-relief valves are frequently of the spring-loaded type, which are designed to automatically reclose after actuation and prevent the further release of gas, vapor, or liquid (Figure 7.2.8).[3]

Other types of pressure-relief devices are (1) pilot-operated pressure-relief valves that include a pressure-relief valve combined with and controlled by an auxiliary pressure-relief valve and (2) rupture disk devices that are nonreclosing differential pressure-relief devices actuated by inlet pressure and designed to function by bursting the rupture disk (Figure 7.2.9).[3]

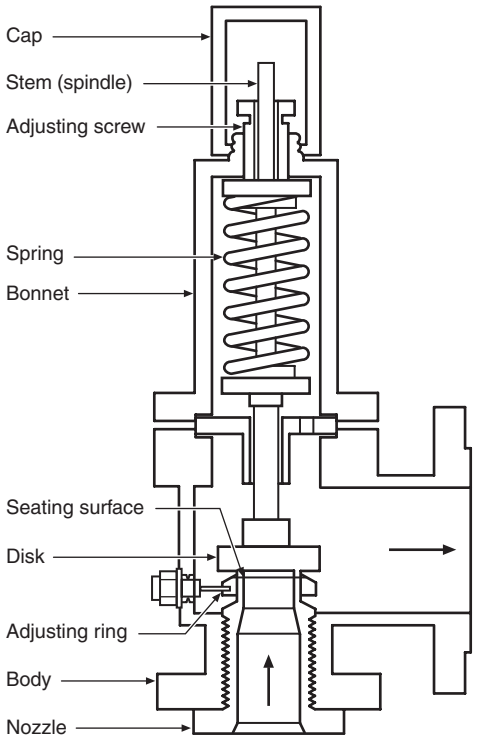

FIGURE 7.2.8 Typical Pressure-Relief Valve Device of the Spring-Loaded Type

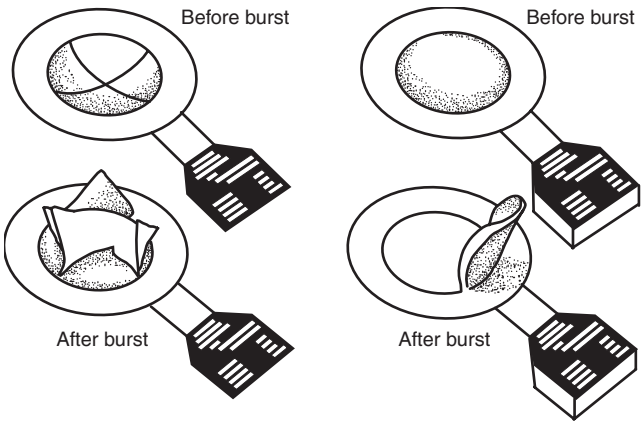

FIGURE 7.2.9 Types of Rupture Disk Devices

Emergency Venting. In addition to the normal operating vents, emergency relief of internal pressure is required for most aboveground tanks in the event a fire occurs under or around the tank. In the absence of a proper provision for such relief, high pressures can be generated when the tank is exposed to external fire, sometimes leading to explosions. Such explosions are infrequent, but when they do occur, the results can be disastrous to life and property. They can be prevented by providing adequate pressure relief, which permits the vapors to escape and burn at the vents and prevents the tank from rupturing. Emergency relief venting can take the form of loose manhole covers that lift under pressure, weak roof-to-shell seams, rupture disks, remotely actuated vapor depressuring, or commonly used pressure-relief devices designed for the purpose. The provision of floating roofs negates the need for emergency relief venting.

Unless they are adequately vented, horizontal cylindrical tanks under excessive internal pressure commonly fail, and failure typically occurs at the ends. For vertical cone-roofed tanks designed with weakened seams at the roof-to-shell joint, the lifting of the roof or top of the roof-to-shell seam affords adequate emergency pressure relief.

The danger of tank failure from internal pressure when exposed to fire depends to a considerable extent on the characteristics of the liquid, the size and type of the tank, and the intensity and duration of the fire. The smaller the tank or the smaller the volume of the liquid in the tank, the shorter the time under fire exposure before an explosion might occur.

On small cone-roofed tanks, under 20 ft (6 m) in diameter, supplemental venting might be needed to prevent preferential failure of the shell-to-bottom seam.

Dome-roofed tank designs should meet the requirements of API 650[1] for construction and venting. Dome-roofed designs should not be mistaken for cone-roofed designs.

Table 7.2.2 is based on the required discharge from both normal and emergency vents. It is derived from a consideration of the probable maximum rate of heat transfer per unit area; the size of tank and the percentage of total area likely to be exposed; the time required to bring tank contents to boil; the time required to heat unwet portions of the tank shell or roof to a temperature where the metal will lose strength; and the effect of drainage, insulation, and the application of water in reducing fire exposure and heat transfer. Due to the wide variance in flow characteristics of manufactured vents, each vent design under 8 in. (200 mm) should be flow tested rather than relying on vent size. The flow capacity of larger vents may be flow tested or calculated in accordance with the formula in NFPA 30.

The wetted area referred to in Table 7.2.2 is the internal portion of the tank in contact with the liquid (assuming a full tank) that is expected to be exposed to the flame from an external ground fire. The requirements for emergency venting are based on the heating of the liquid in the tank. Therefore, the wetted area (exposed to an external ground fire, such as a spill) varies with different tank designs: 55 percent of the total exposed area of a sphere or spheroid, 75 percent of the total exposed area of a horizontal tank, and the first 30 ft (9 m) abovegrade of the exposed shell area of a vertical tank.

For tanks and storage vessels designed for pressures over 1 psig (6.9 kPa), the total rate of venting can be obtained from

TABLE 7.2.2 Wetted Area Versus Amount of Free Air per Hour Required for Relief Venting for Aboveground Tanks. For purposes of calculating the capacity of venting devices, "free air" is defined as air at 14.7 psia and 60°F or 101 kPa and 15.5°C.

ft^2	m^2	ft^3/hr	m^3/hr
20	1.86	21,100	597

2,400	222.96	704,000	19,935
2,800	260.12	742,000	21,011

Note: Interpolate for intermediate values.

Table 7.2.2, except when the exposed wetted area or the surface is greater than 2800 ft^2 (260 m^2), the total rate of venting can be obtained from Table 7.2.3, or it can be calculated by the following formula:

$$CFH = 1107A^{0.82}$$

where

CFH = Venting requirement, in ft^3 of free air per hour

A = Exposed wetted surface, in ft^2

For SI units:

$$m^3/hr = 220A^{0.82}$$

where A is in m^2. The foregoing formulae are based on $Q = 21{,}000A^{0.82}$ where Q is heat absorption in Btu/hr.

The total emergency relief venting capacity for any specific stable liquid can be determined by the following formula:

TABLE 7.2.3 Rate of Venting for Tanks with an Exposed Wetted Area Larger than 2800 Ft^2 (260 m^2)

ft^2	m^2	ft^3/hr	m^3/hr
2,800	260	742,000	21,011
3,000	279	786,000	22,257
3,500	325	892,000	25,258

35,000	3,251	5,900,000	167,070
40,000	3,716	6,570,000	186,043

$$Ft^3 \text{ of free air per hour} = V\frac{1{,}337}{L\sqrt{M}}$$

For SI units:

$$m^3/hr = V\frac{3107}{L\sqrt{M}}$$

where

V = ft^3 or m^3 of free air per hr from Table 7.2.2

L = Latent heat of vaporization of specific liquid in Btu per lb or kJ/kg

M = Molecular weight of the specific liquid

The required rate of venting is permitted by NFPA 30 to be multiplied by a reduction factor listed in the following schedule when protection is provided as indicated (only one factor may be used for any one tank):

- A reduction factor of 0.5 for approved drainage for tanks over 200 ft^2 (18.6 m^2) of wetted area
- A reduction factor of 0.3 for approved water spray and drainage
- A reduction factor of 0.3 for approved automatic water spray
- A reduction factor of 0.3 for approved insulation
- A reduction factor of 0.15 for approved water spray with approved insulation

With some restrictions, the above factors may be reduced by 50 percent for liquids with heats of combustion and rates of burning equal to or less than those of ethyl alcohol (ethanol), but in no case can the factors be reduced to less than 0.15. See NFPA 30.

When pressure tanks or vessels are exposed to fire, a violent BLEVE (boiling liquid expanding vapor explosion) can

result if the steel in the vapor space is softened by heat. Localized overheating of the tank shell has been caused by vent fires impinging on tank surfaces. The outlets of all vents and vent drains on aboveground tanks designed for 2.5 psi (17 kPa) or greater should be arranged to prevent localized overheating of any part of the tank from a vent fire.

Foundations and Supports. Tanks should be set on firm foundations. They should be adequately supported to minimize the possibility of uneven settling and to minimize the corrosion in any part of the tank resting on the foundation. Vertical tanks are normally set on a slightly elevated concrete pad to provide a sound base and normally above the adjacent ground level to protect the bottom of the tank from any water in the area. Exposed pilings or steel supports under any flammable liquid tank should be protected by fire-resistive materials with a fire resistance rating of not less than 2 hours.

In certain situations, the use of water spray protection on tank supports may be approved for use, in lieu of providing fire-resistive materials.

Drainage and Dikes. Where important facilities, waterways, or adjoining properties would be endangered by release of liquids stored in tanks, it is necessary to provide a means to control any spillage. The most desirable method is to locate the tanks on sloping ground. Directional dikes or drainage ditches could then divert spillage away from all tanks and into an impounding basin where the liquid could burn safely without exposing other tanks, property, or waterways. Where impounding basins cannot be used, dikes built around the tanks can prevent the spread of liquid. Dikes may be constructed of earth, concrete, solid masonry, or steel built to withstand the lateral pressure of a full liquid head. When several large tanks are in a single diked enclosure, it may be desirable to place drainage channels or intermediate dikes between tanks. Intermediate dikes, which should be at least 18 in. (457 mm) in height, are effective in preventing small spills from exposing other tanks in the diked enclosure. Such spills typically result from a leaking valve or connection or from overfilling the tank.

Diked enclosures should be designed to contain the greatest amount of liquid that can be released from the largest tank within the enclosure, assuming a full tank. When calculating the volumetric capacity of the diked enclosure, the volume of other tanks within the diked area to the height of the dikes must be considered as unavailable for retaining liquid.

Where needed, diked areas are provided with trapped drains to remove rainwater or water used for fire fighting. The best practice is to keep drain valves normally closed and open them at intervals as needed, since permanently open drains would discharge liquids in case of leakage from the tank. The drain valves should also be accessible under fire conditions (i.e., they should be located outside the dike). Oil separators are effective in skimming off oil flowing on the surface of water, but separators normally will not control oil discharge when the entire flow through the drain is oil.

Dikes higher than 6 ft (1.8 m) are not desirable without additional safety measures. Where circumstances require high, close dike walls, means should be provided for access to tanks, valves, and other equipment and for safe egress from the diked enclosure. Where the average height of a dike containing Class I liquids is over 12 ft (3.6 m) high or where the distance between a tank and the inside edge of the dike wall is less than the height of the dike wall, provisions should be made for normal operation of valves and for access to tank roofs without entering below the top of the dike. These provisions reflect a concern for the accumulation of Class I liquid vapors reaching harmful levels when confined in the narrow space between the high dike wall and the tank.

Aboveground secondary containment-type tanks meeting the requirements of NFPA 30 are not required to meet the provisions for drainage or diking, as long as their capacity does not exceed the capacities allowed by NFPA 30.

Fire Hazards of Aboveground Tanks. A commonly encountered type of aboveground tank installation includes tanks on unprotected steel supports. Tank truck loading can be accomplished by gravity when done immediately adjacent to these tanks. The common fire at such installations originates at the tank vehicle and, in short order, the unprotected steel supports fail and drop the tanks to the ground. The tanks might break the piping or rupture on hitting the ground, releasing their entire contents. To prevent tank collapse, steel supports should be protected by 2 hour fire-resistive coverings. The loading rack should be at least 25 ft (7.6 m) from the tanks if Class I flammable liquids are handled, and 15 ft (4.6 m) with Class II and Class III liquids.

Improper and inadequate emergency venting can be a factor in tank failures during exposure to fire. Because these tank failures can lead to severe explosions, deaths, and injuries to fire fighters and others, it is of vital importance that the requirements on venting be followed. In fighting tank fires, it is essential to cool the shell above the liquid level to keep the steel from overheating. Failure to do so could cause the tank to bulge and rupture, regardless of the adequacy of the venting.

Also, a factor in fires involving storage tanks has been the failure of piping and valves. Such failures have resulted in the addition of their contents to the ground fire. Pipe systems may be located either aboveground or underground. Piping from aboveground tanks is normally placed aboveground to avoid corrosion problems and to aid in detecting pipe leaks. If piping is in open trenches, suitable fire barriers should be placed at certain intervals to prevent the flow of liquid from one section of the facility to another. Underground piping is not subject to fire exposure. All piping must be protected against physical damage and excessive stresses that arise from expansion, contraction, vibration, and settlement. Materials that are subject to failure due to thermal shock, such as cast iron, and low melting point materials such as aluminum, copper, and brass, should not be used. Steel or nodular (malleable) iron pipe and valves should be used for external tank connections through which liquid would normally flow, unless the chemical characteristics of the liquid stored are incompatible with steel. Welded pipe connections or flanged joints are preferred for aboveground piping, particularly for large-size pipe. Screwed pipe connections larger than 3 in. (76 mm) are subject to disengagement in a long-exposure fire unless the connections are back-welded. Pipe joints dependent

on the friction characteristics of combustible materials for mechanical continuity of piping are subject to failure under fire exposure conditions.

Storage tank fires may originate with an internal explosion or by a spill fire exposing the tanks. In a prolonged tank fire, the shell of a large vertical tank is likely to fold into the tank above the burning liquid level, without splitting the tank shell.

Internal explosions of storage tanks can occur when the vapor space above the liquid reaches the flammable range. Liquids with flashpoints near the stored temperature are most susceptible to ignition. Liquids with low flashpoints will have a flammable vapor-air mixture in the vapor space if the temperature is markedly reduced and high-flashpoint liquids will form a flammable vapor-air mixture when heated. During fire exposures, internal explosions have occurred in tanks containing liquids with flashpoints above the stored liquid temperature. Such explosions occur because the liquid is heated by the exposure fire and the vapor passes into the flammable range when a part of the tank shell in the vapor space is hot enough to ignite the vapors.

Floating roof tanks provide greater fire safety for aboveground installations and, as a result, are permitted to be located closer to a property line than are other types of tanks. Explosions might occur when floating roof tanks are virtually empty of liquid and the roof has been allowed to rest on the low-level supports, thus creating a flammable vapor space beneath. When fires occur in floating roof tanks, they are normally restricted to the seal space between the roof and the shell and can be extinguished by portable extinguishers or handheld foam lines. Full-surface fires can result from the roof sinking. Roof sinking can occur as a result of the roof hanging up due to overfill or tank obstructions, excessive snow loading or rainwater, and excessive water or foam from fire-fighting activities. A good tank roof and seal maintenance program, along with proper tank operating procedures, is the best way to prevent problems resulting in fires (Figure 7.2.10).

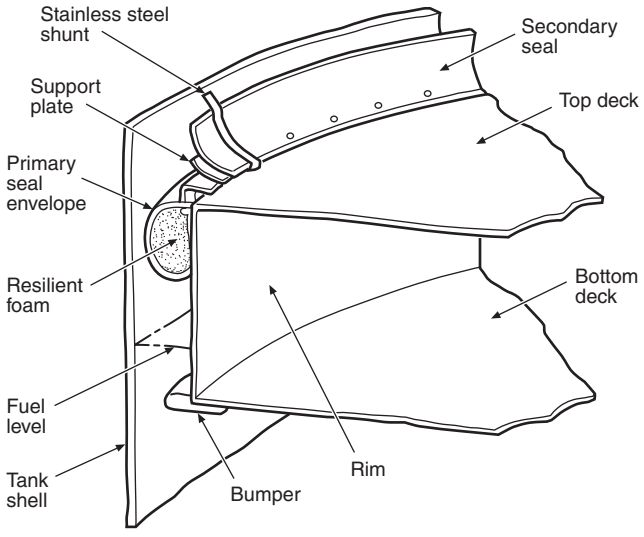

FIGURE 7.2.10 Double-Seal System for Floating Roof Tanks

Fire protection equipment should be installed on tanks where needed. (See NFPA 11, *Standard for Low-, Medium-, and High-Expansion Foam.*)

Underground Storage Tanks

Underground tanks are generally considered the safest form of storage. However, concern about groundwater contamination has increased concern about use of underground storage tanks. Environmental safety regulations should be reviewed when planning installation of underground storage tanks.

Underground tanks must be designed to withstand safely the service to which they are subjected, including the pressure of the earth, concrete, or possible aboveground vehicle traffic. Typical sizes for underground tanks are shown in Table 7.2.4.

Construction. Underground tanks are constructed of coated steel, fiberglass-reinforced plastic, and plastic-clad steel and come in both single-wall and double-wall varieties. Almost all are listed by UL and other testing agencies and most are designed according to industry standards. Underground tanks also can be of unlined concrete for the storage of liquids having a specific gravity of 40 degrees API or heavier. Lined concrete tanks may be used for liquids having a lighter specific gravity, provided the lining is suitable for the liquid being stored and has satisfactory adherence to the concrete.

Installation. Underground tanks may be buried outside or under buildings. Tanks that are buried underneath buildings

TABLE 7.2.4 Typical Sizes of Underground Flammable Liquid Tanks

Capacity		Diameter			Length		
gal	*L*	*ft*	*in.*	*m*	*ft*	*in.*	*m*

10,000	37,854	9	0	2.74	21	0	6.40
10,000	37,854	10	0	3.05	17	0	5.18
10,000	37,854	10	6	3.20	15	7	4.75

should have fill and vent connections outside the building walls. Tanks should be set on firm foundations and surrounded with sand or gravel that is well tamped into place.

Excavation for underground storage tanks should be made with due care to avoid undermining the foundations of existing structures.

Underground tanks must be protected against damaging loads imposed by the cover over the tanks and such factors as building foundations and vehicular traffic. Normally, no special protection is needed if the tanks are well supported underneath and buried sufficiently deep. However, if tanks are located in areas where higher-than-normal loads might be imposed, concrete, paving, or additional earth coverage might be necessary. Piping subject to possibly damaging loads or vibrations is frequently protected by sleeves, casings, or flexible connectors to ensure the integrity of the line.

Poor workmanship is one of the largest causes of failure and leaks in underground tanks. Generally, poorly installed piping systems connected to underground tanks might show evidence of leakage in the first year. The normal life expectancy of a properly installed underground steel tank with either a fiberglass outer wall or cathodic protection is 25 to 30 years.

Environmental regulations or a hazard analysis might require the use of a double-walled tank design and/or the use of groundwater monitoring for tank and piping leaks. The soil in which the tank is buried is very important, because some soils, such as red clay, can be highly corrosive because of their chemical composition or moisture content. This is also true if construction debris, cinders, shale, or other foreign matter is mixed, even in very small quantities, with otherwise "clean" backfill. The use of homogeneous, clean backfill and protective coatings prolongs the life of steel tanks and piping. Cathodic protection of buried tanks and piping is often necessary. NFPA 30 requires that tanks and their piping be protected either by using corrosion-resistant materials of construction, such as special alloys and fiberglass, or by using a properly engineered, installed, and maintained cathodic protection system in accordance with recognized standards of design.

Electrolytic corrosion in an electrically conductive tank and piping system might occur at points where metals having different electromotive qualities, such as steel and brass, are connected. Connections of two dissimilar metals should be avoided to prevent galvanic corrosion.

Stray electrical currents can initiate corrosive action, but their presence might be difficult to determine until after the action has progressed to the point where damage has been done to the tank or piping. Cathodic protection or insulation is sometimes used to protect underground tanks from stray currents.

Fiberglass-reinforced plastic (FRP) tanks for underground installation eliminate the corrosion problem encountered with steel tanks. However, it is vitally important that the manufacturer's instructions for proper installation of these tanks be followed closely. Improper installation can result in major failure of the tank. Care should be taken in the use of FRP tanks to ensure that liquids stored in the tanks are not destructive to the plastic tank construction.

Tanks should be anchored or weighted to prevent floating in locations where the groundwater level is high or might rise in case of flood. Details of installation and protection are covered in NFPA 30.

The proximity of underground tanks to a building foundation is not a direct measure of the potential danger to the building if a leak should develop in the tanks. Leaking contents from underground tanks can travel substantial distances underground or can penetrate 24 in. (610 mm) of waterproofed concrete before appearing in a building. Tanks suspected of leaking should be tested hydrostatically with the same liquid stored in the tank (Figure 7.2.11). Air tests or testing with liquids other than that stored in the tank can be dangerous and inconclusive for detecting suspected leaks in underground tanks. Additional details about the causes of corrosion, locating leaking tanks, and removal of liquids in the ground are covered in NFPA 329, *Recommended Practice for Handling Releases of Flammable and Combustible Liquids and Gases.*

Tanks Inside Buildings and Storage Tank Buildings

Tank installations storing Class I, II, and IIIA flammable and combustible liquids are permitted inside buildings when meeting the requirements of NFPA 30 for storage tank buildings. NFPA 30 imposes no requirements on noncombustible constructed tanks in buildings storing Class IIIB (flashpoints at or above 200°F [93°C]). A tank installation that has a canopy or roof that does not limit the dissipation of heat or dispersion of vapors and does not restrict fire-fighting access and control is considered by NFPA 30 as an outside aboveground tank installation and not a storage tank building.

Design. Tanks designed for installation within buildings have the same shell thickness and design features as required for outside aboveground storage tanks. In certain specialized pro-

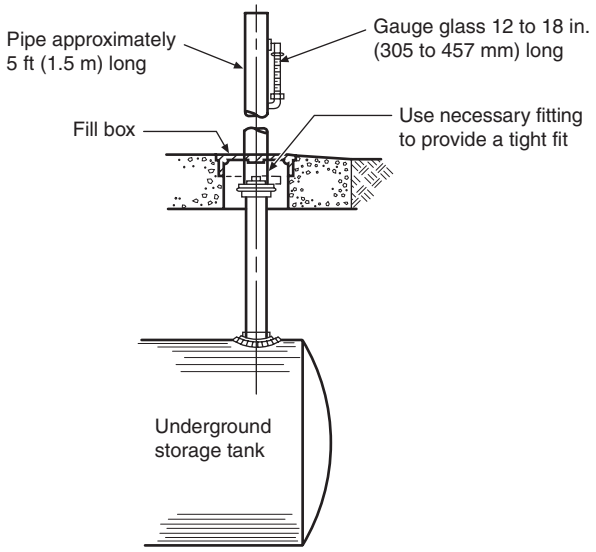

FIGURE 7.2.11 Simple Leak Test Equipment in a Typical Underground Tank Installation

cessing operations, large tanks are required and are designed as low-pressure storage tanks or pressure vessels.

For the storage of flammable and combustible liquids in accordance with NFPA 30, the capacity of any individual storage tank within a building is limited to a nominal capacity of 100,000 gal (380,000 L) unless the authority having jurisdiction permits the use of larger tanks. Storage tank buildings should be constructed so as to maintain their structural integrity for 2 hours under fire exposure conditions and to provide adequate access and egress for unobstructed movement of all personnel and fire protection equipment.

For the storage of fuel oil in accordance with NFPA 31, *Standard for the Installation of Oil-Burning Equipment,* unenclosed supply tanks in buildings are permitted to be connected to oil-burning appliances. Tanks and tank systems with a maximum individual capacity of 1320 gal (5000 L) are permitted; if tanks are located on higher floors, the maximum individual capacity of the tank is limited to 660 gal (2500 L). Where a tank or tank system is not located in a dedicated room or enclosure, the maximum capacity in the building should not exceed 1320 gal (5000 L) for a nonengineered system and should not exceed 1375 gal (5200 L) for an engineered system. Where a tank or tank system is located in a dedicated room or enclosure that is separated from the rest of the building by construction having a fire resistance rating of at least 3 hours, the maximum total capacity in the room is permitted to exceed 1320 gal (5000 L) for a nonengineered system and 1375 gal (5200 L) for an engineered system.

Installation. Tanks and any associated equipment within a storage tank building should be located so that a fire in the area should not constitute an exposure hazard to adjoining buildings or tanks for a period of time consistent with the response and suppression capabilities of the fire-fighting operations available to the location.

For specific requirements covering the installation of storage tank buildings, with respect to exposed property lines, public ways, and important buildings, see NFPA 30.

Storage tank buildings storing Class I liquids or Class II or Class IIIA liquids at temperatures above their flashpoints are required to be ventilated at a rate sufficient to maintain the concentration of vapors within the building at or below 25 percent of the lower flammable limit. The tank vents should be arranged to ensure that flammable vapors are not released inside the building. Also, electrical equipment and wiring should be specified and installed in accordance with NFPA 70, *National Electrical Code®*, to prevent a source of ignition for any flammable vapors that might be present under normal operations or during a spill.

Drainage systems should be provided in storage tank buildings to minimize fire exposure to other tanks and to prevent the discharge of flammable or combustible liquids to public waterways, public sewers, and adjacent properties.

Storage tank buildings should also have fire prevention control systems and methods for (1) life safety, (2) minimizing property loss, and (3) reducing fire exposure to adjoining operations and property. Such systems and methods include emergency alarm systems; automatic sprinkler, foam-water, water spray, or deluge systems; and thermally or remotely actuated valves at liquid transfer connections, along with programs to control ignition sources and static electricity.

Vaults for Aboveground Tanks

Aboveground tanks are permitted to be installed in vaults that meet the construction and protection requirements of NFPA 30. Vaults are permitted to be either above or below grade. For the storage of liquid petroleum products in accordance with NFPA 30A, *Code for Motor Fuel Dispensing Facilities and Repair Garages,* tanks enclosed in vaults are permitted outside and inside buildings where it is impractical because of property or building limitations to install the tanks aboveground or underground in accordance with NFPA 30.

Design. The walls and floor of the vault should be constructed of reinforced concrete at least 6 in. (150 mm) thick. The top of above-grade vaults should be constructed of noncombustible material and should be designed to vent any explosion occurring inside the vault. The top of an at-grade or below-grade vault should be designed to relieve or contain the force of an explosion occurring inside the vault. The vault should be liquid-tight.

Requirements also exist for vaults containing Class I liquids to be ventilated either continuously or upon activation of vapor and liquid detection systems. Tanks in vaults are required to have vent pipes for normal tank venting, emergency vents, and overfill protection in accordance with the requirements of NFPA 30.

Installation. Each tank should be in its own vault and should be completely enclosed by the vault. Sufficient clearance between the tank and the vault must be provided to allow for visual inspection and maintenance of the tank and its appurtenances. No separation distance is required between vaults and property lines, public ways, and important buildings.

Gauging Tanks

Tank openings for gauging or measuring the quantity of liquid can permit the escape of vapors during the gauging operation. Such openings are particularly undesirable in tanks located in buildings or buried under basements and are prohibited by NFPA standards unless protected by a spring-loaded check valve or other approved device. Substitutes for manual gauging include heavy-duty flat-gauge glasses; magnetic, hydraulic, or hydrostatic remote reading devices; and sealed float gauges. These devices, however, must be maintained in reliable operating condition. Ordinary gauge glasses should not be used, since their breakage may permit the escape of liquid.

Cleaning Tanks

Cleaning tanks for the purpose of making repairs requires great care. Precautions must be taken to avoid igniting flammable vapors and to protect personnel against toxic vapors.[4,5]

Work on empty tanks must be performed only under the supervision of persons well versed in fire and explosion hazards and in the procedures required to properly safeguard the

operation. Unless the work can be done with the tank and all connected piping and fittings completely filled with water, all vapors should be removed by cleaning with steam or chemical solutions or by displacement with water, air, or inert gas. In some instances, the tank vapor space can be filled with inert gas by specially qualified personnel to provide a safe atmosphere. The selection of the method of rendering a tank safe will depend on several factors, such as the character of the liquid, the size of the tank, the flammability and reactivity of residues, and the type of work to be performed. With many reactive materials, it will be necessary to obtain information from the manufacturer regarding recommended practices for safe cleaning.

Removal of Flammable Vapors by Displacement. This is sometimes referred to as "purging" and can be accomplished by one of several methods:

1. *Displacement with water.* Where the flammable liquid previously contained is known to be readily displaced by or soluble in water, it can be removed completely by using water to alternately fill and drain the tank. The operation should be repeated several times until tests with a combustible gas indicator show that the vapors are no longer present. Acetone and ethyl alcohol are examples of water-soluble liquids.
2. *Displacement with air.* Frequently, flammable vapors can be removed by purging with air through the use of venturi-type air movers or low-pressure blowers, with a safe atmosphere sustained by continuous ventilation. Air movers should be restricted to those operated by steam, by air, or by electric motors approved for use in the atmosphere involved. When steam operates the air mover, the air mover should be bonded or in electrical contact with the tank. When small tank openings cannot accommodate an air mover, the contents can sometimes be purged with compressed air connected to a metallic pipe bonded to the tank. Care should be exercised to prevent overpressuring a small tank if compressed air is used. Irregularly shaped tanks might not be thoroughly purged by this method because the tank can contain pockets that cannot be reached effectively by the air stream. In air purging, the concentration of flammable vapors in air in the tank might go through the flammable range before safe atmospheres are obtained. Therefore, all precautions must be taken to minimize the hazards of ignition by static electricity. Air movers should be clamped or bolted, and thereby inherently bonded, to the vessel being ventilated. Compressed air or steam is admitted to the bell of the air remover and enters the horn through the annular orifice around the base. As the steam or compressed air passes through the horn, its expansion induces a rapid flow of air, equal to approximately 10 times the volume of the steam or compressed air (Figure 7.2.12).
3. *Displacement with inert gas.* When nitrogen in cylinders or carbon dioxide in low-pressure containers or in solid form (dry ice) is available in sufficient quantity, it may be used to purge the flammable vapors from tanks without the hazards of having the vapor-air mixture in the tank vapor space pass through the flammable range. This procedure should be followed by air ventilation of the tank. High-pressure carbon dioxide, such as that from a fire extinguisher, should not be used because static electricity is generated.

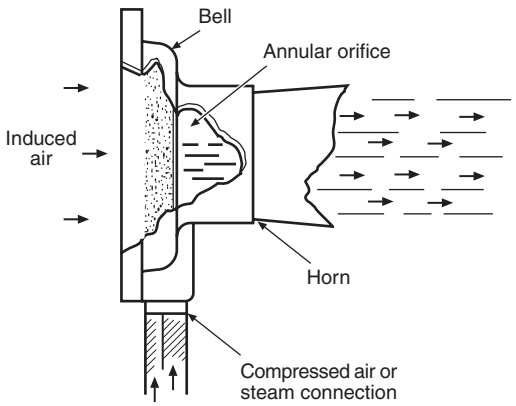

FIGURE 7.2.12 Schematic Drawing of the Operation of an Air Remover

Inerting the Vapor Space. Inerting is a means of safeguarding a tank so that work can be performed on it. Inerting a tank can be accomplished by reducing the oxygen content to the point where combustion cannot take place in the vapor space.

Inerting gases include carbon dioxide and nitrogen. Both may be obtained in pressurized cylinders, and carbon dioxide may also be obtained in solid form. Individuals in direct charge of the work must be thoroughly familiar with the limitations and characteristics of the inert gas being used. Attempting such work without proper knowledge or equipment can be hazardous because a false sense of security is engendered. The oxygen content should be maintained at substantially zero during the entire period work is in progress.

Removal of Residues. The removal of liquid and solid residues is necessary, as they may release flammable vapors during repair operations involving hot work. The removal of residues can be accomplished by steam or chemical cleaning or by other recognized methods. In steam cleaning, the rate of steam supply should be sufficient to exceed the rate of condensation and the steam nozzle should be electrically bonded to the container shell. During the steam cleaning process, the entire container is, of course, heated close to the boiling point of water (212°F [100°C]). Chemical cleaning might be necessary to remove some residues, but this could present personnel health hazards that should be guarded against.

Although a tank's atmosphere is safe for entry, the removal of residues can cause the release of additional hazardous or flammable vapors. During such work conditions, continuous ventilation can maintain the vapor concentration at a safe limit. Tanks can be continuously ventilated by air movers at the roof manholes. Continuous monitoring of the tank's atmosphere will provide notification of potentially hazardous vapor levels.

Special care must be taken to eliminate any source of ignition in the vicinity of the tank or in the path of vapors being displaced. Bonding, either with special bond wires or by metal-

to-metal contact with clamped or bolted connections providing inherent bonding, must be used where static-producing devices are used. All electrical equipment, such as inspection lights and motors, used in connection with the cleaning operations must be designed for such use.

Tests for the presence of flammable vapors constitute the most important phase of the cleaning or safeguarding procedure and must be made before commencing any alterations or repairs; immediately after starting any welding, cutting, or heating operations; and frequently during the course of such work. The tests made with a combustible-gas analyzer in good working order will normally produce reliable readings. Considerable care should be exercised to ensure that the analyzer is calibrated for the vapors involved, correctly scaled, and properly used and read and that the readings are interpreted and applied properly. Where an inert gas is used, the oxygen content of the tank is measured to determine whether a hazardous condition exists. This can be determined directly by the use of an oxygen analyzer or indirectly by the use of an analyzer showing the concentration of the inert gas being used. All testing must be conducted by persons experienced in the operation and in the limitations of the analyzers used.

When hot work is to be done on small tanks or containers that cannot be entered, the combustible-gas analyzer should show no appreciable indication of the presence of flammable vapors. Extra precautions are necessary if the container last contained a high-flashpoint liquid, because no vapor reading will show on the analyzer. If welding or cutting is done, the heat might vaporize some of the liquid, create a flammable vapor-air mixture in the drum, and explode it. Such containers require special precautions.

Hot work can be performed safely, under qualified supervision, in tank cars, tank trucks, and tanks that can be entered when the flammable vapors are under 10 percent of the lower flammable limit. Additional precautions, such as protective clothing and self-contained breathing apparatus, are necessary to protect the health of persons entering tanks that have contained leaded gasoline or other highly toxic residues.

Where toxic materials have been stored in a tank, additional tests might be required to determine if the atmosphere is safe from the standpoint of health. For example, leaded gasoline tanks need to be lead-free before they can be entered without breathing equipment and specialized protective clothing.

More complete instructions for cleaning tanks or containers are covered in NFPA 326, *Standard for the Safeguarding of Tanks and Containers for Entry, Cleaning, or Repair;* NFPA 306, *Standard for the Control of Gas Hazards on Vessels;* API 2013, *Cleaning Mobile Tanks in Flammable or Combustible Liquid Service;*[4] and API 2015, *Cleaning Petroleum Storage Tanks.*[5]

OTHER STORAGE OF FLAMMABLE LIQUIDS

Flammable and combustible liquids are packaged, shipped, and stored in bottles, drums, and other containers ranging in size up to 60 gal (225 L). Additionally, liquids are shipped and stored in intermediate bulk containers up to 793 gal (3000 L) and in portable intermodal tanks up to 5500 gal (20,818 L). Storage requirements for these containers are covered in the NFPA 30 chapter entitled "Container and Portable Tank Storage," with the exception of those portable tanks larger than 793 gal (3000 L) that are required to meet the applicable requirements covered in the NFPA 30 chapter entitled "Tank Storage."

Examples of container types used for the storage of liquids include glass, metal, polyethylene (plastic), and fiberboard. The maximum allowable size for the different types of containers is governed by the class of flammable or combustible liquid to be stored in it (Table 7.2.5).

The principal hazard of closed container storage is the possibility of overpressure failure of the container when exposed to fire. This results in a release of liquid that adds to the intensity of the fire and can cause the rupture of additional containers, resulting in a rapidly spreading fire. Fire tests have shown that automatic sprinkler systems with ordinary sprinkler densities and even newer technology sprinkler systems involving early suppression fast-response sprinklers can be inadequate in preventing overpressure failure and rupture of containers of flammable and combustible liquids, when they are stored in high-piled arrangements. Additionally, the ability to drain away spilled liquid in a fire is critical in controlling a flammable and combustible liquids fire, especially when sprinkler protection consists of water-only sprinkler systems.

Container Storage in Buildings

Container storage of flammable and combustible liquids can be found in mercantile and industrial occupancies and in general-purpose and flammable liquid warehouses. Any liquid-storage building or room or any portion of a building or room where containers are stored should be designed to protect the containers from exposure fires and contain or drain any spilled liquids. This might require the installation of fire walls or partitions or separating the containers from other storage arrangements or processes.

The life hazard to the occupants of buildings, exposure to other buildings, building construction, and the degree of fire protection provided are factors to be considered when evaluating the amount of container storage in buildings. Details and limitations on closed container storage are given in NFPA 30.

Inside Liquid Storage Areas. A room or building used for the storage of flammable and combustible liquids can be considered an inside room or liquid warehouse.

Inside rooms are totally enclosed within a building with none of the walls being part of the building's exterior walls. A liquid warehouse can be either a separate, detached building or an attached building used for warehousing operations. Design and construction requirements vary for each type of inside liquid storage area. These requirements are addressed in NFPA 30.

Inside rooms are limited in the quantities of liquids that are permitted to be stored within the room, whereas the total quantity of liquids stored in a liquid warehouse is not restricted. For all inside liquid storage areas, the permitted storage arrangements, such as quantities and storage heights, are based on the level of fire protection systems provided.

TABLE 7.2.5 Maximum Allowable Size—Containers, Intermediate Bulk Containers, and Portable Tanks

	Flammable Liquids			Combustible Liquids	
Type	*Class IA*	*Class IB*	*Class IC*	*Class II*	*Class IIIA*
Glass	0.5 L (1.05 pt)	1 L (1.05 qt)	5 L (1.3 gal)	5 L (1.3 gal)	20 L (5.3 gal)
Metal (other than drums) or approved plastic	5 L (1.3 gal)	20 L (5.3 gal)	20 L (5.3 gal)	20 L (5.3 gal)	20 L (5.3 gal)
Safety cans	10 L (2.6 gal)	20 L (5.3 gal)	20 L (5.3 gal)	20 L (5.3 gal)	20 L (5.3 gal)
Metal drum (e.g., UN 1A1 or 1A2)	450 L (119 gal)	450 L (119 gal)	450 L (119 gal)	450 L (119 gal)	450 L (119 gal)
Approved metal portable tanks and IBCs	3000 L (793 gal)	3000 L (793 gal)	3000 L (793 gal)	3000 L (793 gal)	3000 L (793 gal)
Rigid plastic IBCs (UN 31H1 or 31H2) and composite IBCs with rigid inner receptacle (UN31HZ1)	NP	NP	NP	3000 L (793 gal)	3000 L (793 gal)
Composite IBCs with flexible inner receptacle (UN31HZ2) and flexible IBCs (UN13H, UN13L, and UN13M)	NP	NP	NP	NP	NP
Bag-in-Box Nonbulk	NP	NP	NP	NP	NP
Polyethylene UN 1H1, or as authorized by DOT exemption	5 L (1.3 gal)	20 L (5.3 gal)*	20 L (5.3 gal)*	450 L (119 gal)	450 L (119 gal)
Fiber drum NMFC or UFC Type 2A; Types 3A, 3B-H, or 3B-L; or Type 4A	NP	NP	NP	450 L (119 gal)	450 L (119 gal)

*For Class IB and IC water-miscible liquids, the maximum allowable size of plastic container is 230 L (60 gal), if stored and protected in accordance with Table 6.8.2(g) of NFPA 30.
NP = Not permitted.
Source: NFPA 30, *Flammable and Combustible Liquids Code,* 2003 ed., Table 6.2.3.

Beginning with the 1996 edition of NFPA 30, credible mandatory fire protection criteria have been included in NFPA 30 for various storage arrangements and protection systems utilized in inside liquid storage areas. These protection criteria include design requirements for water-only and foam-water sprinkler systems. Also, the type of sprinkler systems installed and the type of liquids being protected determine if drainage is required in the storage area. The criteria are based on the results of large-scale fire tests conducted at nationally recognized testing laboratories. Inside liquid storage areas that meet these protection criteria are considered as protected within the scope of NFPA 30. Storage areas not meeting these criteria are considered as unprotected, even though some areas might contain automatic sprinklers.

Flammable Liquid Storage Cabinets. Specially designed storage cabinets are available for storing not more than 120 gal (454 L) of Class I, Class II, and Class IIIA liquids. These cabinets are typically constructed of No. 18 gauge sheet steel consisting of a double wall with 1½ in. (38 mm) air space, although wood cabinets constructed in accordance with the requirements of NFPA 30 are permitted. The door should have a three-point latch, with a sill raised to at least 2 in. (51 mm) above the bottom of the cabinet to retain spilled liquid within the cabinet. The cabinet should be marked in conspicuous lettering: "FLAMMABLE—KEEP FIRE AWAY" (Figure 7.2.13).

Hazardous Material Storage Lockers

Hazardous material storage lockers have become very popular in recent years, as they meet the environmental concerns dictated by the special handling of hazardous chemicals, some of which are flammable and combustible liquids. These lockers are movable, modular, prefabricated storage buildings that provide a safe and cost-effective means of storing hazardous materials. The lockers are equipped with spill containment features and can be provided with electricity, mechanical ventilation, and fire suppression systems. Generally, the lockers are located outside, but NFPA 30 permits the lockers to be utilized as inside liquid storage rooms, as long as the lockers are constructed with the fire-resistive ratings and applicable requirements listed in NFPA 30. NFPA 30 limits the gross floor area of the lockers to 1500 ft^2 (140 m^2) (Figure 7.2.14).

Container Storage Outdoors

Outdoor container storage should be located in such a manner as to reduce the spread of fire to other materials in storage, adjacent buildings, or neighboring properties (Table 7.2.6). The storage area should be graded in a manner to divert possible spills away from buildings or other exposures, or curbing should be used to contain spills. Areas used for container storage should be kept free of ignition sources, such as open flames, and com-

FIGURE 7.2.13 Typical Metal Flammable Liquid Storage Cabinet (Source: Courtesy Justrite Manufacturing Company, Des Plaines, IL)

FIGURE 7.2.14 Hazardous Materials Storage Lockers (Source: Courtesy Justrite Manufacturing Company, Des Plaines, IL)

bustibles, such as weeds and debris. The area should also be protected against tampering or trespassers, and smoking should be prohibited in the area.

HANDLING OF FLAMMABLE AND COMBUSTIBLE LIQUIDS

Loading and Unloading

Spills can occur at loading and unloading stations for tank cars and tank vehicles, which if ignited could endanger neighboring tanks and buildings. Tank vehicle and tank car loading and unloading stations for Class I liquids should be located a minimum of 25 ft (8 m) from storage tanks, other plant buildings, and the nearest line of property that can be developed. For Class II and Class III liquids, the separation distance is 15 ft (4.6 m). Level ground is desirable, and drains, diversionary curbs, or natural ground slope can be utilized to prevent spills from spreading to other parts of the plant or to other property.

Many liquids, including gasoline, jet fuels, toluene, and light fuel oil, can build up dangerous static electrical charges on the surface of the liquid. If a flammable vapor-air mixture is present at the surface of the liquid when high static electrical discharges occur, an explosion or fire can result. Excessive turbulence, pumping two dissimilar materials, the free fall of liquid through the vapor space, and the use of filters capable of removing micron-sized particles are among the most possible causes of explosions or fires originating from static electricity in aboveground tanks, tank vehicles, tank barges, and tank ships.

TABLE 7.2.6 Outdoor Liquid Storage in Containers and Portable Tanks

	Containers Maximum per Pile		Rigid Plastic and Composite IBCs Maximum per Pile[a]		Portable Tanks and Metal IBCs Maximum per Pile[b] (gal)		Distance Between Piles or Racks	Distance to Property Line That Is or Can Be Built Upon	Distance to Street, Alley, or a Public Way
Class	*(gal)*[b,c,d]	*Height (ft)*	*(gal)*	*Height (ft)*	*(gal)*[b,d]	*Height (ft)*	*(ft)*	*(ft)*[c,e]	*(ft)*[c]
IA	1,100	10	—	—	2,200	7	5	50	10
IB	2,200	12	—	—	4,400	14	5	50	10
IC	4,400	12	—	—	8,800	14	5	50	10
II	8,800	12	8,800	12	17,600	14	5	25	5

[a]Storage of Class I liquids in rigid plastic and composite IBCs not permitted.
[b]See 6.7.1.1 of NFPA 30 regarding mixed-class storage.
[c]See 6.7.1.4 of NFPA 30 for smaller pile sizes.
[d]For storage in racks, the quantity limits per pile do not apply, but the rack arrangements shall be limited to a maximum of 50 ft (15 m) in length and two rows or 9 ft (2.7 m) in depth.
[e]See 6.7.1.3 of NFPA 30 regarding protection for exposures.
For SI units, 1 ft = 0.3 m; 1 gal = 3.8 L.
Source: NFPA 30, *Flammable and Combustible Liquids Code,* 2003 ed., Table 6.7.1.

Where flammable vapors may exist, and to reduce static-caused ignitions, it is recommended that the delivery rate be slowed until the fill pipe is covered. A minimum 30 second relaxation time should be provided downstream of a filter.

Bonding provisions for protection against static sparks must be provided at all stations when Class I liquids are loaded or unloaded. The bonding must be provided between the fill pipe or piping and the tank vehicle. Bonding connections should be made before the dome covers are opened and should remain in place until filling or unloading is complete and all dome covers have been closed and secured. Closed metal piping systems (eliminating exposure to air) for loading and unloading can eliminate the need for special bonding provisions, since the piping system is inherently bonded to the vehicle. Bonding provisions are not required when Class II and Class III liquids are being transferred at ambient temperatures and when vehicles are loaded or unloaded with products not having a static-accumulating tendency, such as asphalts, crude oils, and water-soluble liquids.

Stray electrical current protection is necessary for ship and tank car loading and unloading in those areas where stray currents may be present. To protect against stray currents at tank car stations, the fill pipe can be permanently bonded to at least one rail and to the rack structure. In addition, all pipes entering the rack area should be provided with insulating sections to electrically isolate the rack piping from the pipelines.

For further details on control of static, refer to NFPA 77, *Recommended Practice on Static Electricity,* and API Standard 2003, *Protection Against Ignitions Arising Out of Static, Lightning, and Stray Currents.*

Tank ships and barges are loaded and unloaded at wharves (piers) that might or might not be used exclusively for this purpose. The location and arrangement of the piers is governed by direction and velocity of the waterway, the range of tides, and the direction and frequency of prevailing high-velocity winds. Hazards related to the loading and unloading of vessels are comparable to those for tank vehicles and tank cars, except the quantities of liquid involved are generally larger. NFPA 30 contains a number of requirements involving bulk liquid transfer at wharves.

Piping and Valves

Piping systems protected against physical damage are preferable to portable containers for conveying quantities of liquids within buildings. All piping systems should be designed so that, in case of pipe breaks, liquid will not continue to flow by gravity or by siphoning. Valves should be provided at accessible points to control or stop the flow. Emergency remote controls are frequently provided for valves or pumps, particularly at dispensing locations. Other remotely controlled valves installed for normal operating procedures can frequently be used during fire emergency procedures to control or stop the flow of liquids. Valves are available that close automatically if subjected to fire conditions. Dispensing outlets for systems under gas pressure or gravity head should be equipped with self-closing valves.

Pipe materials should be used that (1) are resistant to the corrosive properties of the liquid handled; (2) have adequate design strength to withstand the maximum service pressure (including shock and surge pressures that are expected) and temperature; and (3) when possible, are resistant to physical damage and thermal shock. Where low melting point materials, such as aluminum and brass; materials that soften on fire exposure, such as plastics; or nonductile material, such as cast iron, are necessary, special consideration should be given to their behavior on exposure to fire. After installation, piping systems should be tested at 150 percent of the maximum anticipated pressure of the system, or pneumatically tested to 110 percent of the maximum anticipated pressure of the system, but not less than 5 psig (35 kPa) at the highest point of the system. The test should be maintained for a sufficient time to complete visual inspection of all joints and connections, but not for less than 10 minutes.

Since some valves are used infrequently, it is necessary to make periodic maintenance inspections to ensure that the valves will operate during emergency conditions. All aboveground piping and connections should be inspected periodically to detect and prevent leakage. Internal corrosion in pipes is a particular problem when liquids are corrosive or where piping is used for the continuous flow of liquid under high-pressure operations common at refineries or chemical plants. Maintenance inspections of the thickness of pipe walls can be performed in several ways similar to the inspection of tanks. Underground piping is also subject to external corrosion and should be protected against such corrosion by suitable coatings and cathodic protection. Tests for possible leaks in underground piping can be performed hydrostatically, using the liquid normally handled in the piping system.

Dispensing and Handling Methods

Large quantities of flammable or combustible liquids are best transferred through piping by pumps. Gravity flow is not desirable, except as required in process equipment. If positive displacement pumps are used, they should be provided with a pressure relief that discharges back to the tank or to the pump suction. Only inert gas should be used to transfer Class I liquids. The use of air pressure to transfer Class II and Class III liquids is acceptable, unless the liquids are heated above their flashpoint, in which case inert gas should be used. Whenever air or inert gas pressure systems are used for transfer, the vessels, containers, tanks, and piping systems should be capable of withstanding the operating pressures. In addition, safety and operating controls, such as pressure-relief devices, should be provided to prevent overpressuring any part of the system.

One of the safest methods for handling flammable or combustible liquids is to pump the liquid from underground storage tanks, through an adequately designed piping system protected from physical damage, to the dispensing equipment located outdoors or in specially designed inside dispensing rooms. Such rooms should have at least one exterior wall for explosion relief and accessibility for fire fighting, interior walls with appropriate fire resistance ratings, adequate ventilation and drainage, and free of sources of ignition.

Where solvents are pumped from storage tanks to the point of use in an industrial building, emergency switches should be

located in the dispensing area, at the normal exit door or at other safe locations outside the fire area, and at the pumps to shut down all pumps in case of fire.

Where dispensing is by gravity flow, such as in the filling of containers in an industrial operation, a shutoff valve should be installed as close as practical to the vessel being unloaded. A control valve should be located near the end of the discharge pipe. Additionally, in some filling operations, a heat-actuated valve is desirable to shut off the flow of liquid.

The preferred method of dispensing flammable and combustible liquids from a drum is by use of an approved hand-operated pump drawing through the top. An approved self-closing drum faucet can also be used for dispensing from a drum. However, hand-operated pumps are safer than faucets, because the hazard of leakage is reduced.

For handling small quantities of flammable and combustible liquids, safety cans are preferred. Safety cans are substantially constructed to avoid the danger of leakage and are designed to minimize the likelihood of spillage or vapor release and of container rupture under fire conditions. Typical safety cans have pouring outlets with tight-fitting caps or valves normally closed by springs, except when held open by hand, so that contents will not be spilled if a can is tipped over. The caps also provide an emergency vent when the cans are exposed to fire (Figure 7.2.15).

Liquids can also be dispensed from the original shipping containers. Open pails or open buckets should never be used for storage or the transfer of liquids.

Flammable liquids should always be handled and dispensed in a well-ventilated area free of sources of ignition, and bonding should be provided between the dispensing equipment and the container being filled (Figure 7.2.16).

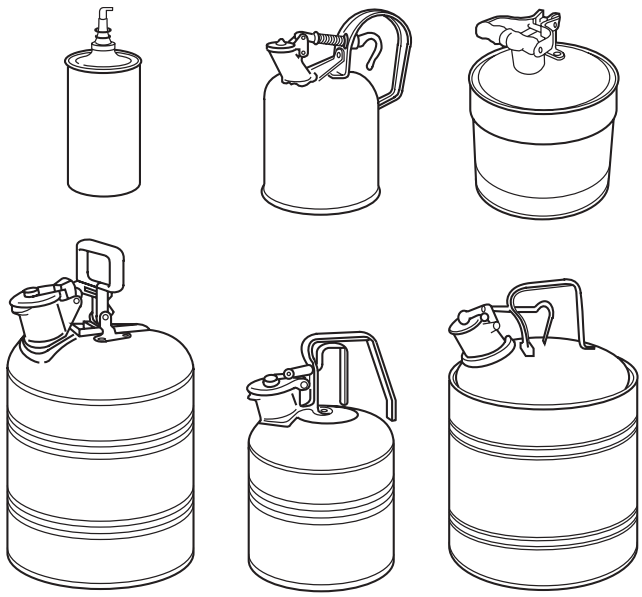

FIGURE 7.2.15 Typical Safety Cans

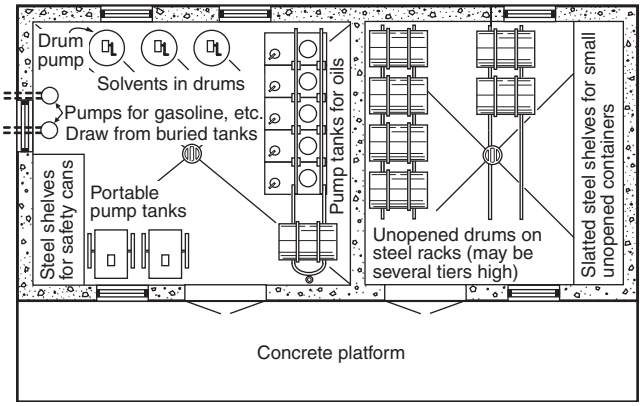

FIGURE 7.2.16 Layout of a Storage and Dispensing House

TRANSPORTATION OF FLAMMABLE AND COMBUSTIBLE LIQUIDS

Tank Vehicles

NFPA 385, *Standard for Tank Vehicles for Flammable and Combustible Liquids,* and rules of the U.S. Department of Transportation provide for substantially constructed vehicles and tanks that present relatively little danger of fire when involved in minor traffic accidents. Under these recommendations, tanks are constructed to withstand all but the most violent impact without rupturing and releasing liquid. Vents are provided so that, if a tank is subjected to fire, vapor will burn at the vent, avoiding the danger of rupture from excessive internal pressure.

For all but viscous liquids, a shutoff valve located inside the shell of the cargo tank is required. It is kept closed, except during loading or unloading operations. A shear section is provided in the piping connected to the internal valve. Therefore, in an accident that could damage the piping, the piping breaks at the shear section, leaving the internal valve undamaged and closed (Figure 7.2.17).

The operating mechanism for the valve is also required to have a secondary control, remotely located, that can be used to shut off the valve in case of fire or severe spillage during unloading. In addition, a fusible element (to operate at not more than 250°F [121°C]) is required in the control mechanism for the valve, to permit the valve to close automatically in case of fire (Figure 7.2.18). Other important fire protection features are detailed in NFPA 385.

Tank-truck traffic through congested districts of cities should be avoided as much as possible, because any fire is likely to have more serious consequences in congested districts than in sparsely settled areas. Bypass routes, such as those commonly specified for all kinds of through truck traffic, are the obvious solution to this particular problem.

Parking of loaded tank vehicles is another activity that can be appropriately regulated by municipalities. Such parking can be prohibited on city streets. Similarly, tank vehicles should not be parked in public garages. Permissible parking locations for tank vehicles may be specified, if necessary. Any property

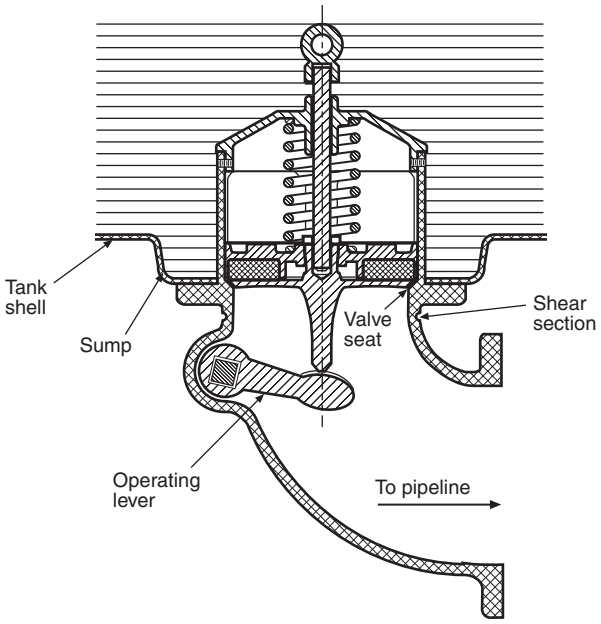

FIGURE 7.2.17 Shutoff Valve Located Inside Tank Shell, with Shear Section to Leave Valve Seat Closed if Discharge Faucet Breaks

zoned for aboveground oil storage (e.g., the ordinary bulk oil plant), should be a location where tank vehicles can be parked without any undue increase in hazard to the public.

To prevent the hazards associated with "switch loading," no tank vehicle compartment that has been utilized for transporting Class I liquids should be loaded with Class II or Class III liquids until the compartment and all piping, meters, and hoses have been completely drained. If Class II or Class III liquids are loaded into a tank vehicle that previously contained a Class I liquid that was not adequately drained out, there exists the potential for the generation of a static spark to occur in a mixture that is within the flammable range, resulting in an explosion.

Transportation of flammable liquids in tank vehicles in interstate commerce is governed by regulations of the U.S. Department of Transportation (DOT), as contained in the Code of Federal Regulations, Title 49, "Transportation."[6] There are comprehensive specifications and labeling requirements for shipping containers for various types of products. (Absence of a label does not necessarily mean that the material is nonhazardous, however.)

Rail, Ship, and Pipeline

The transportation of flammable liquids by railroad tank cars is under the jurisdiction of DOT in the United States.[6] The design of tank cars is rigidly controlled and is governed by the nature of the contents being carried. Emergency venting requirements are included in DOT regulations.

The transportation of flammable and combustible liquids in bulk on board vessels in the United States is under the jurisdiction of the Commandant of the U.S. Coast Guard. These transportation requirements include the design of the vessel, whether a tank ship or tank barge, as well as requirements for extinguishing systems or portable extinguishers. Further requirements include limitations on container storage of drums or portable tanks, restrictions for passenger-carrying vessels, and many other requirements for the safe transportation of flammable and combustible liquids by water. Details of these requirements can be secured at the nearest U.S. Coast Guard Merchant Marine Inspection Office.

Standards for pipelines transporting liquids are published by the American Society of Mechanical Engineers (ASME). These standards include piping requirements and installation recommendations.

SUMMARY

The safe storage of flammable and combustible liquids requires properly designed liquid-tight containers and tanks from which vapor release, if needed, is carefully controlled. Tanks can be installed aboveground, underground, or, under certain conditions, inside buildings. Containers such as bottles and drums can be stored inside flammable liquid storage cabinets, inside liquid stor-

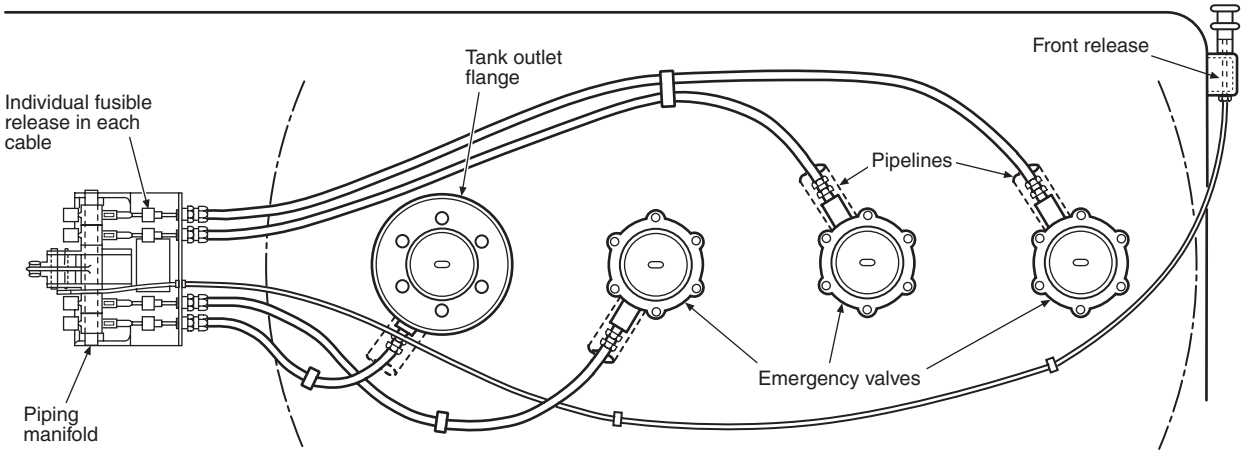

FIGURE 7.2.18 Bottom View of Tank Vehicle Showing Typical Installation of Emergency Valves and Controls

age rooms and warehouses, and outside in yard areas or hazard material storage lockers. Special precautions must be taken when flammable and combustible liquids are handled and transported. Transportation methods include tank vehicles, railroad tank cars, tank ships or barges, and pipelines.

Chapter 3

Storage of Gases

Theodore C. Lemoff ■ Carl H. Rivkin

Chapter Contents

Gas Containers
Storage Safety Considerations

Key Terms

boiling liquid expanding vapor explosion (BLEVE), cabinet heaters, container, cylinder, Interstate Commerce Commission (ICC), overpressure, pipeline

This chapter describes essential fire safety characteristics of containers in which gases are stored, as well as some fundamental precepts for storage arrangements.

A gas must be stored in a container that is gastight for (1) the range of temperature and pressure conditions present at the storage location and (2) the conditions represented by the transportation environment prior to arrival at a storage site. The storage container should contain the source of energy needed to remove the gas from storage and convey it to the point of use. This energy is the pressure of the gas in the container.

In the case of containers in which the gas is entirely in the gaseous phase (compressed gases), the pressure is applied at the charging plant or, in the case of pipelines, by compressors spaced along the pipeline. In the case of containers of gas in which the gas is partly in the gaseous phase and partly in the liquid phase (i.e., liquefied gases, including cryogenic liquefied gases), the pressure is obtained as a result of heat stored in the liquid, which is directly related to how much the temperature of the liquid is above its normal boiling point.

Therefore, gas containers, whether shaped as tanks or as pipelines, are closed pressure vessels containing considerable energy per unit of volume, and they require careful design, fabrication, and maintenance. Furthermore, because the containers are closed and excessive pressures can develop when they are exposed to rather nominal heat sources and fire (or by overfilling, in the case of liquefied gas containers), overpressure protection is usually needed.

For additional material on storage safety considerations, see Section 6, Chapter 10, "Gases."

GAS CONTAINERS

Most countries have similar regulations for the design, fabrication, and maintenance of gas containers. This chapter concentrates on North American practices.

In North America, there are two types of gas containers: (1) cylinders and (2) tanks. Originally, the distinction between cylinders and tanks was based on size. Cylinders, being the smaller, were considered portable; the tanks, being the larger, were essentially used in stationary service. There was also a distinction that reflected the pressures in the containers. Cylinders were thought of as being used for high pressures and tanks for low or moderate pressures. Over the years, these distinctions have lessened so that, today, the only real distinction lies in the regulations or codes under which the container is built.

Practically all gases must be transported from the manufacturer to the user, making the safety of the container in transportation a matter of primary concern. As a result, criteria for many gas containers reflect transportation safety conditions. Because it could be hazardous as well as uneconomical to require gases to be transferred from a shipping container to a separate container for other use, every effort has been made to utilize the same container whenever feasible. This procedure is generally used for the smaller containers.

Gas Cylinders

Gas cylinders are fabricated in accordance with regulations and specifications of the U.S. Department of Transportation (DOT) in the United States and Transport Canada (TC) in Canada.

Theodore C. Lemoff, P.E., is the principal gases engineer on the staff of NFPA.

Carl H. Rivkin, P.E., is principal chemical engineer on the staff of NFPA.

FIGURE 7.3.1 Two-Piece Composite Cylinder (Courtesy of Lite Cylinder Co.)

FIGURE 7.3.2 One-Piece Composite Cylinder (Courtesy of Ragasco)

The requirements are the same in both countries. Prior to April 1, 1967, DOT regulations were promulgated by the Interstate Commerce Commission (ICC). Some cylinders are still in service with ICC markings. Cylinders are limited to a maximum water capacity (i.e., the capacity when completely filled with water) of 1000 lb (454 kg), approximately 120 gal (450 L) of water.

The regulations cover the service pressure for which the cylinder must be designed, the gas or group of gases that it can contain, safety devices, and requirements for in-service (transportation) testing and requalification. The specifications cover such criteria as metal composition and physical testing, wall thickness, joining methods, nature of openings in the container, heat treatments, proof testing, and marking.

Cylinders have historically been constructed of metals; a new type of cylinder made of a composite fiberglass construction, however, has been approved by the Department of Transportation for use in the United States. At this time, these composite cylinders are available in sizes used with gas grills and propane-powered industrial trucks (forklift trucks). Figures 7.3.1 and 7.3.2 show two types of composite cylinders. The cylinder valve is metal, and a metal boss is added to the completed cylinder after the cylinder shell is formed. These composite cylinders have been in use in propane service in the Scandinavian countries since the early 1990s. Composite cylinders have several unique features that make them attractive: they are lighter in weight than steel cylinders and they are translucent so the liquid level can be seen. However, they are currently more costly than steel cylinders.

The use of composite cylinders has been proposed and is being considered by the NFPA Technical Committee on Liquefied Petroleum Gases for use in conjunction with portable space heaters called *cabinet heaters.* Fire tests were conducted at a major fire test facility in fires that simulated room fires. The composite cylinders did not explode or BLEVE (boiling liquid expanding vapor explosion), but released their contents over a period of about 15 minutes when exposed to fire for several minutes. Some observers of the tests stated that the fire was typical of a living room fire. The subject is controversial, and the reader is encouraged to review NFPA 58, *Liquefied Petroleum Gas Code,* on this subject.

Gas Tanks

Gas tanks are fabricated in accordance with Section VIII, "Unfired Pressure Vessels," of the *Boiler and Pressure Vessel Code,* published by the American Society of Mechanical Engineers (ASME), or tank fabrication standards of the American Petroleum Institute (API). ASME tanks are usually smaller tanks under moderate pressure, and API tanks are usually very large tanks under low pressure.

Cylinders or tanks that are part of transportation units, such as cargo vehicles or railcars, are subject to additional criteria in

the regulations, primarily to reflect the fact that the containers are on wheels. Tanks for cargo vehicles are basically ASME code tanks, whereas tanks for railcars are covered by specific DOT and TC specifications.

In the late 1960s and early 1970s, a series of serious railcar derailments occurred in the United States, reflecting the deterioration of tracks and track beds due to inadequate maintenance. For example, an LP-gas distribution plant fire occurred in Kingman, Arizona, in 1973.[1] These incidents were characterized by both impact and fire-caused BLEVEs of tank cars containing liquefied flammable gases. As a result, DOT regulations were revised in 1977 to require that these tank cars be protected thermally and equipped with a type of coupler that prevents vertical disengagement. Unless the insulation is contained in a steel outer jacket, the car also must be equipped with heavy steel-plate head shields for impact protection. Existing cars were required to be retrofitted by the end of 1980. In the few derailments involving tank cars outfitted in this fashion, these safeguards have proved effective—a BLEVE either has not occurred at all or has been delayed for several hours.

Some containers are exempted by the regulations. These containers include certain very small containers and containers with nonflammable cryogenic gases, including oxygen, where the pressure in the container as shipped is below 40 psia (an absolute pressure of 276 kPa).

There is usually a lag in time between the need to ship a gas that is new to commerce and the promulgation of specifications for a transportation container. In such cases, DOT or TC exemptions, which spell out safety criteria agreed on by the authorities, are issued.

The DOT and TC regulations apply then only to cylinders and tanks in transportation in interstate or interprovincial commerce. However, many consensus codes and standards extend these regulations to transportation in intrastate commerce and also extend applicable criteria to use and storage at consumer sites.

The requirements for "in-service" reinspection and requalification of DOT specification containers are also extended to use and storage at consumer sites by the consensus standards and codes. However, the ASME *Boiler and Pressure Vessel Code*[2] and API standards do not contain such provisions. If not covered by consensus standards and codes, in-service inspection and requalification become a matter of owner judgment, applicable state or local regulations, or conditions set forth in an insurance contract.

Regardless of the degree of structural integrity incorporated into gas containers, abuse of the container must be avoided. This is especially true of portable cylinders, which are subject to mishandling. General safety precautions for gas cylinders are contained in the Compressed Gas Association's P-1 "Safe Handling of Compressed Gases in Containers."

Pipelines

Gases used in large volumes are often transported by pipelines. Natural gas is customarily transported by pipeline, as is much LP-gas and some industrial gases, such as anhydrous ammonia, oxygen, hydrogen, and ethylene.

Since 1968, most of the transmission and distribution of flammable gases by pipeline has been regulated in the United States by the DOT Office of Pipeline Safety and is covered by federal regulations. These regulations cover such items as pipe materials; design for pressure and other stresses (which, among other criteria, require stronger piping as population density increases); piping components, including valves (emergency flow control valve spacing in the pipeline system is also affected by population density); joining methods; installation of meters, service regulators, and service lines; corrosion control; test requirements; certain operating requirements; and maintenance, including leakage surveys.

Normally, DOT regulations do not apply to piping on consumer premises. Such piping for the more common gases is covered by consensus codes and standards, notably NFPA 54 (ANSI Z223.1), *National Fuel Gas Code,* and ANSI/ASME B31.1, Power Piping, and B31.3, Process Piping.[3] Note that the expertise of the ASME Boiler and Pressure Vessel Code Committees is in the area of design and construction of pressure vessels, not the use of pressure vessels.

STORAGE SAFETY CONSIDERATIONS*

Fire protection safeguards for gas storage reflect (1) the hazards of the container/gas combination and (2) the hazards of the gas when it escapes from the container. Discussions of the basic hazards of gases, gas emergency control, and specific gases are especially pertinent to the safe storage of gases.

During at least some period, any fire incident can manifest both of these hazards at the same time. However, the container/gas combination hazard always exists. The fire hazard of escaping gas, on the other hand, might be negligible if the gas is nonflammable.

The newer composite cylinders, which are being used initially for propane, have a different failure mode compared to steel and aluminum cylinders when exposed to fire, which is relevant to the indoor storage of propane cylinders in occupancies where allowed, such as industrial occupancies. Refer to the section on Gas Cylinders in this chapter for more information on the subject.

Container/Gas Hazard Safeguards

The major container/gas hazard is the BLEVE. The BLEVE hazard is restricted to containers of liquefied gases and the major cause of such BLEVEs in storage is fire exposure. BLEVEs resulting from corrosion of a container are far less frequent and impact-caused BLEVEs even more so for containers in storage.

Container Insulation. The BLEVE hazard is greatly affected by container features that restrict the opportunity for the container metal to be overheated. Especially notable in this respect is the presence of insulation between an exposing fire and the portion of the container subject to internal pressure. All cryogenic liquefied gas containers are insulated as a matter of functional

*The philosophy of this analytical approach is developed in Section 6, Chapter 10, "Gases"; it would be worthwhile to review that chapter before proceeding further in this chapter.

necessity. The BLEVE hazard can be reduced by the installation of an insulation system. North American standards for storage containers allow insulation of containers. For example, insulation for flammable cryogenic gas containers is required to be noncombustible, and (if in a form such that loss of an enclosing jacket could cause a serious loss in insulating capacity, e.g., powder or granules) the container jacket is required to be steel or concrete rather than aluminum.

Containers of noncryogenic gases are not required to be insulated for operational reasons and are seldom insulated for fire safety reasons. However, insulation of larger liquefied flammable gas tanks is becoming more frequent in specific installations where other BLEVE prevention measures (e.g., water cooling) are deficient.

A basic BLEVE safeguard is to reduce the chances of fire exposure to the container. This safeguard is also applicable to containers of nonliquefied gases (compressed gases) because, although by definition they are not subject to a BLEVE, they can still fail explosively from fire exposure.

Indoor Storage. NFPA 55, *Standard for the Storage, Use, and Handling of Compressed Gases and Cryogenic Fluids in Portable and Stationary Containers, Cylinders, and Tanks,* sets maximum allowable quantities (MAQs) of gases that can be stored per control area. A control area is a space within a building or an entire building that is separated by a fire barrier from exposures. If these MAQs, which are shown in Table 7.3.1, are exceeded, additional fire protection control requirements must be implemented.

Limiting Combustibles in the Area. Essential to reducing the chance of fire exposure is limiting the quantity of combustibles in the vicinity of gas containers. This concern applies whether the storage is indoors or outdoors. Except where small quantities of gas are involved (e.g., one or two cylinders of compressed gas), it is highly desirable that storage rooms or docks be of noncombustible or limited combustible construction. (See NFPA 220, *Standard on Types of Building Construction,* for these definitions.) If the building that houses the storage room presents a substantial fire load, the storage room walls should have a suitable fire resistance rating.

Containers of flammable gases should not be stored with nonflammable oxidizing gases. Oxidizing gases, such as oxygen and nitrous oxide, increase the speed of burning of all flammable gases, resulting in higher flame temperatures. Explosions of flammable gas–oxidizing gas mixtures are also possible. NFPA 55 requires separation of flammable, oxidizing, corrosive, toxic, or highly toxic pyrophoric and unstable reactive class 2, 3, or 4 gases. Gases classified as other gas require no separation. This is illustrated in Figure 7.3.3.

The use of barriers around larger containers of flammable gases is not recommended unless the barriers permit application of cooling water, prevent pocketing of escaping gas, and allow unrestricted egress of personnel from the area in an emergency.

When oxidizing gases are stored near combustibles, the degree of combustibility (i.e., flammable or combustible liquid, fast-burning or slow-burning solid) is not the primary consideration. The flammability of the combustible in an enriched oxygen environment is the primary consideration. An example of the

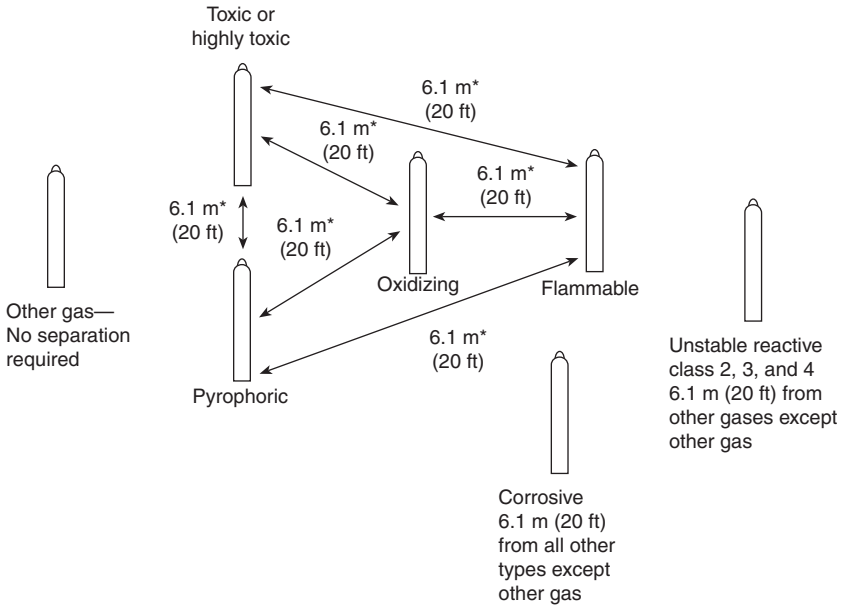

FIGURE 7.3.3 Separation of Gas Cylinders by Hazard. *The 20 ft (6.1 m) distance can be reduced without limit when separated by a barrier of noncombustible materials at least 5 ft (1.5 m) high that has a fire resistance rating of at least one-half hour. (Source: NFPA 55, *Standard for the Storage, Use, and Handling of Compressed Gases and Cryogenic Fluids in Portable and Stationary Containers, Cylinders, and Tanks*)

TABLE 7.3.1 Maximum Allowable Quantity of Gases per Control Area (Quantity Thresholds for Gases Requiring Special Provisions

	Unsprinklered Areas		Sprinklered Areas	
Material	*No Gas Cabinet, Gas Room, or Exhausted Enclosure*	*Gas Cabinet, Gas Room, or Exhausted Enclosure*	*No Gas Cabinet, Gas Room, or Exhausted Enclosure*	*Gas Cabinet, Gas Room, or Exhausted Enclosure*
Corrosive Gas

Unstable Reactive (Nondetonable) Gas, Class 3				
Liquefied	1 kg (2 lb)	2 kg (4 lb)	2 kg (4 lb)	4 kg (8 lb)
Nonliquefied	1.4 m^3 (50 ft^3)	3 m^3 (100 ft^3)	3 m^3 (100 ft^3)	6 m^3 (200 ft^3)
Unstable Reactive Gas, Class 2				
Liquefied	114 L (30 gal)	227 L (60 gal)	227 L (60 gal)	454 L (120 gal)
Nonliquefied	21 m^3 (750 ft^3)	43 m^3 (1500 ft^3)	43 m^3 (1500 ft^3)	85 m^3 (3000 ft^3)
Unstable Reactive Gas, Class 1				
Liquefied	No limit	No limit	No limit	No limit
Nonliquefied	No limit	No limit	No limit	No limit

Note: The maximum quantity indicated is the aggregate quantity of materials in storage and use combined.
*A gas cabinet or exhausted enclosure is required. Pressure relief devices or stationary or portable containers shall be vented directly outdoors or to an exhaust hood.

Source: NFPA 55, *Standard for the Storage, Use, and Handling of Compressed Gases and Cryogenic Fluids in Portable and Stationary Containers, Cylinders, and Tanks,* 2005 edition, Table 6.3.1. For LP-gas storage, see NFPA 58.

importance of an enriched oxygen environment is the concern for any organic material in contact with liquid oxygen. Organic materials in the presence of liquid oxygen can detonate, and the detonation can be initiated by a shock. The unloading areas for liquid oxygen bulk trucks must be paved with concrete for this reason, because asphalt in contact with liquid oxygen spillage from a delivery hose can explode if the truck tire runs over it.

Application of Water. During a fire exposure, the application of water is a basic safeguard to prevent a compressed gas container failure via BLEVE or other overpressure. Outdoor storage areas are usually not provided with sprinkler protection. Indoor storage areas do not require sprinklers for storage of a small number of cylinders (up to 2500 SCF [71 standard m^3]). Storage of larger quantities of flammable gases requires separation of additional groups of cylinders or sprinkler protection. Refer to NFPA 55 for more information on sprinkler protection requirements for flammable gas cylinder storage areas.

A water spray fixed system of similar capacity is also effective and can be installed outdoors. For the protection of larger containers of liquefied flammable gases (chemically not self-reactive), a density in excess of 0.25 gpm of water per ft^2 (10 [L/min]/m^2) of container surface is required by NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection,* to prevent failure.

Water application might not always be appropriate for tanks containing cryogenic liquids. Most cryogenic liquid storage tanks are pressure vessels, but their design pressure is not high enough to retain the internal pressure if the liquid is heated to atmospheric temperature. The liquid is kept at or slightly above its atmospheric boiling point; thus, a BLEVE is not likely. Application of water could result in water entering the pressure relief device and freezing, rendering it inoperative and resulting in pressure vessel failure. Also, water is at a temperature well above the temperature of the liquid and is a heat source that could promote vaporization of the liquid.

Overpressure Limiting Devices. The satisfactory operation of container overpressure limiting devices is vital to controlling the BLEVE or compressed gas container failure hazard. Even though these devices cannot by themselves always prevent container failure, they do extend the prefailure time in all cases and can prevent failure under many fire exposure conditions. It is essential that the device not be blocked closed by corrosion, paint deposits, and so on, and not be damaged mechanically. Portable containers should be checked for this every time they are taken into the facility and whenever they are connected to consuming equipment or are filled.

Spring-loaded pressure relief valves on the larger stationary storage containers should be tested at five- to ten-year intervals (more often if in corrosive or reactive gas service).

Relief devices on liquefied gas containers should always directly contact and monitor the vapor space, because their relieving capacity is determined under vapor discharge conditions and is severely restricted if liquid is discharged. With the exception of some LP-gas containers used in mobile engine fuel systems and 1 ton (907 kg) chlorine containers, portable liquefied gas containers should be stored in an upright position to attain this effect.

Care in Handling. Also reflecting the container/gas hazard, it is important that the containers not be subjected to physical abuse. Although quite sturdy as a result of their design as pressure vessels, any dent or gouge in the container can reduce safety factors and, at the least, shorten failure times from fire exposure or lead to impact failures on subsequent movement. If the valve is broken off on some smaller portable compressed gas containers, the nozzle reaction from escaping gas can be sufficient to propel the cylinder violently. Where the container is designed for a valve-protecting cap or collar, these always should be in place during storage or movement.

DOT Requalification. DOT containers must be requalified at intervals specified in the federal regulations. These intervals vary with the kind of gas and type of container. In most cases, this interval is five years but can be as long as twelve years, depending on the retest method used. A requalified DOT container must be marked with the date of requalification. If such a marking is not present on a compressed gas DOT specification container and the manufacture date marking is more than five years old, it should be brought to the attention of whoever last charged the container.

The container owner is responsible for requalification. In many instances, the user/storer of portable gas containers is not the owner. In others, however, the user/storer is the owner, such as for LP-gas containers used in industrial truck service and filled on site. Those responsible for such containers should be aware of this and of the fact that the requalification procedures are rigorous and require considerable technical expertise.

Safeguards for Escaping Gas

The major escaping gas hazard is combustion of flammable gas and is, in turn, manifest as either a fire or a combustion explosion. Fire can also lead to explosive container failures. See Section 6, Chapter 10, "Gases," for a discussion of the elements of this hazard.

Gases in storage do not leak beyond those already discussed under container/gas hazard safeguards. The container, its valves, and overpressure protection devices are the only sources of escaping gas, provided that the gas is not being transferred into and out of storage.

Inspection for Leakage. All storage containers should be inspected periodically for leakage from container appurtenances or from the container itself. Portable containers should not be placed into storage if they are leaking. To prevent this, incoming shipments should always be inspected on arrival.

The senses of sight, sound, and smell are invaluable leak detectors. Although most gases are invisible, some do have color (e.g., chlorine). Liquefied gases escaping as liquids can lead to the formation of a visible cloud of condensed water vapor. Because gases are stored under pressure, a leak can be accompanied by a hissing sound. Although many gases are odorless, some do possess strong odors (e.g., chlorine and anhydrous ammonia). Natural gas and LP-gas usually have an odorant added to them. Many gas detection instruments are manufactured. Leak detection solutions are available that, when applied to small leaks, show bubbles.

One source of gas leaks in storage locations is the operation of overpressure protection devices. Because the pressure in a gas container is directly related to the gas temperature and the gas temperature in uninsulated containers reflects the temperature of the surroundings, room temperature and solar radiation will affect the pressure. In general, the container pressure will result in the operation of overpressure devices on fully charged containers if the temperature reaches 130 to 140°F (54 to 60°C). Therefore, storage areas should not be allowed to reach such temperatures and reflective paint should be maintained on outdoor containers subject to solar radiation.

Leakage from containers is less common and develops slowly, so leaks can be detected prior to the development of a hazardous situation. Leakage from the inner container of an insulated container for a cryogenic gas is indicated by the formation of water condensate or frost on the outside container due to contact with air on the cold surface. Although this often indicates only a void in the insulation rather than leakage, this appearance should be investigated.

Overpressure Protection. Overfilled liquefied gas containers can lead to overpressure device operation at much lower temperatures. (See discussion of Charles' Law in Section 6, Chapter 10, "Gases.") Portable liquefied gas containers should be checked for proper quantities before being placed into storage. Many such containers can be checked by weighing them. The weight of the empty container (tare weight) must be marked on the container in accordance with DOT regulations. The weight of gas must be determined by the use of data that include the specific gravity of the gas at the fill temperature. In other cases, the quantity is checked by the use of a gauge that measures the liquid level. The most accurate gauge requires that a small amount of gas be released. This release should be done outside under carefully controlled conditions. These gauges are known as fixed-tube gauges or try-cocks. They will release gas only if the level is safe and will release liquid if there is too much in the container.

Ventilation of Spaces. Indoor storage areas should be ventilated, regardless of the chemical hazard of the gas. In areas used solely for storage (no filling of containers), the amount of ventilation need not be great. Storage areas can be ventilated in different ways. Enclosed storage areas that have 25 percent of the available wall area open are considered the same as outdoor storage. Indoor storage areas are required by NFPA 55 to have natural or mechanical ventilation that provides a minimum of 1 cfm/ft^2 (0.3 m^3/min m^2) of floor area. Ventilation systems must discharge a minimum of 50 ft (15 m) from intakes of air handling systems, air-conditioning equipment, and air compressors. However, even inert gases, because they are often odorless, tasteless, and colorless, can present asphyxiation hazards in unventilated areas.

Controlling Ignition Sources. Ignition sources should be controlled in flammable gas storage areas. The vapor density of the gas, in part, determines the extent of the area in which ignition sources should be eliminated or controlled. Many gases are heavier than air at all times. Others will be temporarily heavier than air when they are released in liquid form and vaporize. In general, flammable gas storage areas with no container filling are classified as Division 2 locations for purposes of installing electrical equipment because of the ventilation provided and the nominal leakage potential.

Electrical equipment installed in storage areas used for flammable gases must be selected based on the properties of the gases to be stored. Gases are assigned to a group by testing that determines the gap through which burning gas will propagate. It determines the design, construction, and testing of electrical equipment enclosures for use in classified areas. Most flammable gases are Group C or Group D materials, which allow the largest gaps. Acetylene is a Group A material and hydrogen is a Group B material. Because of the limited availability of electrical equipment for use with Groups A and B materials, electrical equipment for use where Group A or B materials are used might have to be purged and pressurized. For further information on this subject refer to NFPA 70, *National Electrical Code®*, or NFPA 496, *Standard for Purged and Pressurized Enclosures for Electrical Equipment.*

Fire protection and control of gas fires are discussed in Section 6, Chapter 10, "Gases." Sprinkler and water spray protection are also discussed in that chapter. An essential aspect is that the extinguishment of gas fires by the application of extinguishing agents should be restricted to small leaks where the consequences of reignition can be tolerated.

SUMMARY

Gases must be stored in containers that are gastight for both the range of temperature and pressure conditions present at the storage site as well as the conditions of the transportation environment prior to arrival there. The design, fabrication, and maintenance of gas containers, which in North America are either of the cylinder or tank type, are regulated by the U.S. Department of Transportation in the United States and by Transport Canada in Canada. Gases used in large volumes are often transported by pipelines.

Fire protection safeguards for gas storage revolve around the hazards of the container/gas combination and the hazards of escaping gas. Container/gas hazard safeguards include container insulation to restrict overheating of the container metal, the limitation of combustibles in the area, the application of water during fire exposure, the presence of overpressure limiting devices, care in handling of the containers, and the DOT requalification of containers. Safeguards for escaping gas include periodic inspection for leaks, provision of overpressure protection, the ventilation of storage areas, and the control of ignition sources.

Mixture, Transportation, and Disposal of Chemicals

Key Terms

hazardous chemical, hazardous material (chemical), NFPA "diamond," oxidizer, spontaneous heating, Texas City (Texas) explosion

Chemicals are a valuable part of our modern society. They give us better lives by providing sanitation, more and healthier food, warmer clothing, medicines and cosmetics, control of pests, and tires for our vehicles—to name just a few benefits. Many chemicals are building blocks for making other chemicals and products. When safely used, safely transported, and safely stored, chemicals are not a hazard to our health or to the environment. However, when containers are breached or are involved in a fire, some chemicals can pose a serious threat, especially to emergency responders.

The quantity, size, and nature of the container, as well as its storage arrangement, affect the safety of storage. In addition to knowledge of the hazard potential, it is also necessary for safe handling to have details on the process in which the chemical is to be used. The temperature, pressure, and concentration of all chemicals involved in the process must be known. Other factors to be considered include potentially hazardous by-products resulting from normal operating conditions and by-products that could be formed by contamination or operation outside the normal parameters. Only with complete information can safe storage and handling of chemicals be achieved.

Knowledge of the properties of a chemical is the most important factor in deciding how to handle, transport, and store the material. Knowledge of the properties is also important in deciding how to handle a chemical under emergency conditions.

For a discussion of the hazards and properties of cellulose nitrate, see Section 6, Chapter 13, "Polymeric Materials"; and for a discussion of sodium, see Section 6, Chapter 9, "Metals."

SOURCES OF INFORMATION

There are numerous sources of information on chemicals for both designers of chemical handling and storage facilities and for emergency responders. Most of the information originates from chemical manufacturers and is available in various forms and formats.

All manufacturers are required by law to prepare and distribute material safety data sheets (MSDS) for all products they make. The MSDS gives information on toxicity, flammability, reactivity, and stability, as well as safe handling and storage practices. These are available from operators of facilities handling and storing the chemicals in question.

The NFPA publishes the *Fire Protection Guide to Hazardous Materials.* This book contains the previous NFPA 49, *Hazardous Chemicals Data,* NFPA 325, *Fire Hazard Properties of Flammable Liquids, Gases and Volatile Solids,* and NFPA 491, *Guide to Hazardous Chemical Reactions.* These documents give valuable information on properties, emergency response procedures, fire properties, reactivity hazards, and storage recommendations.

The U.S. Coast Guard offers Chemical and Hazardous Response Information System (COMDTINST 16465.12C). This CD-ROM-based system contains physical data and emergency procedures in a searchable format. In addition to the information contained on the CD-ROM, the system contains a search engine to access the USCG website for the most current information.

John A. Davenport is a loss prevention consultant. He is a member of SFPE and a fellow of AIChE. He is also a member of several NFPA technical committees.

The U.S. Department of Commerce, National Oceanic and Atmospheric Administration (NOAA), and the U.S. Environmental Protection Agency have developed a Chemical Reactivity Worksheet. This electronic tool gives the hazardous properties of chemicals and also gives the hazards involved with mixing a number of chemicals as specified by the user. This worksheet is available for download from the NOAA website.

PRINCIPLES OF GOOD STORAGE

Segregation

The first principle of good storage practice for chemicals is segregation, including separation from other materials in storage, from processing and handling operations, and from incompatible materials. Segregation can take the form of isolation in a separate detached structure or isolation in the same building (by means of fire walls and drainage or other liquids control). Segregation can also be achieved by separating chemicals within the same building by an intervening empty area or by intervening storage of inert or nonhazardous materials. The extent of segregation depends on the quantity of materials being stored, the physical state of the chemicals, and their degree of incompatibility. In addition, the known behavior of materials under fire conditions will affect the extent and type of segregation needed. Rupture of vessels and possible mixing of incompatible materials under fire conditions must be considered.

Protection Against Physical Damage

Containers for chemicals are designed to be compatible with the materials they contain. However, when containers are subjected to physical abuse, containers can be damaged and the chemicals released, which can considerably increase fire and explosion hazards. For this reason, protection of the containers against physical damage in shipment, transfer, and storage is very important. In addition, the container might represent a potential hazard under fire conditions. For example, storage of oxidizers in fiber packs or even plastic containers might be safe under normal conditions, but if a fire occurs, the oxidizers and the combustible packages can magnify fire intensity.

Hazard Identification

All storage areas should conspicuously display signs to identify the material stored and handled in the area. The hazard identification system described in NFPA 704, *Standard System for the Identification of the Hazards of Materials for Emergency Response,* should be used. See especially the tables on the degrees of health, flammability, and instability hazards in NFPA 704. When materials having different hazard identifications are stored in the same area, the area should be marked to indicate the most severe health, flammability, and reactivity hazard present. Hazard identifications for many materials can be found in NFPA 49 and NFPA 325, found in the NFPA *Fire Protection Guide to Hazardous Materials* (Figure 7.4.1).

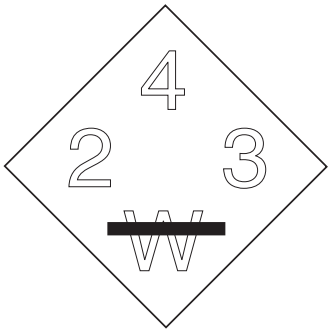

FIGURE 7.4.1 Sample NFPA Marking (Source: NFPA 704, *Standard System for the Identification of the Hazards of Materials for Emergency Response,* 2001 ed., Figure 9.1(a)(c))

Fire Control

The selection of extinguishing agents is determined by the reactivity of the chemical, the physical state of the chemical (i.e., solid, liquid, or gas), the toxicity of the chemical, and its expected products of combustion or decomposition. Water is normally used as the extinguishing agent, except on chemicals that are dangerously water-reactive. However, the toxicity of the material in water must be considered as an additional factor. The contamination of potable water supplies and environmentally sensitive areas by toxic runoff from fire fighting could create a major health and environmental hazard.

Automatic sprinkler protection for storage should be employed wherever possible. The protection must be specifically designed based on the extent of fire hazard, the arrangement of material, and the maximum quantity that can be stored.

Manual fire fighting to supplement the automatic protection might be severely limited by the toxicity of the material, obscuration due to smoke, the nature of the products of combustion, or the possibility that fires might lead to explosions in storage areas for reactive chemicals. Fire fighters should wear self-contained breathing apparatus (SCBA) and other appropriate personal protective equipment (PPE) to avoid the hazard of toxic materials. Where explosion is a possibility, manual fire fighting should be conducted from a remote location. In some cases, the hazard will be sufficiently high so that fire fighters should not approach the area to attempt any type of manual fire fighting.

TOXICITY OF CHEMICALS

The toxicity of chemicals is particularly important from the point of view of fire protection, regardless of the toxic material's fire hazard. A fire or explosion can subject fire fighters to a severe life safety hazard if the toxic material is accidentally released while they are present. In situations where fire officers are aware of a real or potential toxicity hazard, the decision might be made to forgo manual fire fighting. Fire fighters should be aware that products of combustion may present very different

hazards. These products may be more or less hazardous than the uncombusted chemical.

Before using a chemical, one should obtain and evaluate information about its toxicity. When the toxicity problem appears to be severe, an effort should be made to find a suitable less toxic substitute. If there is no practical way to eliminate the toxic material, protection should be provided for those subject to daily exposure and for fire department personnel. Those who might be exposed during a fire or other emergency should be informed of the potential hazard and advised of the proper protective clothing and breathing apparatus to wear. Automatic fire protection should always be provided when a fire hazard is present in conjunction with a toxicity hazard.

In addition to the information sources discussed at the beginning of this chapter, information on the toxicity of chemicals can be obtained from Patty's *Industrial Hygiene and Toxicology* and other references.

There are two ways to protect against the toxic effects of chemicals during handling. First, use the most practical of the available methods for controlling and confining the chemical so that the toxic material cannot be contacted, swallowed, or inhaled in dangerous quantities during normal operations. Second, in areas where toxic chemicals are handled, educate all persons about the hazards, precautionary procedures, danger signals, and emergency procedures to be followed.

Of the methods used to control and confine toxic chemicals, handling them in a closed system is absolutely necessary. However, a leak in the system is always possible and could subject persons to a severe health hazard. If a gas is not an irritant, personnel must be warned of the exposure by automatically operated toxic gas indicators or other alarm devices. In some installations, it might be possible to maintain a slight negative pressure on the closed system to prevent the escape of toxic materials in case of a minor leak. Generally, such systems are ducted to a scrubber where the toxic gas can be neutralized. Wherever possible, processes should be installed outdoors where natural air movement will dilute and dissipate toxic gases or vapors.

OXIDIZING CHEMICALS

In considering storage facilities for oxidizing chemicals, remember that oxidizing chemicals usually are not themselves combustible, but can provide oxygen to accelerate the burning of combustible materials. Combustible materials and flammable liquids, therefore, should not be stored in the same storage areas with oxidizing chemicals. Storage buildings should be of noncombustible or fire-resistive construction. Combustible packaging and wood or plastic pallets represent a severe hazard and should be eliminated. Because certain oxidizing materials undergo dangerous reactions with specific noncombustible materials, the possibility of dangerous reactions should be considered when deciding on acceptable storage facilities. Chlorates, for example, should not be stored with acids or combustible materials. Inorganic peroxides also react with acids, yielding hydrogen peroxide. A suitable storage facility for inorganic peroxides would be a dry, fire-resistive storage room in which there are no combustible contents or acids. When classifying chemicals for storage purposes, one should keep in mind that the label on the container required for interstate shipment classifies the chemical by hazard for transportation purposes only; a thorough knowledge of the fire, health, and reactivity hazards of the chemical should be the guide when arranging storage.

Because of the probability that spilled material will become mixed with combustible refuse, it is important to clean up all spills immediately and thoroughly. Combustible linings of barrels should be removed from the storage area and destroyed as soon as the barrels are empty.

NFPA 430, *Code for the Storage of Liquid and Solid Oxidizers,* addresses storage of oxidizing chemicals.

Nitrates

Awareness of the fire hazard properties of inorganic nitrates is important because these materials are widely used in fertilizers, salt baths, and other industrial applications. Under fire conditions, inorganic nitrates can melt and release oxygen, causing the fire to intensify. Molten nitrates react with organic materials with considerable violence, usually releasing toxic oxides of nitrogen. When solid streams of water are used for fire fighting, they can produce steam explosions on contact with molten material.

Nitrates are soluble in water and some are hygroscopic. Water solubility can be indirectly responsible for serious fires. Paper, burlap, or cloth bags of nitrates that become moist during shipment or storage retain an impregnation of nitrate after drying and are thus highly combustible. For this reason, nitrates should be transferred from bags or wood barrels to noncombustible bins for storage. The bags or barrels should be thoroughly washed. For the same reason, storage of bulk nitrates on wood floors or against wood walls or posts is hazardous.

Common nitrates are discussed in this section. Other nitrates have somewhat similar properties.

Sodium Nitrate. Noncombustible sodium nitrate promotes combustion of other materials. It evolves oxygen when heated to about 700°F (370°C), thereby increasing the intensity of any fire in its vicinity. An intimate mixture of sodium nitrate and organic material can be exploded by a flame.

Potassium Nitrate. The properties and hazards of potassium nitrate are similar to those of sodium nitrate; however, potassium nitrate is less moisture absorbent.

Ammonium Nitrate. Like other inorganic nitrates, ammonium nitrate is an oxidizing agent and will increase the intensity of a fire. The oxidizing gas it gives off is nitrous oxide, rather than oxygen. Chemical- and fertilizer-grade ammonium nitrate must not be confused with certain ammonium nitrate combustible material mixtures used as explosives. All grades of ammonium nitrate can be detonated if they are in the proper crystalline form, if the initiating source is sufficiently large, or if heated under sufficient confinement (the purest material needing the greatest confinement).

As is evident from the shipboard explosions at Texas City, Texas, and Brest, France (both in 1947), and in the Red Sea in 1953; the explosion following a freight train wreck at Traskwood, Arkansas, in December 1960; and explosions in bulk warehouses near Pryor, Oklahoma, in January 1973, and in Toulouse, France, in September 2001, certain conditions other than initiation by explosives can cause ammonium nitrate to detonate. An extensive series of tests to determine the explosion hazards of fertilizer-grade ammonium nitrate under fire exposure was conducted by the U.S. Bureau of Mines,[1] and from that study it would appear that the following conclusions can be reached:

1. Although detonation initiation in ammonium nitrate as a result of fire exposure cannot be ruled out completely, a direct burning-to-detonation transition in commercial fertilizer-grade ammonium nitrate (AN) appears to be possible only in a pile of extremely large dimensions, with ignition at the bottom or center of the pile. (The ammonium nitrate involved in the Texas City, Brest, and Red Sea explosions was organic coated, with substantially different burning characteristics from those of the AN manufactured today.)
2. Projectiles derived from nearby explosions can initiate reactions leading to detonations, particularly in hot AN. Ordinary sporting arms bullets are incapable of initiating detonations of AN under normal storage conditions.
3. When AN is intimately mixed with fuel oil, ground polyethylene, or ground paper, transition from burning to detonation is possible, although quite unlikely, in pile sizes that are typical of those found in storage and transportation. Such mixtures are properly classified as blasting agents and should be stored according to the requirements in NFPA 495, *Explosive Materials Code.*
4. Gas detonations are incapable of initiating detonation of AN.
5. Hot AN can be detonated by projectile impact. (Initiation of detonation of AN in the Traskwood freight train wreck and fire could have been by projectiles derived from a gasoline-nitric acid detonation, because tank cars of gasoline and of nitric acid were also in the wreck. Nitric acid could have become mixed with the burning gasoline.)

Tests conducted many years ago indicate that mixtures of ammonium nitrate and ammonium sulfate containing not more than 40 percent by weight of ammonium nitrate and mixtures of ammonium nitrate and calcium carbonate (calcium ammonium nitrate) containing not more than 61 percent ammonium nitrate are not explosive under conditions met in practice. When exposed to fire, calcium ammonium nitrate forms calcium nitrate and ammonium carbonate, which absorbs heat while decomposing to ammonia, carbon dioxide, and water. However, the contamination problem has not been thoroughly investigated.

Ammonium nitrate in water solution is not hazardous unless spilled into combustible material and permitted to dry. Research, however, has shown that solutions containing up to 8 percent water can be detonated.[2]

Cellulose Nitrate. For hazards and properties of cellulose nitrate, see Section 6, Chapter 13, "Polymeric Materials."

Nitric Acid

(See section entitled "Corrosive Chemicals" in this chapter.)

Nitrites

Nitrites should not be confused with nitrates. Nitrites contain one less oxygen atom than nitrates but are more active oxidizing agents since they melt and release oxygen at lower temperatures. Because nitrites in mixtures with combustible substances are hazardous, such mixtures should not be subjected to heat or flame. Certain nitrites, notably ammonium nitrite, are by themselves explosive. Nitrites should be treated like nitrates with respect to storage, handling, and fire fighting.

Inorganic Peroxides

Sodium, Potassium, and Strontium Peroxide. Although these chemicals are themselves noncombustible, they react vigorously with water and release oxygen as well as large amounts of heat. Large quantities of sodium and potassium peroxides can react explosively with water, and heat from reaction with just a little water might cause the contents of an entire container to decompose. If organic or other oxidizable material is present when this reaction takes place, fire is likely to occur.

Barium Peroxide. Heat releases oxygen from barium peroxide. Intimate mixtures of barium peroxide and combustible or readily oxidizable materials are explosive and easily ignited by friction or by contact with a small amount of water.

Hydrogen Peroxide. In contrast to the four abovementioned peroxides, which are white powders, hydrogen peroxide is a syrupy liquid. In pure form, it is relatively stable. When heated to and kept at a temperature of 212°F (100°C), 99.2 percent hydrogen peroxide decomposes at the rate of 4 percent per year and 50 to 90 percent hydrogen peroxide at a rate of something less than 2 percent a day. An increase in temperature increases the decomposition rate of hydrogen peroxide about 1½ times for each 18°F (–8°C). Near the boiling point, the rate of decomposition is very rapid and, if adequate venting is not provided, the pressure in the container might cause it to rupture. In general, the dilute material is less stable than the concentrated.

The hazards of hydrogen peroxide/water solutions are highly dependent on the concentration. Solutions at concentrations of between 86 and 90.7 percent hydrogen peroxide have been demonstrated to be detonatable.[3] At a concentration above about 92 percent, the liquid can be exploded by shock. Concentrated hydrogen peroxide vapors can be exploded by a spark. At atmospheric pressure, the boiling material must be 74 percent hydrogen peroxide or higher to produce explosive vapors.

Decomposition of hydrogen peroxide produces water, oxygen, and heat. At concentrations above 35 percent, the heat is sufficient to turn all the water into steam, assuming that the decomposition begins at room temperature (72°F [22°C]). This means that a steam explosion is possible with the sudden decomposition of concentrated material. Decomposition can be caused by contamination with iron, copper, chromium, and many other metals (except aluminum) or their salts. Decompo-

sition can also be caused by combustible dust or by contact with a rough surface, such as ground glass.

Hydrogen peroxide is a strong oxidizing agent and can cause ignition of combustible material with which it remains in contact. This possibility, however, is remote unless the concentration is greater than 35 percent.

Chlorates

An adequate understanding of the fire hazard properties of the chlorates can be gained from the best-known member of the group, potassium chlorate.

Potassium Chlorate. This white crystalline substance is water soluble, noncombustible, and a strong oxidizing agent. When heated, it gives up oxygen even more readily than do nitrates. Mixing with combustible materials, for example, floor sweepings, should be prevented because, under such conditions, potassium chlorate might ignite or explode spontaneously. Drums containing chlorates might explode when heated. Sodium chlorate has properties similar to potassium chlorate.

Chlorites

Sodium Chlorite. This is a powerful oxidizing agent that forms explosive mixtures with combustible materials. In contact with strong acids, it releases explosive chlorine dioxide gas. At 347°F (175°C), sodium chlorite decomposes with the evolution of heat.

Dichromates

Among the dichromates, all of which are noncombustible, ammonium dichromate is most readily decomposed. It begins to decompose at 356°F (180°C); above 437°F (225°C) the decomposition becomes self-sustaining and is accompanied by swelling and the release of heat and nitrogen gas. Closed containers rupture at the decomposition temperature.

The other dichromates, such as potassium dichromate, react with readily oxidizable materials which, in some cases, can cause them to ignite. They release oxygen when heated.

Hypochlorites

Calcium hypochlorite at a concentration above 50 percent by weight can cause combustible or organic materials to ignite on contact. When heated, it gives off oxygen. With acids or moisture, it freely evolves chlorine, chlorine monoxide, and some oxygen at ordinary temperatures. It is sold as bleaching powder or, when concentrated, as a swimming pool disinfectant.

Calcium hypochlorite is one of the most widely used oxidizers. As a swimming pool disinfectant, it can be found in many retail establishments, lawn and garden warehouses, and in home utility rooms. It is often packaged in plastic bottles, drums, or bags. If contaminated or exposed to a fire, the material, in conjunction with the plastic container, will decompose rapidly, giving off a large amount of heat. This heat can open a large number of automatic sprinklers and ignite surrounding combustible materials. Depending on the sprinkler system design and the strength of the water supply, the sprinkler protection might be overtaxed, leading to destruction of the building. NFPA 430 discusses the storage and protection of oxidizers in retail occupancies. The protection scheme outlined could also be used for calcium hypochlorite storage in warehouses.

Perchlorates

Perchlorates contain one more oxygen atom than chlorates. They have roughly similar properties, but are more stable than chlorates. They are explosive under some conditions, such as when in contact with concentrated sulfuric acid.

Ammonium Perchlorate. This chemical has great explosive sensitivity when contaminated with such impurities as sulfur, powdered metals, carbonaceous materials, and reducing agents. The pure material in finely divided form can detonate if involved in a fire. A mixture with a chlorate can form spontaneously explosive ammonium chlorate.

Potassium Perchlorate, Sodium Perchlorate, and Magnesium Perchlorate. Each of these chemicals forms explosive mixtures with combustible, organic, or other easily oxidizable materials. Magnesium perchlorate is sometimes used in laboratories in place of calcium chloride as a dessicant. Such use requires vigilance to avoid dangerous contamination.

Permanganates

Mixtures of inorganic permanganates and combustible material are subject to ignition by friction or can ignite spontaneously if an inorganic acid is present. Explosions can occur whether the permanganate is in solution or is dry.

Potassium Permanganate. This chemical reacts violently with finely divided oxidizable substances. On contact with sulfuric acid or hydrogen peroxide, potassium permanganate is explosive.

Persulfates

Persulfates, for example, potassium persulfates, are strong oxidizing agents that can cause explosions during a fire. Oxygen released by the heat of a fire can cause an explosive rupture of the container, or the explosion might follow an accidental mixture of the persulfate with combustible material.

Fire Control Methods

With one or two exceptions, water appears to be the only suitable extinguishing agent for fires involving inorganic oxidizing agents. Water in large quantities should be used to control fires involving nitrates, nitrites, and chlorates. Carbon dioxide and other smothering agents are of little or no extinguishing value for fires involving nitrates, nitrites, and chlorates because the oxidizing material furnishes its own oxygen for combustion. Although inorganic peroxides decompose when moist and liberate oxygen, water should still be used on fires in combustible materials that are located in the vicinity of the peroxide.

It might be possible to extinguish a fire involving a peroxide spill with a dry chemical extinguisher or by smothering with dry sand or soda ash. If these methods fail, the area should be flooded with water from hose streams.

Self-contained breathing apparatuses should be worn by fire fighters. During a fire involving nitrates, one of many dangers is inhalation of oxides of nitrogen. As much ventilation as possible should be provided to permit rapid dissipation of the products of combustion and heat. When water in solid streams strikes molten nitrate, steam explosions can cause a violent eruption of the molten material.

COMBUSTIBLE CHEMICALS

Essentially, all organic chemicals are combustible. Storage practices for such chemicals closely follow those for the more common solid combustible materials discussed in other chapters.

Carbon Black

Carbon black is used in the manufacture of rubber and plastic products, such as tires. Carbon black is manufactured by the decomposition of acetylene, by incomplete combustion of natural gas or a mixture of natural gas and a liquid hydrocarbon, or by cracking hydrocarbon vapor in the absence of air. It is most hazardous immediately following manufacture when bags of the finished product might contain red-hot carbon particles. While carbon black adsorbs oxygen, slow smoldering can develop. To prevent this hazard, carbon black is stored in an observation warehouse before shipment or final storage. It is well established that carbon black will not heat spontaneously after thorough cooling and airing, although it might generate heat in the presence of oxidizable oils.

Tests show that a dust explosion hazard does not exist. Red-hot metal, electric sparks, and burning magnesium ribbon will not cause carbon black dust clouds to ignite explosively, but ignition has been obtained by using 1 oz (28 g) of gunpowder.

Carbon black comprises 98 percent of the world's production of powdered carbon.

Lamp Black

Lamp black is formed by burning low-grade heavy oils or similar carbonaceous materials with insufficient air. It adsorbs gases to a marked degree and often ignites spontaneously when freshly bagged. It has great affinity for liquids and heats in contact with drying oils. The possibility of lamp black dust explosions is increased by the presence of unconsumed oil that adheres to the carbon. U.S. Bureau of Mines' tests indicate that a dust explosion hazard exists if the oil content exceeds 13 percent. Lamp black should be thoroughly cooled before it is bagged and then stored in a cool, dry area away from oxidizing materials.

Lead Sulfocyanate

Lead sulfocyanate burns slowly. It decomposes when heated, yielding decomposition products which include highly toxic and flammable carbon disulfide and highly toxic but nonflammable sulfur dioxide.

Nitroaniline

This combustible solid melts at 295°F (146°C), and its flashpoint is 390°F (199°C). In the presence of moisture, it nitrates organic materials, which could result in their spontaneous ignition.

Nitrochlorobenzene

Nitrochlorobenzene is a solid material at ordinary temperatures and gives off flammable vapors when heated.

Sulfides

Antimony Pentasulfide. This is readily ignited and hazardous in contact with oxidizing materials. On contact with strong acids, antimony pentasulfide yields hydrogen sulfide, a very toxic gas.

Phosphorus Pentasulfide. This ignites readily, and in the presence of moisture may heat spontaneously to its ignition temperature (287°F [142°C]). The products of combustion include highly toxic sulfur dioxide and phosphorus pentoxide. Reaction of phosphorus pentasulfide with water yields hydrogen sulfide, a very toxic gas.

Phosphorus Sesquisulfide. With an ignition temperature of only 212°F (100°C), this chemical is easily ignited and is considered highly flammable. Toxic sulfur dioxide is a product of combustion.

Potassium Sulfide and Sodium Sulfide. These are moderately flammable solids that form toxic sulfur dioxide when burning, and toxic hydrogen sulfide on contact with acids.

Sulfur

Sulfur at ordinary temperatures is a yellow solid or powder consisting of rhombic crystals that melt in the vicinity of 234°F (112°C), depending on their purity. Sulfur boils at about 832°F (444°C). Except in small quantities, it is shipped and stored as a liquid at a temperature below 300°F (149°C). It is combustible, and its vapor forms explosive mixtures with air. (Its flashpoint is 405°F [207°C].) Finely divided sulfur dust likewise possesses an explosion hazard that requires control during storage and handling. Ignition temperatures of dust clouds vary upward from 374°F (190°C).

Sulfur contains varying amounts of hydrocarbons, depending on the source. These hydrocarbons gradually react with the molten material to form combustible and highly toxic hydrogen sulfide. Storage tanks and pits for molten sulfur must be ventilated to prevent accumulation of this gas. Except in the presence of lamp black, carbon black, charcoal, and a few less common substances, spontaneous ignition of sulfur is practically nonexistent. It melts and flows when burning and evolves large quantities of toxic, irritating, and suffocating sulfur dioxide. This gas attacks the eyes and throat, and complicates fire fighting. Sulfur also forms highly explosive and easily detonated mixtures with chlorates and perchlorates and forms gunpowder when mixed with potassium nitrate and charcoal.

Water should be used for fighting sulfur and sulfide fires. For fighting fires of sulfur dust, water spray is recommended, principally to avoid stirring up dust clouds and causing a dust explosion. Fires in closed spaces, for example, tanks of molten sulfur, can best be fought by closing the container and allowing the heavy sulfur dioxide produced by combustion to smother the fire.

Naphthalene

Naphthalene is combustible both in solid and in liquid form. Naphthalene vapors and dusts form explosive mixtures with air.

UNSTABLE CHEMICALS

Special precautions must be taken for storage of chemicals that are subject to spontaneous decomposition or other dangerous reactions. The precautions should be planned to minimize the possibility of a dangerous reaction and to prevent injuries and extensive property damage if one should occur. Steps to be taken to protect against the hazard will depend on the conditions that affect the stability of the chemical being stored. Points peculiar to unstable chemicals to be considered are: (1) the catalytic effect of containers, (2) materials in the same storage area that could initiate a dangerous reaction, (3) the presence of inhibitors, and (4) the effect of direct sunlight or temperature changes. There is a need for pressure-relief vents for containers and explosion venting for the storage area in addition to the usual considerations, such as automatic sprinkler or water spray protection, and elimination of all combustible material from the storage area. Whenever possible, unstable chemicals should be stored in a detached outside location.

Fire fighters should be thoroughly briefed on the proper procedures to be followed if called on to fight a fire involving or exposing a storage area containing unstable chemicals.

Acetaldehyde

Acetaldehyde is a highly reactive compound. Under suitable conditions, the oxygen or any hydrogen can be replaced. Acetaldehyde undergoes numerous condensation, addition, and polymerization reactions, which can take place with explosive violence.

Ethyl Acrylate, Methyl Acrylate, Methyl Methacrylate, and Vinylidene Chloride

These are flammable liquids that can polymerize at elevated temperatures, as in fire conditions. If the polymerization takes place in a closed container, the container can rupture violently. These liquids usually contain an inhibitor to prevent polymerization.

Ethylene Oxide

Ethylene oxide can polymerize violently when catalyzed by anhydrous chlorides of iron, tin, or aluminum; oxides of iron (i.e., iron rust) and aluminum; and alkali metal hydroxides. Violent polymerization of ethylene oxide can be initiated by heat or shock. Ethylene oxide reacts with alcohols, organic and inorganic acids, ammonia, and many other compounds. The heat liberated by these exothermic reactions can cause polymerization of the unreacted ethylene oxide. Ethylene oxide vapors can detonate if some initiating heat source is present. Ethylene oxide vapors in a tank exposed by fire can be rapidly heated to their ignition temperature unless the tank is kept wet with water spray. The flammable range of ethylene oxide in air is 3 to 80 percent. Although the upper limit is frequently reported to be 100 percent, explosions of mixtures containing greater than 80 percent ethylene oxide are the result of chemical decomposition.

Hydrogen Cyanide

Hydrogen cyanide is flammable and poisonous. In either liquid or vapor states, it has a tendency to polymerize. The reaction is catalyzed by alkaline materials and, since one of the products of the polymerization reaction is alkaline (ammonia), an explosive reaction will eventually take place. By adding sulfuric, phosphoric, or some other acid to neutralize the ammonia, the rate of polymerization in the liquid can be held down to a safe rate. Potassium cyanide and sodium cyanide on contact with acids release poisonous and flammable hydrogen cyanide vapor.

Nitromethane

Nitromethane is a combustible liquid. At 599°F (315°C) and 915 psig (6308 kPa), it decomposes explosively. Noteworthy detonations of nitromethane in railroad tank cars occurred at Niagara Falls, New York, and at Mt. Pulaski, Illinois, in 1958. Although undiluted nitromethane can detonate under certain conditions of heat, pressure, shock, and contamination, the causes of these two tank car explosions were not definitely determined. A possible explanation is contamination of the nitromethane by some material previously carried in the tanks. For a discussion of the hazards of nitromethane and other nitroparaffins, see AIA Research Report No. 12.[4]

Organic Peroxides

Organic peroxides are an important group of chemicals widely used in the plastics industry as polymerization reaction initiators, in the milling industry as flour bleaches, and in the chemical and drug industries as catalysts. All organic peroxides are combustible and, as in the case of inorganic peroxides, increase the intensity of a fire. Many organic peroxides can be decomposed by heat, shock, or friction. The rate of decomposition depends on the particular peroxide formulation and the temperature. Some, such as methyl ethyl ketone peroxide, are detonatable. Organic peroxides can be liquid (e.g., *t*-butyl perbenzoate) or solid (e.g., benzoyl peroxide) and are often dissolved in flammable or combustible solvents. The peroxides are often found wet with water or diluted with stable liquids. With solutions, sensitive crystals can be formed by freezing.

This widely used group of unstable chemicals deserves special attention. Many organic peroxides are diluted to the point where hazardous reactions are impossible; others require special precautions. Organic peroxides are shipped in specific containers that are designed not to confine the peroxide under

fire conditions. Care should be taken if the peroxide is transferred to another container. The manufacturer of the peroxide should be consulted for specific recommendations.

NFPA 432, *Code for the Storage of Organic Peroxide Formulations,* gives quantity and arrangement specifications for various formulations.

Benzoyl Peroxide. In undiluted form, benzoyl peroxide ignites very readily and burns with great rapidity, similar to burning an equal amount of black powder. Decomposition by heat is rapid, and, if the benzoyl peroxide is confined when heated, explosive decomposition will occur. Decomposition can also be initiated by heavy shock or frictional heat. Most benzoyl peroxide is shipped diluted or water-wet to reduce the fire hazard.

Ether Peroxides. During storage, practically all ethers form ether peroxides. When the ether peroxide mixture is heated or concentrated, the peroxide can detonate. With some ethers, the quantities of peroxide formed are too small to be of significance. Peroxide formation is a hazardous property of diethyl ether, ethyl tertiary butyl ether, ethyl tertiary amyl ether, and the isopropyl ethers. Isopropyl ether is said to be considerably more susceptible to peroxide formation than other ethers. When pure, dry ether is stored under laboratory conditions in a clear and colorless bottle, it will develop detectable amounts of peroxides in one month. Light seems to be a more important factor than heat, although peroxides have been known to form in amber bottles. Ether sealed in copper-plated cans or in otherwise inhibited cans is not likely to form peroxides. Although there is apparently no means yet available to completely eliminate peroxide formation, using any one of numerous patented inhibitors or copper or iron along with storage in metal or opaque amber glass containers provides sufficient stability for all practical purposes. Ether should not be dry-distilled unless peroxides have been proved absent.

Styrene

Styrene polymerizes slowly at ordinary temperatures, and the rate increases as the temperature increases. Since the polymerization reaction is exothermic, the reaction will eventually become violent as it is accelerated by its own heat. Inhibitors are added to styrene to prevent dangerous polymerization.

Vinyl Chloride

Vinyl chloride is a toxic and flammable gas that can polymerize at elevated temperatures, as in fire conditions, and cause violent rupture of the container. Vinyl chloride usually contains an inhibitor to prevent polymerization.

Fire Control Methods

Water is the recommended extinguishing agent for fires involving unstable chemicals, including organic peroxides. Automatic sprinklers are the best protection because fires involving such materials can lead to explosions. Manual fire fighting must be conducted from a distance where the fire fighters will be protected from an explosion.

WATER- AND AIR-REACTIVE CHEMICALS

Water-reactive and air-reactive chemicals present significant fire hazards. Significant quantities of heat are liberated during the reactions. If the chemical is combustible, it is capable of self-ignition; if noncombustible, the heat of reaction might be sufficient to ignite nearby combustible materials.

Water-Reactive Chemicals

Anhydrides, carbides, hydrides, alkali metals (lithium, sodium, potassium), and similar chemicals should be stored in dry areas in waterproof and airtight containers that are kept off the floor on skids. The storage area should not contain combustible material and/or incompatible chemicals.

Air-Reactive Chemicals

Aluminum hydride, aluminum alkyls, yellow phosphorous, and similar chemicals must be stored to avoid contact with air. Yellow phosphorous, for example, is stored under water. Other materials, such as aluminum alkyls, which react with both water and air, must be stored under inert liquids or inert gas. Storage areas should contain no incompatible materials.

Alkalies (Caustics)

Caustic soda (sodium hydroxide or lye) and caustic potash (potassium hydroxide) are the most common alkalies. Although caustics are noncombustible, they generate heat when mixed with water. In contact with water, dry solid caustics will react. The heat generated (heat of solution) can be sufficient to ignite combustible material. Caustic solutions can generate hydrogen on contact with zinc, galvanized metals, or aluminum.

Aluminum Trialkyls

Most of these organic metal compounds are pyrophoric, that is, they ignite spontaneously on exposure to air, and react violently with water and certain other chemicals. Triethylaluminum, the most common member of this group, ignites spontaneously in air and on contact with water. When it is mixed with strong oxidizing agents or with halogenated hydrocarbons, violent reactions or detonations can occur.

Anhydrides

Acid anhydrides are compounds of acids from which water has been removed. They react with water, usually violently, to regenerate acids. Organic acid anhydrides are combustible and usually are more hazardous than their corresponding acids, because their flashpoints are lower. Acetic anhydride has a flashpoint of 129°F (54°C); propionic anhydride, 165°F (74°C), open cup; butyric anhydride, 190°F (88°C), open cup; and maleic anhydride, 218°F (103°C). Inorganic acid anhydrides, for example, chromium anhydride and phosphorus anhydride, are not combustible.

Carbides

The carbides of some metals, such as sodium and potassium, can react explosively on contact with water. Many, such as calcium

carbide, lithium carbide, potassium carbide, and barium carbide, decompose in water to form acetylene. In addition to the hazard of the formation of flammable gas, another fire hazard of certain carbides is the generation of heat in contact with water. When one-third its weight of water is added to a water-reactive carbide, the temperature can be raised sufficiently to ignite the gas generated. Sodium carbide becomes heated to incandescence when placed in chlorine, carbon dioxide, or sulfur dioxide. The carbides of silicon and tungsten are very stable.

Charcoal

Under certain conditions, charcoal reacts with air at a sufficient rate to cause the charcoal to heat spontaneously and ignite. Charcoal made from hard wood by the retort method appears to be particularly susceptible. Spontaneous heating occurs more readily in fresh charcoal than in old material; the more finely divided it is, the greater the hazard. Among the conditions that can lead to spontaneous heating of charcoal are (1) lack of sufficient cooling and airing before shipment; (2) charcoal becoming wet; (3) friction in grinding of finer sizes, particularly of material insufficiently aired before grinding; and (4) carbonizing of wood at too low a temperature, leaving the charcoal in a chemically unstable condition.

Coal

Under some conditions, virtually all grades of coal (except high-grade anthracite) are subject to spontaneous heating and ignition. Although the basic causes for the spontaneous heating of coal are not well defined, it is believed that adsorption of oxygen or oxidation of finely divided particles is the main cause.

Among the conditions believed to affect the susceptibility of coal to spontaneous heating are (1) the fineness of the particles, (2) the oxygen adsorptive abilities of the particles, (3) the trapped and confined moisture content of the coal, (4) air trapped in voids in coal piles, (5) the presence of sulfur in the form of pyrites or marcasites, (6) free gases in the pile, (7) foreign substances in the pile, (8) the method and depth of piling, (9) the temperature of the containing walls and floor or of surrounding or surrounded surfaces, and (10) the type and amount of ventilation.

Hydrides

Most hydrides are compounds of hydrogen and metals. Metal hydrides react with water to form hydrogen gas.

Sodium Hydride. A gray-white crystalline, free-flowing powder, sodium hydride will ignite with explosive violence on contact with water. When exposed to air, absorption of moisture may cause ignition.

Lithium Hydride. When this combustible solid reacts vigorously with water, hydrogen gas and heat are evolved. Lithium hydride dust is likely to explode in humid air. Static electricity can cause the dust to explode in dry air.

Lithium Aluminum Hydride. Like lithium hydride, this chemical is a combustible solid that reacts rapidly with water to form hydrogen gas and heat. The heat will probably cause the hydrogen to ignite. When lithium aluminum hydride is in a solution with ether, a fire involving the solution is essentially an ether fire. Small amounts of water cause the burning to intensify. Combustible materials on which the solution has spilled may ignite spontaneously or be ignited by light friction.

Oxides

Oxides of some metals and nonmetals react with water to form alkalies and acids, respectively. This reaction takes place violently with the infrequently used sodium oxide. Calcium oxide, more commonly known as quicklime or unslaked lime, also reacts vigorously with water (slaking) with the evolution of enough heat to ignite paper, wood, or other combustible material under some conditions.

Phosphorus

Two forms of phosphorus, that is, white and red, are in common use.

White (or Yellow) Phosphorus. This type is the more dangerous because of its ready oxidation and spontaneous ignition in air. It is common practice to ship and store white phosphorus under water, usually with the mixture in a hermetically sealed metal container. Periodic checks should be made to ensure that containers do not leak. White phosphorus is very toxic and should not be permitted to come in contact with the skin. On ignition, dense white clouds of toxic fumes are evolved which attack the lungs.

Red Phosphorus. This type is less hazardous than white, does not oxidize and burn spontaneously at ordinary temperatures, and can be shipped and stored without the protection of water, although it should be kept in closed containers away from oxidizing agents. It is formed by heating white phosphorus. The solid form is not toxic but, once vaporized, it takes on all the fire hazards of white phosphorus to which it reverts on condensation. Care should be taken in opening containers of red phosphorus because spontaneous ignition can take place with exposure to air.

Sodium

(See Section 6, Chapter 9, “Metals.”)

Sodium Hydrosulfite

Sodium hydrosulfite burns slowly and produces sulfur dioxide as a combustion product. On contact with moisture and air, sodium hydrosulfite heats spontaneously and can ignite nearby combustible materials.

Fire Control Methods

The value of automatic sprinklers depends on the type of chemical reaction that will occur when the chemical comes in contact with water. Fires involving hydrides, for example, can be smothered with a special graphite-base powder or with inert material,

such as dry, finely divided calcium magnesium carbonate (dolomite). Hydride fires in an enclosed space should not be put out because the continued evolution of hydrogen after extinguishment will create an explosion hazard. For the fires involving air-reactive white (or yellow) phosphorus, water will solidify the phosphorus melted by the heat of the fire, after which it can be covered with dry sand or dirt. All of the chemical must be disposed of before it can dry out and reignite.

Several of these chemicals are both air- and water-reactive and the water reaction can be particularly violent, for example, aluminum alkyls. Fires of such materials can be contained by dry chemical while the material burns out under control. Metallic sodium, which is both water- and air-reactive, can be extinguished by the use of dry chemical. The residual sodium should then be submerged in oil.

CORROSIVE CHEMICALS

The term *corrosive* refers to those chemicals that have a destructive effect on living tissues. Although some corrosive chemicals are strong oxidizing agents, they are separately classified to emphasize their injurious effect on contact or inhalation. It should not be inferred, however, that a chemical is not injurious because it is otherwise classified. For example, caustics, classified as water- and air-reactive chemicals, are also corrosive.

Inorganic Acids

Concentrated aqueous solutions of the inorganic acids are not in themselves combustible. Their chief hazard lies in the danger of leakage and possible mixture with other chemicals or combustible material stored in the vicinity, since fire or explosions could occur from mixing of the chemicals.

Hydrochloric Acid. In concentrated solution, hydrochloric acid is hazardous because its reaction with certain metals (including tin, iron, zinc, aluminum, and magnesium) forms hydrogen gas. Strong oxidizing agents mixed with hydrochloric acid cause the release of chlorine gas. A mixture of nitric and hydrochloric acids generates chlorine and nitrous oxide.

Hydrofluoric Acid. Either anhydrous or aqueous hydrofluoric acid is noncombustible and does not cause ignition of combustible materials with which it comes in contact. However, it is highly toxic, irritating to the eyes, and inflicts severe skin burns. When it comes in contact with metals, hydrogen is generated.

Nitric Acid. Under certain conditions, nitric acid nitrates cellulose material. Thus, wood that comes in contact with the acid or its vapor can ignite much more easily. Spontaneous heating follows if strong solutions of the acid mix with organic material. In general, concentrated nitric acid nitrates organic materials; dilute acid oxidizes them, giving off oxides of nitrogen during the process. These oxide fumes (colorless to brown) are usually present in fires in buildings where nitric acid is used. A concentration of this gas (actually a mixture of several gases) so small that it is not objectionable at the time of inhalation can result in serious illness or death to the victim, although no effects might be felt for some time. If white fuming nitric acid (more than 97.5 percent nitric acid) is spilled into burning gasoline, it will detonate.[1]

Perchloric Acid. When misused or used in concentrations greater than 72 percent, perchloric acid can be extremely dangerous. At the normal commercial strength (72 percent), it is a strong oxidizing and dehydrating agent when heated, but a strong nonoxidizing acid at room temperature. Because of this and other advantageous properties, it is widely used in analytical laboratories. The rate of burning of organic substances is greatly increased by contact with perchloric acid. Explosions have occurred at wood and plastic laboratory hoods after long exposure of the hoods to perchloric acid vapors. Strong dehydrating agents, such as concentrated sulfuric acid or phosphorus pentoxide, convert perchloric acid solution to anhydrous perchloric acid, which decomposes even at room temperature and explodes with terrific violence. It also explodes on contact with many organic substances. For these reasons, dehydrating agents should never be mixed with perchloric acid.

Sulfuric Acid. This chemical has the added hazardous property of absorbing water from organic material with which it might come in contact. Charring takes place and sufficient heat can be evolved to cause ignition. Particular care must be taken to avoid painful skin burns inflicted by bodily contact. Dilute sulfuric acid will dissolve metals with the evolution of hydrogen.

The Halogens

The members of the halogen (salt-producing) group are all chemically active and have similar chemical properties. The individual elements, that is, fluorine, chlorine, bromine, and iodine, differ from each other in decreased chemical activity in the order named. Bromine and iodine have the least fire hazard. They are noncombustible, but will support combustion of certain substances. Turpentine, phosphorus, and finely divided metals ignite spontaneously in the presence of the halogens. The vapors are poisonous, as well as corrosive and irritating to the eyes and throat.

Bromine. This is a dark reddish-brown corrosive liquid which can cause fire when in contact with combustible materials.

Chlorine. This is a heavy, greenish-yellow, highly toxic gas given off in some manufacturing processes and by bleaching powder (chloride of lime), especially in the presence of strong acids. It is not flammable itself, but can cause fires or explosions, especially if it comes in contact with acetylene, ammonia, turpentine, hydrocarbons, or finely powdered metals. At 484°F (251°C), mild steel ignites and burns in chlorine. Adequate ventilation should be provided in any process where this gas is generated.

Fluorine. A greenish-yellow gas, fluorine is one of the most reactive elements known. It combines, in most cases spontaneously, with practically all known elements and compounds under suitable conditions. Fluorine reacts violently with hydro-

gen and many organic materials. It explodes on contact with metallic powders, attacks glass and most metals, and reacts explosively on contact with water vapor. It can be safely handled in nickel or Monel™ cylinders. Fluorine reacts with these two metals, but forms a protective nickel fluoride layer that prevents further action. However, moisture or other impurities within the cylinder can cause such violent reaction that the metal will melt and ignite in the fluorine. The tank will then burst and scatter molten metal.

Iodine. This chemical is usually in the form of purplish-black volatile crystals that are corrosive. Reports indicate that iodine is explosive when diffused with ammonia (it forms explosive nitrogen triiodide) and when mixed with turpentine or lead triethyl.

Fire Control Methods

Water in spray form is recommended for fighting fires in acid and alkali storage areas. Water from straight streams mixing with concentrated acid or a caustic agent will heat and spatter the corrosive chemicals. A fire involving perchloric acid can cause an explosion if the acid becomes mixed with organic material. Ample precautions should be taken to protect fire fighters from possible explosions. Fire fighters should avoid contact with spilled acids and inhalation of their toxic fumes by the use of self-contained breathing apparatuses.

Chlorine and fluorine do not represent fire hazards, but the release of dangerous toxic gases should be expected if cylinders are present in a fire. It is mandatory that a self-contained breathing apparatus be used when fighting a fire where chlorine or fluorine cylinders are located.

RADIOACTIVE MATERIAL

Radioactive elements and compounds have fire and explosion hazards identical to those of the same material when not radioactive. An additional hazard is introduced by the various types of radiation emitted, all of which are capable of causing damage to living tissue. Under fire conditions, vapors and dusts (smoke) can be formed that could contaminate not only the building of origin, but also neighboring buildings and outdoor areas. The fire protection engineer's main concern with radioactive materials is to prevent the release or loss of control of these materials by fire during fire extinguishment.

Fire Protection for Radioactive Materials

The life safety hazard introduced by an escape of radioactive dusts and vapors during a fire makes it vitally important to take all practical steps to prevent a fire from involving these materials. Radioactivity is not detectable by any of the human senses. Special instruments and measuring techniques are required to identify and evaluate it. The hazard is affected by the form of the material—whether solid, liquid, or gas—and by the container in which it is kept or handled.

Radioactivity can cause loss of life, injuries, and damage to and extended loss of materials used, as well as damage to equipment and buildings. Manual fire fighting might be limited by the danger to fire fighters from exposure to radioactivity. Salvage work and resumption of normal operations at a property can be delayed where a fire or explosion causes loss of control over radioactive substances. The need to decontaminate buildings, equipment, and materials presents a serious and complicated problem.

Smoke and products of combustion from fires in places where there are radioactive materials must be controlled. The runoff of water used in fighting fires must also be controlled. Fire fighters require protective clothing and respiratory protection equipment. Fire control must be thoroughly preplanned. With radiation hazards, automatic sprinklers are preferable to measures requiring manual fire fighting. This lessens the amount of radioactive smoke or products of combustion and water runoff to be dealt with manually.

Handling Radioactive Materials

The possibility of accidental release of radioactive material because of a fire or explosion, with the resultant health hazard to fire fighters and others, is a strong argument for careful attention to methods of fire prevention and control in laboratories and other occupancies handling radioactive materials.

More information can be obtained from NFPA 801, *Standard for Fire Protection for Facilities Handling Radioactive Materials.* This publication calls attention to basic information concerning radiation protection methods and provides some guidance on fire protection practices to those who design and operate such facilities. Most radioactive materials introduce little or no fire or explosion hazard, so the fire hazard of facilities handling radiation usually can be determined by a knowledge of the combustibility of the building and its furnishings and of the fire and explosion hazards of the nonradioactive chemicals.

The fire and explosion hazard can be substantially reduced by use of a fire-resistive building, noncombustible interior finish and furnishings, wherever possible, and enforcement of strict controls to minimize the hazards of flammable liquids and other chemicals that are necessary for laboratory work or for other occupancies. In any facility handling radioactive materials, one feature that can cause trouble, unless the building has been properly designed, is the duct system usually required for the safe disposal of contaminated vapors, gases, and dusts. Unless this system is properly arranged, it can spread radioactive contaminants to noninvolved parts of a facility during a fire.

Fire Control Methods

Due to the need to immediately control any fire that might eventually release radioactive materials and the potential health hazard to those who could be exposed to radiation during manual fire control, there can be no question as to the desirability of automatic sprinkler protection for radiation laboratories and other areas where radioactive materials are handled. Special precautions to be followed by fire-fighting personnel are described in *Hazardous Materials Response Handbook.*[5] The procedures stress steps that should be taken to protect fire fighters at all

times, including the use of radiation monitoring devices, self-contained breathing apparatuses, and regular fire department protective clothing.

MATERIAL SUBJECT TO SELF-HEATING

Charcoal

Spontaneous heating hazards with charcoal can be controlled by thorough cooling and ventilation before bagging and storage. It is important to keep the charcoal dry, to prevent contamination with foreign combustibles, and to avoid contact with heat sources. Small quantities of charcoal are normally stored in heavy paper bags. The spontaneous heating hazard of individual small bags, as might be found in a dwelling, is not serious.

When fire occurs in charcoal, water should be used, but directed only on the fire, without wetting nonburning material. The damaged and wet materials should be removed from the storage building at once, because wet charcoal is even more susceptible to self-heating than when dry.

Agricultural Products

Spontaneous heating in agricultural products can be prevented by control of moisture. Proper curing (as for hay) and adequate aeration will prevent heat buildup. Where the moisture content cannot be controlled, or where any suspicion of spontaneous heating exists, thermocouples can be used in stacks or bales. Pointed, hollow metal rods or pipes with holes drilled in the lower ends often are used to permit insertion of temperature-recording instruments into the subsurface areas of the stored material. Regular checks can then be made for the development of any hazardous temperature conditions. Where evidence of dangerous spontaneous heating is noted, the material should be removed quickly from storage.

When spontaneous heating occurs in agricultural products, it is important to have ample fire-fighting facilities available. Water hoses are needed to combat a fire that might occur spontaneously on exposure of the hot spots to air. Hay, in and around hot spots, should be wetted thoroughly before complete uncovering or attempted removal.

MIXTURE, TRANSPORTATION, AND DISPOSAL OF CHEMICALS

Mixtures of Chemicals

This chapter has presented several examples of dangerous reactions that can occur when certain chemicals are mixed. Examples have been given of chemicals that can increase the ease of ignition or the intensity of burning of the combustible materials with which they are mixed. In order to recognize the innumerable combinations of so-called incompatible chemicals, it is necessary to have a knowledge of the potentially dangerous reactions of individual chemicals. NFPA 491 contains more than 3400 dangerous reactions that have been reported in chemical literature and elsewhere. NFPA 491 can be found in NFPA *Fire Protection Guide to Hazardous Materials.*

Transportation of Chemicals

The safe transportation of chemicals depends on a knowledge of the hazardous properties of the chemicals, the normal and abnormal conditions to which the chemicals might be exposed during shipment, and the conditions of packing and shipping that will minimize the possibility of accidental release or reaction of chemicals.

In the United States, shipments of hazardous chemicals in interstate or foreign commerce by land, water, or air must comply with U.S. Department of Transportation's (DOT) Hazardous Materials Regulations (HMR). Among the subjects covered by the HMR are (1) responsibilities of shippers; (2) construction of and performance standards for containers; (3) a marking code for hazardous materials packaging, which includes information on package type, material of construction, and maximum allowable gross mass; (4) marking and labeling of packaging; (5) loading, placarding, and movement of railroad cars; and (6) regulations for carriage by rail, by aircraft, by vessel, and by public highway. In addition, the HMR contains a Table of Hazardous Materials, which identifies the Proper Shipping Name, United Nations (UN) Number, Hazard Class, Packing Group, and allowable packaging types for the transport of hazardous materials. State regulations for intrastate transportation usually agree with DOT interstate commerce regulations.

In Canada, Transport Canada (TC) regulates shipment of explosives and other dangerous chemicals. Chemicals shipped in accordance with Canadian regulations are allowed to be shipped to a destination in the United States or through the United States en route to or from a point in Canada. International transport of hazardous materials by sea is regulated by the International Maritime Organization (IMO) through the International Maritime Dangerous Goods Code (IMDG), and transport by air is regulated by the International Civil Aviation Organization (ICAO) through its Technical Instructions (TI). The International Air Transport Association (IATA) also issues Dangerous Goods Regulations (DGR), which are similar to ICAO's TI. In general, hazardous materials packaged in compliance with the IMDG or the TI may be shipped by other modes within the United States before or after they are shipped by sea or air, even if they are not in full compliance with the HMR.

Principles governing the safe transportation of chemicals include the following:

1. Constructing the container of material that will not react with or be decomposed by the chemical
2. Excluding chemicals that can react dangerously with each other from the same outside container
3. Packaging toxic and radioactive chemicals so they will not present a health hazard during normal transportation conditions and will not be released in an accident or under other abnormal conditions
4. Providing sufficient outage for maximum expansion of liquids under conditions to be expected during transportation
5. Limiting the amount of chemical that can be released through container breakage or leakage by limiting maximum size of individual containers; this principle must be balanced against the efficiencies inherent in the use of larger containers

6. Cushioning containers to minimize the possibility of breakage

Waste Chemical Disposal

The safe disposal of hazardous chemical waste is controlled by a 1976 federal law—the Resource Conservation and Recovery Act (RCRA PL 94-590, Subtitle C, Hazardous Waste Management). This act provides for cradle-to-grave regulation of potentially dangerous by-products spawned by industrial technology. Specifically, the law covers any solid, liquid, or gaseous waste that exceeds federal criteria established for the following characteristics: (1) toxicity, (2) persistence and degradability in nature, (3) potential for accumulation in tissue (bioaccumulation), (4) reactivity, (5) flammability, (6) corrosivity, and (7) radioactivity.

Standards have been published that regulate generators of hazardous waste in several different areas, that is, recordkeeping practices, labeling and containerization, disclosure of waste composition to haulers and disposers, use of a manifest to monitor the life cycle of a waste stream, and reporting requirements to applicable local, state, and federal agencies. Additionally, standards have been developed to control the storage, transportation, and final disposition to ensure that these compounds are handled in properly designed facilities. For example, secured chemical landfills must have a sufficiently impervious base to prevent contaminated leachate from entering adjacent groundwater, and incinerators must achieve a 99.9 percent destruction efficiency. Significant legal liabilities can accrue to violators of these standards.

Recognizing the hazards involved, it is advisable to verify the capabilities of any firm utilized for disposal of hazardous wastes. At the very minimum, operating permits should be reviewed to confirm that a particular waste can be legally processed by any company under consideration for this service.

SUMMARY

Safe storage and handling of chemicals requires knowledge of all of the hazardous properties of the chemical, which can be obtained from the manufacturer's material safety data sheet. Safe storage also depends on the quantity, size, and nature of the containers and their storage arrangement. Principles of good storage include segregating the chemical from other materials in storage, from processing and handling operations, and from incompatible materials; protecting containers from physical damage; using a hazard identification system; and providing fire protection based specifically on the nature of the hazard.

Specific Wastes

Key Terms

Environmental Protection Agency (EPA), gaseous waste, hazardous materials incident, hazardous waste, Hazardous Waste Operations and Emergency Response (HAZWOPER) standard, liquid waste, solid waste, waste handling systems and equipment, waste recovery

Waste is a by-product of many human activities. Increased technological development can lead to activities that may involve more waste, more hazardous waste, or at least different hazards in waste. With the proper emphasis it can also lead to waste that is less hazardous and less in volume. The Environmental Protection Agency (EPA) estimated that, in 2005, municipal solid waste alone totaled 245 million tons.[1] This is but a small fraction of the total solid waste produced by commercial, mining, construction, agricultural, manufacturing, and other industrial activities. During the course of a year, roughly over 3.5 billion tons (3.3 billion metric tons) of solid waste is produced—100 lb (45 kg) per day for every man, woman, and child.[2]

In addition to solid waste, many gaseous products, such as those produced in combustion processes (e.g., CO_2, NO_x, SO_2, soot, and hydrocarbons), and to a lesser extent chlorofluorocarbons (CFCs), are generated as waste and released into the atmosphere as gases. The pollution of air with such gaseous waste products not only is detrimental to human health but also reduces visibility and contributes to corrosion and deterioration of clothing, art treasures, historical structures, metals, rubber, and paint. Acid rain, the product of further atmospheric oxidation and dissolution of NO_x and SO_x in rain water, adversely affects the growth of forests and agricultural products and the survival of aquatic life in streams, ponds, and lakes. The accumulation of CO_2 in the atmosphere may be causing warming of the planet with dire climatological, agricultural, and ocean-level implications. CFCs destroy the ozone layer in the stratosphere; ozone protects us against harmful ultraviolet radiation from the sun. The depletion of this layer increases the risk of skin cancer.

Domestic, commercial, and industrial liquid wastes, if not treated properly, may find their way to bodies of water and add to the problem of the dwindling potable water supply by causing pollution of existing supplies. Industrial liquid waste might contain metallic salts that have immediate or long-term effects on humans. High concentrations of these salts can also build up in fishes, crustaceans, and plants, with similar effects on people who consume them. Some organic wastes from commercial, household, and industrial sources reduce the concentration of dissolved oxygen in water supplies. This can lead to the loss of aquatic life and the growth of disease-carrying bacteria and parasites. Other wastes might contain known or suspected carcinogens, such as chlorinated hydrocarbon solvents, benzene, and polychlorinated biphenyls (PCBs).

Although all waste is a nuisance to society, not all waste is necessarily hazardous. Hazardous waste can be defined as that which poses a threat to human health, the environment, or public property if handled or disposed of improperly. The hazard is created by virtue of the toxicity, flammability, explosivity, reactivity, radioactivity, corrosivity, or etiologic (disease-causing) potential of the waste.

Under Section 313 of the Emergency Planning and Community Right-to-Know Act of 1986, which was expanded under the Pollution Prevention Act of 1990, EPA collects annual data on the emission rates of over 570 listed toxic chemicals and 30 chemical categories from over 23,000 qualifying companies. These companies employ 10 or more full-time employees and process or manufacture more than 25,000 lb (11,340 kg) or use more than 10,000 lb (4536 kg) of the listed

Paul R. Severson, CHMM, QEP, is a senior environmental engineer at 3M in St. Paul, Minnesota.

chemicals. These data[3] show that, in 2003, the reporting facilities released 5.0 billion lb (2.3 billion kg) of the listed chemicals in on-site and off-site releases to the environment. The preferred hierarchy in dealing with waste is (1) reduction or reuse at the source, (2) recycling the waste, and (3) treatment or disposal (Figure 7.5.1).

This chapter (1) discusses the regulation of hazardous waste and the sources and characteristics of waste materials with particular emphasis on hazardous waste, (2) summarizes waste handling, disposal, and recovery procedures, and (3) examines the various approaches to fire prevention and protection in cases involving hazardous waste.

See also Section 11, Chapter 1, "Waste Handling and Control."

REGULATION OF HAZARDOUS WASTE

Many federal, state, and local laws and regulations have been enacted to protect the public and the environment against exposure to hazardous waste. The federal laws attempt to specify and control the quantities, concentrations, and types of chemicals released and how they are packaged, stored, transported, and disposed of.

Table 7.5.1 is a summary of relevant federal laws and related terms used in this chapter. In addition to the federal acts listed in the table, parts of other laws and amendments to existing laws regulate specific waste-disposal and handling operations. For example, the Marine Protection, Research, and Sanctuaries Act regulates ocean dumping and incineration on the high seas; the Hazardous Materials Transportation Act regulates the packaging and containerization of hazardous materials, including hazardous wastes; the Hazardous and Solid Waste Amendments to RCRA (Subtitle I) provide for the development and implementation of a comprehensive regulatory program for underground storage tanks; and the Safe Drinking Water Act establishes maximum contaminant levels for drinking water and regulates underground injection of hazardous wastes.

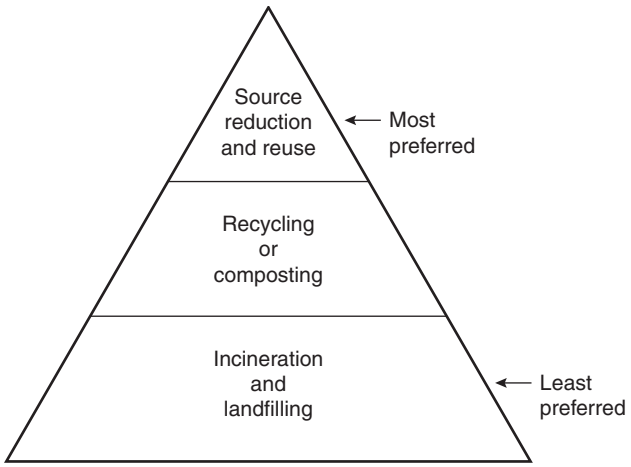

FIGURE 7.5.1 Solid Waste Management Hierarchy (Source: http://www.denvergov.org/recycle/rr.asp)

SOURCES OF WASTE

There are many sources of waste materials in present-day society. To a great extent, the source determines the waste composition, density, quantity, and the type and degree of hazard that it might present. These factors, together with regulatory requirements, determine how the waste should be collected, processed, or disposed of in a practical and safe manner.

Domestic, Commercial, and Industrial Sources

Figure 7.5.2 shows typical breakdowns of the contents of collected solid waste from domestic, commercial, and industrial sources.

The nature of an industry determines the content of the waste generated. A typical furniture plant, for example, produces scrap wood, sawdust and shavings, oily rags, stain, varnish, lacquer, glue, paper, metal, and other commercial items. The waste products of chemical processing plants vary considerably depending on the raw materials used and the end products made. These plants might discard substantial amounts of off-grade or reject products, by-products, tars, spent catalyst, precipitates, and so on. Nuclear power plants produce radioactive waste.

In addition to waste materials produced during machine maintenance, some materials may be spilled in storage and handling. Cleanup operations from filling equipment, fabrication operations, and general plant maintenance will generate some waste. Rejected and aged products, damaged packages, off-specification materials, and overruns will also be discarded.

Transportation Sources

Broken packages, leaking drums, and overheated or frozen cargo can occur during transit. Washing tank cars or tank trucks

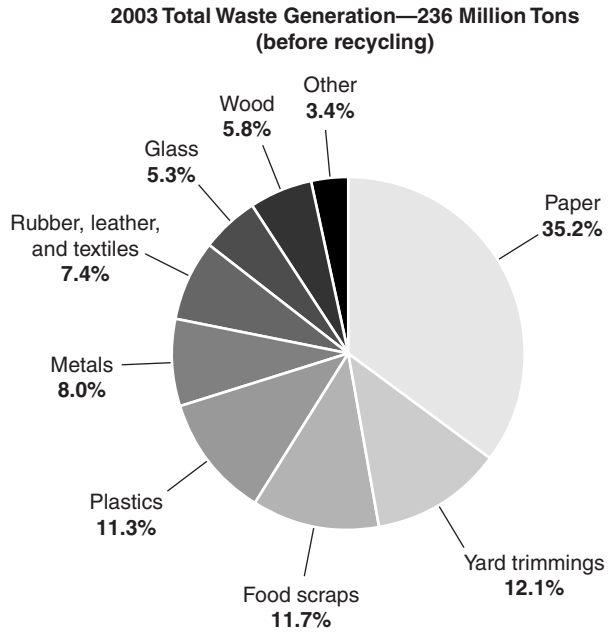

FIGURE 7.5.2 Typical Contents of Solid Waste (Percent by Weight) (Source: http://www.epa.gov/msw/facts.htm)

TABLE 7.5.1 Summary of Pertinent Federal Laws and Terminology

CAA	Clean Air Act (1966, 1970, 1977, 1990)—a federal law that mandates and enforces toxic emissions standards for stationary sources and motor vehicles. The CAA amendments of 1990 added restrictions on air toxics, ozone-depleting chemicals, stationary and mobile emission sources, and emissions implicated in acid rain and global warming. They also required industries that handle threshold quantities of listed hazardous chemicals to prepare a risk management plan.
CERCLA	Comprehensive Environmental Responsibility, Compensation and Liability Act (1980, 1986), sometimes referred to as Superfund—a federal law that authorizes the identification and remediation of abandoned hazardous waste sites.
CWA	Clean Water Act (1972, 1987)—a federal law that regulates the discharge of pollutants into surface waters and to publicly owned and municipal water treatment facilities.
EPA	Environmental Protection Agency—established under the Reorganizational Plan 3 of 1970 as an independent federal agency to ensure the protection of the environment by abating and controlling pollution. It coordinates all governmental action; conducts research; and monitors, sets, and enforces environmental standards.
FEMA	Federal Emergency Management Agency—a federal agency that is accountable for all federal emergency preparedness, mitigation, and response activities for all natural, man-made, or nuclear emergencies; also responsible for administering certain training funds under SARA.
FIFRA	Federal Insecticide, Fungicide, and Rodenticide Act (1972, 1988)—a federal law that mandates toxicity testing and registration of pesticides and establishes tolerance levels for residues of these agents in food.
OSHA	Occupational Safety and Health Act (1970)—a federal law that called for the establishment of the Occupational Safety and Health Administration, which oversees and regulates workplace health and safety. OSHA standards require facilities that process specified quantities of listed toxic and flammable chemicals to comply with 29 CFR 1910.119, "Process Safety Management." It also requires employers to inform and train employees in the hazards of the chemicals they handle, under 29 CFR 1910.1200, "Hazard Communication."
RCRA	Resource Conservation and Recovery Act (1976, 1984)—enacted as an amendment to the Solid Waste Disposal Act, RCRA protects human health and the environment and encourages the conservation of valuable material and energy sources. It provides assistance to state and local governments for prohibiting open dumping; regulating the management of hazardous wastes; and encouraging recycling, reuse, and treatment of hazardous wastes. RCRA provides for "cradle-to-grave" tracking of hazardous waste, from generator to transporter to treatment, storage, or disposal.
SARA	Superfund Amendments and Reauthorization Act (1986)—a federal law that reauthorizes and expands the jurisdiction of CERCLA and designates requirements mandated in Title III of SARA for public disclosure of chemical information and the development of emergency response plans.
TSCA	Toxic Substances Control Act (1976)—a federal law that authorizes EPA to gather information on new and existing chemical risks to human health and the environment.
UST	Underground Storage Tanks—regulated by RCRA, Subtitle I, these are tanks with 10 or more percent of their volume underground, used to store CERCLA-regulated hazardous chemicals or petroleum products.
DOT	The United States Department of Transportation (DOT)—established by an act of Congress in 1966. Among other responsibilities, DOT is responsible for oversight of transportation of hazardous and other materials.

can produce substantial amounts of waste material that may be emulsified or dissolved in water. A spill of a hazardous liquid or solid chemical cargo, as a result of a railway, truck, ship, or pipeline accident, may contaminate soil and/or nearby bodies of water and create a public hazard and another waste disposal problem. This is particularly true of incidents occurring in remote areas where trained personnel may not be readily available to assess the potential hazard to the public and the environment and provide guidance in controlling the hazard.

Storage Sources

Warehouse inventory control sometimes necessitates that unmarketable or undesirable materials be occasionally discarded. Tanks must be cleaned as storage needs change. The washing of transfer lines and tanks results in a waste product.

Materials may inadvertently be released in plants, such as when packages are damaged by forklifts, requiring cleanup and disposal. Water, fire, or explosion damage can also result in substantial amounts of waste material.

Other Sources

Several other human activities produce waste. Harvesting of agricultural products, mining operations, and demolition of structures are examples of operations that generate large quantities of waste products with various characteristics.

CHARACTERIZATION OF WASTE

Safe handling, collection, and disposal of hazardous waste can be accomplished only if the physical, chemical, and hazardous

properties of its components are known and that information is properly applied. Often the composition is not known because the waste is a mixture of many components with differing properties. This section discusses the physical, chemical, and hazardous properties that might influence the selection of response procedures to accidental releases and the appropriate disposal techniques for wastes.

Physical State

The ease of handling and disposal of waste is highly dependent on its physical state.

Solid Waste. Solid waste includes most domestic, commercial, and industrial trash, metal, wood, plastic scrap, chemicals, and food (see Figure 7.5.2). It also includes agricultural waste products, demolition waste, spent ore from mining operations, combustible metal waste (e.g., magnesium shavings), and semisolids, such as waxes, soaps, and elastomers.

Liquid Waste. Liquid waste includes aqueous and nonaqueous solutions and suspensions generally produced as a result of cleaning operations. Nonaqueous solvents might be flammable (e.g., toluene and xylene) or noncombustible (e.g., trichlorethylene). Viscous liquids, such as pastes and tars, and suspensions, such as acid sludges, require special handling procedures and equipment.

Gaseous Waste. Most gaseous waste is generated from industrial operations and is disposed of by venting into the atmosphere. Hazardous gaseous-waste products may be regulated by the EPA. They are controlled by heating, flitering, scrubbing, recovery, or destruction of the hazardous components by other means. Of particular concern to fire-fighting and other response personnel are unidentifiable gas cylinders with walls that might have become weakened due to age and corrosion. Discarded small butane and LP-gas cylinders in household trash can also pose an explosion hazard to trash collectors and compactors, and to operators of shredding equipment.

Properties of Hazardous Waste

Few discarded materials are so compatible with the environment or so inert as to have no short-term or long-term impact. Hazards that appear minor can have unexpected impacts long after disposal. When two or more hazards pertain to a material, the lesser might not receive the necessary consideration. Mixing two discarded substances can result in a chemical reaction with severe and unexpected consequences.

Since waste is generally a mixture of many components, its physical and chemical properties usually cannot be defined with any degree of accuracy. Whenever possible, the approximate composition of a hazardous waste should be obtained from the originating source or from the manifest accompanying the waste being transported. Generally, when one component predominates, the physical and chemical properties of the waste mixture are nearly those of the major component. This is not true for the hazardous properties of waste mixtures consisting of a relatively harmless major component and small amounts of highly toxic, radioactive, or etiologically active components. The hazard, in this case, is determined by the smaller components.

Hazardous Solid Waste

The EPA defines hazardous solid waste as that which might "(i) cause, or significantly contribute to, an increase in mortality or an increase in serious irreversible, or incapacitating reversible, illness; or (ii) pose a substantial present or potential hazard to human health or the environment when it is improperly treated, stored, transported, disposed of, or otherwise managed." The determining characteristic of a hazardous solid waste must be "measurable by an available standardized test method . . . or reasonably detectable by generators of solid waste through their knowledge of their waste."[4]

Basically, EPA standards require that a solid waste be treated as hazardous if it is a listed waste and/or if it meets the ignitability, corrosivity, reactivity, and/or toxicity characteristics prescribed by the standard. Highlights of the standard are given below.[5]

Ignitability. A solid waste exhibits this characteristic if a representative sample of the waste has any of the following properties:

1. It is a liquid and has a closed-cup flashpoint less than 140°F (60°C) (Class I and Class II liquids, excluding wine and latex paint, as defined in NFPA 30, *Flammable and Combustible Liquids Code*), as determined by an approved test method.
2. It is not a liquid and is capable under standard temperature and pressure of causing fire through friction, absorption of moisture, or spontaneous chemical changes and, when ignited, burns so vigorously and persistently that it creates a hazard.
3. It is a flammable compressed gas as defined by another federal standard.[6] A flammable compressed gas is defined as one that forms flammable mixtures with air at concentrations less than 13 percent (by volume) or has a flammability range with air which is wider than 12 percent regardless of the lower flammable limit (LFL). The standard specifies additional criteria for defining flammable vapors and aerosols.
4. It is an oxidizer, such as a chlorate, permanganate, inorganic peroxide, or a nitrate, that yields oxygen readily to stimulate the combustion of organic matter.[7]

Corrosivity. A solid waste exhibits this characteristic if a representative sample of the waste has either of the following properties:

1. It is aqueous and has a pH of less than or equal to 2 (i.e., highly acidic) or greater than or equal to 12.5 (i.e., highly alkaline, or basic).
2. It is a liquid and corrodes steel at a rate greater than ¼ in. (6.35 mm) per year at a test temperature of 130°F (55°C).

Reactivity. A solid waste exhibits this characteristic if it behaves in any of the following ways:

1. It is normally unstable and readily undergoes violent change without detonating.
2. It reacts violently with water.
3. It forms potentially explosive mixtures with water.
4. When mixed with water, it generates toxic gases, vapors, or fumes in a quantity sufficient to present a danger to human health or the environment.
5. It is a cyanide-bearing or sulfide-bearing waste that, when exposed to pH conditions between 2 and 12.5, can generate toxic gases, vapors, or fumes in a quantity sufficient to present a danger to human health and the environment.
6. It is capable of detonation or explosive reaction if it is subjected to a strong initiating source or if heated under confinement.
7. It is readily capable of detonation or explosive decomposition or reaction at standard temperature and pressure.
8. It is a known forbidden or a Class A or B explosive.

Toxicity. The EPA defines toxic wastes as those that have been found to be fatal to humans in low doses or, in the absence of data on human toxicity, it has been shown in studies to have an oral LD_{50} toxicity (rat) of less than 50 mg/kg, an inhalation LC_{50} toxicity (rat) of less than 2 mg/L, or a dermal LD_{50} toxicity (rabbit) of less than 200 mg/kg or is otherwise capable of causing or significantly contributing to an increase in serious irreversible, or incapacitating reversible, illness. A toxic waste is also one that contains or degrades into a listed toxic material in large enough concentrations to pose a potential hazard to the public and/or the environment. The standard for toxicity provides descriptions of laboratory tests for extracting and analyzing the potentially toxic components of wastes.

Hazardous Medical Waste

During the summer of 1988, a number of incidents were reported where medical waste, such as blood vials and bags, syringes, pill bottles, and bandages, washed ashore at various public Atlantic coast beaches. The publicity associated with these incidents and others involving the disposal of medical waste in dumpsters hastened the promulgation of the Medical Waste Tracking Act of 1988. The law required EPA to develop a two-year demonstration "cradle-to-grave" tracking system for four participating states. This law has since expired. Individual states have developed their own environmental standards in which they define what constitutes hazardous medical waste and identify acceptable disposal methods. Further, the Occupational Safety and Health Administration (OSHA) has promulgated a standard[8] for the protection of employees against exposure to bloodborne pathogens. The Department of Transportation (DOT) has also developed standards for the proper packaging and shipment of hazardous medical waste.[9]

Medical waste is generated during the diagnosis, treatment, or immunization of human beings or animals; in medical research; and in the production or testing of regulated biologicals. It is generated at facilities such as hospitals, health care centers, nursing homes, funeral homes, blood banks, veterinary clinics, and medical-research laboratories.

Medical waste is a likely source of pathogens (infectious agents). Some of the diseases that can be transmitted through improper disposal and handling of infectious medical waste are acquired immune deficiency syndrome (AIDS), typhoid, cholera, dysentery, anthrax, salmonellosis, tuberculosis, and burcellosis. Development and implementation of a well-thought-out medical-waste management plan can reduce the risk of infection to staff, patients, and the general public.

Medical waste can be categorized as follows:

1. *Cultures and stocks.* Cultures and stocks of infectious agents and associated biologicals, including cultures from medical and pathological laboratories; cultures and stocks of infectious agents from research and industrial laboratories; wastes from the production of biologicals; discarded live and attenuated vaccines; and culture dishes and devices used to transfer, inoculate, and mix cultures.

2. *Pathological wastes.* Human pathological wastes, including tissues, organs, and body parts and body fluids that are removed during surgery, autopsy, or other medical procedures, and specimens of body fluids, and their containers.

3. *Human blood and blood products.* Liquid-waste human blood; products of blood; items saturated and/or dripping with human blood; items that were saturated and/or dripping with human blood that are now caked with dried human blood, including serum, plasma, and other blood components, and their containers, which were used or intended for use in either patient care, testing, and laboratory analysis, or the development of pharmaceuticals. Intravenous bags are included in this category.

4. *Sharps.* These are objects that have been used in animal or human patient care or treatment, or in medical, research, or industrial laboratories. They include hypodermic needles, syringes (with or without the attached needle), pasteur pipettes, scalpel blades, blood vials, needles with attached tubing, and culture dishes (regardless of presence of infectious agents). Also included are broken and unbroken glassware that came into contact with infectious agents, such as used slides and cover slips.

5. *Animal waste.* Contaminated animal carcasses, body parts, and bedding of animals that were known to have been exposed to infectious agents during research (including research in veterinary hospitals), production of biologicals, or testing of pharmaceuticals.

6. *Isolation waste.* Biological waste and discarded materials contaminated with blood, excretion, exudates, or secretions from humans who are isolated to protect others from certain highly communicable diseases, or isolated animals known to be infected with highly communicable diseases.

7. *Unused sharps.* Unused, discarded sharps, for example, hypodermic needles, suture needles, syringes, and scalpel blades.

COLLECTION, HANDLING, AND DISPOSAL OF WASTE

The safe disposal of hazardous waste introduces challenges for the facility generating the waste, the waste-transporter, the

disposal facility, and fire fighters and other response forces who might be called on to clean up an unintentional release. These issues arise because the contents of waste may usually not be well defined—perhaps even known. Waste is often a mixture of many components with differing hazardous properties. One component, for example, might be a flammable solvent and another a highly toxic pesticide. Disposing of the solvent by incineration might release the pesticide (or its toxic combustion products) to the atmosphere. Additional problems can arise during handling and storing waste products. Self-heating and ignition, corrosion of pipe and tank-wall materials, and reaction with other noncompatible wastes can cause major catastrophic events. Fire fighters can also be inadvertently exposed to a hazardous-waste material released as a result of an unrelated fire or an explosion to which they have responded.

Refuse recycling and the recovery of energy from waste streams have become economically more attractive as the costs of energy and raw materials increase. Otherwise, the disposal of waste can be achieved through a variety of techniques and processes, depending on the physical, chemical, and hazardous properties of the waste. These techniques range from improvements in operations that reduce the quantity of waste produced, reduce the concentration of hazardous components to acceptable levels, or eliminate the hazardous component entirely.

Treatment of Gaseous Waste

Industrial gaseous waste can be released in the atmosphere, provided that the concentrations of the contaminants meet allowable levels set by EPA and state agencies, the Clean Air Act, and applicable permits. Table 7.5.2 summarizes the primary ambient air quality standards set by EPA for typical contaminants. Also shown are contaminant background levels in nature.

Gaseous waste streams can be purified by removing undesirable components or by reducing their concentrations to acceptable levels. This can be achieved by chemical conversion, absorption, adsorption, particulate removal, or thermal destruction.[10]

TABLE 7.5.2 Ambient Air Quality Standards[11,12]

Contaminant	*Background Level*	*EPA Primary Level*	*Allowable Exposure*
SO_2	<0.002 ppm	0.03 ppm	AAM
		0.14 ppm	Max. 24-hr conc., N
CO	0.03 ppm	9 ppm	8-hr AC, N
		35 ppm	1-hr AC, N
O_3	0.01–0.05 ppm	0.12 ppm	1-hr AC, N
NO_2	4 ppb	53 ppb	AAM
Particulates (PM_{10})	10–60 μg/m^3	150 μg/m^3	24-hr AC
		50 μg/m^3	AAM

Note: AAM = annual arithmetic mean, AC = average concentration, hr = hour, and N = not to exceed once per calendar year.

Chemical Conversion. An undesirable component can be allowed to react chemically with other compounds to form a harmless component or one that is removed easily. Sulfur dioxide, for example, is removed by reaction with lime or magnesia. Catalytic converters and other thermal oxidizers are used to convert nitrogen oxides and hydrocarbons into nitrogen, CO_2, and H_2O.

Absorption. Several gaseous pollutants can be removed by absorption. Ammonia and hydrogen chloride, for example, can be removed by water scrubbing. Sulfur dioxide can be absorbed in an alkaline solution.

Adsorption. Certain solids with a large pore-surface area selectively adsorb small concentrations of specific gases. Activated carbon, silica or alumina gel, fuller's earth and other clays are typical adsorbents. The operator is left with the problem of disposing of the contaminated adsorbent or the concentrated stream of undesirable gas released on adsorbent regeneration.

Particulate Removal. Many industrial gaseous streams contain undesirable dusts, mist, or smoke. These suspensions can be removed by filtration, sedimentation, centrifugal separation, electrostatic precipitation, and wet scrubbing.

Thermal Destruction. Many gaseous components can be destroyed or converted to less hazardous components, using the proper combination of elevated temperature and residence time.

Liquid Waste Treatment

In many cases volume and strength of industrial aqueous waste can be reduced by various process modifications. Although the hazard is not completely eliminated, a smaller volume of contaminated water or a stream with a lower concentration of a hazardous component is usually easier to handle and dispose of. Neutralization of acidic or alkaline waste can be achieved by chemical reaction with the appropriate compounds. Inorganic salts can be removed by precipitation, ion exchange, and adsorption by carbon beds. Holding ponds may be used to retain industrial waste so that it can be disposed of with domestic waste at a constant rate rather than overloading the sewage disposal system at any one time of the day.

Suspended solids can be separated by such processes as sedimentation (allowing heavy particles to sink to the bottom), flotation (skimming floating materials off the surface), drying followed by incineration, centrifuging, and filtration. Colloidal solids are more difficult to remove because their particle size range falls between that of suspended and dissolved solids. Colloidal solids will not settle unless chemicals are added that help coagulate the solid into larger masses that will sink. Many toxic pesticides, insecticides, and herbicides can be removed by adsorption in certain clays and carbons.

Many food-processing operations, as well as textile making and papermaking processes, produce waste that is high in organic matter. Biological degradation is generally achieved by

lagooning, treatment with biologically activated sludge, using trickling filters, wet combustion, deep-well injection, and other methods.

Wastewater from tanneries, slaughterhouses, and canneries might contain etiologic agents. These waters must be sterilized by processes such as chlorination, ozonization, or ultraviolet radiation before they are discharged into public water supplies.

Organic liquid waste components can be recovered by fractional distillation. The remaining components may be disposed of by incineration or burial in environmentally acceptable locations.

Disposal and Recovery of Solid Waste

Figiure 7.5.2 shows that a large fraction of domestic, commercial, and industrial solid waste is combustible. Burning scrap and refuse under controlled conditions is a common method of disposal. Municipal incinerators operated primarily for domestic and commercial trash will usually accept industrial refuse as long as it does not introduce additional hazards or operating problems.

Recovery of glass and metal from these wastes and the use of the recovered energy from the combustible component has become economically attractive. The basic steps involved in these recovery operations are waste collection, transportation to the disposal site, storage, shredding, separation and recovery of glass and metal, burning of the combustible component, and ash removal (Figure 7.5.3).

Air-pollution-control equipment is commonly needed on industrial incinerators. The choice of environmental control devices depends on the composition of the stack effluent. Such devices include the following:

- Afterburners to ignite combustible particles
- Cyclones to remove larger particles
- Low-energy scrubbers to remove larger particulates
- High-energy venturi scrubbers to remove fine particulates and/or water-soluble acid gases
- Electrostatic precipitators to remove fine particulates and mists
- Fabric filters (bag houses) to remove fine particulates

Principal hazards of operating an incinerator are the following:

- Overheating due to feeding a large amount of volatiles
- Overheating due to an increase in the heat of combustion
- Structural failure due to overheating and/or corrosion
- Corrosion of scrubber due to acid
- Failure of scrubber system

Compacted trash on transportation vehicles can cause fires. Ignition sources might be smoldering ashes from fireplaces or unextinguished cigarettes. Shredding operations can also have occasional explosions and fires, sometimes as a result of discarded explosive materials. Small butane and LP-gas cylinders and gasoline containers with some fuel remaining in them can be the source of the flammable vapor. The ignition sources are frictional sparks between the grinding or shredding teeth, the walls of the shredder, and other solid components of the refuse.

Another approach for recovering the heating content of combustible waste is by pyrolysis. When polymers and organic materials are heated, they yield oils and other recoverable compounds. Although pyrolysis has not yet been widely adopted, it has promise as a conservation measure. A retort is charged with selected scrap and then heated to cause decomposition and distillation of the volatiles and oils. The process is somewhat similar to a coke oven, and similar operating hazards should be expected (Figure 7.5.4).

Much of the nonhazardous domestic, commercial, and industrial waste today is disposed of in sanitary landfills. In a landfill operation, discarded material is mixed with earth and then compacted in a wide trench or other depression. Layer upon layer of mixture is added and then a layer of earth is spread and compacted on top. This process helps control odors, rodents, and scavenger birds.

Successful decomposition of landfilled materials depends heavily on biological activity within the fill material. There is a tendency for methane gas to be generated during biological activity. There can be fires and explosions in buildings constructed over old landfills due to the buildup of biologically generated methane into the building and its eventual ignition. The recovery and use as fuel of natural gas from waste landfills occurs in parts of the United States.

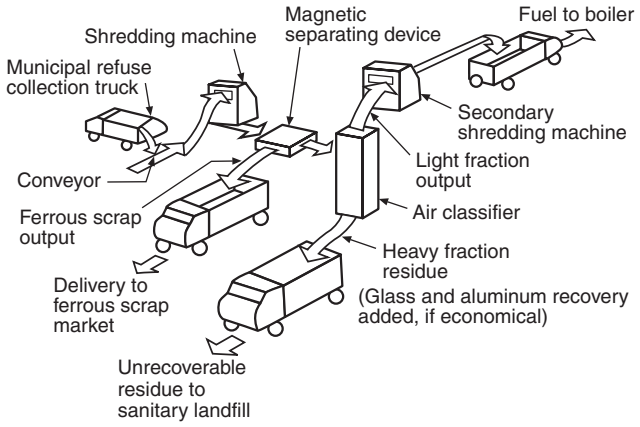

FIGURE 7.5.3 Typical Refuse Recovery Process

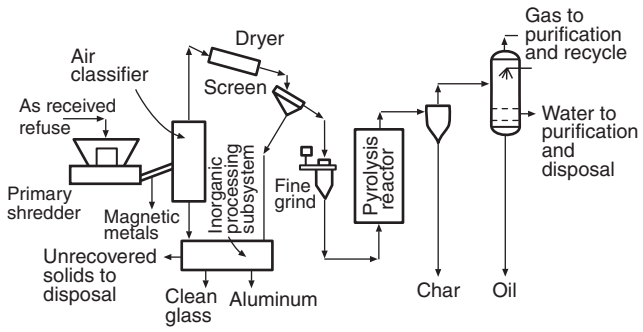

FIGURE 7.5.4 Pyrolysis Recovery System

Hazardous wastes must not be disposed of in a sanitary landfill. They must be either chemically treated or incinerated in properly designed furnaces that ensure the complete degradation of the hazardous components of the waste. Otherwise, they may be disposed of in secure landfills. These are properly designed and engineered containment facilities that ensure that no waste seeps into the underground water system to pollute natural bodies of water or the public water supply system. Transporting the hazardous waste from the source to the disposal site requires special permits. Waste must be packaged or containerized in approved containers. A manifest describing the contents, and their hazards must accompany the shipment. The operator of the secure landfill generally requires a chemical analysis of the hazardous waste so that it may be handled and sited properly.

Treatment of Hazardous Medical Waste

State standards differ governing the packaging, segregation, and identification of hazardous medical waste. These standards generally require reporting, recordkeeping, and tracking of medical waste. The standards apply to waste generators, transporters, on-site incineration facilities, and off-site treatment, destruction, and disposal facilities.

Noninfectious medical waste generated at any medical facility typically constitutes most of the total medical waste. To reduce disposal costs, the noninfectious waste is commonly segregated from infectious medical waste at the source. This reduces the potential for cross-contamination and allows disposal at sanitary waste-disposal sites without further treatment. Segregation at the source also reduces the volume of medical waste that needs to be treated before disposal.

A standard operating procedure (SOP) should be developed by all facilities that store, handle, transport, or dispose of infectious waste.[13] Unsightly pathological waste should be placed in opaque plastic bags. All containers and bags should be red and labeled with the word "infectious" and/or with the international biohazard symbol (Figure 7.5.5). Wastes that are to be transported should be double-bagged and placed in a semirigid container to prevent leakage. Wastes should be loaded and unloaded manually and never compacted, to prevent compromising the integrity of the packaging. These wastes should be arranged chronologically to meet state regulations for storage periods. All storage facilities should have limited access with the entrances marked by the international biohazard symbol and the word "infectious."

FIGURE 7.5.5 International Biohazard Symbol

Infectious medical waste must be treated and rendered harmless prior to disposal at a sanitary waste disposal site. Several treatment methods are available, including the following methods:

- Steam sterilization
- Incineration
- Thermal inactivation (dry heat sterilization)
- Gas/vapor sterilization
- Sterilization by irradiation
- Chemical disinfection

Steam sterilization is the most commonly used method for destroying pathogens in medical waste. It is preferred for contaminated solid surfaces such as sharps and low-density waste, which are easily penetrated by steam. Incineration is the preferred method for treating AIDS-contaminated and combustible infectious waste. Proper incineration of waste reduces the volume that needs to be disposed of by up to 95 percent and renders the waste harmless. Like steam sterilization, thermal inactivation is used for the sterilization of contaminated surgical instruments and equipment. Dry heat has the advantage of not corroding instruments, thereby increasing their life.

Although the remaining three methods can be used to treat medical waste, they tend to be more costly and require special precautions to protect the operator. Gas/vapor sterilization, for example, requires the use of ethylene oxide or formaldehyde, both of which are highly flammable and hazardous to human health. Irradiation with ultraviolet (UV) and gamma radiation is a more recently developed technology that is used for presterilization of medical products and can be used to treat waste water. Chemical disinfection is carried out by applying hydrogen peroxide, acids, or alcohols to exposed surfaces, utensils, and medical supplies.

To ensure the effectiveness of any treatment, it is important that an SOP be established for each waste stream to be treated. Each SOP should address the type of waste, variations in the waste stream, and the limitations of the treatment apparatus. The SOP must also specify procedures for biologically monitoring and testing of the treated waste to ensure that it is no longer hazardous.

Protection of Hazardous Waste Operators

OSHA standard "29 CFR 1910.120: Hazardous Waste Operations and Emergency Response" protects workers involved in hazardous-waste operations, and in responding to accidental releases of hazardous materials and wastes. This regulation[14] requires the following:

1. The development and implementation of a written safety and health program for employees (and subcontractors' employees) who are involved in hazardous-waste operations. The program must be designed to identify, evaluate, and control safety and health hazards, and provide for emergency response for hazardous-waste operations.
2. Hazardous-waste-site characterization, analysis, and control in order to identify specific site hazards, determine appropriate safety and health control procedures, and implement these procedures to control employee exposure to the identified hazards

3. Extensive training and retraining of employees before they are permitted to engage in hazardous-waste operations and informational programs to ensure that employees and subcontractors are aware of the degree and nature of safety and health hazards specific to the work site
4. Medical surveillance of employees exposed to (or potentially exposed to) hazardous substances or health hazards and of employees who wear respirators
5. Implementation of engineering controls, work practices, and personal protective equipment and the continuous monitoring of the work area to ensure that employees are not exposed to levels that exceed permissible exposure limits for hazardous substances at the site
6. Development of a written emergency-response plan to handle anticipated emergencies prior to beginning of hazardous-waste operations
7. Additional requirements for the development and implementation of decontamination and materials-handling procedures and ensuring the presence of adequate illumination and sanitation facilities at the work site and that proper excavation procedures are followed

HAZARD PREVENTION AND CONTROL

Prevention Measures

The probability of exposure to hazardous waste can be reduced through preventive actions achieved through pre-incident planning, proper waste-handling, and storage-handling procedures. Preventive measures include the following:

1. Segregating chemically incompatible wastes, for example, by ensuring that combustible waste is separated from self-heating or oxidizing materials
2. Disposing of hazardous waste promptly so that large quantities are not allowed to accumulate at any one time
3. Storing combustible waste piles away from buildings, roadways, and ignition sources
4. Maintaining flammable and corrosive liquid wastes in approved metal containers
5. Inspecting hazardous-waste containers regularly to ensure their integrity
6. Properly identifying and marking waste containers. The hazards associated with each waste should be shown clearly on the exterior of each container, storage tank, transport vehicle, or building
7. Training personnel in proper waste-handling procedures, use of personal protective equipment, and emergency response measures to an accidental release of hazardous waste. Training should include drills simulating a variety of credible release scenarios

Emergency Response Planning

A fire department should coordinate and preplan its approach to the handling of hazardous-waste emergencies with all waste-generating industries or disposal facilities within its jurisdiction. The fire department should be aware of the types, quantities, and hazards of raw materials, products, and wastes stored at each plant site and those that are transported to and from the plant. The fire department should ensure the availability to its personnel of any necessary specialized handling equipment and materials, detection devices, and personal protective equipment.

In preparing fire-response plans, fire fighters should recognize that water used to control or extinguish fires at chemical plants or warehouses where hazardous materials are stored will itself likely become contaminated with these materials and may become a hazardous waste. If the contaminated water is allowed to reach natural bodies of water, such as through the rain-water drainage system, the hazard will spread outside the plant and may endanger the public and the environment. A good example of such an event is the fire that occurred in November 1986 at a warehouse for agricultural chemicals located along the Rhine River in Basel, Switzerland. The contaminated water resulted in a massive fish kill and a water-pollution problem that spread all the way to Germany and Holland.

It is very important that the fire department, together with plant personnel, predetermine the locations of storm-water drains and sewers and the general layout and slope of the land on which the plant is built. Plant personnel should invite fire department representatives for regular facility tours. Precautions must then be built into the emergency-response plan to ensure that fire-fighting water will not pollute natural water bodies or drinking-water supplies.

Response Procedures

The potential severity of an incident involving the release of a hazardous waste can be reduced through response measures developed and tested under realistic drill conditions. In the absence of emergency plans, or when the waste components are unknown, it should be assumed that an industrial waste could present any hazard and to treat it as an extreme hazard until more reliable information becomes available. In general, response procedures include the following:

1. Wearing full protective clothing and breathing apparatus
2. Using the appropriate detection devices to check for the flammability, toxicity, or radioactivity of the released waste or its products of combustion
3. Stemming the flow of the waste at the source
4. Diking the area around a liquid spill to limit its spread to sewage lines and drains and to reduce the vapor release rate
5. Staying upwind when vapors or fumes are being generated
6. Controlling ignition sources
7. Evacuating people who are downwind

The decision to extinguish burning waste should be made only after a full assessment of the consequences. Questions to be considered include the following:

1. Is the extinguishing agent to be used compatible with the waste?
2. Are sealed drums or containers of flammable liquids or compressed gases in danger of exposure to the fire?
3. Are there radioactive, explosive, or oxidizing materials in the burning waste or near the fire?

4. Will extinguishment exacerbate the problem by allowing flammable or toxic vapors to be released once the fire is extinguished?
5. Will the use of water result in a severe pollution problem?

SPECIFIC WASTES

Combustible Refuse

Highly combustible refuse, such as dry waste paper, excelsior, and so on, should be collected in metal containers and not allowed to accumulate in large quantities. Quantity storage of these materials should be separated from buildings, roadways, and ignition sources by a distance of 50 ft (15 m) or more. Transport to an incinerator, recycler, or landfill on a frequent schedule will minimize the fire hazard.

Drying Oils

Rags or paper that have absorbed drying-type oils, such as linseed oil or turpentine, are subject to spontaneous heating. To prevent fires they should be kept in well-covered metal cans and thoroughly dried before collection or transport.

Flammable Liquids and Waste Solvents

Waste solvents have variable flashpoints, depending on composition. Some contain solids, tars, waxes, and other materials that impede flow. Chlorinated solvents and water might also be present.

Common methods of disposal for these wastes are (1) incineration, (2) recycling, and (3) fuel blending. If a contractor is used, the approximate composition of the waste must be provided. Some contractors are able to recover reusable materials through distillation or other processes. Reuse of these materials reduces the demand for virgin materials and can help to protect the environment.

Locations having substantial amounts of waste solvent may choose to install their own solvent-recovery system or incinerator. For an incinerator, an auxiliary gas or oil burner is needed to maintain adequate destruction temperature. Usually a scrubber section is used to remove acid gases and other pollutants. See NFPA 82, *Standard on Incinerators and Waste and Linen Handling Systems and Equipment,* for further information on industrial incinerator installations.

Polychlorinated Biphenyls (PCBs)

PCBs were manufactured and used in a variety of electrical and mechanical applications from the early 1930s until regulated by the Toxic Substances Control Act in 1976. They had been extensively used as a dielectric fluid in capacitors and transformers and as a lubricant in compressors and other machinery. They continue to be used today, but only in enclosed systems.

PCBs can cause temporary skin irritations and nervous-system abnormalities in humans and are suspected carcinogens. Improper combustion of PCB-containing material can produce highly toxic and carcinogenic products.

Extreme care must be taken in handling PCBs and fires involving PCBs. Waste PCBs from old electrical equipment must be disposed of by incineration at an approved site, buried in an approved secure landfill, or other approved method.

Liquid and Solid Oxidizing Materials

Spilled oxidizing materials and leaking or broken containers should be immediately removed to a safe area to await disposal in conformance with applicable regulations and manufacturers' instructions (see NFPA 430, *Code for the Storage of Liquid and Solid Oxidizers*). Most, if not all, oxidizers can be rendered harmless by dilution with water.

Combustible and Reactive Metals

Small scraps of sodium from laboratory use can be dissolved in ethyl alcohol (not isopropyl alcohol) and the resulting alkoxide neutralized with acid. Large quantities may be offered to a vendor for purification and recycling. Oil-contaminated dispersions or other moderate quantities can be burned in dry pans if provision is made to control the oxide fumes, which are highly alkaline. Disposal of sodium by throwing it directly into water is spectacular but extremely hazardous and will contaminate the water with sodium hydroxide. Equipment contaminated with small amounts of sodium may be cleaned by a remotely controlled introduction of water or steam. Potassium, sodium-potassium alloy (NaK), and lithium are handled in the same manner as sodium. Lithium reacts somewhat less violently with water.

It is usually feasible to reclaim magnesium fines and scrap in the form of defective castings, clippings, and coarse chips. If this is to be done, either locally or through a smelting firm, the scrap should be thoroughly dried before remelting. Scrap in the form of fine chips and dust-collector sludge can be disposed of in a specially constructed incinerator or by burning in a safely located outdoor area paved with fire-brick or hard-burned paving brick. By spreading the scrap or sludge in a layer about 4 in. (102 mm) thick, on which ordinary combustible material is placed and ignited, the combustion of magnesium can be safely conducted. Another method of deactivating magnesium sludge is to treat it with a 0.5 percent solution of ferrous chloride. Since hydrogen is generated by this reaction, this method of disposal is conducted in an open container in an outdoor location where the hydrogen can safely dissipate. (See NFPA 484, *Standard for Combustible Metals.*)

Spontaneous combustion of titanium has occurred in fines, chips, and swarf that were coated with water-soluble oil. Disposal containers should be tightly closed and segregated so that if spontaneous burning occurs it will not involve other materials. Incineration in the open, as for magnesium scrap, might be feasible (see NFPA 484).

Whereas small amounts of zirconium fines can be mixed with sand or other inert material and buried, incineration of this combustible metal is generally preferred for larger quantities. Because of the spontaneous ignition potential, personnel carrying scrap should wear flame-protective clothing and equipment and carry the scrap in buckets on a yoke between them. A layer can be ignited with excelsior (see NFPA 484).

Lithium hydride and lithium aluminum hydride can ignite on contact with water or moist air. Alkaline oxides resulting from incineration can be collected and neutralized.

Radioactive Waste

Radioactive waste is generated at nuclear power plants in the form of spent fuel and contaminated instruments, equipment, piping, and other objects such as clothing, gloves, and cleaning rags. Other sources include nuclear physics research laboratories and tailings from uranium mines.

Recent advances in the use of radioactive materials in medical diagnostics and therapy has led to an increase in the sources of radioactive medical waste. Radioactive isotopes of iodine, cesium, iridium, phosphorus, and gallium are widely used in hospitals and laboratories for diagnostics and patient treatments. Contaminated vials, containers, and capsules are growing in quantity. All radioactively contaminated materials must be properly disposed of.

The packaging of all radioactive waste, including radioactive medical waste, is regulated by the Nuclear Regulatory Commission (NRC) and DOT regulates transportation of all radioactive waste. The EPA has developed standards for protecting the public against exposure to nuclear-reactor wastes in general and for the proper storage and disposal of such waste. The specific requirements vary greatly and depend on the type of radioactive waste that is generated.

For most installations, a contractor licensed to dispose of radioactive materials can be employed. (See NFPA 801, *Standard for Fire Protection for Facilities Handling Radioactive Materials.*) Radioactive materials that are flammable or combustible must be handled with particular care. Combustible radioactive wastes should not be allowed to accumulate. Storage of such wastes near an air intake is particularly undesirable. If the products of combustion of waste materials containing long-lived radioactive materials are dispersed through air-conditioning or compressed-air systems, extensive decontamination might become necessary.

Liquid radioactive waste can be concentrated and retained until the radioactivity has decayed to a safe level. Combustible radioactive waste, such as absorbent paper used to wipe contaminated surfaces, should be placed in approved containers for disposal.

The treatment of radioactive medical wastes is less extensive than that for other medical wastes. For radioactive medical waste with a half-life of less than 65 days, the waste may be stored in a secure area for a minimum period of 10 half-lives and discarded as sanitary wastes. Most "spent" or used nuclear fuel is currently being stored in specially designed deep pools of water at nuclear reactor sites.[15] Some radioactive military waste is being stored at federal reservations aboveground in heavy, thick-walled metal or concrete structures. All of these storage facilities are temporary. In 1982 the Office of Civilian Radioactive Waste Management was charged by Congress to develop a mined geologic repository for the disposal of these wastes. Although there is movement to prepare the Yucca Mountain, Nevada, site to receive and store spent nuclear reactor fuel, as of 2006, no permanent site had been established.

Oil Spills on Water

Using booms is effective in containing spills of oil and other floating liquids on relatively calm and current-free waters. Makeshift designs of booms are relatively ineffective, but commercially available booms designed for the hydrodynamics and aerodynamics involved in the confinement of spills on water can be quite effective. Because of ecological considerations, this has become an important means of containing an oil spill and more effective equipment continues to be developed.

Following the confinement of spills on water, various ways of removing the confined liquid are used, including skimming devices or absorbents. Absorbents, such as straw, plastics, sawdust, peat moss, and commercially available products have been spread on the surface of the spill and then collected and disposed of on shore. Skimming devices operate on several principles, including pumps and separators. Power boats with skimmers on the bow can scoop up oil and water, sending it through an oil separator and rollers to which oil adheres. The oil is then removed by scraping or compression.

Sinking agents to which oil adheres and sinks to the bottom have been used in the past. Several proprietary sinking agents have been developed, but such products as carbonized sand, brick dust, crushed clinkers, and cement also have been used. However, sinking agents are objectionable because they contribute to water pollution and should not be used, except possibly in the ocean far from land.

Regardless of whether a spill occurs on land or on water, pre-incident planning is imperative. Planning should include prompt notification of all appropriate local, state, or federal agencies dealing with water pollution.

Underground Storage Tanks

Before implementing more restrictive requirements EPA estimated there were more than two million underground-storage-tank (UST) systems in the United States located at more than 700,000 operating facilities nationwide.[16] Today EPA estimates that number has been greatly reduced by removal of existing tanks. In addition, there are numerous retired-in-place tanks. Although most of these tanks are (or were) used for the storage of motor and other fuels, many are (or were) used for the storage of other hazardous chemicals.

Liquid leaks from underground tanks can readily find their way to groundwater. Leaking petroleum products also contaminate the soil and the air. Their vapors can accumulate in confined spaces, such as septic tanks, sewers, and building basements. The vapors are hazardous to human health. If ignited, they can result in a fire or an explosion.

To protect the public and the environment against leaks from USTs, the federal government extended and strengthened the provisions of the Solid Waste Disposal Act as amended by RCRA. Subtitle I of RCRA regulates USTs containing "regulated substances" and releases of these substances to the environment.

Subtitle I defined a UST as a tank system, including its piping, that has at least 10 percent of its volume underground. Regulated substances include those defined as hazardous under CERCLA as well as petroleum products. This standard requires USTs installed after 1988 to be built to certain specifications, certified, equipped with overfill protection and detection systems, and, if made of steel, protected against corrosion. By 1998, all existing USTs had to have corrosion protection for steel tanks and piping, and devices to prevent overfilling.

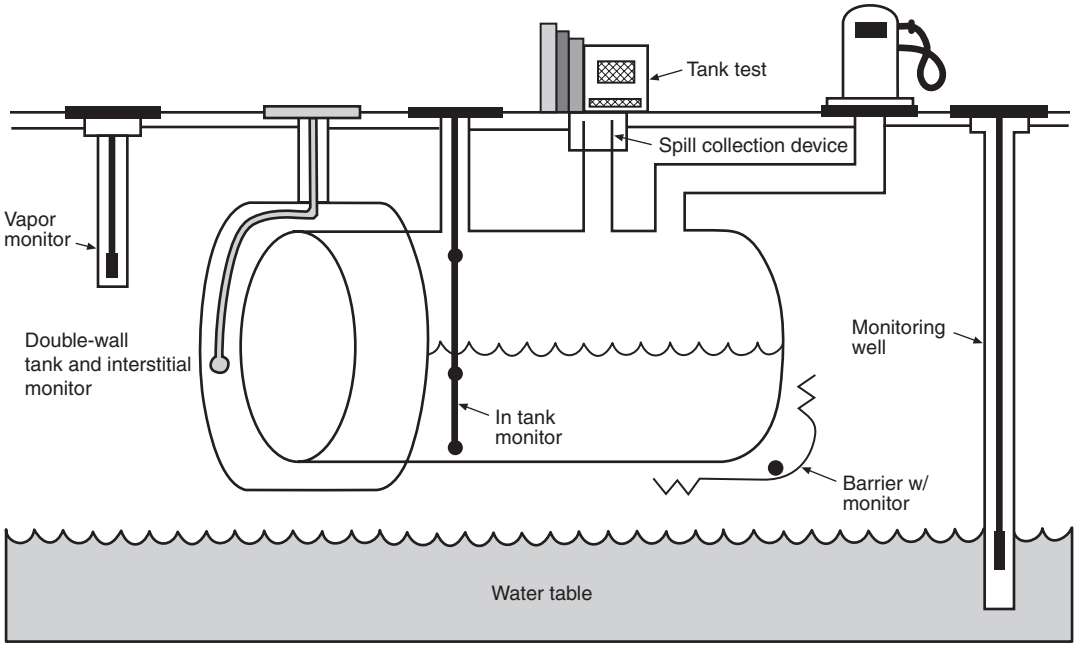

FIGURE 7.5.6 UST Leak Detection Alternatives

Existing tanks must also be tested for leaks in accordance with a schedule determined by their age[17] (Figure 7.5.6).

USTs must have at least one (or a combination) of the following leak monitoring methods:[18]

- Automatic tank gauging
- Monitoring for vapor in the soil
- Interstitial monitoring between the inner and outer walls of the tank (double wall)
- Monitoring for the presence of contaminants in groundwater

SUMMARY

Waste is a by-product of many human activities. The source of the waste—whether domestic, commercial, industrial, transportation, or storage—determines its composition, its degree of hazard, and how it should be safely handled and disposed of. An emphasis today is placed on reducing the amount of waste generated, as well as reusing or recycling the waste material. These options should be attempted before deciding to dispose of the waste.

A large fraction of solid waste, including most domestic, commercial, and industrial trash, is combustible, with an ever increasing amount being recovered. Most nonhazardous solid waste is discarded in sanitary landfills, although a substantial amount is burned for fuel. Hazardous solid waste, however, must be chemically treated, incinerated in properly designed furnaces, or disposed of in secure landfills. Liquid waste, which includes aqueous and nonaqueous solutions and suspensions, can sometimes be reduced by various process modifications (e.g., neutralization, sedimentation, adsorption, distillation, reformulation), depending on the nature of the material. Gaseous waste can be purified through chemical conversion, absorption, adsorption, particulate removal, or incineration.

Standards regarding hazardous medical waste generally require the reporting, record keeping, and tracking of this special category of waste. Prevention and control of hazardous waste include taking preventive measures such as following proper waste- and storage-handling procedures and having a rehearsed written emergency response plan and proper equipment in place, should a release occur.

Special Equipment

L. Jeffrey Mattern

8.1 Air-Moving Equipment
8.2 Chemical Processing Equipment
8.3 Materials-Handling Equipment
8.4 Automated Equipment
8.5 Lasers
8.6 Protection of Electronic Equipment
8.7 Heat Transfer Systems and Fluids
8.8 Industrial and Commercial Heat Utilization Equipment
8.9 Oil Quenching and Molten Salt Baths
8.10 Stationary Combustion Engines and Fuel Cells
8.11 Fluid Power Systems
8.12 Refrigeration Systems
8.13 Electrical Systems and Appliances

Continuity of business operations are extremely important in a competitive environment. Unnecessary fires negatively affect a corporate business plan. This section reviews the hazards, prevention, and suppression concepts for equipment commonly associated with industrial operations, with additional, but more limited, coverage of other occupancy classifications. Many fires in industry occur due to inadequate fire prevention and control for specialized equipment. This section strives to identify basic design, fire prevention, and fire control concepts which will help prevent and mitigate fires. Approximately half of the section concentrates on a particular manufacturing or commercial process, and half focuses on the hazards of a specific manufacturing operation.

Chapter 1, "Air-Moving Equipment"; Chapter 3, "Materials-Handling Equipment"; Chapter 7, "Heat Transfer Systems and Fluids"; Chapter 10, "Stationary Combustion Engines and Fuel Cells"; Chapter 11, "Fluid Power Systems"; Chapter 12, "Refrigeration Systems"; and Chapter 13, "Electrical Systems and Appliances," are all chapters covering equipment or operations that support manufacturing or commercial processes. Each chapter details the nature of the operation and the associated hazards along with the fundamental fire prevention and fire control concepts.

Additional chapters in this section, including Chapter 2, "Chemical Processing Equipment"; Chapter 4, "Automated Equipment"; Chapter 5, "Lasers"; Chapter 6, "Protection of Electronic Equipment"; Chapter 8, "Industrial and Commercial Heat Utilization Equipment"; and Chapter 9, "Oil Quenching and Molten Salt Baths," deal with specific manufacturing operations. These chapters emphasize the hazards associated with these processes and how to prevent or mitigate a significant fire.

L. Jeffrey Mattern is retired from FM Global in Philadelphia, where his most recent positions were senior account engineer and chief engineer of mid-Atlantic operations. He has served on various NFPA technical committees and the NFPA Standards Council since 1968.

Chapter 1

Air-Moving Equipment

Jane I. Lataille

Chapter Contents

Components of Air-Moving Systems
Hazards of Specific Uses
Fire Protection

Key Terms

air-moving device (AMD), collecting equipment, duct, duct system, dust collection system, exhaust system, gas, mist, particulate, restaurant-type cooking equipment, separating equipment, smoke control, smoke management, vapor, vapor (corrosive), vapor (flammable), ventilation, venting

Many industrial and commercial operations require the removal of airborne materials that are generated by normal processes. These materials could include vapors, gases, and particulate solids. Some facilities also require emergency smoke control or smoke management systems. Properly designed air-moving equipment can serve either of these purposes. These air-moving systems are in addition to the normal building systems for heating, ventilating, and air conditioning. NFPA 90A, *Standard for the Installation of Air-Conditioning and Ventilating Systems,* covers those systems. Also see Section 10, Chapter 4, "Air-Conditioning and Ventilating Systems," and Table 8.1.1.

Air-moving equipment for use during normal operations is addressed in NFPA 91, *Standard for Exhaust Systems for Air Conveying of Vapors, Gases, Mists, and Noncombustible Particulate Solids,* and NFPA 654, *Standard for the Prevention of Fire and Dust Explosions from the Manufacturing, Processing, and Handling of Combustible Particulate Solids.* NFPA 91 covers air-moving equipment for vapors, gases, mists, and noncombustible particulate solids and includes the following:

- Specifies that concentration of combustible vapors not exceed 25 percent LEL
- Contains requirements for duct construction and clearance
- Identifies where fire dampers must be provided
- Describes protection by special extinguishing systems with provision of adequate drainage for system discharge
- Requires inspection, testing, and maintenance of the air-moving system and its protective features

NFPA 654 covers air-moving equipment for combustible particulate solids. It contains applicable material from NFPA 650, which has been withdrawn, and includes guidance on preventing fires and explosions in this equipment.

Other codes and standards also apply to air-moving equipment for specific materials or operations (Table 8.1.2).

NFPA 92A, *Standard for Smoke-Control Systems Utilizing Barriers and Pressure Differences,* covers smoke control systems; NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria, and Large Spaces,* covers smoke management systems for large spaces; and NFPA 204, *Standard for Smoke and Heat Venting,* covers heat and smoke venting.

Air-moving systems play an important role in fire protection. If the materials they remove were allowed to accumulate, the result could be an explosion from vapor-air mixtures, a flash fire due to accumulations of lint or other combustibles, and generally poor housekeeping conditions conducive to fires in general.

Additional information about hazards of air-moving equipment can be found in Section 6, Chapter 1, "Fire Hazards of Materials"; Section 8, Chapter 2, "Chemical Processing Equipment"; Section 8, Chapter 8, "Industrial and Commercial Heat Utilization Equipment"; Section 9, Chapter 1, "Woodworking Facilities and Processes"; Section 9, Chapter 5, "Metalworking Processes"; Section 10, Chapter 4, "Air-Conditioning and Ventilating Systems"; Section 10, Chapter 5, "Ventilation of Commercial Cooking Operations"; and Section 11, Chapter 5, "Control of Electrostatic Ignition Sources."

Jane I. Lataille, P.E., ARM, has over 30 years experience working in fire protection and loss prevention.

COMPONENTS OF AIR-MOVING SYSTEMS

Air-moving equipment includes all mechanical-draft duct systems, of both the pressure and exhaust types, for removal of dusts, vapors, and waste material, and for the conveying of materials. The hazards of such systems lie in the possibility of igniting flammable materials or vapors by sources such as sparks generated by fans or foreign material, for example, tramp metal, or by overheated fan bearings. Also, such systems could inadvertently spread fires through the building. Tables 8.1.3 through 8.1.10 describe patterns of fires originating in ducts, separating homes from other structures. Note that many fires originate not in materials being conveyed into or through ducts, but rather in elements that are installed in or near ducts, such as insulation, wiring or cables, and structural members. Note also the role of torch operations in starting fires in ducts.

Air-moving systems usually contain axial flow fans or centrifugal blowers; several different designs of each kind are available (Figure 8.1.1). A straight-blade centrifugal fan is suitable for exhausting materials containing large particles, because it resists clogging and the blades can withstand considerable abra-

TABLE 8.1.3 Structure Fires Other Than Homes Originating in Duct as Area of Origin, by Item First Ignited, 1999–2003 Annual Average

Item First Ignited	*Fires*	*Percentage*
Dust, fiber, or lint	280	25
Electrical wire or cable insulation	140	13
Unclassified item first ignited	140	13
Cooking materials	70	6
Rubbish, trash, or waste	60	6
Insulation within structural area	60	5
Flammable or combustible liquid or gas	30	3
Structural member or framing	30	3
Pipe, duct, conduit, or hose	20	2
Agricultural crop, including fruits and vegetables	20	2
Conveyor belt, drive belt, or V-belt	20	2
Multiple items first ignited	20	2
Filter, including evaporative cooler pads	20	2
Exterior roof covering	20	2
Interior ceiling covering	20	2
Unclassified structural component or finish	20	2
Other known item first ignited	160	14
Total	1130	100

Notes: These are national estimates of fires reported to U.S. municipal fire departments, excluding fires reported as confined fires, and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Fires are estimated to the nearest ten and reflect a proportional share of fires with unknown or unreported area of origin and duct fires with equipment involved in ignition unknown or unreported.

Source: NFIRS and NFPA survey.

TABLE 8.1.4 Home Structure Fires Originating in Duct as Area of Origin, by Item First Ignited, 1999–2003 Annual Average

Item First Ignited	*Fires*	*Percentage*
Electrical wire or cable insulation	170	20
Structural member or framing	120	14
Dust, fiber, or lint	110	13
Unclassified item first ignited	70	8
Insulation within structural area	60	7
Exterior wall covering or finish	30	3
Appliance housing or casing	30	3
Rubbish, trash, or waste	20	3
Flammable or combustible liquid or gas	20	3
Unclassified structural component or finish	20	3
Interior wall covering excluding drapes	20	3
Pipe, duct, conduit, or hose	20	2
Other known item first ignited	170	20
Total	860	100

Notes: These are national estimates of fires reported to U.S. municipal fire departments, excluding fires reported as confined fires, and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Fires are estimated to the nearest ten and reflect a proportional share of fires with unknown or unreported area of origin and duct fires with item first ignited unknown or unreported.

Source: NFIRS and NFPA survey.

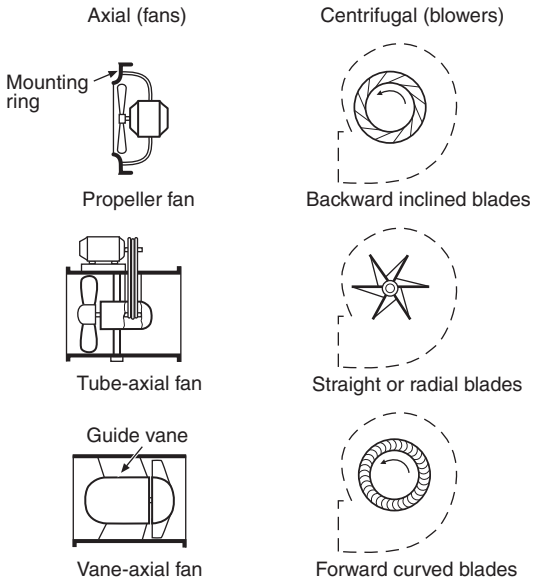

FIGURE 8.1.1 Fan and Blower Designs Suitable for Use in Exhaust Systems

sion. Propeller fans will move large volumes of air, but only against small resistance. Because these fans could not operate efficiently against the friction a duct would introduce, they are not suitable for ducts of any appreciable length.

TABLE 8.1.5 Structure Fires Other Than Homes Originating in Duct as Area of Origin, Excluding Fires Where Item First Ignited Is Organic or General Material, by Type of Material First Ignited, 1999–2003 Annual Average

Type of Material First Ignited	*Fires*	*Percentage*
Unclassified type of material	80	18
Plastic	50	10
Sawn wood	40	9
Cotton, wool, or rayon fabric or fiber	40	9
Unclassified wood or paper	20	5
Paper	20	4
Cooking oil or transformer or lubricating oil	20	4
Fiberboard, particleboard, or hardboard	20	4
Multiple types of material	20	4
Plywood	10	3
Wood chips, sawdust, or shavings	10	3
Fat, grease, butter, margarine, or lard	10	2
Unclassified fabric, textile, or fur	10	2
Natural gas	10	2
Other known type of material	100	22
Total	470	100

Notes: These are national estimates of fires reported to U.S. municipal fire departments, excluding fires reported as confined fires, and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Fires are estimated to the nearest ten and reflect a proportional share of fires with unknown or unreported area of origin and duct fires with the indicated items first ignited that have type of material first ignited unknown or unreported. Beginning in 1999, type of material first ignited is not required when item first ignited is organic material (e.g., cooking materials) or general material (e.g., electrical wire or cable insulation; papers; dust, fiber or lint; rubbish, trash or waste); these items first ignited are excluded from the calculations.

To reduce the hazard of fire, fans should be (1) of noncombustible construction, (2) able to be shut down by remote control in case of fire, (3) accessible for maintenance, and (4) structurally sound enough to resist wear and overcome distortion and misalignment caused by structural weakness or overloading. Fans used for heat and smoke venting should be able to withstand temperatures of 932°F (500°C) for 4 hours. Construction materials for all fans must be appropriate for the intended use. A spark caused by a blade hitting the housing, due to distortion or misalignment, could result in ignition when the exhaust contains flammable solids or vapors. This possibility of friction sparks is minimized if the fan and fan housing are of nonsparking material. Aluminum and magnesium alloys are not compatible with ferrous alloys, which can rust.

Components of smoke control and smoke management systems have additional requirements, including the following:

- Reliability of power source(s) under fire conditions
- Arrangement of power feeds to remain in service when facility power is shut down
- Integrity of controls and wiring under fire conditions

TABLE 8.1.6 Home Structure Fires Originating in Duct as Area of Origin, Excluding Fires Where Item First Ignited Is Organic or General Material, by Type of Material First Ignited, 1999–2003 Annual Average

Type of Material First Ignited	*Fires*	*Percentage*
Sawn wood	140	28
Unclassified type of material	70	14
Plastic	50	11
Cotton, wool, or rayon fabric or fiber	40	7
Unclassified wood or paper	30	6
Plywood	30	5
Multiple types of material	20	5
Fiberboard, particleboard, or hardboard	20	4
Natural gas	20	3
Kerosene or No. 1 or 2 fuel oil	10	2
Paper	10	2
Other known type of material	60	12
Total	490	100

Notes: These are national estimates of fires reported to U.S. municipal fire departments, excluding fires reported as confined fires, and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Fires are estimated to the nearest ten and reflect a proportional share of fires with unknown or unreported area of origin and duct fires with the indicated items first ignited that have type of material first ignited unknown or unreported. Beginning in 1999, type of material first ignited is not required when item first ignited is organic material (e.g., cooking materials) or general material (e.g., electrical wire or cable insulation; papers; dust, fiber or lint; rubbish, trash or waste); these items first ignited are excluded from the calculations.

- Equipment materials and construction that will withstand fire conditions
- Supervision of condition/status of system
- Ability to handle expected pressure differentials

Design of smoke control and smoke management systems depends on the occupancy and layout of the facility, whether air pressure or airflow is used to control smoke movement, and whether the system is dedicated or nondedicated.

HAZARDS OF SPECIFIC USES

Ventilation of Flammable Vapors

Because flammable vapors ignite easily, precautions must be taken to eliminate ignition sources in ducts that carry them. Using a single system to exhaust flammable vapors and particles from spark-producing processes is obviously dangerous. Similarly, drawing different vapors that individually may not be flammable, but that may be hazardous as a mixture in a single exhaust system, is extremely poor practice. For example, perchloric acid acts as an oxidizing agent at elevated temperatures. If perchloric acid vapors were drawn into a system exhausting organic materials, the combination could cause a fire or explosion.

It is important that vapors be withdrawn from the rooms or equipment in which they are generated and taken directly to the outside of the building or to suitably protected pollution-control equipment. Processes generating flammable vapors are best located along an outside wall of the building to facilitate efficient vapor removal.

When flammable vapors cannot readily be picked up at a specific source, general ventilation through a system of suction ducts with inlets to the room or area may be used. Because suction inlets have minimal directional effect beyond a few inches (1 in. equals 25.4 mm) from the face of the inlet, they should be located so that they produce a sweeping or purging effect that will eliminate pockets in which vapors may accumulate. A makeup air supply, properly located in relation to the point where vapors are generated, and openings for exhaust ducts will aid in the dilution and removal of vapors. The ventilation system should provide sufficient air movement to maintain the vapor concentration below 25 percent of the lower flammable limit (LFL) in the area where vapors are being liberated. If vapors are toxic, it may be necessary to maintain concentrations well below those required for flammability.

NFPA 86, *Standard for Ovens and Furnaces,* gives procedures for calculating the volume of air per minute necessary to dilute flammable vapors below their LFL.

National estimates are projections. Fires are estimated to the nearest ten and reflect a proportional share of fires with unknown or unreported area of origin and duct fires with heat source unknown or unreported.

Source: NFIRS and NFPA survey.

Where heavier-than-air vapors or mixtures are handled, exhaust openings located near the floor line are generally the most effective. Conversely, for vapors or mixtures lighter than air, exhaust openings located near the top of the room, hood, or enclosure are the most effective. Adjusting the vapor density is necessary for unusual temperatures and pressures.

Fans. All fans should be suitable for moving vapors and air. If the vapor contains a material that could condense and build up on the fan blades, this possibility should be minimized by selecting a fan with backward curved blades. Both the fan and the fan housing should be of nonferrous construction. The construction material chosen should not be adversely affected by the vapors handled.

Ducts. Ducts for systems handling flammable vapors need to be structurally capable of withstanding some fire exposure. Where vapors can condense, continuously welded joints in the ducts will prevent leakage.

Because flash fires or explosions can occur in ducts, ductwork should be installed away from combustibles, but where it will be readily accessible. Ducts should never be concealed in a wall or ceiling. Duct systems that exhaust flammable materials should terminate outside in an area where the vapors cannot be ignited and where they will not form deposits, such as overspray residue, on the building or other structures. An enclosure is sometimes used around the discharge end of a duct to prevent deposits on exposed property. These enclosures should be sprinklered.

Frequent cleaning of ducts, filters, and any enclosures will minimize both the intensity of a fire in a duct system and any spontaneous heating of deposits subject to this phenomenon.

Electrical Equipment. All equipment that may be exposed to flammable vapors should comply with NFPA 70, *National Electrical Code*®, for such hazardous locations.

Ventilation of Corrosive Vapors and Fumes

The degree of expected corrosion is the governing factor in the construction of ducts exhausting corrosive vapors. In some cases, a heavier-gauge metal is used, and in others, protective coatings may be sufficient. Occasionally, however, the corrosiveness is so extreme that a special lining is required. Stainless steel has been used very successfully in some cases.

Plastic duct systems are also used, but only if the corrosive vapors are nonflammable and the plastic has a flame-spread rating of 25 or less and a smoke-developed rating of 50 or less, when tested in accordance with NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials.*

Source: NFIRS and NFPA survey.

Automatic fire protection is necessary in the ducts and also at the hood, canopy, or intake to plastic duct systems. Figures 8.1.2 and 8.1.3 show typical exhaust systems.

Ventilation of Restaurant-Type Cooking Equipment

Exhaust systems for restaurant equipment require careful design, because grease condenses in the interior of the ducts. Grease accumulations may be ignited by sparks from the cooking appliance or by a small fire on the cooking appliance caused by overheated cooking oil or fat in a deep-fat fryer or on a grill. If the duct did not have a grease accumulation, cooking appliance fires could often be extinguished before causing appreciable damage. Fire risk is especially high in frying because cooking oils and fats are heated nearly to their flashpoints. Thus, fats and oils can reach their self-ignition temperatures by being inadvertently overheated or by being ignited when spilled on a cooking appliance. Details of a typical kitchen range exhaust system are shown in Figure 8.1.4. The duct riser shown in Figure 8.1.4 should either be outside or be enclosed in an approved fireproof material.

Fans. Fans should be selected according to their ability to exhaust the required quantity of air against all calculated friction losses.

Ducts. The following should be considered when designing a duct system for commercial cooking equipment:

- The system should be designed to minimize grease accumulations, with a minimum air velocity of 1500 ft/min (458 m/min) through any duct.
- Ducts should be arranged with ample clearance from combustible materials to minimize the danger of ignition, in case of fire in the duct.
- Ducts of substantial construction (not lighter than No. 16 Manufacturers Standard Gauge steel or No. 18 Manufacturers Standard Gauge stainless steel) should be used with all seams and joints having a liquid-tight, continuous weld.
- Systems should be separated to ensure there is no connection with any other ventilating or exhaust system.
- Ducts should be led directly outside the building, without dips or traps, unless automatic grease removers are employed at the dips and traps.
- Openings should be provided for inspection and cleaning. Dampers should not be installed in any duct system, unless required as part of a grease extractor or extinguishing system.

Grease-Removal Devices. All kitchen exhaust systems require a means for removing grease. These may be grease extractors, grease filters, or other grease-removal devices, such as water-wash systems and special fans designed to remove grease vapors effectively and provide a fire barrier. Grease filters should be listed for use in commercial cooking operations. Mesh filters should not be used.

Electrical Equipment. Manual control of the fan motor should be provided near the motor and also near the hood. In addition, it is desirable to have automatic shutdown of the motor by a heat-sensitive device in the hood close to the outlet.

All electrical equipment that may be exposed to vapors, grease, or heat should be installed in accordance with NFPA 70 requirements for those conditions. Fixtures should not be installed in ducts or hoods used for removal of cooking smoke or grease-laden vapors or located in the path of travel of such exhaust products, unless they are specifically designed and tested for such use. Electrical equipment may be placed outside the path of vapor travel by locating it on the outside of the hood with illumination through tight-fitting glass panels in the hood.

Dust Collecting and Stock and Refuse Conveying Systems

These systems consist of suction ducts and inlets, air-moving equipment, feeders, discharge ducts and outlets, collecting equipment, vaults, and other receptacles designed to collect powdered, ground, or finely divided material.

Collecting and conveying systems are often a very important part of the operations of a plant. When the material they handle is a combustible dust, there is danger of a fire or explosion.

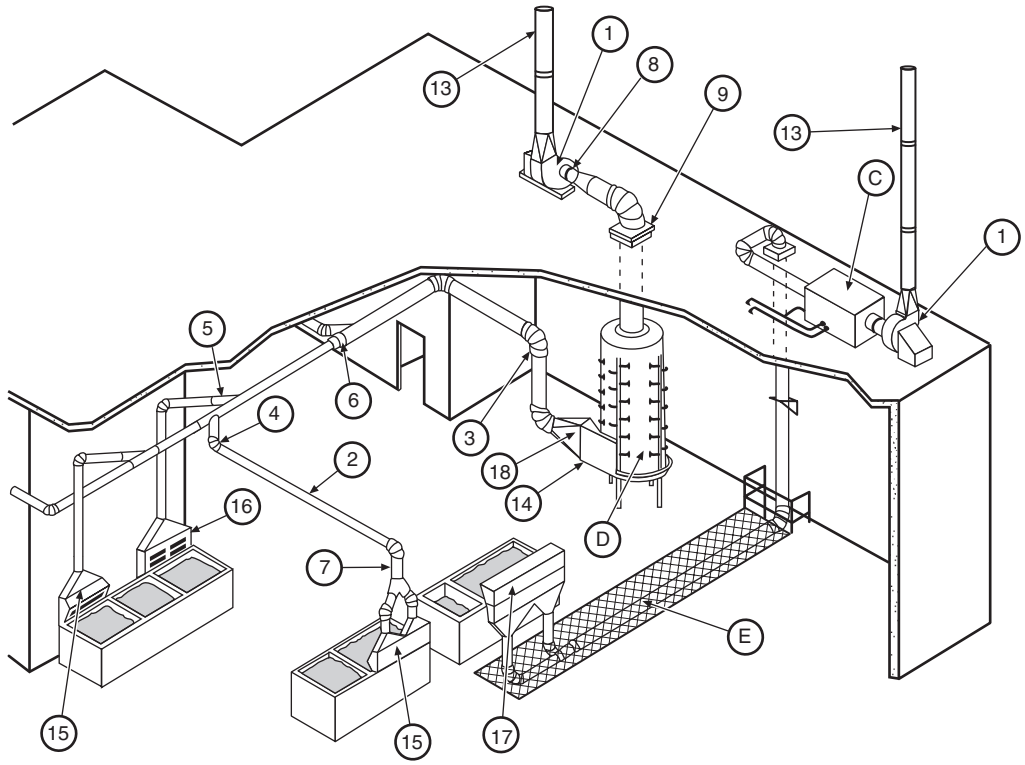

FIGURE 8.1.2 Industrial Exhaust System for Fume Hoods with Vertical Fume Scrubber and Service Trench

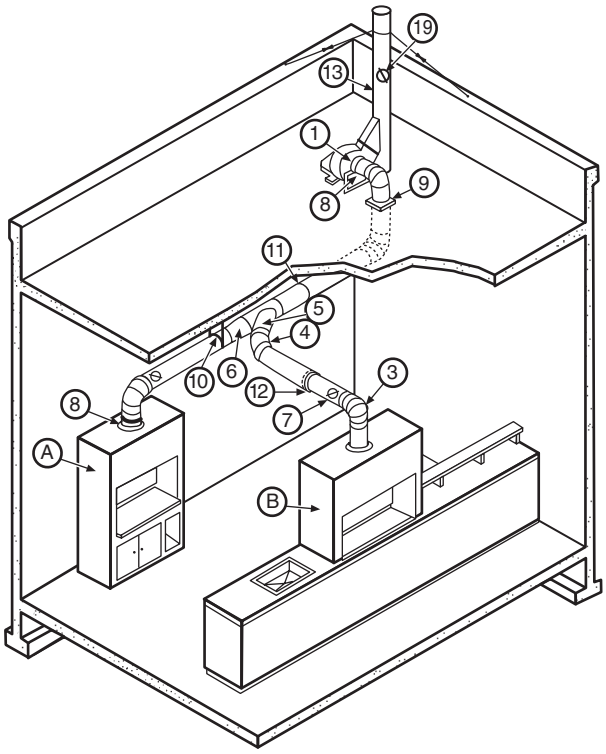

Nomenclature for Figures 8.1.2 and 8.1.3:

I. Equipment
- A. Cabinet-type fume hood
- B. Bench-type fume hood
- C. Horizontal-type fume scrubber
- D. Vertical-type fume scrubber
- E. Service pit or trench

II. System components
1. Air-moving equipment (centrifugal-type exhaust fan)
2. Horizontal duct section
3. 90-degree elbow
4. Elbow (less than 90 degrees)
5. Lateral entry
6. Transition
7. Manual balancing damper
8. Flexible connection
9. Counterflashing
10. Duct hanger
11. Circumferential girth joint (butt welded)
12. Bell end duct seam
13. Fan discharge stack
14. Flanged duct connection
15. Open-face tank exhaust hood (updraft)
16. Slotted-face tank exhaust hood (updraft)
17. Open-face tank exhaust hood (downdraft)
18. Round to rectangular (or square) transitional fitting
19. Gravity-operated backdraft damper

FIGURE 8.1.3 Laboratory Exhaust System for Cabinet-Type Fume Hoods and Bench-Type Fume Hoods

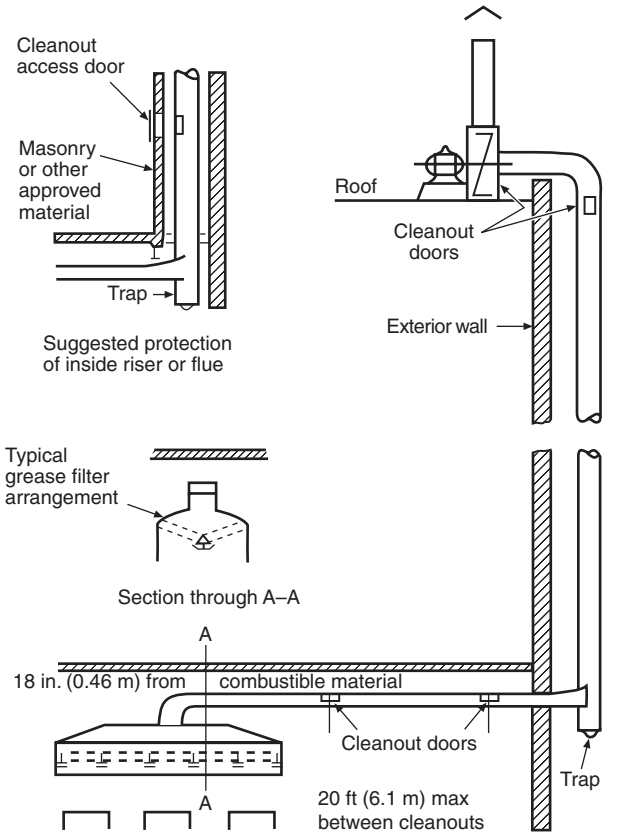

FIGURE 8.1.4 Typical Commercial Cooking Exhaust System for Building with Two Stories or More

These factors make it a prime necessity that the design, construction, and operation of the systems conform to recognized standards. The general recommendations given in the first part of this chapter should be observed, as should the following more specific ones.

Fans. Systems conveying combustible dust should be arranged so that the fan is on the clean air side of the collector, so that the system operates under suction, and dust collecting equipment removes the dust before the air stream reaches the fan. This arrangement prevents combustible dust from passing through the fan where it may be ignited. If such an arrangement is not possible and the fan must be located between the dust-producing equipment and the collector, the blades and spider of the fan and the fan housing should be made of nonsparking material, with ample clearance between the blades and the housing. Fan bearings and motors should be outside of casings unless the fan and motor assembly are designed and tested for use in the dust atmosphere present.

Ducts. For conveying dusts or stock, ducts should be constructed of metal. Changes in direction in the duct system should be made with long bends or elbows. This minimizes accumulations of solid particles at the turns.

Following are some general design techniques recommended for ducts conveying dusts and other solid materials:

- Every duct should be kept open and unobstructed throughout its length.
- Not more than two branches should connect to any section of the main suction duct.
- Branch ducts should be connected to the top or side of the main duct at an angle not exceeding 45 degrees, inclined in the direction of airflow.
- Main suction and discharge ducts should be as short as possible.
- Flexible duct sections should not restrict airflow and should be as short as possible.
- Systems handling combustible dusts should, as far as possible, be located outside of the building. Branch ducts from each floor should pass through the wall and discharge into the main duct outside.
- Additional branch ducts should not be added without redesigning the system. Disconnected or unused portions of the system should not be blanked off without providing orifice plates to maintain required airflow.

System design must incorporate adequate pickup and carrying velocities for the materials being conveyed. These velocities are achieved through appropriate fan and duct sizing and duct routing. Design information is contained in *ASHRAE Handbook—HVAC Applications* and in *ASHRAE Committee on Industrial Ventilation—Industrial Ventilation.*

Separating and Collecting Equipment

Separating equipment includes cyclones, condensers, wet-type collectors, cloth screen and stocking arresters, centrifugal collectors, and other devices used for the purpose of separating solid material from the airstream in which it is carried. Then the material is collected in hoppers, bins, silos, and vaults. See Figures 8.1.5 through 8.1.8 for typical examples of some of this equipment and how sprinklers may be used in some types.

Separating and collecting equipment is designed to withstand anticipated explosion pressures, allowance being made for deflagration relief vents. This equipment should be constructed of steel or enclosed in steel and located outside the building. To prevent the equipment from collapsing (which could result in an explosible dust cloud), equipment should be well supported on steel, masonry, or concrete. Equipment and discharge ducts should be well separated from combustible construction and unprotected openings into buildings.

Collectors that must be located indoors, and that cannot be constructed of sufficient strength to withstand anticipated explosion pressures, can be located in rooms near outside walls to facilitate deflagration venting.

Gravity feed through tightly fitted ducts is the best arrangement for delivering stock from separators, cyclones, or other collection equipment to storage receptacles. Delivery ducts from collection equipment should not convey refuse directly into the fireboxes of boilers, furnaces, refuse burners, or incinerators.

Where processes produce very fine dusts or where combustible metal dusts are handled, wet collectors provide efficient dust control. Dust is removed by passing the flow of air through a water curtain and is collected as a sludge sub-

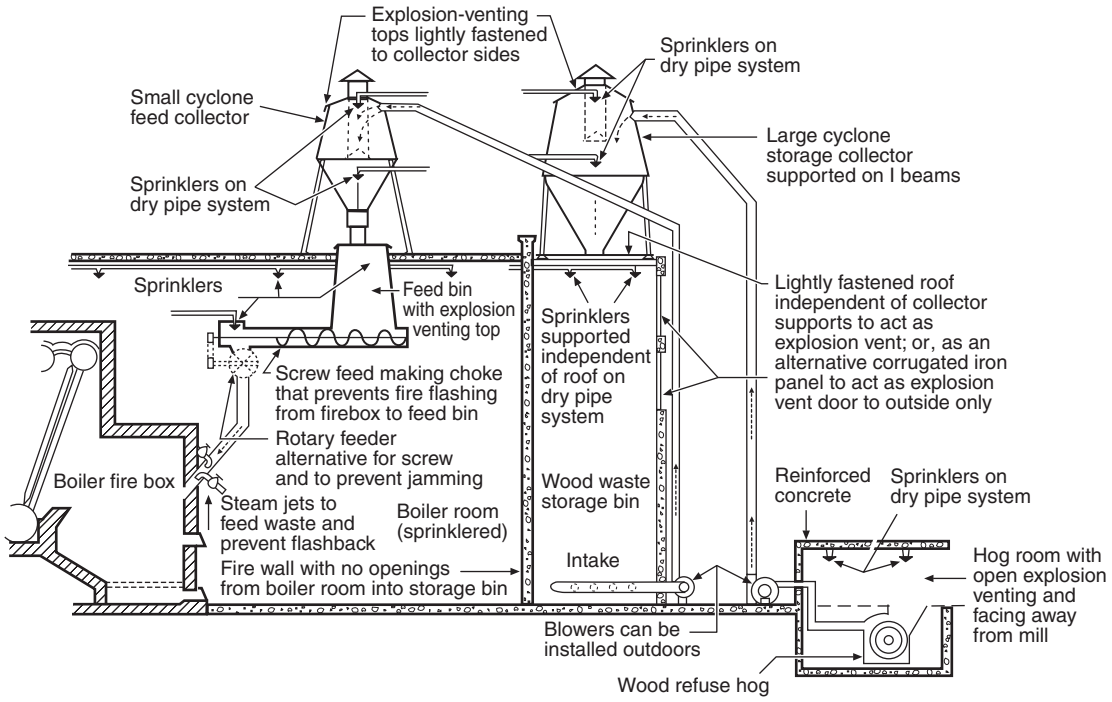

FIGURE 8.1.5 Suggested Arrangement for Wood Waste Firing of Boiler to Minimize Explosion and Fire Hazard

merged in water. Except where combustible metal dusts are collected, these wet collectors generally have no fire or explosion hazards.

Where refuse is to be used as fuel, the discharge system from the storage receptacle or intermediate feed bin to the furnace should be designed to prevent a flashback from the furnace. This may be accomplished by means of a choke feeder or choke conveyor so that a positive cutoff is provided. The installation of a steam spray in the duct to the furnace that blows steam in the direction of the fuel flow is recommended because it provides an added safety factor in preventing a flashback. See Figure 8.1.5 for a typical installation of this type.

The installation of screw conveyors or rotary feeds at appropriate points in stock or dust conveying systems has been used to good advantage in many plants by providing a "choke," which helps stop the spread of a flash fire. The installation of a deflagration vent also relieves the pressure of an explosion and prohibits its progress. This combination can prevent small fires or explosions from becoming large and disastrous.

High-Efficiency Air Filter Units. Particulate air filter units are used to remove very fine particulate matter, that is, to remove not less than 99.97 percent of 0.3-micron-diameter particles, from the air of industrial and laboratory exhaust systems.

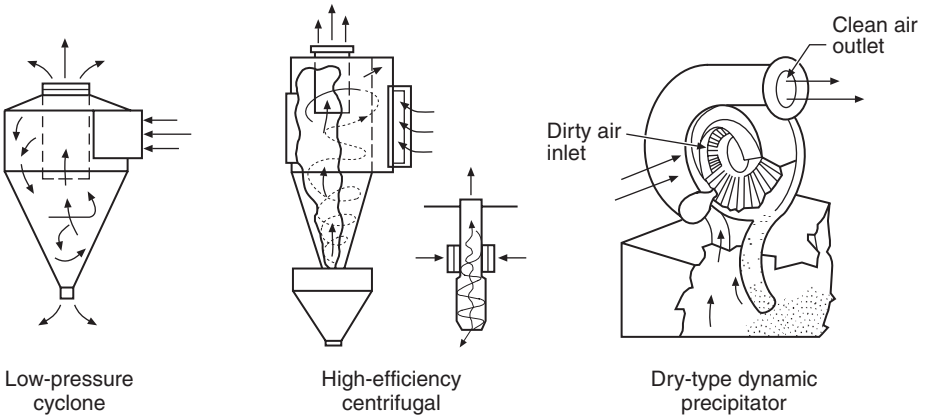

FIGURE 8.1.6 Typical Types of Dust Collecting Equipment

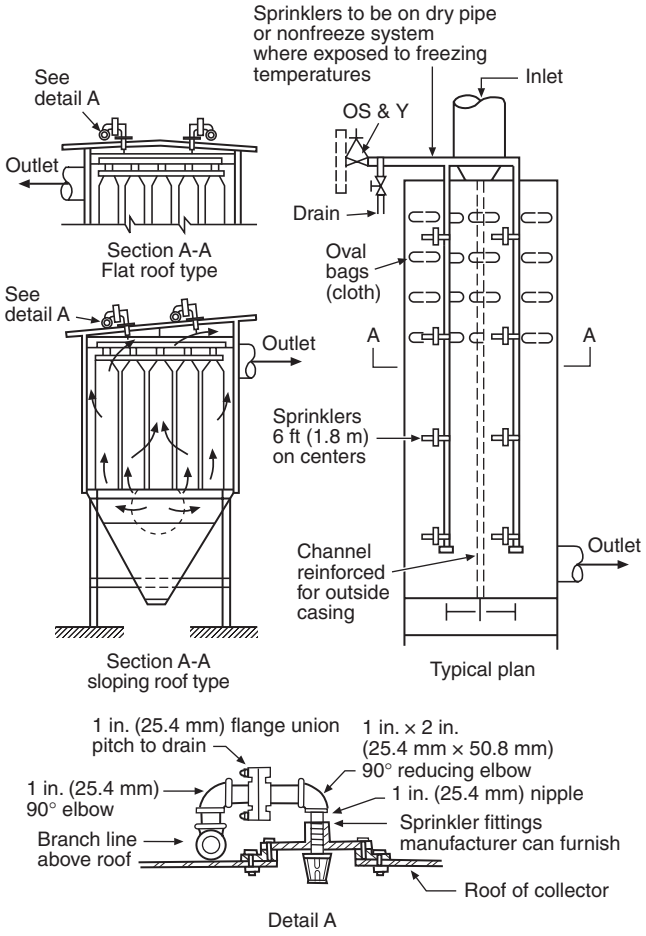

FIGURE 8.1.7 Typical Sprinkler Protection for a Bag-Type Dust Collector

These filters are commonly used in cleanrooms to keep air in the cleanroom pure. They are also used in equipment, such as glove boxes, to keep the air exhausting from the glove boxes pure (nonpolluting).

Glove Boxes. Glove boxes are used to perform operations involving hazardous materials, such as biological, toxic, and radioactive materials. The Nuclear Regulatory Commission (NRC) requires high-efficiency filters for filtering air exhausted from spaces where radioactive materials are handled. The filter units used are made of a filter medium of glass fiber, or equivalent inorganic material. Although the adhesive used is combustible, it contains a self-extinguishing additive. Fire of sufficient temperature and duration to melt glass fibers can damage the filter at points of contact, but will not stop the exhaust of filtered air through the undamaged area. The NRC regulations generally require large banks of these filters, limit the number of filters in a fire area, and require automatic sprinkler protection. DOE Standard 1066 and DOE Order 420.1A contain guidance for designing and protecting these glove boxes.

Battery Rooms

Battery banks often supply backup power for critical systems. Keeping these batteries charged can generate hydrogen gas. To keep hydrogen buildup from reaching dangerous levels, specially designed ventilation is provided for battery rooms. NFPA 111, *Standard on Stored Electrical Energy Emergency and Standby Power Systems,* provides guidance for these power backup systems.

FIRE PROTECTION

Fire Extinguishing Systems

Because of the combustibility either of the ducts themselves or of the material being transferred through them, the installation of automatic extinguishing systems is justified. The systems may be automatically or manually controlled and may use any of several appropriate extinguishing agents.

For example, if the material being transported is a flammable vapor or an easily ignited combustible dust, a deluge system actuated by heat-sensitive devices may be most appropriate. If the problem is the combustibility of the duct itself, an automatic sprinkler system may be adequate. In still other systems, a special extinguishing agent may be required or deemed more suitable. Sprinklers and discharge nozzles may have to be coated or covered to protect them from the environment inside the duct; they may have to be inspected on a regular basis and cleaned periodically to avoid serious buildup of deposits. Similarly, heat detectors or other types of detectors used to activate the extinguishing system may have to be periodically cleaned of deposits that might hamper their proper operation.

One important problem frequently overlooked is the obstruction of automatic sprinklers or other discharge nozzles by the ductwork. Care should be taken that ductwork does not seriously interfere with the discharge pattern. In many cases, additional sprinklers or nozzles will have to be extended down below the ductwork to provide satisfactory coverage. NFPA 13, *Standard for the Installation of Sprinkler Systems,* contains guidance for locating sprinkler heads near ducts so their water distribution pattern will not be obstructed.

Separating and Collecting Equipment. Cloth screen or bag-type dust collectors used for the collection of fine dusts present a special problem because of the use of a combustible fabric even where the dust is noncombustible. Automatic sprinkler protection may be needed where cloth dust collectors are important for continuity of production or where they provide exposure to other property. Figures 8.1.7 and 8.1.8 show typical layouts of sprinkler protection for cloth dust collectors.

Equipment of large volume, such as bins, or dust collectors in which pulverized stock is stored or may accumulate, should be protected by automatic sprinklers. Automatic carbon dioxide, dry chemical, or water spray extinguishing systems can be used effectively in dust collecting systems. Inert gas, such as nitrogen, may be effectively used to create safe atmospheres in conveying systems.

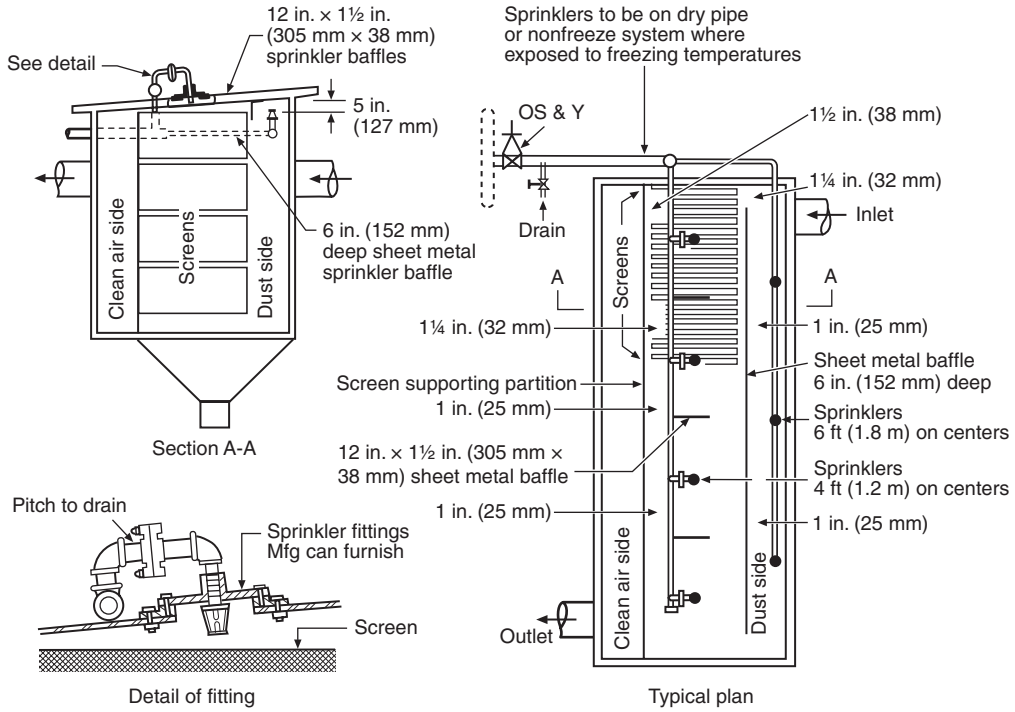

FIGURE 8.1.8 Typical Sprinkler Protection for a Screen-Type Dust Collector

Ventilation of Flammable Vapors. Fixed fire suppression systems suitable for the flammable material involved, as well as portable fire extinguishers, should be provided. The extinguishing agent should be water, foam, dry chemical, or CO_2 as appropriate for the hazard.

Ventilation of Kitchen Cooking Equipment. For cooking installations, this equipment may consist of fixed-pipe carbon dioxide, dry chemical, wet chemical, foam-water sprinkler, water spray, or sprinkler systems, supplemented by portable alkaline (sodium bicarbonate or potassium bicarbonate) dry-chemical extinguishers.

Acidic base extinguishing agents, such as ammonium-phosphate-based multipurpose types (ABC rated), impede saponification. Therefore, if the cooking equipment being protected involves exposed liquefied fat or oil in depth, such as deep-fat fryers, extinguishers employing these extinguishing agents are not recommended, as they may interfere with alkaline-based fixed systems.

Where fixed extinguishing systems are installed, they should (1) be located so that they easily can be manually activated from the path of egress; (2) be arranged for simultaneous automatic operation of all systems in a single hazard area, upon operation of any one system; and (3) automatically shut off all sources of fuel and heat to all equipment protected, upon operation of the system.

Portable Extinguishing Equipment

Portable fire extinguishers of appropriate type and small hose with spray nozzles are helpful where fires may occur in ducts. This is true even where fixed extinguishing systems have been provided. Judicious placement of extinguishers and hose lines with respect to location of access panels will make them more effective.

Magnetic Separators

As with flammable-vapor conveying systems, combustible-dust collecting systems should not be used with processes that may produce sparks. If there is a possibility of particles of ferrous materials ("tramp metal") entering the collecting systems, permanent magnetic separators should be installed at points where ferrous particles may enter. After collection, the dust passes into rooms or bins. These places of collection should be made of noncombustible construction and provided with deflagration vents terminating outside of the building.

Explosion Prevention and Deflagration Venting

When ignition sources are difficult to control, inerting may be used to create a safe atmosphere within the system, or an explosion suppression system or spark extinguishing system may be used. There are limits to these systems—inerting is generally practical for essentially closed systems, while explosion suppression is limited to those materials and enclosures that can be successfully protected. Efforts to suppress explosions in some materials, for example, metal dusts, have not been successful. Spark extinguishing systems are suitable for fibers and flyings.

Refer to NFPA 69, *Standard on Explosion Prevention Systems,* for additional information.

Deflagration relief vents prevent or minimize damage to duct systems that carry explosible mixtures. The vents should lead by the most direct practical route to the outside of the building. NFPA 68, *Standard on Explosion Protection by Deflagration Venting,* gives information on designing deflagration vents. The use of suppression and inerting systems is limited by the configuration of the equipment and the physical and chemical properties of the material being conveyed.

Control of Static Electricity

When flammable vapors, dusts, or other materials pass through a duct, static charges on the duct are generated. If a charge is allowed to accumulate on an electrically insulated portion of a duct system, it could discharge to an adjoining duct section, at a joint for example, and ignite the material being conveyed. For this reason, exhaust systems carrying flammable vapors, dusts, gases, or other materials should be electrically bonded and grounded. Methods of eliminating dangerous static charges are treated in detail in NFPA 77, *Recommended Practice on Static Electricity.*

Dampers

Whenever ducts penetrate rated walls, floors, or partitions, dampers with equivalent fire resistance ratings should be provided to preserve the integrity of the fire area. Dampers should also be used to prevent backdrafts in manifolded duct systems to keep undesirable vapors, dusts, or impurities from being sucked upstream of their collection point and being spread. Firestopping spool pieces are available for plastic ductwork. These pieces collapse when warm and block the duct, preventing fire spread.

Cleaning

Although clean ducts are essential in preventing fire spread, cleaning them may be neglected because it is difficult and unpleasant, and can be dangerous if flammable solvents are used. Satisfactory cleaning results have been obtained with a powder compound consisting of one part calcium hydroxide and two parts calcium carbonate. This compound saponifies the grease or oily sludge, thus making it easier to remove and clean. Proper ventilation must be provided and safety precautions taken if cleaning is done inside the duct or fan housings.

Spraying the duct interiors with hydrated lime after cleaning is a fire prevention method in commercial use. Though this tends to saponify the grease and may facilitate subsequent cleaning, it does not provide any permanent fire protection or flame resistance, for grease eventually coats the compound.

Filters

High-efficiency particulate air filter units (HEPA filters) should be UL 900 listed. Filters so listed will not contribute to any fire in a duct system. They will also reduce the chance of spreading contamination, such as toxic or radioactive contamination, to the environment.

SUMMARY

Air-moving equipment includes all mechanical draft systems for removing gases, vapors, and solid particulates from processes, and for conveying materials. The primary hazard associated with air-moving equipment is ignition of combustible or flammable materials in the equipment by sparks, overheated bearings, or outside heat sources.

Despite the hazards associated with air-moving equipment, this equipment is essential for removing combustible, flammable, and other hazardous materials from processes and buildings. As with providing sprinklers, providing fire protection features for air-moving equipment protects people, property, and the environment.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on air-moving equipment discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 13, *Standard for the Installation of Sprinkler Systems*
NFPA 33, *Standard for Spray Application Using Flammable or Combustible Materials*
NFPA 34, *Standard for Dipping and Coating Processes Using Flammable or Combustible Liquids*
NFPA 45, *Standard on Fire Protection for Laboratories Using Chemicals*
NFPA 61, *Standard for the Prevention of Fires and Dust Explosions in Agricultural and Food Processing Facilities*
NFPA 68, *Standard on Explosion Protection by Deflagration Venting*
NFPA 69, *Standard on Explosion Prevention Systems*
NFPA 70, *National Electrical Code®*
NFPA 77, *Recommended Practice on Static Electricity*

Chapter 2

Chemical Processing Equipment

Richard F. Schwab

Chapter Contents

Plant Siting
Exposure Protection
Ignition Sources
Control of Spills
Heat Transfer Hazards
Stability and Shock Sensitivity
Chemical Plant Operations and Equipment

Key Terms

Bhopal (India), chemical processing, chemical release, endothermic reaction, exothermic reaction, explosion, flammable liquid, hazardous material, heat transfer fluid, hot work, nucleate boiling, separation, vapor cloud

This chapter discusses chemical reactions, the means of controlling them, and the equipment used to produce chemicals and synthetic materials, such as fibers, plastics, and drugs. Operations that chemically change the properties of materials, as in chemical pulping of wood and the tanning of leather, are also covered. However, in discussing fire and explosion prevention and loss control, the hazards of each system must be considered as a whole when appropriate separation and other means of minimizing damage are examined.

For information on related topics see Section 2, Chapter 8, "Explosions"; Section 6, Chapter 8, "Dusts"; Section 8, Chapter 7, "Heat Transfer Systems and Fluids"; Section 17, Chapter 8, "Explosion Prevention and Protection."

PLANT SITING

Loss Prevention in the Process Industries[1] notes that safety is a prime consideration in plant siting. The most important feature is distance between the site and areas of high population density. Distance tends to reduce casualties—that is, if a toxic release occurs, the effect of distance reduces the concentration of gas and allows time for evacuation. The disaster at Bhopal, India, in December 1984 was undoubtedly exacerbated by the very high population density immediately adjacent to the plant. If the hazard is fire or explosion, distance will reduce the intensity of heat or blast overpressures as well as damage done by missiles. The density of population adjacent to the liquefied petroleum gas storage tanks involved in a fire and explosion in Mexico City, Mexico, in September 1984, led to a very high loss of life.[2] These two incidents resulted in 15,000 and 500 fatalities, respectively, and rank among the worst industrial accidents in history.[3]

Population Control

A consideration associated with plant siting is the function of government control of population around industrial plants. The effect of this is frequently overlooked. There have been numerous cases where industrial plants are initially located in remote areas, which are then subsequently populated with homes and other businesses unrelated to the operation of a chemical processing plant. To avoid this situation, a company must acquire sufficient land area around the operation and maintain it population free. This might become an economic problem for the operating company because of the imposition of taxes on the land acquired for this purpose. It also requires action on the part of the government to maintain the area population free by zoning restrictions

A plant with the potential for the release of toxic gases or the potential for a major fire or explosion must be designed to high standards of safety and loss prevention. Distance and siting alone cannot be relied on to prevent such disasters, but they must be considered as key features in limiting the potential magnitude of the incident.[4]

Richard F. Schwab, P.E., is a fellow of the American Institute of Chemical Engineers and the Society of Fire Protection Engineers. He is the retired manager of process safety and loss prevention at Honeywell International (formerly Allied Signal, Inc.) in Morristown, New Jersey.

Separation Distances

Block Approach. Single or allied processes are usually located on individual blocks of land surrounded by access roads. The theory behind the block approach is that fires or unignited spills of flammable material can then be attacked from all directions. This approach provides maximum latitude to take advantage of both wind direction and the shelter afforded by peripheral structures in the block. If the right of way for these roads is 50 ft (15 m) wide a minimum distance of 50 ft (15 m) between structures on adjacent blocks is ensured. This distance has proved adequate to prevent the spread of fires through highly protected properties.

Chemical manufacturing plants pose a special danger of explosion, especially in a large-loss incident. During the years 1971 to 2005, for example, there were 36 chemical manufacturing plant large-loss fires reported to NFPA, each involving at least $5 million in direct property damage in the year of occurrence (Table 8.2.1). Collectively, these 36 incidents caused

TABLE 8.2.1 Large-Loss U.S. Fires in Chemical Manufacturing Plants, Involving at Least 5 Million in Direct Property Damage in Year of Occurrence, 1971–2005

				Direct Property Damage (in Millions of Dollars)		
Year	*State*	*Did Explosion Occur?*	*Deaths*	*In Year of Occurrence*	*In 2005*	*CPI for Year*

Total			60	959.3	1596.4	2.466

Note: Does not include some fires in chemical, plastic, or petroleum plants of unknown specific type. The 15 highest ranking fires on this list are the 15 costliest chemical manufacturing plant fires in 1971–2005. Other fires on this list have inflation-adjusted losses that could be less than the inflation-adjusted losses for other, earlier fires whose losses in the year of occurrence were less than 5 million. A 5.0 million loss in 1971 would be 24.0 million in 2005.

Source: NFPA Fire Incident Data Organization, NFPA analysis of reports to determine whether explosion occurred.

$959.1 million in direct property damage without adjustment for inflation (or $1,596.3 million in 2005 dollars) and also caused 60 deaths. Of the 36 incidents, 27 involved explosions (17 as the cause of the fire, 6 only as a result of the fire, and 4 of undetermined type), 6 did not, and 3 were undetermined.

Where an explosion is possible, the 50 ft (15 m) distance does not provide sufficient protection. One solution has been to place any unit involving an explosion hazard away from the perimeter of the block. This gives a minimum distance (in the adjacent blocks) of 100 ft (30.5 m) between explosion hazards. In the case of equipment explosions resulting from an increase in internal pressure, the shock wave would be adequately attenuated by that distance. This is true whether the explosion is of the thermal type, represented by an ordinary runaway reaction and the failure of the reaction vessel, or of the shock type, where the pressure release is caused by a reaction at supersonic speed. In the latter case, the rapid pressure increase could produce shrapnel, so a containment barricade might be needed. If the material that might cause the explosion is a true explosive, whether formed intentionally or accidentally and whether inside or outside of the equipment, spacing should be in accordance with the American Table of Distances for Storage of Explosives. (See also NFPA 495, *Explosive Materials Code.*)

Conservative views on spacing are taken by the American Oil Company (now BP). Its *Engineering for Safe Operations* states: "Generally a distance of 250 ft (76.2 m) between units or between tankage has been used as a desirable spacing."[5] Figures 8.2.1, 8.2.2, and 8.2.3 show recommendations developed by GE Global Asset Protection Services (GE GAP), formerly Industrial Risk Insurers (IRI), with respect to process units and storage tanks in petrochemical plants. / = no spacing requirements.

FIGURE 8.2.2 Intraunit Spacing Requirements for Oil and Chemical Plants

distances for separation of units in refineries, gasoline plants, terminals, oil pump stations, and offshore property.[6]

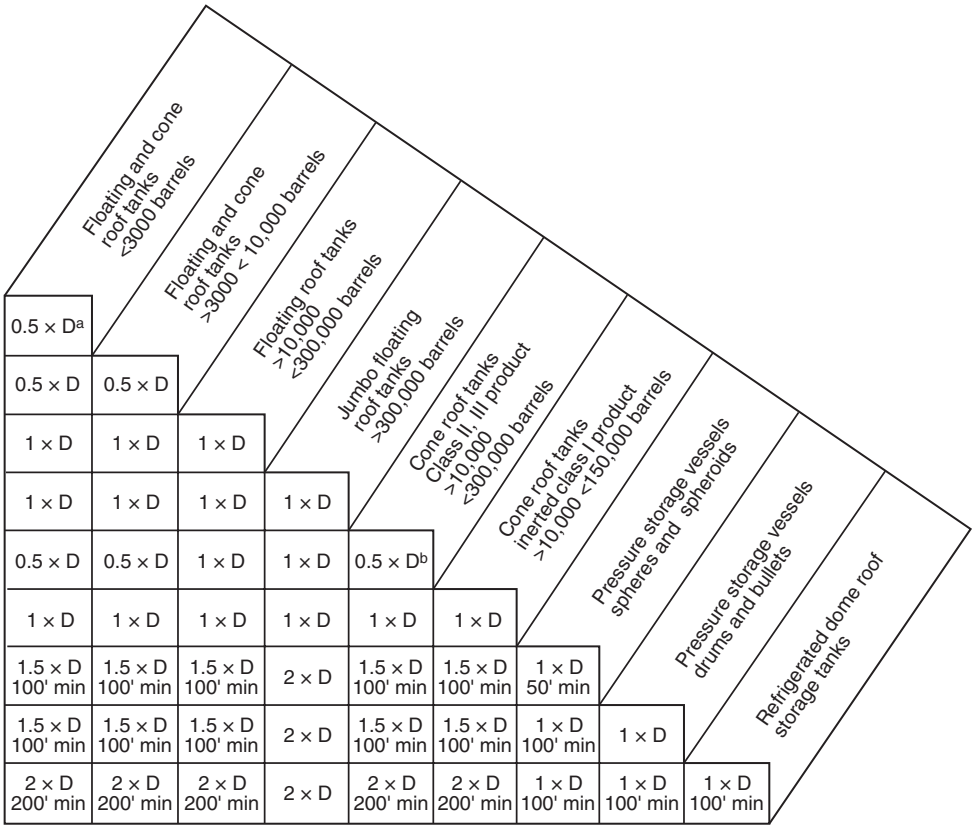
The greater distance suggested by BP and GE Global Asset Protection Services are justified by the large amounts of flammable liquids usually present in equipment and piping in oil refineries and petrochemical plants. They are probably adequate for controlling even large flammable liquids fires.

Hazard Ranking Approach. Another method for plant spacing is the MOND Fire, Explosion and Toxicity Index.[7] This index was developed as a result of the official inquiry into the Flixborough disaster in 1974. It requires a ranking of hazards of various process units at an early stage of design. The rankings are used to lay out the plant to minimize potential losses.

For another type of explosion hazard, no spacing standards exist. This is the type of explosion hazard that results when a flammable gas or superheated flammable liquid is released into the atmosphere and mixes with air to form a vapor cloud with a volume in the flammable range. Such a vapor cloud can release 2 to 10 percent of its heat of combustion in the form of explosive energy. In estimating potential losses from vapor clouds, GE GAP uses the 2 percent figure. This decision was reached after studying the results of 79 cases of vapor cloud formation.[2,8] In 70 cases there was no ignition; in 17 there was ignition but no pressure was generated. If a hydrocarbon material releases 20,000 Btu/lb (47 MJ/kg) when burned and 2 percent of that, or 400 Btu/lb (0.93 MJ/kg) were released explosively by igniting its mixture with air, then 5 lb (2.3 kg) of hydrocarbon would release about 2000 Btu (4.7 MJ) explosively—the same as about 1 lb (0.5 kg) of TNT. Where such releases are possible, spacing is not a reliable defense against damage, because no one can predict where the cloud will drift before it is ignited.

Procedures used to estimate the damage from explosion pressure resulting from ignition of a flammable vapor cloud are as follows:[9,10]

1. Estimating the volume of the vapor produced by the release



D = Largest tank diameter.
1 barrel = 42 gallons (159 L).
°C = (°F – 32) × 0.555.
1 ft = 0.305 m.

[a]For Class II, III products, 5 ft spacing is acceptable.
[b]Or Class II or III operating at temperatures > 200°F.

FIGURE 8.2.3 Storage Tank Spacing Requirements for Oil and Chemical Plants

2. Assuming that a percentage of the heat of combustion of this volume will be released as explosion energy
3. Equating this energy to an equivalent amount of TNT
4. Estimating the damage, based on the explosion of that amount of TNT

These procedures are discussed briefly by Davenport.[8,11] More extensive comments, with a table of pressure ranges at which different units of equipment can be expected to fail, have been made by Nelson.[12]

Van Wingerden et al.[9] extensively discuss the problems of evaluating vapor cloud explosions. Experimental work has been performed to develop an improved method to predict the blast effect from vapor clouds.[13] The method recognizes the importance of partial confinement with regard to the strength of vapor cloud explosions. The experiments were made to quantify the influence of obstacles and partial confinement.[9]

Other Means of Loss Control

As chemical plants process larger quantities of materials, it becomes impractical to provide ever increasing separation of process units. Where toxic, flammable, reactive, or otherwise hazardous materials might be spilled, the logical approach is to do the following:

1. Minimize the possibility of uncontrolled spills
2. Minimize the size of a possible spill (if spills do occur, the design features should keep them small)
3. Minimize the spread of a possible spill (if spills are large in volume, design features should keep them confined)
4. Prepare alarm and evacuation plans if toxic releases can occur
5. Control sources of ignition
6. Provide protection for exposed property if ignition does occur

A number of means are available to control spills. One is the obvious technique of providing diking or curbing to restrict the spread of a liquid spill. Another is the use of foam to cover the liquid spill so as to inhibit vaporization of the liquid, carefully considering the physical and chemical properties of the liquid to make sure that the foam is compatible.

Another is the use of water spray, using either a fixed sprinkler or water spray system with monitor nozzles (in some cases remotely controlled) to wash the vapor from the atmosphere. This method is appropriate for vapors that are water soluble and also for liquids that can be expected to be released as a mist. It also requires a large water supply at high pressure to be immediately available to respond to the emergency. In many cases,

fire water systems have been tapped, because they are usually available at the required pressure and amount.

Steam fogging systems have also been used to help dissipate vapor releases in plants where a large steam supply is always immediately available for this purpose. Generally speaking it would be unusual to have a large available steam supply available for an emergency in a modern plant where the requirements of steam demand and steam supply are closely balanced, mostly for economic reasons. In all cases, drainage systems are required and must be designed to accommodate the expected water or foam discharge along with the expected spill.[14]

EXPOSURE PROTECTION

Automatic fire control and extinguishing systems are the first line of defense against fire and explosion emergencies. However, if an explosion hazard exists, system design would require barricades for the protection of important components, such as deluge valves and dry pipe valves.[15] If they might be exposed to explosion pressure, however improbably, process control houses, including areas where people congregate (e.g. change houses), should be of explosion-resistant design.[16–20] The procedure cited in "Design of Control Houses to Withstand Explosive Forces"[16] is based on resistance to static overpressure. In Chemical Manufacturers Association (CMA, now known as the American Chemistry Council) Safety Guide SG-22,[17] it is based on elastic response—dynamic response to a pressure impulse (see Lawrence and Johnson[19]).

Reliably available water at pressure and volume sufficient to supply maximum foreseeable fire-fighting and exposure protection demand for a minimum of 4 hours is desirable. Of course, built-in or added fire resistance can give excellent exposure protection.

Protection for a chemical plant generally requires a specialized fire department where each fire fighter is equipped with full protective clothing, including self-contained breathing apparatus (SCBA), as well as acid-resistant hose and special extinguishing equipment where available. Appropriate symbols from NFPA 704, *Standard System for the Identification of the Hazards of Materials for Emergency Response,* posted at locations on the property where chemicals are present, can give helpful guidance on inherent hazards of materials present and on planning effective fire-fighting operations.

IGNITION SOURCES

As recommended in Figure 8.2.2 open flames should be kept at least 100 ft (30.5 m) from any hazardous area. This recommendation refers to fixed equipment; however, it could also apply to maintenance work. A better approach is to prohibit open flames or other hot work in all but predetermined specified areas, except where hot work is to be done under a permit that limits scope and duration. It must be remembered that piping for high-pressure steam, heat transfer media, and hot-process streams might need insulation to keep from being a source of ignition. When piping operating at high temperatures is insulated, it might be necessary to leave flanges uninsulated. If the bolts joining flanges get too hot, their thermal expansion will relax the compression on the joints, and that could lead to leakage.

CONTROL OF SPILLS

Confinement

Large flammable liquid spills should be confined where they occur. Although diking is often used, it might not prevent liquid around a source of the spill from igniting and burning. Equipment can be damaged further or the spill aggravated unless efficient, prompt, and preferably automatic fire control measures are taken. A better approach is to provide drainage to an impounding basin located where a burning liquid can burn out harmlessly or a nonburning toxic material can be appropriately neutralized. A spill can be ignited some time during the drainage process, so care must be taken to avoid damage during drainage. If the facility's sewer system is underground and is not provided with liquid seals at all entrance points, explosions in the system can result. Fire in open drainage systems could damage anything without adequate protection that is located alongside the ditches or that crosses them, such as utility or piping systems. Problems associated with such drainage can be avoided by using the trench system described in NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection.*

Total confinement of a large flammable gas or vapor spill is not possible, due to the gaseous nature of the spill. Hose lines or monitors with spray nozzles can be used, because of the air entrained by the spray, to dilute the gas cloud and to move it in a desired direction until it dissipates. Fixed water spray nozzles can be used to set up water curtains, which will prevent a cloud from drifting to a furnace or other ignition source. Units that have been effective in experiments with small, low-level vapor releases were discussed in a number of articles in *Loss Prevention.*[18,21]

The use of steam nozzles to dilute and direct vapors upward at an installation have been reported.[22] There are problems with this approach. Large steam capacity must always be available, and there is need for meticulous grounding of all metallic material that could be charged by steam passing over it or condensing on it in order to avoid static electric sparks that might ignite the material being dispersed.

Keeping Spills Small

Hazardous spills can be kept small by keeping the amount of hazardous material used in a process small. Where this is impractical, valves to isolate all large quantities of material should be provided. These valves should be installed at each outlet of any large container through which material might escape (except at relief devices). They can also be used to subdivide long runs of large diameter pipe. The valves should be fire safe; that is, they should not leak appreciably when exposed to fire after being closed, and they should be arranged to operate both remotely and at the valve.

If operated by electric motor, both the power wiring to the motor and the signal wiring to the starting switch should be arranged to remain functional during any fire or other emer-

gency requiring valve operation, for at least as long as it might take to discover the emergency, transmit the alarm, and operate the valve. A minimum of 15 minutes for this fire protection sequence is suggested. If valves are held open by instrument air pressure and closed by spring or gravity when air pressure is lost, plastic tubing can be used in the air line, at least near the valve. The plastic should melt quickly in a fire and the valve will then close before it is damaged. Because it is necessary to detect spills before ignition, flammable vapor detectors of the diffusion head type can be used for that purpose.[23]

The distinction between a small spill and a large one must be fixed individually for each plant. A small spill is one that can be easily handled by means of exposure protection and confinement. All others are large spills. In case of jets of liquefied flammable gas[24,25] or hot flammable liquid,[26] where spacing is not a reliable defense against explosion damage, various quantities have been proposed as limits that must not be exceeded. One organization suggests 10,000 lb (4500 kg) of gas or vapor as a maximum permissible leakage rate that would permit formation of no more than 1000 lb/min (450 kg/min) of flammable gas or vapor.

Preventing Spills

Because many chemicals cause unusual corrosion or abrasion problems or their processing requires unusually high or low temperature, chemical plants should be constructed of appropriate materials and should follow good maintenance practices. Assuming that there are no problems in these areas, the reaction systems themselves might cause trouble.

In general, reactions are used to produce desired commodities that differ chemically from the raw materials from which they are made. The differences are produced by controlled chemical changes. Uncontrolled changes tend to produce unwanted materials and violent system failures that result in spills. The common denominator in these failures is overheating—that is, the overheating of a container, so that it softens and fails, or the overheating of the content, so that the container bursts from overpressure.

Accidents of these types result from a failure to move adequately from a heat source to a heat-absorbing system or to a coolant from a heat-releasing system. Heat is usually produced when materials dissolve, crystallize, condense, or are adsorbed. Heat is also produced mechanically, by crushing, grinding, milling, compressing, and pumping, and by exothermic chemical reactions. Heat transfer is also required when heat is needed for evaporation, melting, decreasing viscosity, initiating exothermic chemical reactions, and driving endothermic reactions. In any case, loss prevention requires an understanding of heat transfer.

HEAT TRANSFER HAZARDS

Heat Transfer Process

When a hot fluid, gas, or liquid transfers heat to a cooler fluid with a barrier such as the metal wall of a vessel, the resistance to heat flow, as shown by a temperature drop, is mainly by a thin film of fluid on the metal surfaces rather than the thermal conductivity of the metal (Figure 8.2.4). Flow in the heating and heated fluids is usually turbulent, with invisible swirls and eddies, but in the films, it is laminar with thin layers of molecules sliding slowly over each other.

The film layer nearest the metal moves slowest and its temperature is nearest to that of the metal. This is important because temperature causes decomposition of most organic and some inorganic fluids. Although a large temperature differential between the fluids moves heat faster than a small one, the hottest of the heated film must be kept cool enough so that it does not decompose and form a solid film. When such a solid film forms, the temperature of the metal on the heated side will increase, so that the metal is damaged (softened or chemically altered) and a "burnout" occurs.

Precautions consist of methods to detect fluid breakdown, such as checking the fluid for tar, solids, or significant change in viscosity or volatility. Where the heater is a single tube design, an internal buildup will cause an easily observable increased pressure drop as the fluid flows through the tube. For this reason single-pass tube heaters are preferred over those of multiple fluid path designs.

When the breakdown of the fluid is intentional, as in the case of cracking a petroleum fraction, the internal deposits are removed on a scheduled basis before they reach a dangerous thickness. This is usually done by burning them out with air or mixture of air and steam.[27] Requirements for safety involve the following:

- Purging the unit of flammables, usually with steam, before introducing the oxidizing atmosphere
- Purging after burning out the deposits
- Safely disposing of the materials purged
- Having a system of valves, usually involving double valves with a purged or vented space between, to ensure against mixing air and combustibles

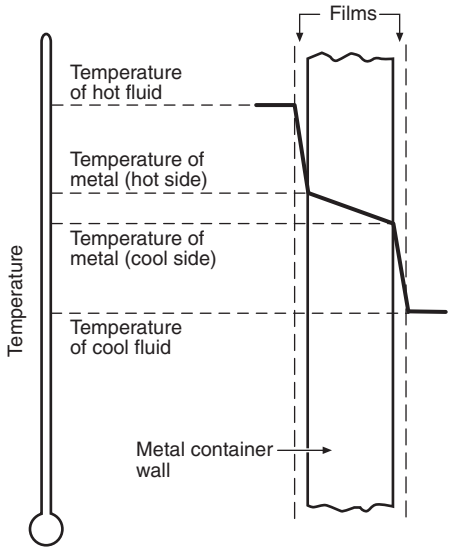


FIGURE 8.2.4 Effect of Fluid Films on Temperatures at the Surfaces of the Metal Wall of a Vessel

If the heated fluid is a liquid and starts to boil, heat transfer improves as the film is thinned by the action of the bubbles on the metal, growing and breaking away. The formation of bubbles on the heated surface is called "nucleate boiling." If the temperature of the heat source is then raised in an attempt to increase the rate of boiling, the temperature might become too high. Vapor bubbles then coalesce into vapor film instead of breaking away individually. This is called "film boiling." Vapor films offer more resistance to heat flow, so again "burnout" could occur.

Endothermic Reactions

Endothermic reactions are most commonly supplied with heat by combustion processes. This energy might be obtained by partial oxidation of the reaction stream, for example, cracking natural gas to acetylene by burning part of it with oxygen and then quenching the partially oxidized stream suddenly; or concentrating liquid by submerged combustion (burning a premixed gaseous fuel beneath the surface of a liquid); or roasting ore or cementitious material in a kiln. The energy might also be supplied through the walls of a container via a heat transfer media or by hot gases from a combustion process or another hot stream.

The same general hazards exist whether the material being heated is a reacting system or one being decomposed or heated. All cases require consideration of the metallurgical and construction characteristics of the equipment. These problems are accentuated in the case of direct-fired equipment. The heater must resist corrosion, pitting, and scaling from the materials being heated as well of the stream supplying the heat.

Construction must be such that heated and cooled portions can expand and contract freely. This is particularly important if the alloys used enter or pass through a brittle phase at any stage of heating or cooling.

Two more important but sometimes overlooked points are the following:

1. The metal of the heater and the heat transfer system and the fluids with which they are in contact must be compatible. A common molten heat transfer medium, a mixture of sodium nitrate and sodium nitrite used in indirect fired heaters, will support the combustion of steel if the temperature is high enough and ignition occurs.[28] Steel and copper in thin sections, as in the fins of heat transfer tubes, can ignite easily in hot chlorine.
2. The heat transfer medium should not create a hazard if it leaks into the material being heated or vice versa. Where leakage one way but not in another can be temporarily tolerated (e.g., sulfuric acid into water as opposed to water into sulfuric acid), pressures of the coolant and the cooled material must be suitably different. Alternatively, annular tubes with the annulus separating the two fluids can be used, with means to detect leakage into the annulus from either direction. To promote heat transfer, the annulus can be filled with a conducting liquid inert to both fluids or, as in "still" tubes, intermittently bridged with heat-conducting metal wires or perforated discs. The preceding discussion applies equally well when the heat transfer is from an exothermic reaction to a fluid used for cooling.

It is impossible to be all inclusive about the hazards of heat transfer. Two examples, however, indicate the scope of the problem. In the first example, electric inductive heat was being used on a cast-iron vessel with thermostatic controls. Cast-iron growth caused intercrystalline cracking. The cracks interrupted the flow of the induced electric currents throughout the vessel, the thermostats called for more heat, and the vessel eventually failed from localized overheating. In another instance, sodium silicate was condensed on a stainless steel pipe where it acted as a flux to remove the alloying elements so that the pipe lost its corrosion resistance and failed.

Exothermic Reactions

Proper application of heat transfer principles is essential to the control of exothermic reactions. Such use requires knowledge of the reaction system. First it is necessary to know the thermal stability and shock sensitivity of the system and its components, raw materials, intermediates, products, and by-products. Second, the reaction kinetics, that is, the total amount of heat released and how fast it is released, must be known.

For process design, it is necessary to have all of this data under conditions that would exist if the reactants were supplied in grossly incorrect proportions, in the wrong order, without mixing (both with and without a subsequent late start in the mixing system), at the wrong temperatures, if power failed, if the coolant line broke, or any other upset condition imaginable should occur. These matters need to be reviewed and documented during a hazard operations review (hazop).[29,30]

STABILITY AND SHOCK SENSITIVITY

Most chemicals are reasonably stable and insensitive. Where this is not true, data are available from the supplier or in the literature. NFPA 704 and *The Handbook of Reactive Chemical Hazards*[31] are excellent references in this field and provide an extensive bibliography.

When data are not available, thermodynamic calculations and laboratory-scale stability testing should be used.[32–37] Many test procedures have been developed by ASTM International Committee E27 on Hazard Potential of Chemicals and are published by the ASTM.

Hazard Reduction

Where explosive materials are involved, the hazard can be reduced to an acceptable level by diluting the explosive material in an inert chemical or by providing barricades. If the instability hazard is less than explosive, there are various ways to reduce it. Chemical reactions progress faster as the temperature rises, so the methods used involve keeping the material from being heated to an unsafe level. For example, the boiling point of a liquid is lowered by vacuum. Vacuum or freeze drying can help avoid overheating. A high boiling material (containing water) that becomes unstable at or near its boiling point can have steam

bubbled through it at a temperature below its (normal) boiling point. Vapor from the material goes along with the steam and separation can be made after condensing the steam-vapor mixture. Viscous materials can be concentrated by running them down the heated interior walls of a wiped film evaporator. Mechanically operated blades keep wiping the interior surface and the film cannot thicken, so the film layer nearest to the hot wall cannot overheat (see Figure 8.2.4). Liquid nitrogen or dry ice (solid CO_2) can be added to the grinder. This not only takes care of the heat produced mechanically but also tends to inert the atmosphere and reduce chances of a dust explosion.

In some cases, pressure can affect stability. Liquids such as propargyl bromide and nitromethane will simply boil away when heated at atmospheric pressure. If heated under pressure however, the boiling point might be raised to a point where the liquid decomposes violently with resulting explosion of the container. Pure gases, such as acetylene, ethylene, and nitrous oxide, will decompose violently under pressure. The testing described earlier should be thorough enough to detect such a possibility. Also, when considering systems, one should keep in mind that pressures might cause a phase change. For example, chlorine gas liquefies fairly easily, and a system easy to control when using a gas could be difficult to control if chlorine liquid is formed.

Reactors

Reaction systems are of two types: (1) continuous and (2) batch. A continuous reacting system can be thought of as a pipe, although it contains pumps, compressors, elongated vessels, and so on, with the raw materials and possibly inert carrier flowing in at one end or at appropriate intervals along the pipe and products and by-products flowing out the other end. In a batch process, the chemicals are added to a single process unit all at once or at appropriate feed rates; then the reaction takes place, the unit is emptied, and the process is repeated. Batch process systems have more flexibility in that, generally speaking, the equipment can be used to make several different products. Continuous process equipment is generally limited to the production of one product.

Continuous Reactors

It is common to have one reactant, pure or diluted, circulating continuously throughout the reactor with another being added, reacting, and its products removed by condensation, washing, filtering, or similar appropriate means. In normal operation, the major safety control is automatically cutting off the appropriate feed stream if the heat transfer system fails. Arrangements are often made for alternative means of supplying heat transfer fluids. Reliability of the shutoff system can be enhanced by using two valves in series with a vent between (known as a double block and bleed system). Depending on the complexity of the system, this same shutoff can be actuated by changes in the process conditions. An example of process change might be too low a temperature, which would indicate that the reaction was not proceeding properly. This signals that the concentrations of unreacted materials could be building up to the point where they could react with violence and overpower the means for heat removal or could react in a part of the system designed to recover product rather than control the reaction. Also when starting up or shutting down, the continuous reactor could go through situations that are more hazardous than its normal operation.

Batch Reactors

The essential parts of a batch reactor are as follows:

- A vessel to contain the reaction at its maximum pressure
- A heat transfer system to control the temperature of the reacting material
- A stirrer or agitator to keep the temperature and composition of the reacting mixture uniform
- A relief system to protect the vessel against overpressure

Vessel. The process vessel can range from an open wood or rubber-lined steel tank in which bauxite ore reacts with sulfuric acid to produce a solution of alum to a glass-lined or stainless steel pressure vessel. Regardless of the size of the configuration, the vessel used as a batch reactor will probable have to be entered for cleaning and inspection, whereas the continuous reactor can be cleaned automatically with a cleaning fluid. Cleaning or entering vessels will require special precautions if flammable cleaning agents are used or if vapors or residues make entry hazardous.

Heat Transfer Methods. Common methods of heat transfer use jackets or coils on the exterior of the vessel or coils in the interior. Others circulate the reacting mixture from the vessel through an external heat exchanger and back into the vessel. A third method allows the reacting mixture to boil. The heat of vaporization is then removed by condensing the vapor externally, which allows the condensed liquid to run back and thus continue the cycle. This last method does not provide means to heat the material in the vessel, which might be needed to start the reaction, even though cooling is needed as the reaction progresses. These methods can be used in combination.

Mixing. Mixing is usually performed with an agitator mounted on a shaft driven by an external motor. If an external heat exchanger is used, the mixture leaving it can be recirculated back into the vessel to accomplish the needed mixing. Where heat-sensitive materials are involved and it is necessary to avoid frictional heating by moving parts, mixing can be accomplished by "sparging" (bubbling) an inert gas, or possibly air, through the reactants.

Pressure Relief of Batch Reactors. Batch reactors in which a flammable atmosphere might sometimes exist are usually designed to contain the pressure that might result from ignition or they are purged or inerted to eliminate the hazard. If vessels are constructed according to the *Pressure Vessel Code* of the American Society of Mechanical Engineers (ASME), they are required to have a relief device adequate to keep the vessel from being overpressured because of heating from an external source, including an exposure fire, normal heating, or the introduction of fluids at pressures higher than those for which the vessel is designed. The code gives no guidance for the relief of pressure

caused by the heat of reaction or, as it is more commonly known, a runaway reaction.

Most chemical reactions double in speed with each rise in temperature of 18°F (–8°C). This means that a heat removal system would have to remove twice as much heat at 140°F (60°C) as at 122°F (50°C), four times as much at 158°F (70°C) and so on. For this reason, it is unsafe to run a batch reaction more than 30°F (16 to 18°C) above that of the cooling medium.[38] If the cooling system is overpowered, the reaction keeps increasing in speed, the retained heat builds up pressure, and the pressure must be relieved or the vessel will rupture. Austin gives a good explanation of this problem.[39] The Dow Chemical Company's *Guidelines for Process Scale-Up* asks the following questions about runaway reactions.[40]

Can you prevent runaway reactions?	*Yes*	*No*
By adequate heat transfer	—	—
By quenching the reaction	—	—
By stopping feed streams	—	—
By dilution of the reactor contents	—	—

Score: Two or more methods—You're in good shape. Only one method—Better find a second line of defense. None of the above—You'd better stop right now and reconsider your design for safety.

However, since even multiple safeguards can fail, emergency venting is supplied as a last ditch protection for the vessel. For example, loss of mixing could make all the suggested preventive measures inoperative or dangerously inefficient. Materials that have leaked into the hollow shaft of the agitator have created pressure and spewed materials into the main reaction system, which speeds up the main reaction so that it overpowers the cooling system. Other problems were discussed earlier in this chapter in the subsection "Endothermic Reactions." The problem of adequate sizing of emergency venting was recognized by the AIChE and a committee was organized to study the problem. This became known as the Design Institute for Emergency Relief Systems (DIERS).[30] Twenty-nine companies sponsored the work and spent $1.6 million on research. The project was successively completed in 1985. The key contributions developed to provide the chemical process industry with tools necessary to evaluate emergency vent requirements are as follows:

1. Emphasizing the importance of proper determination of the source term (i.e., energy release rate and gas generation rate for vapor and gassy systems, respectively) under upset conditions and the development of a new bench-scale apparatus in which such determination can be obtained and extrapolated directly to a full-scale application
2. Emphasizing the importance of two-phase flow in the emergency relief discharge process and development of vent sizing techniques that are valid for multiphase behavior

The DIERS methodology can be complex and time-consuming and is sometimes beyond the capability of many small plants. As a result, some inexpensive and easily employed techniques have been developed. These commercially available tools should make it possible for all facilities to design adequate emergency venting for process vessels and equipment. A number of articles have appeared in AIChE publications, *Chemical Engineering Progress* and *Process Safety Progress* (also its predecessor *Plant/Operations Progress*) concerning the DIERS program and the ways to use it.[41–50] The theoretical advances allowing a rational design procedure to be used for handling potentially runaway reaction conditions are best summarized in reference by Fisher et al.[51] Symposia on this subject primarily sponsored by DIERS and AIChE are held periodically.[52]

Safety Instrumentation

Safety instrumentation will vary from process to process and from plant to plant. There are, however, a few general rules:[53]

1. Measure, as directly as possible, the variables of interest. If an agitator is driven by an electric motor, a relay can be used to show that the switch to the motor is closed. An ammeter would be better because that would show that the current is flowing; a wattmeter would be best because it would show that work is being done and that the impellor had not fallen off the agitator shaft.

2. Ensure that reliability and maintenance are of high quality—for example, if an external fire could upset the reaction, the warning instrument should not be disabled by the fire. Since safety instruments will not have to operate often, frequent checks must be made to ensure they are in operating condition.

3. Provide redundancy or diversity in the system. If temperature is critical, provision of two thermocouples could lead to two different readings. It is best to provide three and trust the majority of the readings. Since a temperature increase is usually accompanied by a pressure increase, one pressure sensor and one thermocouple could be used, with credence given to the more pessimistic report.

CHEMICAL PLANT OPERATIONS AND EQUIPMENT

The generally accepted unit physical operations require equipment to carry out the following functions:

- Heat transfer
- Fluid flow
- Crushing and grinding
- Mixing
- Mechanical separation
- Distillation
- Evaporation
- Crystallization
- Filtration
- Absorption
- Adsorption
- Drying

Descriptions of individual pieces of equipment can be found in most chemical engineering handbooks.[54–56]

Heaters and Coolers (Heat Transfer)

Heaters and coolers (heat transfer) are either (1) direct (flue gas, kilns, spray cooling, vaporization) or (2) indirect (coils and

jackets). Heat transfer media usually work by boiling to absorb heat or condensing to give it up, but can work just by becoming hotter or cooler without phase change. Hazards of heat transfer have been discussed previously in this chapter.

Fluid Flow

Fluid flow is accomplished by (1) fans and compressors, (2) pumps, or (3) vacuum jets. Fans, compressors, and pumps heat the material they move because of mechanical work. Compressors require good aftercoolers. The liquid in pumps can boil and the pump bearings can fail from overheating if the pump operates against a closed discharge valve. If the suction head of a centrifugal pump is inadequate, cavitation might cause the pump rotor to fail. Failure of vacuum devices could permit unwanted air to enter the equipment and cause the temperature in the equipment to rise.

Crushing and Grinding

Equipment for crushing and grinding operations includes (1) mills (impact, ball, hammer, roller, disk) and (2) crushers (cone, gyratory, jaw). All of these devices produce heat and can produce fine material capable of a dust explosion. Ball mills can become overpressured as liquid in their contents are heated. If gaskets fail and the fluids are flammable, a dangerous situation will result.

Mixing

Devices used in the mixing process include (1) tumblers; (2) venture mixers; (3) kneaders, rolls, and mullers; and (4) propellers, blades, and turbines. These devices also produce heat to varying degrees. When it is necessary to produce a hazardous mixture, for example, a blend of starch and an oxidizer for use as a flour aging material, the mixer should be vented to prevent explosions. Any dust collector should be of the water-wash type.

Mechanical Separation

Equipment for mechanical separation include (1) cyclones, (2) bag filters (shake or blowback), (3) ore tables, (4) screens, (5) electrostatic precipitators, (6) flotation separators, and (7) centrifuges. The first five are usually dry type and the latter two wet type, although there are liquid cyclones and wet screening processes. Devices used in dry service for combustible dusts should have explosion (deflagration) venting or an explosion suppression system.

If collectors have internal combustible bags, an internal sprinkler system is desirable. It might not save the bags, but it will save the housing and the mechanical devices. When materials wet with flammable liquids are centrifuged, the operation should be conducted under inert gas or with an explosion suppression system.

Distillation

The types of stills are (1) batch, (2) continuous, (3) pressure, (4) vacuum, and (5) steam. All distillations involve heat transfer. The major hazard of this operation is that flammable vapor can be released to the atmosphere.[57]

Evaporation

The three types of evaporators are (1) multiple-effect, (2) vacuum, and (3) wiped film. All three use heat transfer. The multiple-effect system condenses vapor from the first unit to heat the second, and so on. The initial heat transfer medium is used in the first. Vacuums and wiped film evaporators have been discussed previously in this chapter.

Crystallization

Crystallization is the formation of solid particles within a homogeneous phase. It can occur as the formation of solid particles in a vapor (snow), as solidification from a liquid melt, or as crystallization from a liquid solution. Dissolved or molten substances are recoverable in solid form by precipitation on cooling or on removal of the solvent or by the addition of precipitating agents. Crystallization requires an understanding of phase equilibrium with respect to temperature and pressure. The equipment to accomplish this is extensively described in Perry and Green and other sources.[54,55]

Filtration and Agglomeration

Filtration and agglomeration involve (1) plate and frame filters, (2) Nutsche vacuum filters, (3) drum-type filters, (4) rotary-cell-type filters, (5) agglomerating tables, and (6) pelletizers. No unusual hazards are involved other than possible exposure of flammable liquids to the air.

Adsorption

The two types of adsorbers are (1) activated carbon and (2) zeolites (molecular sieves). Adsorption can result in heat just as absorption does. However, when the material being adsorbed is a flammable vapor or gas, the heat is retained on the surface of the adsorbent. Heat can build up enough to cause a fire (or "hot spot") in the activated carbon. In some cases it can initiate polymerization of adsorbed reactive materials, such as ethylene.

Drying

The six general types of dryers are (1) spray, (2) fluidized bed, (3) vacuum, (4) tray, (5) belt, and (6) drum. All involve the transfer of heat. In many of these dryers, when a flammable liquid or vapor is removed from the solid material, which may be in the form of a powder, it enhances the danger of igniting a dust explosion. (See Section 6, Chapter 8, "Dusts.")

SUMMARY

The following summarizes the necessary knowledge those dealing with chemical processing equipment should have and the procedures they should follow to ensure safe chemical processing:[58]

1. Know the total reaction energy in the system
2. Know the rate of energy release
3. Evaluate thermal and shock sensitivity data

4. Design the process to control the rate of energy release; ensure the process addresses the following concerns:
   a. Detection of trace compounds or catalytic impurities that could accelerate reaction rates
   b. Prevention of buildup or concentration of high-energy materials in the system
   c. Calculation of a material balance
   d. Designed mechanism within the process to safely accommodate inadvertent releases

Before beginning operations, a hazard analysis of the proposed or modified process is generally required.[59,60]

Chapter Contents

Powered Industrial Trucks
Mechanical Conveyors and Elevators
Pneumatic Conveyors
Cranes

Key Terms

automatic guided vehicle (AGV), bucket elevator, crane, hot work, mechanical conveyor, pneumatic conveyor, powered industrial truck

Materials-handling equipment, particularly powered industrial trucks and automatic guided vehicles (AGVs), mechanical and pneumatic stock conveying systems, and cranes, provides essential services to industry and commerce. This chapter describes the basic types of equipment and systems for handling of materials, describes inherent fire and explosion hazards, and outlines protection methods. Materials-handling equipment has accounted for a large number of vehicle fires as reported to U.S. local fire departments, including large loss property damage, injuries, and even deaths.

Readers interested in or concerned with materials-handling equipment should also consult Section 6, Chapter 8, "Dusts"; Section 6, Chapter 9, "Metals"; Section 8, Chapter 1, "Air-Moving Equipment"; Section 8, Chapter 13, "Electrical Systems and Appliances"; Section 9, Chapter 6, "Welding, Cutting, and Other Hot Work"; Section 9, Chapter 7, "Storage and Handling of Grain Mill Products"; Section 11, Chapter 5, "Control of Electrostatic Ignition Sources"; Section 16, Chapter 9, "Water Spray Protection"; and Section 17, Chapter 8, "Explosion Prevention and Protection."

POWERED INDUSTRIAL TRUCKS

Industrial trucks, which include lift trucks and AGVs, are among the most common types of materials-handling equipment. Lift trucks are available in many special designs to suit the many different uses and types of loads to be handled, with the fork and squeeze/clamp types being most common. They may be propelled electrically or by diesel, gasoline, liquefied petroleum (LP) gas, or compressed natural (CN) gas engines. AGVs are usually propelled electrically. Unless these vehicles are of a type listed by a recognized testing laboratory and properly maintained and operated, they may introduce serious hazards such as fires, explosions, container damage, spills, and leaks. All vehicles should be selected, outfitted, maintained, and operated in accordance with the hazards of the specific environment in which they are operated.

Type Designations and Areas of Use

NFPA 505, *Fire Safety Standard for Powered Industrial Trucks Including Type Designations, Areas of Use, Conversions, Maintenance, and Operations,* lists 18 different type designations of powered industrial trucks or tractors. These designations are divided by power types: CN (compressed natural gas), D (diesel), E (electric), G (gasoline), and LP (liquified petroleum gas). The designation letter reflects the power type. In addition, dual-fuel trucks are available. The power types are additionally subtyped to indicate the level of safeguards inherent in the particular truck, as determined by testing and evaluation by a recognized testing laboratory. For example, a Type ES truck

John K. Bouchard is a vice-president and senior property risk control consultant with Wachovia Insurance Services in Boston. He holds a bachelor of science degree in fire protection engineering from the University of Maryland and has been involved with the insurance industry and the fire protection engineering community since 1968. He currently is a member of three NFPA technical committees and served as chair of the Technical Committee on Industrial Trucks.

is an electrically (battery) powered unit that meets the minimal requirements for Type E units and has additional safeguards for the electrical system to prevent emission of hazardous sparks and to limit surface temperatures.

To review and understand the "minimal" and "additional" safeguards included in these "type" designations, refer to NFPA 505 and the appropriate UL Classification test standards (UL 558, *Standard for Safety Industrial Trucks, Internal Combustion Engine-Powered,* and UL 583, *Standard for Safety Electric-Battery-Powered Industrial Trucks*). The level of safeguarding determines the acceptability of a particular truck in a specific environment within an occupancy. Various types of industrial trucks are limited to the locations specified in Table 8.3.1. Fires and/or explosions can result if less than minimum type trucks are operated in hazardous locations.

A potential fire source for gasoline-, diesel-, and LP- and CN-gas–powered trucks is fuel leaks that are ignited by the hot engine, hot muffler, ignition system, other electrical equipment, or other sparks. Additionally, the potential of ignition of hydraulic oils should also be recognized. The danger of ignition is somewhat lower for diesel-fueled trucks and hydraulic oils because of the higher flashpoint of these liquids.

A special hazard in LP-gas trucks is that the vapors are difficult to disperse and tend to gravitate toward lower spots or pits. Care must be exercised with LP- and CN-gas trucks to avoid high temperatures near ovens, furnaces, and similar heat sources. Special safeguards in the design of some types of gasoline, diesel, and LP- and CN-gas trucks help to reduce these fire hazards, but the hazards cannot be completely avoided and areas of use should be strictly controlled (Table 8.3.1).

To facilitate identification of truck types and their areas of use, a uniform system of marking has been developed and is described in NFPA 505 and included here (Figures 8.3.1 and 8.3.2). Using these trucks and building markers allows easy and quick recognition of vehicles approved for the location.

Conversion of Powered Industrial Trucks

Certain powered industrial trucks can be converted to another type designation. Trucks designated as Type G, LP, or G/LP can

TABLE 8.3.1 Recommended Types of Trucks for Various Occupancies

Location	*Typical Occupancies*	*Types of Trucks*[b,c] *Approved and Listed*
Indoor or outdoor locations containing materials of ordinary fire hazard	Grocery warehouse Cloth storage Paper manufacturing and working Textile processes except opening, blending, bale storage, and other Class III locations Bakery Leather tanning Foundries and forge shops Sheet-metal working Machine-tool occupancies	Electrical—Type E Gasoline—Type G Diesel—Type D LP-gas—Type LP Compressed natural gas—Type CN Dual fuel—Type G-LP —Type G-CN
Class I, Division 1.[a] Locations where explosive concentrations of flammable gases or vapors may exist under normal operating conditions or where accidental release of hazardous concentrations of such materials may occur simultaneously with electrical equipment failure	Few areas in this division in which trucks would be used	Electrical—Type EX[f] Gasoline, diesel, LP- and CN-gas—not recommended for this service
Class I, Division 2.[a] Locations where flammable liquids or gases are handled in closed systems or containers from which they can escape only by accident or locations where positive mechanical ventilation normally prevents hazardous concentrations	Paint mixing, spraying, or dipping Storage of flammable gases in cylinders Storage of flammable liquids in drums or cans Solvent recovery Chemical processes using flammable liquids Paper and cloth coating using flammable solvents in closed equipment Rubber-cement mixing	Electrical—Types EE, EX[g] Diesel—Type DY[g] Gasoline, diesel Types D & DS, LP- and CN-gas—not recommended for this service
Class II, Division 1.[a] Locations where explosive mixtures of combustible dusts may be present in the air under normal operating conditions or where mechanical failure of equipment might produce such mixtures simultaneously with arcs or sparks from electrical equipment or where electrically conductive dusts may be present	Grain processing Starch processing Starch molding (candy plants) Wood-flour processing	Electrical—Type EX[d] Diesel—Type DY Gasoline, diesel Types D & DS, LP- and CN-gas—not recommended for this service

TABLE 8.3.1 Continued

Location	*Typical Occupancies*	*Types of Trucks*[b,c] *Approved and Listed*
Class II, Division 2.[a] Locations where explosive mixtures of combustible dusts are not normally present or likely to be thrown into suspension through the normal operation of equipment but where deposits of such dust may interfere with the dissipation of heat from electrical equipment or where such deposits may be ignited by arcs or sparks from electrical equipment	Storage and handling of grain, starch, or wood flour in bags or other closed containers Grinding of plastic molding compounds in tight systems Feed mills with tightly enclosed equipment	Electrical—Types EE, EX, ES[e] Gasoline—Type GS[e] Diesel—Type DY, DS[e] LP-gas—Type LPS[e] Compressed natural gas—Type CNS[e]
Class III, Division 1.[a] Locations where easily ignitable fibers or materials producing combustible flyings are handled, manufactured, or used	Opening, blending, or carding of cotton or cotton mixtures Cotton gins Sawing, shaping, or sanding areas in woodworking plants Preliminary processes in cordage plants	Electrical—Types EE, EX Diesel—Type DY Gasoline, diesel Types D & DS, LP- and CN-gas—not recommended for this service
Class III, Division 2.[a] Locations where easily ignitable fibers are stored or handled (except in process of manufacture)	Storage of textile and cordage fibers Storage of excelsior, Kapok, or Spanish moss	Electrical—Types EE, ES, EX, preferred; E[e] Gasoline—Type GS Diesel—Type DS, DY LP-gas—Type LPS Compressed natural gas—Type CNS

[a]Hazardous location as classified in NFPA 70, *National Electrical Code®*.
[b]Type G (gasoline), Type D (diesel), Type LP (LP-gas), and Type CN (compressed natural gas) trucks are considered to have comparable fire hazard.
[c]Type GS (gasoline), Type DS (diesel), Type LPS (LP-gas), and Type CNS (compressed natural gas) trucks are considered to have comparable fire hazard.
[d]Acceptable for Groups G and F, but subject to special investigation.
[e]Acceptable but subject to special investigation.
[f]Class I, Division 1, Group D, only; no truck should be used in Groups A, B, and C.
[g]Class I, Division 2, Group D, only; may be used in Groups A, B, and C areas subject to local authority.

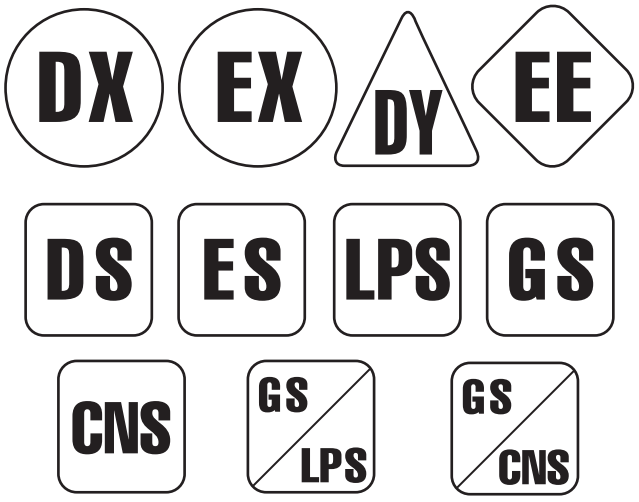

FIGURE 8.3.1 Markers Used to Identify Types of Industrial Trucks

be converted to another of those designations, and the converted unit must conform to the requirements of the new designation in accordance with the test standard (UL 558). Kits available for these conversions must conform to the requirements of the new type designation in accordance with the test standard (UL 558). These kits must be approved by a recognized testing laboratory.

A conversion kit must include certain items, including all parts necessary to complete the installation, instructions, and a new plate to indicate the converted type designation for mounting on the truck next to the manufacturer's (original) nameplate. Also, specific elements of a kit that apply to specific types of trucks are required.

The responsibility for the acceptance of an industrial truck that has been converted rests entirely with the inspection authority having jurisdiction. The responsibility for determining whether a truck has been properly converted is that of the authority having jurisdiction because it is impractical to ship each converted truck back to the testing laboratory to be reexamined or retested, and it is also impractical for the laboratory to send a representative into the field to examine or test every converted truck.

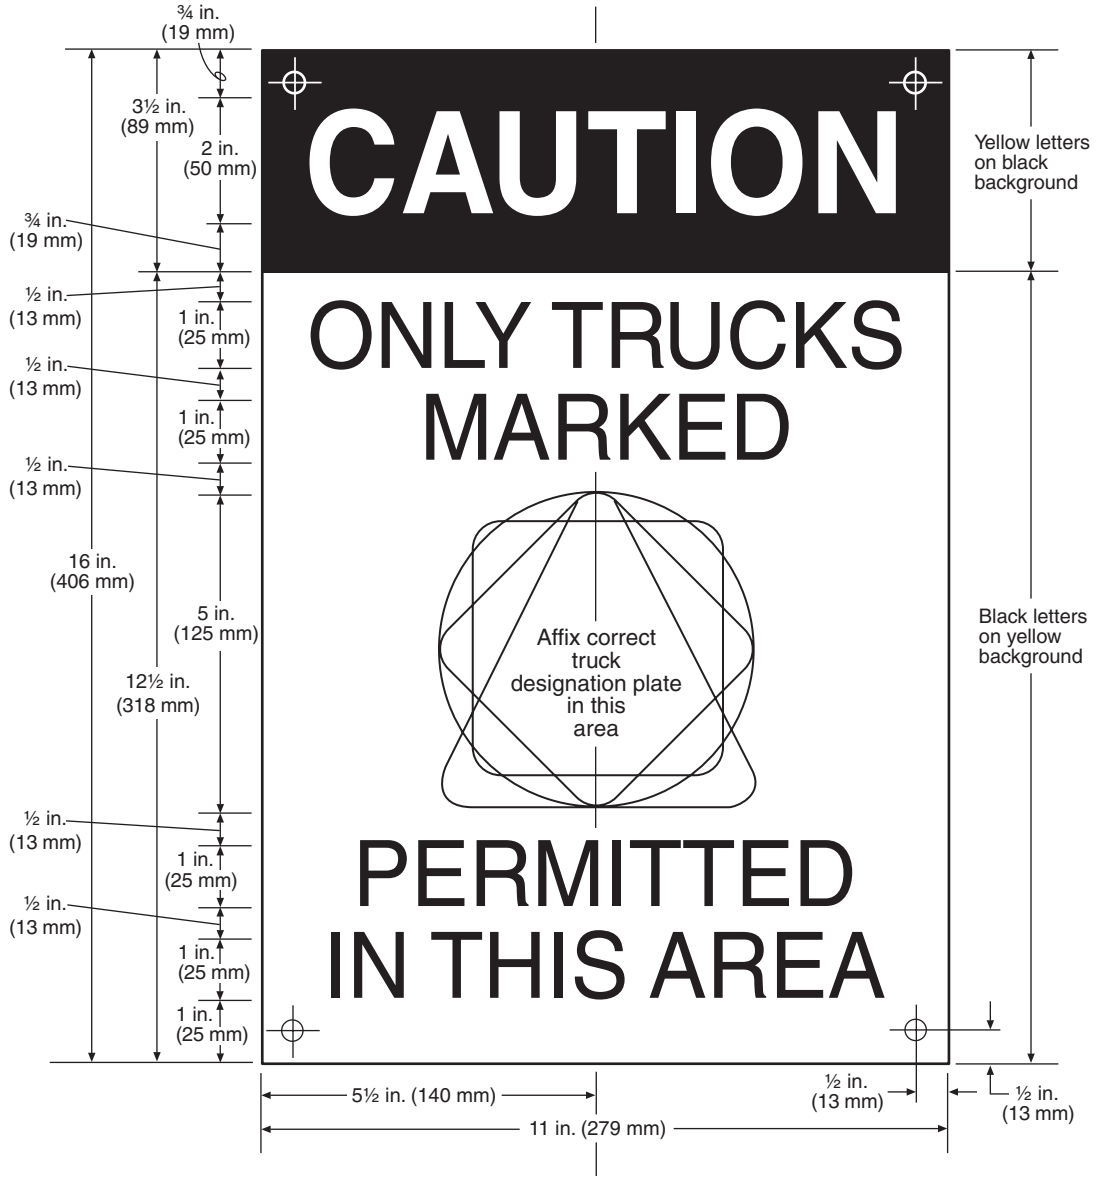

FIGURE 8.3.2 Building Signs for Posting at Entrances to Hazardous Areas

Fire Hazards and Prevention

Industrial trucks can contribute to property loss through careless operation or operation by inadequately or improperly trained operators. Collision with sprinkler piping, fire doors, and other fire protection equipment; excessively high stacking of storage; and careless handling of loads, such as containers of flammable liquids, can contribute directly to fires and make fire fighting more difficult. This aspect of the danger of powered industrial trucks has long been recognized, and guidelines for these vehicles are included in OSHA standards.

A comprehensive instruction course for truck operators can reduce the risk of such accidents. Adequate, clear passageways for truck travel and clear warnings of overhead and exposed piping also reduces the number of incidents. Good sources for safe operating rules are ANSI B56.1, *American National Safety Standard for Low Lift and High Lift Trucks,* and the Code of Federal Regulations 29, Part 1910 (*Occupational and Health Standards*), Section 178, *Powered Industrial Trucks*.

Fires involving industrial trucks can be caused by equipment failure due to inadequate or improper maintenance. Regularly scheduled maintenance should be based on engine-hour or motor-hour experience to reduce the risk of these fires. Because many trucks operate on a nearly continuous basis, maintenance programs must be carefully followed. OSHA standards require an inspection of each truck before each day/shift of operation. Especially important is detecting faulty or damaged fuel connections on gasoline, diesel, and LP- and CN-gas trucks and removing accumulated grease, lint, and dirt. Portable extinguishers suitable for the hazards presented by the truck and the envi-

ronment are recommended. If provided, such fire extinguishers should be subjected to inspection and maintenance requirements per NFPA 10, *Standard for Portable Fire Extinguishers.*

LP-gas fuel containers require special care to prevent fires. They must not be overfilled; a calibrated scale is recommended to verify "full" weight. A soap solution should be used to check for leaks, never a match or an open flame.

Means should be provided in the LP-gas fuel system to minimize the escaping fuel when exchanging removable LP-gas containers, for example, closing the valve on the LP-gas container and using an approved automatic quick-closing coupling in the fuel line. Removable LP-gas containers must be securely mounted to keep them from jarring loose, slipping, or rotating. The powered industrial truck must not be operated without all clamps, couplings, and mounting devices fully closed/engaged. The pressure relief device inlet should always be in contact with the vapor space at the top of the container. An indexing pin is provided to assure that the LP-gas container is positioned correctly. It is good practice to examine all LP-gas containers for defects or damage before refilling.

Fires involving battery-powered trucks can occur due to electrical short circuits, hot resistors, arcing and fused contacts, lint accumulation, or exploding batteries.

Two types of batteries commonly used are lead and nickel-iron. They contain corrosive chemical solutions, either acid or alkali, and therefore present a chemical hazard. When charging, they generate hydrogen and oxygen, which, when combined in certain concentrations, can explode.

Battery-charging installations should be located in areas specifically set aside for that purpose. The facilities should include means for flushing and neutralizing spilled electrolyte; barriers for protecting charging apparatus from damage by trucks; adequate ventilation for dispersal of fumes from gassing batteries; and adequate fire protection. A carboy filler or siphon is needed for dispensing acid from carboys. Open flames, smoking, sparks, or electric arcs in battery-charging areas should be avoided when charging batteries. Also, the vent caps should be kept in place to avoid electrolyte spray, and ensure that vent caps are functioning. The battery or compartment cover(s) should remain open during charging to dissipate heat and gas.

Recharging and Refueling

Refueling and battery-charging operations should be performed by trained and designated personnel, and only in specified, well-ventilated areas away from manufacturing and service areas; outdoor refueling is recommended where practicable. Smoking should be prohibited in these areas. Scales for weighing LP-gas containers should be calibrated periodically to ensure accurate filling.

Many hazards present in filling operations can be avoided by utilizing a local supplier in an exchange program. The vendor will deliver full tanks while retrieving empty tanks (to be filled off-site at the vendor's facilities). On site, tanks should be stored in a secure, exterior, well-ventilated location, with a noncombustible weather cover.

Trucks using liquid fuels, such as gasoline and diesel fuel, should be refueled only from approved dispensing pumps in safe locations away from heat and ignition sources. Care must be taken not to spill fuel or overfill the vehicle fuel tank, as many fires involving trucks using liquid fuels result from spillage during refueling.

Maintenance and Repair

Trucks should never be repaired in Class I, II, and III hazardous locations. Repairs to the fuel and ignition systems of industrial trucks that involve fire hazards should be conducted in locations designated for such repairs. Repairs to the electrical system of battery-powered industrial trucks should be performed only after the battery has been disconnected. All parts of any industrial truck that need to be replaced should be replaced only with parts providing the same degree of fire safety as those used in the original design. Water mufflers should be filled daily or as frequently as needed to maintain the water supply at 75 percent of filled capacity or above. Vehicles with clogged mufflers, screens, or other parts should not be operated. Any vehicle that emits hazardous sparks or flames from its exhaust system should be immediately removed from service and not returned to service until the cause of sparks and flames has been eliminated. When the temperature of any part of any truck exceeds normal operating temperature, a hazardous condition is created, and the vehicle must be removed from service until the cause of overheating has been eliminated.

When hot work (welding, soldering, cutting, grinding, etc.) is necessary for the repair, a formal hot work permit program should be followed. For this reason it is preferred that such repair work be carried out outside of the facility in an open area. (See Section 9, Chapter 6, "Welding, Cutting, and Other Hot Work.")

It is good practice to keep industrial trucks clean and free of lint, excess oil, and grease. The conditions under which the truck operates and frequent inspections should govern the frequency of cleaning. Noncombustible agents should be used for cleaning trucks; low-flashpoint (below 100°F [38°C]) solvents must not be used. Precautions regarding toxicity, ventilation, and fire hazard should be appropriate for the agent or solvent used. When the cooling system requires antifreeze, a glycol-based material should be used.

MECHANICAL CONVEYORS AND ELEVATORS

Commonly used equipment in materials-handling operations are mechanical conveyors and elevators that efficiently transport bulk and packaged materials. There are many classes and designs of mechanical conveyors. The primary selection considerations are the distance and inclination over which material is to be conveyed; the types of atmosphere and location through which material is to be conveyed; and the lump size, density, fluidity, abrasiveness, toxicity, corrosiveness, and other properties of the materials to be conveyed. Dust materials, dust atmospheres, or both require equipment that can be enclosed adequately. The lump size screw and en masse conveyors can handle high temperatures that often rule out belt conveyors; long distances usually require belt conveyors. Bucket elevators best handle substantial vertical lifts.

Important fire protection considerations around conveyors and elevators include location, housekeeping, temperature, dust, and the material being conveyed. For belt conveyors both the belt's combustibility and the material being conveyed must be considered; both can contribute to fire and its spread. When conveyors are designed and installed, protecting openings and controlling static charges must be given careful attention.

Temperature

Screw, vibrating, and certain pan conveyors are normally the best choices for handling very hot materials or for use in very hot atmospheres. Although the upper limit for most belt conveyors is 200°F (93°C), their use is normally restricted to atmospheres of less than 150°F (65°C). The highest rate of flame propagation occurs with rubber belts but the ignition characteristics of neoprene, rubber, and polyvinyl chloride differ little. Thus, most belt conveyors are not suitable for moving hot or molten materials and are not used in high-temperature atmospheres. Less combustible, fire-retardant belt materials are available for some applications.

Fire Protection

Often the criticality of a belt conveyor may warrant the use of fire-retardant, or less combustible, belts. Automatic sprinkler or water spray protection is generally needed for important belt conveyors, particularly if they are enclosed. Controls should be provided to shut down the conveyor when sprinklers operate. Hose stream protection to reach all portions of the conveyor is also needed. This protection can be provided by 1½ in. (38 mm) hose connections to sprinkler piping or from hydrants.

Another important factor to consider is the location of the conveyor. Exposures to critical conveyors, particularly exterior conveyors, must be carefully considered. Structures, buildings (including temporary buildings and/or trailers), or operations can create severe exposure to overhead conveyors. The route and height of conveyors should be carefully reviewed early in the design stage to avoid exposures. In addition, the height of the conveyor may make it difficult for manual fire fighting, which may warrant the installation of automatic sprinkler or water-spray protection.

Dust Control

Factors in fires involving mechanical conveyors can include dusty material, a dust atmosphere, and dust usually created by the materials-handling process. Dust is produced in most materials-handling systems, especially at inlet and discharge points and at long chutes for free-falling materials.

Dusty material should be fed to belt conveyors through a choke feed to prevent dust clouds. Where dusty conditions prevail, adequate aspiration should be provided to remove dust to collectors in safe locations. If dust clouds cannot be avoided, it is better to use spiral or enclosed conveyors where the escape of dust can be more readily prevented. When combustible or explosive dusts are handled, conveyor piping should be strong enough to withstand the maximum pressure produced in explosions of the dust involved; adequate static grounding is essential. Sharp changes in direction should be avoided wherever possible, and vent pipes to outdoors should be provided at any necessary changes in direction and at the ends of lines. (This should not be construed as prohibiting the use of explosion-relief vents.)

Screw conveyors should be fully enclosed in tight, noncombustible housings with free-lifting covers at the discharge end and over each shaft coupling. En masse or drag-type conveyors should be of substantial metal construction designed to prevent the escape of dust. Covers on cleanout, inspection, and other openings should be securely fastened. Conveyors should be designed and constructed to withstand anticipated explosion pressures, considering the pressure release that explosion-relief vents afford. A choke or seal of proper design or a suppression system should be installed in a conveyor (other than pneumatic) to prevent an explosion from propagating from one building to another, or from one portion of a building to another portion separated by a fire wall, division wall, or other fire-resistive barrier.

Dust collectors should be located outdoors or in detached rooms with adequate explosion vents for the collectors and the rooms. Where it is necessary to use bag-type collectors, they should be enclosed in a metal housing. A single dust collector should not serve several separate processes. Individual collectors for progressive stages should be used in any one process. Water spray collectors may be located within buildings, but they are not recommended for certain types of dust.

Housekeeping and maintenance are very important when dusty material is transported by conveyors. Dust can collect on rollers and bearings, creating friction, which can accelerate degradation or cause excessive temperatures and result in ignition of the material or belt. Rollers or bearings could seize, creating friction with the moving belt, which could generate adequate heat for ignition or generate a static charge. See the Friction and Overheating section for more detail.

Static Protection

All machinery and conveyor parts should be thoroughly bonded and grounded to minimize static discharge. The chances of generating static electricity increase when heated or dry materials are pneumatically conveyed or a conveyor belt is operated in a heated or dry atmosphere. Static electricity can be controlled by using belts made of conductive material, by applying conductive dressing to the belt surface, or by installing a grounded static collector nearly in contact with the belt just beyond the point where the belt leaves the pulley. Pulleys, guards, and other metal bodies should also be grounded. Caution is necessary when handling or disposing of sludge from water wet-type collectors, as certain metal-dust and water combinations are hazardous. See NFPA 484, *Standard for Combustible Metals.*

Protection of Conveyor Openings

Water Spray Method. Protecting wall and floor openings through which conveyors pass presents difficulties in installing ordinary forms of closures due to the objects carried through the opening. Where fire doors or shutters are impractical for conveyor openings, a method of protection incorporating the pressure effect and the cooling action of water spray from directed spray nozzles is available for both horizontal and vertical

openings (Figure 8.3.3). With proper nozzle design and water pressure to provide suitable water velocity and droplet size, the pressure effect from the nozzles will overcome draft due to the temperature difference between one side of the wall and the other, and the height of the opening above floor level, unless adverse air currents are prevalent.

Since the spray's cooling effect is directly proportional to the time of exposure of hot gases in the draft to the spray, the effectiveness of the heat absorption may be increased by adding an enclosure to the opening (Figure 8.3.4). Although seldom used, this method may also protect conveyor openings through floors (Figure 8.3.5).

Fire Doors. That conveyorized openings cannot be protected by fire doors is a misconception. Where possible, conveyor penetration of a fire wall should be avoided by rerouting. If alterations to a labeled fire door are contemplated, a cutout of a labeled fire door done in the field to allow closure around a conveyor track or other components voids its label. This practice should be avoided, if possible. Where notching is distinctly advantageous and inspection finds the notched door in compliance with the laboratory standards in all other aspects, a certificate may be furnished by the testing laboratory affixing the label.

Figures 8.3.6, 8.3.7, and 8.3.8 illustrate some conveyor designs and/or programming devices that minimize or eliminate the threat of obstruction to complete fire door closure by the conveyor or conveyed stock. For details and more figures, see NFPA 80, *Standard for Fire Doors and Other Opening Protectives*.

The illustrations can show only basic concepts. Proper performance depends equally on conservative design, good workmanship in installation, operating inspection, and

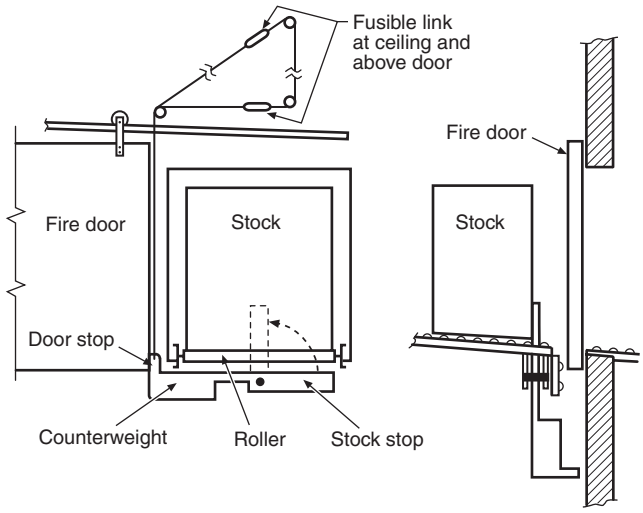

FIGURE 8.3.7 Method of Stopping Stock on a Gravity Roller Conveyor

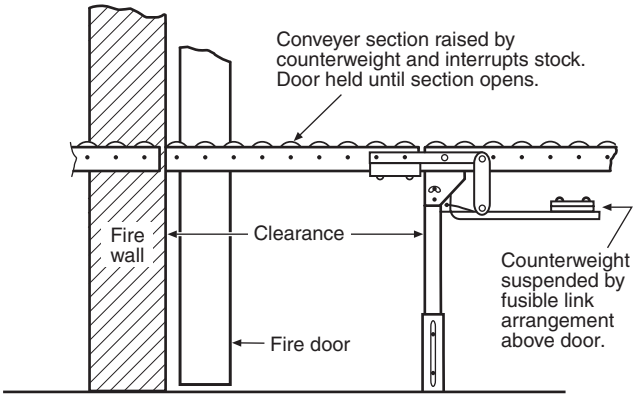

FIGURE 8.3.8 Counterweighted, Hinged Section of a Roller Conveyor

maintenance. Guidelines for design and installation include the following:

- Select a design that acts as simply and directly as possible. Emphasis should be on "fail-safe" operation.
- Program the sequence of operating steps and interlocks so that obstruction (conveyor or conveyorized material) to the door closure is positively and permanently—until manually reset—removed from the door's path before the door is released to close.
- Design structural and mechanical components, linkages, clearances, and so on conservatively. Counterweights, springs, and other operating forces that are uninterruptable by initial fire stages must have enough reserve strength to handle overload introduced by reasonably anticipated minor changes in configuration and weight of conveyorized material, normal wear, and friction. Major changes necessitate complete reengineering to ascertain design adequacy.
- Incorporate self-releasing features in conveyor component design, such as trolley track, chain, and supports.
- Maintain ⅜ in. (9.5 mm) clearance between the door and the sill.
- If advisable, provide another fire door on the opposite side of the opening to increase the reliability of the protection of the wall opening in the event of a fire. Similarly, when the property is sprinklered, consider reinforcing the protection of the opening by a water curtain from automatic sprinklers. Take care that sprinkler discharge does not impede the operation of fusible links on the fire door assembly. Water shields attached at the top of sprinklers below any ceiling sprinklers may be advisable.
- Following installation, conduct operating tests that reflect the range of varied adverse conditions anticipated to ascertain that all components operate smoothly, in proper sequence, within a specified time interval, and with adequate clearances and tolerances. Revisions to the installation may be necessary to correct deficiencies revealed by these tests.
- Close all fire doors during inoperative periods.
- Note that routine closure that simulates emergency operation can indicate the continued adequacy and reliability of the protection of the opening.

Friction and Overheating

The heat of friction can cause fires involving conveyors, such as those used for materials like raw cotton, grains, powders, and coal. This situation results from accumulated grease and dirt and overheating of defective or unlubricated parts, especially rollers and bearings. This common fire hazard is easily reduced and controlled by patrolling belts, by frequent equipment inspection, and by the removal of dirt and grease buildups on a frequency basis that is determined by routine inspections or patrols. Maintenance, including early replacement of old and worn parts, is also important. Maintenance and housekeeping should be included in any plant preventive maintenance program.

Bucket Elevators

Bucket elevators are used in bulk processing plants to convey loads vertically and are susceptible to the same fire hazards as mechanical conveyors. The same precautions need to be taken for temperature, dust control, protection of openings, and elimination of friction and overheating via maintenance and housekeeping. Elevators should be enclosed in substantial dust-tight casings of noncombustible construction; extend without reduction in size through the roof; and be fitted with light, weatherproof covers designed to lift readily and relieve explosion pressure.

Elevators should be installed close to an outside wall of the building and provided with short direct vents through the wall at 20 ft (6 m) intervals on tall elevator legs. Doors should be installed to provide access to head and boot pulleys and to facilitate housekeeping. All doors in elevator leg casings should be dust-tight. Ample clearance around elevator boots should be provided for cleaning and oiling. Safeguard elevators against overheating or choking by automatic releases actuated by overloading or a reduction in operating speed.

PNEUMATIC CONVEYORS

Pneumatic conveying is a common method of transferring powders and small solid particles from place to place in a building or from one building to another. This process presents an explosion hazard due to the ease and rapidity by which explosive proportions of dust can be introduced into the air.

Description of Systems

Pneumatic conveying systems consist of an enclosed piping system that normally transports material by an airstream with a velocity sufficient to keep the conveyed material suspended in motion. Noncombustible gases may be used in place of, or mixed with, air. (See Inert Atmospheres section.) These systems are of two principal types—pressure or suction—or a combination of the two types.

Pressure Systems. Pressure systems transport material using air at greater than atmospheric pressure. These systems basically consist of a blower that draws air through a filter, an airlock feeder that introduces materials into the system, piping or ducts, and a suitable air-material separator.

Suction Systems. Suction systems transport material using air at less than atmospheric pressure. These systems basically consist of a material and air intake, piping or ducts, a suitable air-material separator, and a suction fan or blower.

Conveyor Ducts

Conveyor ducts are fabricated of nonferrous, minimum-sparking metal or of nonmagnetic, minimum-sparking stainless steel. They are electrically bonded and grounded. Plastic or other nonconductive liners are not desirable but may be necessary, depending on the characteristics of the conveyed material. Where duct construction or liners are composed of combustible materials, automatic sprinkler protection within the ducts is often strongly recommended.

Inert Atmospheres

Inert gas is recommended in conveying systems wherever the concentration of powder or dust may come within the explosive range. The inert gas, such as nitrogen, argon, or helium, with a limited oxygen concentration based on the explosive characteristics of the particles in the system, is essential for preventing fires and explosions. Basically, it contains insufficient oxygen to permit combustion and no carbon monoxide, and it has a dew point such that no free moisture can condense or accumulate at any point in the system. The type of material being conveyed and the character of the inert gas dictate further limitations. For example, the inert gas for magnesium dust systems should not contain carbon dioxide. Oxygen limits of 3 to 5 percent should be maintained in aluminum powder systems using a controlled type of flue gas. Other limits are applicable where other inert gases and dusts are present. A continuous monitor is needed to sound an alarm if the oxygen content of the inert gas is not within the established safe range.

Various mechanical means of particle size degradation produce light metal and light metal alloy powders. These processes, as well as certain finishing and transporting operations, tend to expose a continuously increasing area of new metal surface. Most metals immediately experience a surface reaction with available atmospheric oxygen, which forms a protective oxide coating that then serves as an impervious layer to inhibit further oxidation. This reaction is exothermic, producing sensible heat. If a fine or thin lightweight particle having a large area of new surface is suddenly exposed to the atmosphere, enough heat will be generated to raise its temperature to the ignition point.

A completely inert gas will not promote operational safety and is not used for transport of light metal powder in a pneumatic or fluidized transfer device. This practice would be very unsafe because somewhere in the process of manufacture, packaging, or ultimate use, the powder is eventually exposed to the atmosphere where the unreacted surfaces react suddenly with available oxygen to produce sufficient heat to cause either a fire or an explosion. To provide maximum safety, a means for controlling oxidation of newly exposed surfaces is provided—as soon as they are exposed—by regulating the oxygen content of the inert gas. An inert gas containing a limited and controlled amount of oxygen is effective for this purpose. This mixture controls the oxidation rate, thus providing an environment that materially reduces the fire and explosion hazard.

Air Conveying

If the conveying gas is air, as it often is in atomizing, the dust-air ratio throughout the conveying system is held below the minimum explosive concentration of the metal dust. Although the metal-dust-air suspension may be held below the explosive concentration in the conveying system, the suspension necessarily passes through the explosive range in the collector at the end of the conveying system unless the dust is collected in a liquid, such as in a spray tower. Such wet collection is not always possible or desirable. Any liquid used must be nonflammable, nonreactive with metal dust, or reactive at a controlled minimum rate under favorably controlled conditions. The liquid remaining in or on the product must be compatible with subsequent processing requirements.

In an air conveying system, any dry collector must be considered an explosion hazard containing a dust-air mixture in the explosive range. It is, therefore, located in a safe place and provided with requisite barricades or other design means of protecting personnel. Construction should be of nonferrous, nonsparking metal or of nonmagnetic, nonsparking stainless steel. The entire system, particularly the collector, should be thoroughly and completely bonded and grounded. When checked with an ohmmeter, the ground system should show less than 5 ohms resistance to ground.

Where the conveying duct is exposed to weather or moisture, it should be moisture tight, because any moisture entering the system can react with the dust, generating heat and serving as a potential ignition source. A minimum conveying velocity is employed throughout the conveying system to prevent the accumulation of dust at any point and to pick up any powder that might drop out during an unscheduled system stoppage. If the

conveying gas is inducted into the system in a relatively warm environment and the ductwork and collectors are relatively cold, the gas temperature may drop below the dew point, causing condensation. To avoid this, the ducts and collectors should be insulated or provided with a heating means.

Relief Vents for Conveyor Ducts

Vents of sufficient area connected to ducts or openings protected with antiflashback swing valves and extending to the outside of the building can provide explosion relief. Care should be taken to limit the inertia of swing valves to the minimum required. Rupture diaphragms can be used in place of swing valves. Wherever damage may result from a ruptured duct, the duct is designed for a minimum internal working pressure of 100 psi (690 kPa) in case the relief vent fails to offer sufficient pressure relief. Where the duct is so located that no damage will result if it bursts, it may be of very light construction to intentionally fail as an auxiliary vent for the system.

Fan Construction and Arrangement

Fan blades and housings that are used to move air or inert gas in conveying ducts are constructed of conductive, nonsparking metal, such as bronze, nonsparking stainless steel, or aluminum. In no case should the design be such that it draws the dust through the fan before entering the final collector. Personnel should not be permitted within 50 ft (15 m) of the fan during operation. This means that the fan and associated equipment are shut down for oiling, inspection, or preventive maintenance. Appropriate lock out–tag out procedures (LOTO) should be followed. If the area must be approached during operation for a pressure test or other technical reasons, it must be done only under the direct supervision of competent technical personnel and with the knowledge and approval of the operating management. Ultimately, all fans in dust collector systems accumulate enough dust to be a potential hazard; for this reason, locating them outside of all manufacturing buildings is preferable.

It is good practice to equip fan bearings with suitable instruments for indicating the temperature or to monitor vibration. Such instruments are wired with an alarm device to warn of overtemperature or imbalance.

Sight Glasses

Avoid sight glasses in pneumatic systems whenever possible. If installed, they should be of noncombustible material that is not readily subject to physical damage. The ducting is supported above and below each sight glass so that the sight glass does not carry any of the system weight and is not, in itself, subject to resulting stresses or strains. The system's electrical bonding must be continuous around all sight glasses. The strength of the sight glass, its mounting mechanism, and its inside diameter are equal to the adjoining tube system. In pressure-type systems, connections between sight glass and tubing are butted squarely and fastened together with rigid, airtight couplings, connectors, or comparable devices. In suction systems, connections between the sight glass and tubing are butted squarely and sealed with approved sleeves extending a minimum of 3 in. (76 mm) above and below the sight glass and tubing connections. The sleeves are of a material with elastic properties that provide an airtight seal.

Air-Material Separators

Air-material separators should preferably be located outside the building and provided with lightning protection. Material discharge outlets are provided with positive choke devices. The separator should be electrically conductive and bonded. Exhaust air should be always discharged to the outside, except where provision is made to recirculate transport air directly back into the pneumatic conveying system. The air-material separators should be constructed of noncombustible materials and the cloth filters of low-hazard materials. Where using combustible filter media is necessary, flame-retardant treatment is desirable. In addition, the cloth filters should be housed in grounded metal enclosures, with provision for cleaning the filters. The construction of separators should eliminate ledges or other areas where dust may accumulate. (For additional information, see Section 8, Chapter 1, "Air-Moving Equipment.")

CRANES

Cranes are an essential and necessary part of many industrial or manufacturing operations where heavy materials must be lifted or moved. Many cranes, such as overhead traveling, gantry, tower, and bridge-type cranes, move along rails. Overhead traveling can be used effectively indoors or out, whereas gantry, tower, and bridge cranes are used mainly outdoors. Mounting other cranes on wheels makes them mobile. Cranes can be powered by electricity or by internal combustion engine drive. Normal safeguards and maintenance must be observed with these power systems.

Outdoor cranes are susceptible to damage by high winds, unless a positive means of anchorage is provided, in addition to the operating or service brakes. Large cranes that move along rails are generally provided with automatic or manual rail clamps. Other means of anchorage are crane traps, wedges, and cables. Anchorage and support are particularly necessary and advisable when a crane is not in use and unattended.

Crane operators should be thoroughly trained in the equipment's proper operation, including emergency action that may be necessary in a fire or other hazardous incident. The crane operator's cab should be of noncombustible construction and provided with an emergency means of egress. It should be kept free of oily waste, rubbish, and other combustibles. All electrical equipment should be in conformance with NFPA 70, *National Electrical Code®*, and securely mounted and maintained.

Portable fire extinguishers may be desirable in some operators' cabs. For large equipment, automatic fixed-piping extinguishing systems may be advisable.

SUMMARY

Materials-handling operations are found in nearly all industries. Although they can be considered critical to some occupancies, they are often incidental operations and do not always receive

the careful attention required for preventing fires. However, even an incidental operation can prove to be a major bottleneck, and if the materials-handling operation is shut down, it may have serious and/or lengthy impact on the overall production scheme, causing a large business interruption loss. Improper equipment selection, operation, and maintenance can result in ignition. Also, normally present hot surfaces, liquid and gaseous fuel handling, and high-amperage electrical equipment provide ignition and injury potential.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on materials-handling equipment discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

Overview
Automated Equipment Analyzed
Analysis of the Process
Design Solutions
Standards Related to Automated Equipment

Key Terms

automated equipment, automated shelving (carousel), automated systems, central processing unit (CPU), controller, electrical equipment, power network

Like many other facets of industry, automation has benefited greatly from the technological developments of the last few decades. Thirty-five years ago, automation was accomplished by use of large relay control panels. In 1969, programmable controllers (PCs) began to replace relays in the automotive industry. By 1971, other industries were using PCs. In 1977, microprocessor-based PCs were controlling automated processes. Today, automation has become very complex and sophisticated. A great deal of care is needed to design safe automated systems.

Programmable controllers have introduced new fire protection problems into the processes that they automate. This is because the PC has been given control over such things as flammable liquids flow, the position of combustible materials, the initiation of sparks and flames, the motion of friction-causing parts, and other potential sources of fuel and ignition. As a result, any kind of failure in the PC can cause a fire or explosion. This chapter addresses how to analyze and deal with the increased potential for fire or explosion with automated equipment. The chapter does not cover the hazards and protection of individual pieces of equipment that are included in other chapters of this handbook. Many of the issues raised are also germane to independently operated machines.

For related topics see Section 8, Chapter 1, "Air-Moving Equipment"; Chapter 2, "Chemical Processing Equipment"; Chapter 3, "Materials-Handling Equipment"; Chapter 8, "Industrial and Commercial Heat Utilization Equipment"; and Chapter 11, "Fluid Power Systems." See also Section 16, Chapter 5, "Sprinkler Systems for Storage Facilities."

OVERVIEW

Automated Equipment Defined

Modern automated machinery usually consists of many pieces of equipment acting in a coordinated manner without operating personnel control. These systems are commonly referred to as manufacturing cells or flexible manufacturing systems. Common examples include numerically controlled machine tools (NC), computerized numerically controlled machine tools (CNC), industrial robots, work-handling machines or systems, material/workpiece transfer equipment, and associated control and information-handling equipment. Automated systems also control many other types of processes.

Automated equipment is found in many different business and industrial applications. Although most often thought of in the robotic manufacturing frame of reference, it is also found in other areas of the industrial community. Other areas include material transportation and handling, weighing and filling operations, as well as packaging. The use of these types of operations is expanding dramatically.

Carousels

In some unique operations, incoming materials and subassembly parts are received, sorted, and stored in automated shelving systems referred to as carousels. These automated storage systems

L. Jeffrey Mattern is retired from FM Global in Philadelphia, where his most recent positions were senior account engineer and chief engineer of Mid-Atlantic Operations. He has served on various NFPA technical committees and the NFPA Standards Council since 1968.

can be open grid shelf systems, typically between 8 and 12 ft (2.4 and 3.7 m) in height and 50 to 60 ft (15.2 to 18.3 m) deep or even deeper, which are referred to as horizontal carousels (Figure 8.4.1). A carousel can also, for example, be a "metal box" with rotating moveable shelves within it, with dimensions of 8 ft (2.4 m) wide, 6 ft (1.8 m) deep, by 12 ft (3.7 m) high. These carousels are referred to as vertical carousels (Figure 8.4.2).

Carousels often have plastic trays or bins on the shelves. Even when containing metal products or parts, the plastic containers create a formidable fire hazard in themselves. Additionally, the typical open-top containers, whether combustible or noncombustible, can collect water from automatic sprinklers and prevent the water from reaching the seat of the fire. Both of these conditions require special fire protection consideration in order to afford adequate protection.

Transportation and Handling

Another aspect of automated equipment is that associated with transportation and handling. This includes the packaging, palletizing, and storage of finished product. In this case, finished product is transported via a conveyor and loaded robotically into its shipping container, dispatched on a second conveyor to an automated palletizer, where shipping containers (for example, cartons) are loaded on pallets and then conveyed to a storage area. A conveyor then transfers the entire pallet into an automatic storage and retrieval system of high racks, often 80 to 100 ft (24.4 to 30.5 m) in height.

Hazards

A key hazard of this type of operation is the accumulation of pallets at the automatic palletizer. In addition to the design of adequate automatic sprinkler protection for the product storage racks, the storage of idle pallets at the palletizer requires a high-density automatic sprinkler system design to adequately control a fire involving this type of storage. See Section 16, Chapter 5, "Sprinkler Systems for Storage Facilities," for more information regarding fire protection of rack storage configurations.

FIGURE 8.4.1 Schematic of Horizontal Carousel (Source: Courtesy of SJF Material Handling, Inc.)

FIGURE 8.4.2 Schematic of Vertical Carousel (Source: Courtesy of SJF Material Handling, Inc.)

Another hazard is associated with conveyor systems that penetrate fire walls. The operational design of these conveyors must include arrangements to allow specially designed fire doors to close in the event of a fire.

The pharmaceutical, food processing, and various agricultural-type industries are among the largest users of automated equipment. Raw materials are blended into a specific formulation. The product then flows to a hopper, which feeds an automatic filling machine, which in turn places the exact amount of the product, likely by use of a load-cell, into the container, seals it, labels it, and then sends it on to the automatic cartoning unit (Figure 8.4.3).

Each application of automation must be reviewed for any hazardous situations it might introduce. This is done by reviewing both the PC as well as all aspects of the process being controlled.

Operation of Automated Systems

Automated systems consist of two or more machines grouped together to perform a series of operations on materials or parts.

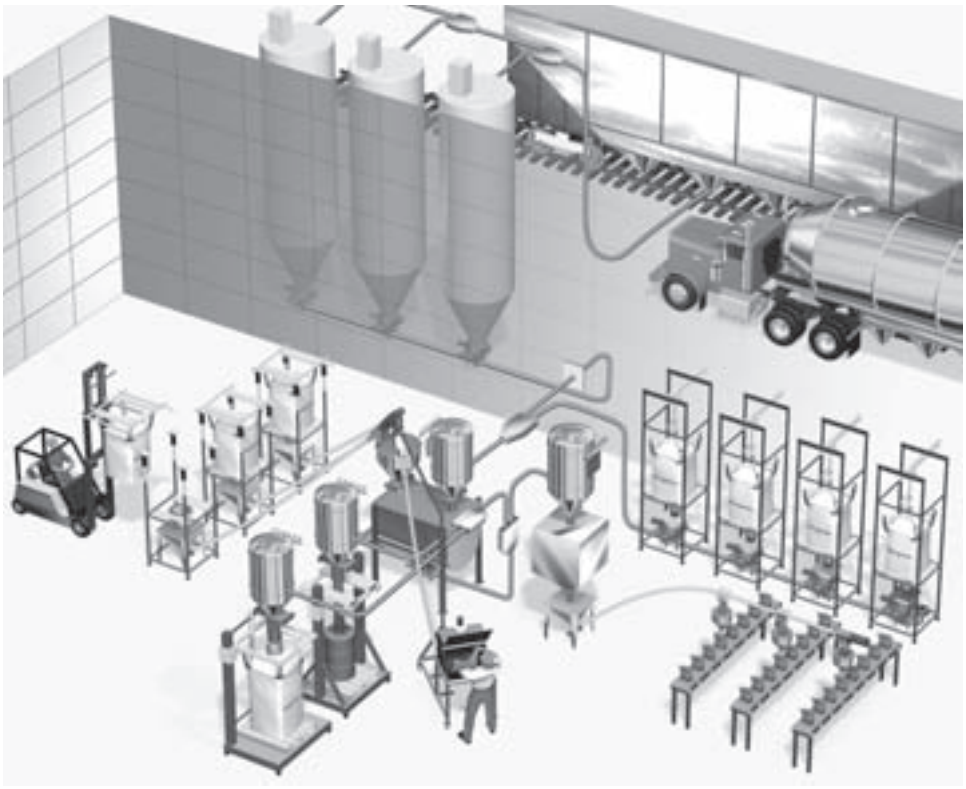

FIGURE 8.4.3 Conveying, Loading, Unloading, Weighing, Feeding, and Processing Bulk Solid Materials (Source: Courtesy of Flexicon Corp., http://www.flexicon.com)

Typically, these machines run automatically without an operator, or sometimes one person runs more than one machine. A supervisory controller (usually a computer) directs the interrelations between these machines, transmits information to the individual machine controllers, and monitors the process. The individual machine units (machine and controller) may be supplied by different vendors, thus requiring compatibility between the individual units and the supervisory controller. The issue of compatibility places additional responsibility on the manufacturer for proper installation, maintenance, and training of the end user. In addition, the machine controllers and the supervisory controllers utilize sophisticated computer equipment, operating in a real-time mode, that transmits large amounts of information at low levels and high speeds—conditions that require greater attention to the design, installation, operation, and maintenance of these systems.

AUTOMATED EQUIPMENT ANALYZED

Analysis of the Controller

Microprocessor-based PCs introduce failures never before dealt with in relay-controlled automation. The most common of these failures are described in Table 8.4.1.

Problems of personnel safety, power networks and distribution, grounding, electrical noise interference, software application and maintenance, and fail-safe requirements are more

TABLE 8.4.1 Programmable Computer Failures

CPU STALL	Processor ceases to execute the program.
INPUT/OUTPUT SCAN FAILURE	Processor fails to scan input/output signals for change in status.
INPUT FAILURE	Input module locks in "on" position and does not respond to further input changes.
ADDRESSING FAILURE	Processor fails to correctly consult input/output intelligence.
OUTPUT FAILURE	Output module locks in "on" position and does not respond to the controller.
MEMORY FAILURE	Incorrect bit in memory causes an improper instruction to be given.
WATCHDOG TIMER FAILURE	Timer controlling execution of instructions fails.
PROGRAM CARD FAILURE	Any problem with the program card occurs.
MOMENTARY POWER OUTAGE	Temporary loss of power to controller occurs.

evident in these integrated manufacturing systems. The introduction of PCs can also introduce fire or explosion potential by providing a new heat source into an area with easily ignited fuel. An example would be using a PC as an alternative to a relay control panel that didn't fit the space available, in an area subject to flammable vapors in the atmosphere. When this is done, the controller should be intrinsically safe as described in UL 913, *Standard for Safety for Intrinsically Safe Apparatus and Associated Apparatus for Use in Class I, II, and III, Division 1 Hazardous (Classified) Locations.*

Safety

The operation of integrated manufacturing systems is more automated than individual machines, in terms of starting motions and the transferring of material or parts, without operator intervention. Integrated systems can also cover more complex operations on larger areas of a factory floor or warehouse areas. It is, therefore, necessary to provide additional safety measures beyond those for conventional single-machine workstations. Typical measures include barriers and gates, presence-sensing devices, and visual or audible warning devices to announce pending machine operation and/or material movement.

Movement of a machine or workpiece and/or a material-handling device that occurs at unannounced times could catch personnel in a "pinch point" and result in a serious injury. Thus, the primary safety consideration is to keep personnel out of the work area while the system is operating. Enclosing the system in a cage or fence is one possible solution to the problem, but it is not always practical, since many systems require personnel in the work area during operation. Often it is not possible to determine if anyone is in the work area when the equipment is operating. One alternate solution in particularly hazardous work areas is to provide physical barriers and/or guards, interlocked with the individual controllers or the supervisory controller. All hazardous motions should be automatically stopped if the interlock is interrupted.

Another alternative is to provide presence-sensing devices, such as pressure-sensitive floormats or light-beam curtains, that will either stop all dangerous motions immediately or stop the automatic cycle once the motions in progress have been completed. Visual or audible annunciators that warn of pending axis motions or the cycling of auxiliary equipment also can be used if personnel must be in the work area during automatic operation.

Fail-safe travel limits, such as mechanical stops or hard-wired travel switches, should always be used in systems in which software controllers for individual machines or system monitoring are utilized. The fail-safe travel limits ensure that, if the controller should fail or a runaway condition should exist in either an axis motion or an auxiliary cycle, the motion would be physically restrained or the power would be removed from that motion. One added consideration involves the order in which the automated equipment is shut down. A sequential shut-down order may be necessary to ensure that a bad situation does not become worse.

ANALYSIS OF THE PROCESS

For some processes, failure of a PC will merely result in inconvenience. It is not unusual, however, for more serious problems to be introduced. For example, PC-controlled robot welders can destroy parts if the arc is not turned off at the right time. They could also ignite combustible materials that mistakenly end up in the area.

PCs controlling hazardous processes, such as spray painting, solvent drying, and fuel firing, also present many potential fire and explosion hazards. A PC failure could create hazardous conditions by not stopping paint guns, solvent introduction, or fuel flow.

Another complication of automated processing is the potential for interruption of production. In automated processes that cannot be run manually, PC failures will stop production. The length of time needed to repair or replace controllers must be considered. Off-the-shelf controllers are easier to replace than custom-made ones. Since off-the-shelf controllers would require reprogramming, software backup should be maintained in a safe location.

Power Networks and Distribution

Careful consideration must be given to the design of the automatic factory power network when large systems are installed. Busbars, which supply electrical power to machines and equipment that are highly inductive or utilize power converters, should be isolated from those that supply power to sensitive electronic equipment. Electrical noise on common power distribution lines or loss of phase can cause malfunctions or permanent damage to electronic equipment. Separate power buses, isolation transformers, and filtering devices are some of the techniques used to minimize the problems associated with power distribution. In some cases, it is necessary to monitor bus loading and automatically schedule the sequencing of particularly heavy electrical loads on the network.

Grounding

The grounding of electrical equipment has always been a consideration for the safety of personnel to guard them from electrical shock. In systems using sensitive electronic equipment, grounding is a primary concern to protect the controller and its input/output connections from the effects of electrical noise. The grounding of control equipment in industrial environments should be integrated by the equipment user into a coordinated ground system. When control equipment is grounded, it is interconnected into the system ground by building columns or ground rods.

In electrical/electronic controllers, there are usually subsystems that are tied to the ground system. It is essential that the noncurrent-carrying metallic enclosures be grounded, including all internal frames and equipment support structures. A specific ground point is provided within the enclosure for the equipment ground to make connection to the ground system. A separate tie point is provided to connect the control common (the zero potential reference point for the electrical and electronic

equipment) to the ground system. Having two separate ground reference points separates the two ground systems within the controller, eliminating ground loop problems. Providing two separate ground reference points within the enclosure allows the equipment ground to be connected to the building, whereas the control ground is connected to a separate ground rod independent of the building structure.

DESIGN SOLUTIONS

To ensure a high degree of reliability in programmable controller control functions, particularly those that are safety related, these functions should be either periodically checked for proper operation, continuously monitored, or be installed with either redundant or diversified circuits using independent circuitry. Input circuits, input/output addressing, and input/output scanning should be verified with a dynamic safety check, on the order of several times per second. Output devices, particularly those that control hazardous conditions, should be monitored and, in critical areas, designed using independent redundant circuits. The central processing unit (CPU) as well as output devices are monitored using a watchdog timer, which itself is provided with a dynamic safety check. Sum and parity checks are used on memories.

Above all else, the entire process control system must be designed to fail safely. The response to detection of PC abnormalities can be an alarm, the shutdown of chosen process functions, or both. However, if a PC failure can result in unsafe process conditions, the process should be safely shut down upon this failure. In other words, the system should be able to fail without serious consequences.

Process control devices that might fail in a shorted condition (e.g., rectifiers) can be arranged to be disabled manually. Critical controller functions can be independently hardwired to ensure the ability to operate properly in the event of failure.

Electrical Noise Interferences

Because entire books have been written on this complicated subject, only the most important considerations are covered here. The effects of coupling electrical noise into control equipment become more pronounced as the operating speed and equipment complexity increase, whereas the immunity to disturbances decreases. This is certainly the case with controllers applied to industrial automation equipment. The microelectronic circuits operate above 1 MHz, with harmonics in the range of 2100 MHz to 1 GHz. Signal levels are typically below 15 V. Noise coupling from disturbing sources, such as power inverters, motors, contactors, and relays, and associated wiring runs can be detrimental to the operating system unless proper techniques are used to reduce the disturbances or minimize coupling into the sensitive circuits. Commonly used methods of reducing the disturbing effects of electrical noise are (1) employing transformers or filters to isolate power wiring from signal and control wiring, and (2) shielding sensitive control and signal wiring by using shielded conductors or coaxial cable. Proper grounding of the shield (usually at only one end) is a must. For extremely sensitive circuits, the use of double shielding (one shield tied to the equipment ground and the other tied to the control common) may be required. Some circuits or subsystems may have to be entirely enclosed in a grounded shield.

Sensitive signal conductors should be separated to the greatest degree practical from noise sources. One example of this problem involves power leads that are run in the same cable or raceway as digital transmission or analog signal lines. Wherever possible, these lines should be in separate cables or raceways. When this is not possible, it is necessary to use shielding or additional conductors that are tied to the ground. Remember that all unused conductors should be grounded at one end to minimize coupling.

The effect of electrostatic discharge is another potentially serious problem that is often overlooked. Microelectronic devices (memory and logic chips) must be handled by personnel who are grounded by either a wrist strap or conductive plates located on the soles of their shoes. However, nonconductive materials (clothing, paper, etc.) in close proximity to the chips also carry an electrostatic charge that can be neutralized by ionized air. The precautions taken for handling microelectronic parts are typically discontinued once the chips are inserted into a printed circuit assembly. Although a completed printed circuit assembly will dissipate some of the charge, the chips are still subject to damage from electrostatic discharge. The grounding or discharging of personnel who are required to work with integrated circuits, including those who assemble, inspect, test, ship, or maintain the equipment, is important to ensure reliable operation of the electronic equipment. An electric charge of thousands of volts can be developed by simply getting up from a chair or paging through a set of schematic drawings. With the present technology, as little as 50 V of electric charge can permanently damage, degrade the performance of, or shorten the life of these components. In industrial systems employing thousands or tens of thousands of these devices, the potential for a malfunction or failure due to electrostatic discharge is very high and should be considered as serious a problem as shock hazard.

Software Application and Maintenance

The use of programmable electronic controllers and software programming has introduced a new series of problems that were not present with hardware systems. Failure modes and malfunctions are harder to detect and correct since the controllers must first verify the proper operation of the hardware and then test with application software. Since the software tends to be unique for each controller (one of the major advantages of programmable electronic controllers), elaborate testing and verification methods must be devised to ensure that the software functions properly under all dynamic conditions. This problem is compounded when the controllers must interact in a manufacturing system. Even if the software is properly certified before shipment to the end user, it is often modified in the field to correct for unexpected conditions of actual use. Many times, the corrected software is put into operation without a complete recertification, or, even worse, it is corrected at the job site without

being retested. In a large, complex system, the results of this "on-the-fly" modification method can be disastrous.

The typical failure mode being "failure to prevent a hazardous condition or situation" is another problem created by the introduction of electronic circuitry. Silicone-controlled rectifiers, triacs, and electronic switching devices usually fail in a shorted condition, resulting in such hazards as axis or auxiliary cycle runaway. Short of removing power to the portion of the system that has failed, the condition cannot be corrected. Typical methods of overcoming this problem are redundant circuits, hardwired contacts that can break the connection to the drives or motors that control motions or auxiliary cycles, or control circuits that monitor and automatically disable equipment that can create hazardous conditions.

The transmission of large amounts of digital information between system elements presents the potential of system malfunctions if the data are not properly received. Wrong axis commands, machine conditions, or even entirely incorrect part programs might be sent or received. Since there is no operator intervention before machine or controller action is initiated, injury can result to personnel or damage can occur to the machine or the work in progress. Redundant transmission or error checking and correction are means of reducing the effects of this problem. Proper shielding and protection of these transmission lines is mandatory if these problems are to be kept to a minimum.

STANDARDS RELATED TO AUTOMATED EQUIPMENT

A number of standards have been or are in the process of being developed that relate to factory automation and address subjects previously covered in this chapter. ANSI B11, *Construction, Care, and Use of Machine Tools,* correlated the hazards to persons created by various types of machine tools and the measures to be used to ensure minimum exposure to these hazards. A standard on safety issues related to manufacturing systems/cells (ANSI B11.20, *Safety Requirements for Construction, Care, and Use of Machine Tools, Manufacturing Systems/Cells*) has been developed. This standard deals with the hazards and their associated risks created from the interaction of a number of machines working in a coordinated manner to produce discrete parts or assemblies. There is also a safety standard for robots, developed by a committee sponsored by the Robotics Industries Association (RIA). In turn, these standards incorporate the electrical requirements found in NFPA 79, *Electrical Standard for Industrial Machinery.*

Internationally, safety standards have been developed to encompass industrial manufacturing systems and robots, as well as electrical equipment of industrial machines. International Organization for Standardization (ISO) Technical Committee 199 is responsible for basic safety standards related to machinery. International Electrotechnical Commission (IEC) Technical Committee 44, electrical standard IEC 60204-1, *Electrical Equipment of Industrial Machines—Part 1: General Requirements,* has been adopted as a European standard as part of a series of standards used to support the European Directive (law) 98/37/EC, on machinery safety. The Machinery Safety Directive has been in full effect since January 1, 1995, and affects all machinery manufacturers that are marketing their products in the European Union.

Within Europe itself, a number of standards related to general requirements for machines and machining systems have been or are in the process of being developed. These include requirements for machines, such as machine tools, rubber and plastic machines, and material-handling systems, as well as various types of devices, such as light screens, two-hand control, and interlocking devices. It is anticipated that much, if not all, of the research in Europe related to safety of machinery will be elevated into the international standards community (ISO and IEC) within the next few years, making it vital for the United States to participate in these activities, if U.S. industry does not wish to be severely affected in its ability to sell machinery and related products.

Standards related to programmable controllers have been developed by an IEC technical committee. These standards are divided into two series. The first covers such topics as operating conditions, input/output structures, and programming languages. The second is directed toward safety issues, including both hardware and software. There are no corresponding U.S. standards on programmable controllers, since all effort in this area has been focused on IEC activities.

There is also a new European directive on electromagnetic compatibility (89/336/EEC), which went into effect on January 1, 1996. This directive requires that all electrical equipment (with few exceptions) must not generate sufficient electrical fields to disturb other electrical equipment, and, at the same time, must not be susceptible to effects of electromagnetic interference (both electric fields and common mode) and electrostatic discharge in such a manner that a malfunction or failure of the equipment will result. Both European and IEC standards are being developed to provide guidance on the levels of emission and immunity, means for reducing the effects of electromagnetic interference, and testing methods.

The Institute of Electrical and Electronics Engineers (IEEE) has produced a standard on electrical interferences: IEEE 518, *Guide for the Installation of Electrical Equipment to Minimize Electrical Noise Inputs to Controllers from External Sources,* which covers various types of noise that can affect the operation of electrical equipment (e.g., common mode, electromagnetic, and electrostatic) and aims to reduce the effects of these interferences.

Considerable effort both in the United States and internationally has been expended on the encoding and transmission of digital information over industrial networks. The most prominent of these activities is the manufacturing automation protocol (MAP) specification, which is based on the international open system interconnection (OSI) model. Coupled with this work are the series of international standards on the manufacturing message specification (MMS). Adjunct to this work is standard IEC 61491 on the digital transmission of encoded serial information between machine controllers and drives.

Fire Protection Evaluation

As discussed throughout the chapter, there are many safety and fire protection considerations related to automated equipment. In addition to those already discussed, another concern is that

some of the industrial assembly operations contain hydraulic oil–operated equipment or central lubrication systems. In both cases, the oil, if not of the less-hazardous type, can present a severe fire exposure.

The oil tank and pumps ideally should be in some type of fire resistance rated enclosure so that the potential for a spray fire at the oil pump or a catastrophic spill at the tank is reduced. It is also important to consider that an oil spray fire may occur at the end point. These types of leaks can be detected by a low-level switch on the oil tank, but additional detection should be provided by the use of heat detection over the area where high-pressure oil piping is located. The heat detection is then interlocked to the hydraulic or oil lubrication pump and arranged for automatic shutdown when the heat detector is activated. (See Section 8, Chapter 11, "Fluid Power Systems.")

Fire protection for the area should also take into consideration the normal occupancy hazards present, such as in-process goods storage, rack storage in warehouses, and general work processing operations. The hazards outside the scope of those associated with the automated equipment may be greater than those of the automated equipment itself.

SUMMARY

Automated systems typically consist of two or more machines grouped together to perform a series of operations on materials or parts. In 1977, microprocessor-based programmable controllers (PCs) began controlling automated processes. Because PCs have been given control over potential sources of fuel and ignition, such as flammable liquids flow and position of combustible materials, they have introduced new fire protection problems into the processes they automate. This chapter has looked at how to analyze and deal with the increased potential for fire or explosion with automated equipment.

electrical shock, flammable gas, hertz, laser, laser safety officer (LSO), maximum permissible exposure, monochromaticity, optical spectrum, reactive gas

Lasers have become a common part of life. To increase fire protection practitioners' understanding of lasers, this chapter examines how lasers work, their fire hazards, their safety classifications, and several hazard protection measures. Lasers have many applications, for example, in medicine, industry, and education. One of the most widely used applications of lasers is their use to scan product codes for identification and pricing. In the business world, lasers are used in printers and in CD-ROM drives in computers. In the entertainment industry, lasers are used to record music, movies, and special movie effects and to present public displays at theme parks. The medical field has taken advantage of lasers' properties for use in surgery. Additionally, veterinarians have also used lasers on their patients. In the construction industry, lasers are used for measuring distances and maintaining alignment for pipes, tunnels, ceilings, and floors. Manufacturers use lasers to cut, weld, and drill in items as diverse as metal, paper, and fabric. Lasers also have significant roles in research and military applications.

A primary benefit of lasers can also be a significant fire hazard. Lasers that are powerful enough to be used to cut, weld, and drill are an ignition hazard. Without proper attention and controls they can start fires. The laser itself also has potential fire concerns from the use of flammable liquids and gases, as well as high-voltage electrical components. Ideally, laser fire protection is achieved through physical controls. However, in certain fields, particularly the medical industry, administrative controls are the primary fire protection measure.

Further information on lasers can be found in Section 6, Chapter 11, "Medical Gases." The Bibliography references other applicable sources of information.

LASER PROPERTIES AND COMPONENTS

Laser Defined

The word *laser* is an acronym for "light amplification by stimulated emission of radiation." The radiation referred to in the acronym should not be confused with ionizing radiation associated with radioactive materials; rather, it refers to the broad spectrum of electromagnetic radiation that includes infrared light, visible light, and ultraviolet light.

Visible light is one form of electromagnetic radiation. Other forms of electromagnetic radiation—such as radio waves, ultraviolet light, and microwaves, which differ in frequency and wavelength—are not visible to the human eye.

All forms of electromagnetic radiation taken together produce the electromagnetic spectrum. Different portions of this spectrum describe the frequency and wavelength of the various electromagnetic wave forms (Figure 8.5.1).

Wavelength, which refers to the distance between peaks on a wave or the distance for the wave to complete one cycle, is measured in meters, micrometers, and nanometers. Frequency refers to

Fred P. Seeber, Ph.D., is professor emeritus of photonics at the Laser Institute of Technology for Education and Research in Blackwood, New Jersey. He is also the chair of the ANSI Z-136.5 Committee, Laser Safety in Educational Institutions; a member of the NFPA 115 Laser Safety Committee; and a fellow of the Laser Institute of America and the Institute for Applied Laser Surgery. He also serves on the LIA Board of Laser Safety.

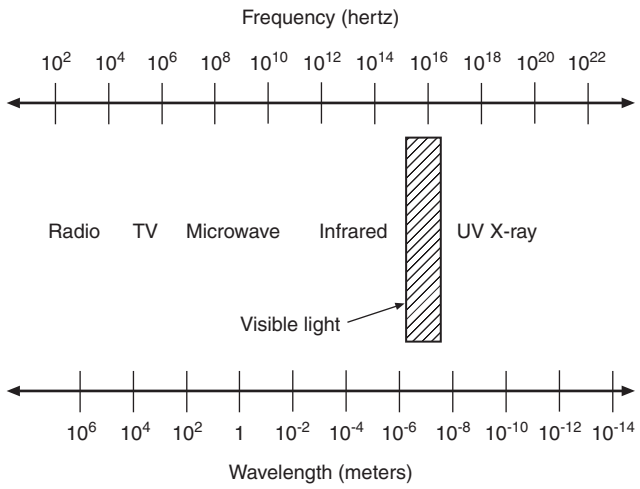

FIGURE 8.5.1 Electromagnetic Spectrum

the number of cycles the wave completes in one second. A *hertz* is one cycle per second and is the normal term of expression for frequency.

Figure 8.5.1 shows that low-frequency, long-wavelength radiation is found at the low end of the spectrum, whereas high-frequency, short-wavelength radiation is found at the high end of the spectrum. Examples of low-frequency, long-wavelength radiation are radio waves, television waves, and microwaves. Examples of high-frequency, short-wavelength radiation are ultraviolet light and x-rays. Radiation visible to the human eye in the form of light makes up a small portion of the entire spectrum. Figure 8.5.2 illustrates the visible light range within the electromagnetic spectrum.

The study of laser light is generally concentrated in the optical spectrum, or that portion of the electromagnetic spectrum from infrared to ultraviolet light, which includes visible light. Infrared radiation is radiation with wavelengths ranging between 10^{-4} and 10^{-6} m. The word *infrared* comes from the fact that the wavelengths are longer than the visible red end of the spectrum. Visible light has a wavelength between 400 and 700 nanometers (a nanometer is one billionth of a meter), as shown in Figure 8.5.2. The eye is most sensitive to green and yellow colors in the range of 555 nanometers and least sensitive to blue and red near their respective ends of the electromagnetic spectrum. Ultraviolet light is that portion of the electromagnetic spectrum with wavelengths between 10 and 400 nanometers, just beyond the visible portion of the electromagnetic spectrum at the violet end.

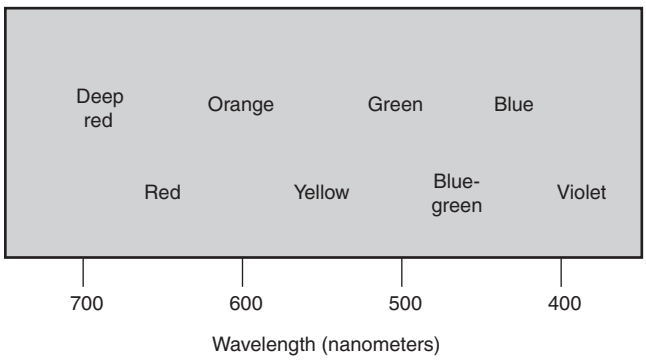

FIGURE 8.5.2 Visible Light Spectrum

Properties

Laser light has several unique properties. One of those properties, called monochromaticity, is that laser light consists of only a single color. In addition, the wavelengths of this single color are within a very narrow range. A second property is directionality. Normal light is radiated in all directions in random fashion. Laser light, however, is radiated in a narrow beam in a single direction. The third unique property of laser light is coherence. Laser light is radiated in an orderly pattern known as being "in phase." When all the separate waves are in phase, the resultant combination wave is much stronger because of constructive interference. Thus, laser light is a very intense light of a single color, being radiated in a single direction, with little divergence. It is these properties that give laser light its diverse applications and its hazards.

Components

A laser, then, must be constructed of components that can produce the necessary photons in sufficient quantities to produce a useful light beam. Lasers generally consist of three components: (1) a lasing medium, (2) an energy source (or pumping system), and (3) a feedback mechanism. Other accessories, such as lenses, mirrors, Q-switches, mode-lockers, and shutters, might be added to the system to produce special effects, but only the basic three are needed for lasing action.

Lasing Medium. The lasing medium is a collection of atoms that can be excited to a state to produce a stimulated emission of photons. The active medium may be a solid, liquid, or gas, or a semiconductor material. Some examples are ruby and Nd:YAG crystals; CO_2, Argon, and Excimer gases; and InGaAsP semiconductor materials.

Energy Source. The pumping system is a source of energy that can be used to raise the electrons in the lasing medium to their excited state. The pumping system can take one of several forms: (1) optical pumping systems use strong sources of light, such as xenon flashtubes or flashlamps, or a continuous arc lamp; (2) electron collision pumping is created when an electric current is passed through the laser material; or (3) chemical pumping is created by the making or breaking of chemical bonds. All of these forms of pumping are commonly in use. Other lasers are also used as an energy source.

Feedback Mechanism. The feedback mechanism is an apparatus that returns a portion of the laser light created in the lasing medium back to the lasing medium. This feedback creates a situation where the photons created in the lasing medium are passed back through the lasing medium, creating more photons. If suffi-

cient feedback is created, the creation of laser light can be made continuously and at high levels. The normal feedback mechanism is a pair of mirrors aligned to reflect the laser light back and forth. One of the mirrors is only partially reflective, permitting some light to leave the laser. The portion of the light that is not emitted continues to be reflected, creating more photons.

LASER OPERATION

Operation Steps

Laser operation can best be described in three steps:

1. Energy is supplied to the laser material by the pumping system. This energy is stored by the laser material in the form of electrons in their excited state. The pumping system must continue until a population inversion (i.e., more electrons in the excited state than in their normal state) takes place for laser light to be produced.

2. Once the population inversion is achieved, the decay of a few electrons to a lower energy level will start a chain reaction. Photons released will strike electrons, creating more photons of the same wavelength, phase, and direction.

3. When the photons reach one of the mirrors, they will be reflected back into the laser material, supporting continued chain reaction and the production of even more photons. Some photons will strike the partially reflective mirrors; when that occurs, some of them will be reflected back into the laser material and some will be emitted as laser light in the form of the beam.

Energy Delivery Rate

The modes of laser operation are differentiated by the rate at which energy is delivered. Some lasers produce a steady flow of light. These lasers are known as continuous wave lasers, or CW lasers. Pulsed lasers are operated to create repetitive laser pulses. A special type of pulsed laser is a Q-switched laser. In the Q-switched laser, a shutter-like device is placed between the mirrors of a laser to interrupt the lasing action. The shutter can act as a mirror in itself, allowing the continued reflection of photons and buildup of excited electrons, but not allowing any photons to escape through the partially reflective mirror. When the shutter opens, a very intense pulse is released.

HAZARD CLASSIFICATION OF LASERS

The American National Standards Institute (ANSI) has adopted a classification system for lasers, based on the ability of the primary laser beam or reflected primary laser beam to cause biological damage to the eye or skin during intended use. The hazard classification categories use maximum permissible exposure (MPE) to laser radiation as a threshold for determining potential hazard.

Old ANSI Laser Classification System

The old ANSI classification system found in the Z-136.1 (2000) follows:

Class 1. Low-powered laser devices that cannot, under normal circumstances, emit laser radiation that creates an optical hazard. These are sometimes called exempt lasers. (See note after Class 4 lasers.)

Class 2. Low-powered laser devices operating in the visible spectrum that cannot injure a person accidentally, but that might injure the eye when viewed directly for an extended period of time.

Class 3. Medium-powered laser devices that are capable of causing eye damage with short-duration exposures to the direct or specularly reflected beam. Occasionally, some upper level Class 3B lasers could be considered a fire hazard. These lasers would be in the half watt range of power.

Class 4. Lasers that can cause injury if viewed directly or if specular and diffuse reflections are viewed. These lasers can also cause severe skin damage and are considered a fire hazard. *Note:* Some Class 4 lasers are called "embedded lasers" and given a lower classification. They still have the same inherent fire risk due to the power of the beam. However, because of engineering controls, they do not have the same risk of laser radiation hazards as the normal Class 4 laser.

New ANSI Laser Classification System

The new ANSI laser classification found in the Z-136.1-2007 and the International Laser Safety Standard IEC 60825-1 follows.

Class 1. Class l lasers or laser systems may produce visible or invisible laser radiation. Under all normal conditions of operation, Class 1 lasers are considered to be incapable of causing injury when the beam is viewed directly.

Class 1M. Class lM lasers may produce visible or invisible laser radiation. A Class IM laser or laser system is considered to be incapable of producing hazardous exposure conditions during normal operation unless the beam is viewed with an optical instrument such as an eye loupe (diverging beam) or a telescope (collimated beam). Such viewing is prohibited by this standard.

Class 2. Class 2 lasers produce low-power visible laser radiation. The output power of a Class 2 laser does not exceed 1 mW and eye protection is normally afforded by the natural blink reflex time (0.25 sec), also called *natural aversion.* Direct viewing of Class 2 laser radiation is prohibited.

Class 2M. Class 2M lasers or laser systems emit visible laser radiation. Eye protection is normally afforded by the natural blink reflex time (0.25 sec); however, direct viewing of Class 2M laser radiation with certain optical aids is potentially hazardous and is prohibited.

Class 3R. Class 3R lasers produce moderate levels of visible or invisible laser radiation and require more stringent controls than

Class 2 lasers. The CW output power of a Class 3R visible laser is between 1 and 5 mW, and the normal aversion response is generally sufficient to prevent injury from inadvertently viewing the output with the unaided eye. However, the use of collecting optics, for example, binoculars, can produce retinal irradiances that are considered capable of causing injury. Optically aided eye exposure to Class 3R lasers that produce ultraviolet or infrared emissions may not be perceived by the eye at the end of injury. For such lasers, the Class 3R accessible emission limit does not rely on the normal aversion response, but rather on the fact that the eye does not fixate on the beam long enough to cause injury.

Class 3B. Class 3B lasers may produce visible or invisible emissions. The output power of CW visible and infrared Class 3B lasers range from 5 to 500 mW. They are considered medium-power lasers and are capable of producing eye injury when they are viewed directly or with optics, even if viewed momentarily. For visible Class 3B lasers, the normal aversion response (0.25 sec) does not prevent injury. Class 3B lasers do not usually produce a hazardous diffuse reflection or fire hazard. At the upper end of the Class 3B range, skin burns may be possible and also under some circumstances a fire hazard.

Class 4. Class 4 lasers are visible or invisible lasers emitting radiation capable of causing injury to the eye and skin as well as producing dangerous specular and diffuse reflections. They can also produce a fire hazard.

HAZARDS AND CONTROL MEASURES

In addition to the biological hazards classified by the ANSI system, lasers produce several other hazards—namely, electrical, ignition, flammable liquid, and flammable and reactive gas hazards—that must be considered.

Electrical Hazards

The most common hazard associated with lasers of all types is the electrical shock hazard. Almost all lasers contain high energy power supplies. These power supplies can produce both electrical shock hazards and, as in all electrical pieces of equipment, fire hazards. Using normal electrical safety devices—fuses, circuit breakers, insulation, grounding devices, and interlocks—and following standard maintenance guidelines can effectively control these hazards.

Many lasers use capacitors. Capacitors store electrical charges, with the intent to release high electrical charges in a very short period of time. Inadvertent discharge of capacitors is, therefore, extremely dangerous. Shorting or internal electrical faults can cause capacitor rupture, fires, or explosions. Because of these possible hazards, capacitors require certain safety precautions. Capacitors should be isolated within screens, shields, barriers, or uninhabited rooms designed to protect against shock, burns, and fire, and to contain fragments from an explosive capacitor failure. Covers or doors to capacitors should be interlocked to prevent charging (when open) by dumping and grounding the capacitors.

Ignition Hazards and Controls

The beam from Class 4 lasers and some Class 3B lasers is powerful enough to ignite combustible materials. The ignition hazard applies in all applications of use, including health care, industrial, manufacturing, commercial, research, and military. Some lasers are embedded lasers and are considered Class 1 lasers by the ANSI classification system. They are, in fact, a higher-class laser (generally a Class 4 laser), and the beam is a fire hazard.

Many different precautions can be taken to minimize the potential for fire from the laser beam ignition hazard. Some of them are engineering controls; however, the majority of the precautions are administrative, directed by a knowledgeable laser safety officer (LSO). Examples of these controls are instituting standard operating procedures (SOPs), providing warning signs, and mandating use of personal protective equipment. In addition, the beam intensity profile and alignment should be verified prior to use, appropriate beam stop materials should be in place, and attention needs to be given to the materials adjacent to the laser beam to ensure that they are not combustible.

Particular attention is required when using lasers in the health care field. The laser beam (which should be treated as though it were an open flame or other ignition source) is used in conjunction with many combustible materials.

The database established by the NFPA Technical Committee on Laser Fire Protection has recorded many case studies of laser fire incidents. With the exclusion of some metals, no material is "fire safe" around lasers. In the medical field, flammable anesthetic gases are still used in research in the United States and in some other countries.

CASE STUDY: Laser Ignites Bronchoscope and Endotracheal Tube During a Tracheal Stenosis Procedure. In 1997, during a tracheal stenosis procedure in a southwestern U.S. hospital, a nonfire-resistant endotracheal tube (ETT) was inserted into the patient's trachea, followed by a bronchoscope to view the area to be treated. A 0.6 mm laser fiber was then inserted through a biopsy port and positioned about 5 mm beyond the distal tip of the bronchoscope and then connected to a KTP/YAG laser. The oxygen concentration in the lasing area was about 100 percent. Combustible material included the ETT, the bronchoscope, and the outer coating of the fiber.

About midway through the procedure, the surgeon saw a flash of light related to a fire in the patient's throat and terminated the procedure. An investigation determined that the products of combustion had turned the inside of the ETT black and that the portions of the outer and inner coatings of the bronchoscope had melted. The laser functioned normally and the fiber was reusable, but it was not known how many times it had been used previously. The fiber was not stripped and cleaved prior to use. Investigators identified the ignition point as near the tip of the fiber and determined that ignition was most likely due to a fracture at the tip or a piece of the outer coating of the fiber lying slightly over the tip of the catheter.[1]

Flammable Liquid Hazards and Controls

Lasers can use flammable liquids as part of the process. In particular, dye lasers use a lasing medium of a complex fluorescent organic dye dissolved in an organic solvent as part of the process of exciting selected atoms. Often the organic solvent is a flammable liquid. Many of these lasers use only 1 qt (1 L) of solvent. Others use from 5 gal (20 L) to hundreds of gallons (liters) of solvent. In the event of a spill, there are ignition sources present, such as the laser beam itself and electrical components.

Many of the protective measures for handling flammable liquids are already well documented. It is important to incorporate into the design or installation a means of containing a spill. Pumps, motors, and other electrical components should be appropriately rated for the application or designed as intrinsically safe. Use of metal tubing instead of plastic tubing for the flammable liquids is suggested.

Compression-type fittings are recommended for flammable liquid lines instead of slip-on friction fittings without clamps. The integrity of tubing and connections should be checked periodically. Good housekeeping is necessary in these areas. Warning signs appropriate for the flammable liquids should be posted. Storage should follow accepted practice for flammable liquids. During cleanup and disposal, it needs to be recognized that the waste still has the properties of a flammable liquid. For larger-volume laser systems, the fire protection measures are similar to any industrial process using large quantities of flammable liquids. Methods to monitor the volume level, flow, and pressure of the systems should be installed. Consideration of the adequacy of the ventilation in the area is required. Remote shutdown capability should be incorporated into the system design.

Flammable and Reactive Gas Hazards and Controls

Occasionally, lasers use flammable or reactive gases. These gases should be checked to determine whether they are used in their pure form or mixed with an inert gas, for example, Excimer lasers. The smallest quantity and percentage of gas appropriate for the system should be used. Whenever possible, the gases should be stored outside the building or in a ventilated gas cabinet designed for that purpose. The ventilation in the area where the gases are used should be assessed to determine the consequences of a gas leak; that is, whether it is possible for the area to be within the flammable range for the particular gas. The integrity of the piping systems should be checked at regular intervals.

Consideration should be given to the installation of combustible gas detectors designed to activate at 25 percent of the lower flammable limit. Exhaust vents from gas piping should be located away from air intakes. The exhaust gases might need to be mixed with an inert gas, depending on the hazard. Care is required to ensure that the exhaust gases do not stagnate in the exhaust piping system. The regulator for the gas should not be used as a flow control valve; a supplemental valve should be installed. All piping should be labeled to identify specific contents. The general vicinity of the gases should have signs indicating the hazard. Emergency shutdown of the gases should be built into the system at the gas supplies and at another remote location.

Laser Safety Officer

It is recommended that any sites using lasers and laser systems and associated equipment have individuals who are trained and knowledgeable of laser safety hazards and fire safety practices. This individual is the laser safety officer (LSO). Only personnel trained by the LSO on the lasers should be permitted to use them. Other documents should establish training requirements for laser use. Maintenance should be performed only by knowledgeable personnel. A log of both the user and the maintenance activity should be kept. Manufacturers' recommendations and precautions should always be considered.

Emergency Response

Prior to using a laser that is considered a fire hazard, appropriate personnel should be familiar with emergency procedures. Issues to consider are the location of exits, emergency panic shutdown buttons, laser shutdown procedures, notification procedures, and location and use of fire extinguishers. Personnel in the vicinity of lasers generally have duties different from those involved in fire fighting; therefore, training about what to do in a fire is important. Responding fire fighters should be made aware of the hazards involving lasers.

SUMMARY

Lasers are a part of everyday life and are beneficial for humanity. However, adequate precautions must be taken to minimize their fire hazard. In particular, Class 4 lasers, embedded lasers (however they are classified), and some Class 3 lasers have significant fire safety concerns. The laser beam itself is an ignition hazard, and other products used in the process to generate the laser beam and laser procedures are fire hazards. It is important that those involved with using lasers are aware of the fire hazards and take appropriate control measures. With proper attention, lasers can be used in a fire-safe manner.

Chapter 6

Protection of Electronic Equipment

Revised by
Brian P. Rawson

Chapter Contents

Information Technology (IT) Systems
Physical Facility, Location, and Construction
Equipment and Installation Features
Fire Protection
Automatic Sprinkler System
Special Extinguishing Systems
Smoke Alarms
Emergency Plans and Procedures

Key Terms

automatic sprinkler system, clean agent, electronic equipment room, information technology equipment, smoke alarm, uninterruptible power source

In 1953, the first commercial electronic computers made their debut and started to take on the tasks of their mechanical predecessors: punch card sorters and tabulating machines. The jobs that they performed at a much faster rate were the same, primarily related to the repetitive routines associated with accounting and inventory. Electronic data processing (EDP) was born and computer users often relabeled responsible departments as EDP. In the decades since, the electronics, computer hardware, and application programs have evolved at incredible rates. The data to be processed are actually all types of information from audio files and bank account numbers to travel reservations and real-time video. In recent years, the term *data processing* has again transformed to become information technology (IT). IT is a collective term that can be defined as applied electronic computer systems comprising both hardware and software, and often including wired and/or wireless networks and telecommunications, usually in the context of a business or other enterprise. This chapter examines the equipment, location, and construction features of IT systems and the factors and features involved in the protection of these systems from fire.

Other information relevant to protecting computers and electronic equipment from fire may be found in Section 9, Chapter 8, "Protection of Records"; Section 14, Chapter 1, "Fire Alarm Systems"; and Section 14, Chapter 2, "Automatic Fire Detectors."

INFORMATION TECHNOLOGY (IT) SYSTEMS

IT Centers and Equipment

The electronics hardware that comprises an information technology center is not just computers. The hardware includes an extensive selection of specialized devices that are connected together and configured to analyze, collect, distribute, manage, and store information. Some commonly recognized system hardware component types include, but are not limited to, blades or blade centers, computers, converters, local area networks (LAN), direct access storage devices (DASD), magnetic tape libraries, processors, routers, servers, storage area networks (SAN), and switches.

In addition to the actual information technology electronics, there is also a variety of support equipment required such as computer rated air-conditioning (CRAC) units, electrical power distribution units (PDU), and uninterruptible power system (UPS) units. Typically, all the equipment necessary to form a functional IT system would be installed in a special location referred to as an IT equipment room. In the context of building codes, this classification carries the responsibility of compliance with specific room design and construction. Figure 8.6.1 provides a graphical representation of some of the equipment that may be found in the makeup of an IT equipment room.

Brian P. Rawson is a technical program manager for Information Technology Equipment Installation Planning at International Business Machines Corporation in Poughkeepsie, New York. He is a member of the NFPA Technical Committee on Electronic Computer Systems.

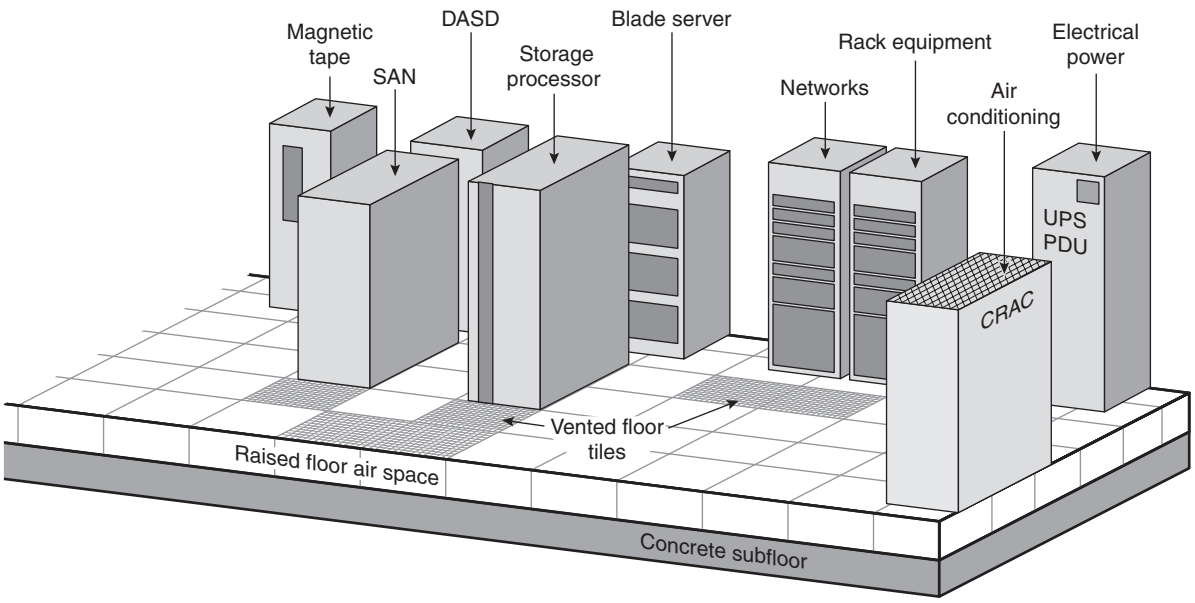

FIGURE 8.6.1 Equipment That May Be Found in an IT Equipment Room

Special Electronics

Besides IT equipment, there are also other sensitive electronics that people and business have come to depend on. Communications and control equipment play a vital role in our daily lives. Automation of one type or another permeates our world and is so commonplace that to many it has become invisible. Most large-scale manufacturing incorporates electronics and microprocessors to control assembly lines and robotics. Medical and scientific research also relies on highly specialized electronic equipment. Special electronic equipment is vital in the development, fabrication, and testing of semiconductors.

These special electronics are no longer relegated to business and government. The personal computer (PC), introduced in the early 1980s, has become a household necessity. Today there are over 800 million PCs in operation worldwide. Despite the growing numbers of PCs and the direct relationship between most of the business and home PCs and the larger, more complex, commercial computer systems through connectivity via business networks or the Internet, this chapter does not address the home computer. The focus is, instead, on the commercial and enterprise systems to which the business and home computers may communicate and with which they may transfer information. There is a strong and growing dependency for the commercial IT systems to be available to communicate with these remote PCs. Today, in the comfort of our own homes, we can do many tasks online. We have moved from fear and uncertainty to an almost total embrace of the online world.

Availability as an IT System Objective

Availability is an important objective of IT systems. Whether we learn, shop, or work from our PCs, we expect the IT systems to be available. This availability is key to the existence of many businesses. Business resilience practices examine the various potential interruptions and disruptions that could impact availability and service to clients. Among those is the threat of fire. Fire protection cannot be overemphasized. Because we have become so dependent on electronic systems, information technology centers can be attractive targets for arson and sabotage. Advances in technology allow for several backup and recovery strategies in the event of an interruption. The highest level of backup requires a fully redundant remote site, with mirror image application software and equipment hardware and real-time updates of information/data. This level of backup is not economically feasible for every IT system owner. There are less costly methods of providing backup and recovery, but each has a trade-off of time and/or lost information. IT system owners must evaluate their availability objectives along with a risk assessment and determine which strategies best fit their financial capabilities.

PHYSICAL FACILITY, LOCATION, AND CONSTRUCTION

State-of-the-art IT equipment hardware is designed with a very high level of reliability. Some electronics equipment has projected mean time before failure rates of over 100,000 hours, or 11.4 years, of operation, provided the intended operating environment is maintained. This reliability is well beyond anticipated need because electronics technology performance advances at a much faster rate of 1.5 to 2.0 years. Electronic equipment may be replaced or upgraded on a similar schedule with entire systems being replaced over a 5- or 6-year period.

Physical Facility and Location

Electronics and IT hardware are sensitive and are designed to be installed and operated in a specific environment that provides for optimum performance and reliability. Because the equip-

2003	300	0	2	11	11

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections, and these estimates include proportional allocation of fires with area of origin unknown or unreported. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest hundred, civilian deaths and injuries to the nearest one, and direct property damage to the nearest million dollars. Adjustment for inflation is done in the last column using the consumer price index. From 1999 on, the area of origin code is changed from *electronic equipment room* to the narrower *computer room or control center,* which may account for the decline in fires after 1998. From 1999 on, estimates are made using fires reported only in NFIRS Version 5.0, and confined and nonconfined fires are analyzed separately because incident details such as area of origin are not required for confined fires.

Source: NFIRS and NFPA survey.

ment and systems are complex and expensive, they should be installed in areas specifically designed for their purpose. Ideally, the IT room should be located in a separate, single-story fire-resistive or noncombustible building. IT areas need security, fire protection, and a controlled environment (Table 8.6.1). IT equipment installations may also be located in noncombustible and fire-resistive buildings where the IT rooms are adequately separated from other parts of the building. Local area networks (LANs) and wide area networks (WANs) commonly use host mainframes and servers that may be located 3000 miles (4828 km) away. Ancillary occupancies, such as programmer and maintenance offices, high-capacity printers, paper supplies, records, and data, should be separated from the IT room by rated partitions.

For ordinary hazard occupancies, the partitions should not have less than a 2-hour rating. Where IT equipment controls a process creating a higher hazard, the rating of the partition should be increased to a rating that is commensurate with the hazard. Listed fire doors and shutters of an equivalent rating should be provided to protect openings. Also, listed fire dampers should be provided to protect any necessary duct penetrations. The IT room should not be located above, below, or adjacent to areas housing hazardous processes, unless means for controlling that process and reliable protection and commensurate separation are provided (Table 8.6.2).

Construction

IT centers vary in size and complexity, depending on the size of the business, as well as the functions performed. An IT room may be as small as a typical single office, if it has only PC-based equipment installed. The more complex enterprise business on the other side of the spectrum, in contrast, may occupy 50,000 ft^2 (4645 m^2) or more. The larger IT room presents a greater opportunity for fire hazard and an equally greater challenge for fire detection and protection.

TABLE 8.6.2 Structure Fires Excluding Homes Originating in Electronic Equipment Rooms, by Equipment Involved in Ignition, 1994–1998 Annual Averages

Equipment Involved in Ignition	*Fires*	*Civilian Deaths*	*Civilian Injuries*	*Direct Property Damage (in Millions of Dollars)*
No equipment involved	133	0	1	5.14
Electronic equipment	120	0	4	8.92
Fuse, circuit breaker, or other overcurrent protection device	96	0	3	1.07
Fixed wiring	91	0	1	2.23
Unknown-type electrical distribution equipment	76	0	2	3.40
Transformer	71	0	0	0.41
Unclassified electrical distribution equipment	38	0	0	1.67
Meter or meter box	24	0	0	0.39
Separate motor or generator	21	0	0	0.08
Light fixture, lampholder, or sign	20	0	0	0.09
Switch, receptacle, or outlet	16	0	0	0.02
Office machine	16	0	0	0.14
Central air conditioning or refrigeration equipment	15	0	0	0.01
Cord or plug	15	0	0	0.23
Unclassified special equipment	13	0	0	0.23
Central heating unit	12	0	0	0.01
Television, radio, VCR, or phonograph	10	0	0	0.27
Room air conditioner	10	0	0	0.00
Torch	10	0	0	0.14
Unclassified appliance	10	0	0	0.80
Other known equipment involved in ignition	123	0	1	2.46
Total	944	0	13	27.71

Note: These are fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. Fires and civilian deaths and injuries are estimated to the nearest one; and direct property damage is estimated to the nearest ten thousand dollars and has not been adjusted for inflation. Statistics include a proportional share of fires with unknown area of origin. Electronic equipment room fires with unknown equipment involved in ignition have been proportionally allocated. Sums may not equal totals because of rounding error.

Source: National estimates based on NFIRS and NFPA survey.

Auxiliary and support equipment are typically more extensive for the larger IT centers. Rather than a small uninterruptible power source (UPS), there may be separate battery rooms and diesel generators for backup power in case of an electric utility disruption. To facilitate redundancy and dual electrical power distribution, there may be large transformers and electrical switch gear in adjacent rooms. The heating, ventilation, and air-conditioning (HVAC) demand is also greater and more complex, as is overall security. Fire detection and suppression technologies have kept pace with electronics systems and offer a solution that can be engineered for every need.

Equipment Protection. Most fires damaging IT rooms do not originate in the IT equipment itself, but rather from ordinary equipment in or adjacent to the IT room. Only listed IT and IT support equipment should be allowed in the IT room. Control and operations offices or rooms strictly related to the IT system operation may also be allowed in or adjacent to the IT room. Combustibles and nonessential items should be kept out of the IT center or kept to minimum levels required for efficient operation. Personnel allowed access to the IT room should also be restricted to essential individuals for operations and maintenance.

Data and Record Protection. Important and vital records generated by the IT computer system should be protected according to their importance and difficulty to reproduce. In most cases, information stored is more valuable than the IT hardware itself. Keeping and protecting backup copies is extremely important. Most backup information is stored on magnetic tape or disks; however, other media may be used, including paper. All of these are subject to damage from fire, heat, combustion products, or water. Keeping backup copies of extremely critical information in a safe and/or remote location is very important. Backup systems should be tested on a regular basis to ensure that regenerated data are in a readily usable format.

Raised Floor as Protection Feature. Mainframe IT systems are generally installed on an access or raised floor. The raised floor facilitates equipment reconfigurations and room layout, provides a space for electrical wiring and connectivity, and allows for cooling air distribution to the electronic equipment. The floors, including structural supports, should be made of approved, noncombustible materials. Openings in the floor for cable access should be kept to a minimum to prevent debris and other combustibles from collecting beneath the floor. Edges of any cut openings should also be trimmed to prevent damage

to electrical cables. Where openings to another area under the raised floor are required, fire wall separations must be maintained with appropriate materials. Carpeting and the adhesive attaching it to the floor could increase damage to equipment involved in a fire. Carpeting should, therefore, be avoided on raised floor systems. Access panels in the raised floor shall be provided to allow for inspection and maintenance. Appropriate devices to remove these panels should also be provided in the room and be clearly marked.

When any equipment is removed from the IT room, the associated connection cables must also be removed. Abandoned or unused cables can add to potential fuel for a fire in the form of insulation and connectors. In addition to increased fuel load, the unused cables impede cooling airflow. A cable management program should be developed and implemented for the underfloor and cable spreading areas.

EQUIPMENT AND INSTALLATION FEATURES

Only equipment that meets the requirements of UL 478, *Standard for Electronic Data Processing Units and Systems,* or UL 1950, *Standard for Safety of Information Technology Equipment Including Electrical Business Equipment,* should be used. Where available, equipment should be listed in accordance with these standards. Equipment of combustible construction should be avoided. Some equipment such as automated information storage systems (AISS), or magnetic tape libraries, may be constructed to hold enough plastic tape modules to be considered a significant fuel source for a fire. Equipment of this type may be provided with internal detection and protection. Protection can be exempted only where the materials and their configuration in the equipment have undergone large-scale testing.

Power communications and signal cables as well as plugs and connectors should be listed and properly sized and applied in accordance with NFPA 70, *National Electrical Code®*. These should be suitable for installation under raised floors. Floor openings should be smooth to prevent damage to cables. Complex wiring of electronic equipment does not always allow power cables to be run in conduit. Where installations allow, the preferred arrangement of wiring power cables is within conduit. No splices or connections should be permitted in the power or wiring under the floor, except within listed junction boxes or approved receptacles or connectors. When used, the number of junction boxes should be minimal.

Cables should be arranged to avoid serious multiple failures because of fault or overheating in any one conduit. Very large computers and some other electronic data processing equipment produce a great deal of heat and require a large amount of air to pass through the equipment for cooling. Air-conditioning system design should be based on the requirements of NFPA 90A, *Standard for the Installation of Air-Conditioning and Ventilating Systems.* Each computer room should have its own air-conditioning system. Air intake should be located to minimize its exposure to flame, smoke, and undesirable fumes. All filters should be Class 1, in accordance with UL 900, *Standard for Air Filter Units.* Ductwork and its insulation should be noncombustible. The system should be capable of going to 100 percent makeup and exhaust automatically on detection of smoke. The air handling system should be capable of purging the room of combustion products. Shutting down minimizes recirculation contamination. As technology advances, IT systems become more dense and more powerful. As a result, they generate more heat. In plans for upgrading a computer system, cooling requirements may need modification for proper operation. The modern supercomputer may use coolant media other than air. Where liquid coolants are necessary, only noncombustible liquids or gases should be used for equipment cooling. An alarm for loss of fluid should be provided for any liquid coolant system.

Most large computer systems rely on an uninterruptable power source (UPS) for protection against power loss and voltage fluctuation. The UPS is commonly a large rechargeable battery system that is normally "on charge" while it provides power to the computer. The UPS has the capacity to maintain system operations during a power failure until power is restored or systematic shutdown can be accomplished. Electrical power supplies and other electrical equipment, such as transformers, motor generators, distribution controls, and circuit breakers, should have a disconnect switch and be located in a separate cutoff room. Larger battery banks should be kept in a separate, well-ventilated detached room. Diesel, natural gas, or gasoline generators for emergency power supplies should be in separate machinery rooms or outside the building. These units should be tested and maintained in accordance with NFPA 110, *Standard for Emergency and Standby Power Systems.* A minimum of a one-day fuel supply should be maintained.

FIRE PROTECTION

Computers and other IT equipment are particularly susceptible to fire damage and the accompanying heat, steam, and combustion products. Elevated temperatures may even damage equipment and data. There are many variations of electronic components and media and their failure points will differ somewhat. Tests have shown that above 120°F (49°C), permanent damage can begin. At 125°F (52°C), magnetic tapes, floppy disks, and similar materials start to lose information. A sustained ambient temperature of 150°F (66°C) damages hard disks. Equipment components begin to fail at 174°F (79°C), with major component failures occurring between 300 and 500°F (149 and 200°C). Microfilm damage begins at 225°F (107°C) in the presence of high humidity. Even paper products can be damaged at 350°F (176.5°C). Finally, between 650 and 750°F (310 and 399°C), polystyrene cases and reels degrade, producing flammable styrene monomer. Further evidence of this vulnerability may be seen in the high average loss per fire in electronic equipment room fires, even when they are confined to the object of origin (Table 8.6.3).

Computer rooms should be equipped with CO_2 or Class BC clean agent extinguishers in accordance with NFPA 10, *Standard for Portable Fire Extinguishers.* Dry chemical extinguishers should not be used. If paper or ordinary combustibles are present, a sufficient number of Class A pressurized water extinguishers should also be provided. Occupants need to be instructed on the proper use of extinguishers.

TABLE 8.6.3 Structure Fires Excluding Homes Originating in Electronic Equipment Rooms, by Extent of Flame Damage, 1994–1998 Annual Averages

Extent of Flame Damage	*Fires*	*Civilian Deaths*	*Civilian Injuries*	*Direct Property Damage (in Millions of Dollars)*	*Average Loss per Thousand Fires (in Thousands of Dollars)*
Confined to object of origin	626	0	9	9.13	14.6
Confined to area of origin (part of room)	127	0	2	2.70	21.3
Confined to room of origin	79	0	1	2.85	36.1
Confined to fire-rated compartment of origin	4	0	0	0.11	30.3
Confined to floor of origin	11	0	0	1.03	89.4
Confined to building of origin	86	0	1	10.97	127.1
Beyond building of origin	11	0	0	0.92	87.0
Total	944	0	13	27.71	29.4

Note: These are fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. Fires and civilian deaths and injuries are estimated to the nearest one; and direct property damage is estimated to the nearest ten thousand dollars and has not been adjusted for inflation. Statistics include a proportional share of fires with unknown area of origin. Electronic equipment room fires with unknown extent of flame damage have been allocated. Sums may not equal totals because of rounding error.

AUTOMATIC SPRINKLER SYSTEM

Automatic sprinkler protection should be provided in accordance with NFPA 13, *Standard for the Installation of Sprinkler Systems.* The sprinkler protection should be installed on a hydraulic design basis arranged as a wet pipe or preaction system. With the increased delay time, a double interlock preaction system should not be used. Water distribution density should be evaluated for each installation. Few computer room installations meet the definition of light hazard occupancy, based on the amount of combustibles found in the room. Computer facilities with super printers that often handle a large amount of paper should be considered Group 2, ordinary hazard. Special media storage arrangements could affect sprinkler location and necessary discharge densities. Any areas exposing the IT area should be protected with automatic sprinkler protection that is commensurate with the hazard. In reported U.S. electronic equipment room fires in structures other than houses, automatic suppression equipment is more often absent than present, but when present, it reduces average loss per fire by three-fourths (Table 8.6.4).

SPECIAL EXTINGUISHING SYSTEMS

When the value of the equipment and risk of IT system interruption dictates, a fixed extinguishing system should be provided. The use of a gaseous agent is critical where there is a need to protect data in process, reduce damage to the equipment, or allow for rapid return to full operation. Where provided, gaseous agent systems should be designed in accordance with NFPA 12, *Standard on Carbon Dioxide Extinguishing Systems,* or NFPA 2001, *Standard on Clean Agent Fire Extinguishing Systems.* Power should be disconnected on activation of extinguishing systems unless a risk assessment indicates there would be less severe damage if power were maintained. Air handling should

TABLE 8.6.4 Structure Fires Excluding Homes Originating in Electronic Equipment Rooms, by Performance of Automatic Suppression Equipment, 1994–1998 Annual Averages

Automatic Suppression Equipment Performance	*Fires*	*Civilian Deaths*	*Civilian Injuries*	*Direct Property Damage (in Millions of Dollars)*
Equipment present	379	0	7	3.89
Equipment operated	52	0	1	1.74
Equipment did not operate but fire not too small	14	0	0	0.20
Fire too small to activate equipment	313	0	5	1.95
No equipment present	551	0	6	23.66
Unclassified	14	0	1	0.16
Total	944	0	13	27.71

Note: These are fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. Fires and civilian deaths and injuries are estimated to the nearest one; and direct property damage is estimated to the nearest ten thousand dollars and has not been adjusted for inflation. Statistics include a proportional share of fires with unknown area of origin. Electronic equipment room fires with unknown performance of automatic suppression equipment have been allocated. Sums may not equal totals because of rounding error.

Source: National estimates based on NFIRS and NFPA survey.

be interrupted wherever possible. Systems are typically designed for total flooding where the air handling is interrupted or for extended discharge where it must be left running. In the past, fixed total-flooding Halon 1301 systems were used. Serious environmental concern involving Halon 1301 and its effect on the ozone layer demands consideration of alternative means of protection. A few Halon 1301 extinguishing systems remain. These systems should be tested and maintained in accordance with NFPA 12A, *Standard on Halon 1301 Fire Extinguishing Systems.* Replacement agents, also called clean agents, now in the market are capable of handling fires below raised floors. FM 200® and Inergen® have both been installed in extremely important computer rooms. Selection of substitute agents needs to include their long-term impact on the environment. Avoid replacements already scheduled for discontinuation.

SMOKE ALARMS

Smoke detection should be installed at ceiling level and under the raised floor system. Protection devices installed under floor areas should be listed specifically for this application. Airflow characteristics of underfloor plenums make many types of smoke alarms unsuitable. High-sensitivity sampling type and spot detectors should be listed for use under high-airflow conditions. Regardless of the smoke alarm used, the manufacturers' instructions for installation in high-flow areas should be consulted. Alarms and detection systems should be designed and installed in accordance with *NFPA 72®*, *National Fire Alarm Code®*. In reported U.S. electronic equipment room fires in structures other than houses, three of five fires show smoke alarm equipment present, with an associated two-thirds reduction in average loss per fire (Table 8.6.5).

TABLE 8.6.5 Structure Fires Excluding Homes Originating in Electronic Equipment Rooms, by Performance of Automatic Detection Equipment, 1994–1998 Annual Averages

Automatic Detection Equipment Performance	*Fires*	*Civilian Deaths*	*Civilian Injuries*	*Direct Property Damage (in Millions of Dollars)*
Detector present	589	0	6	9.00

EMERGENCY PLANS AND PROCEDURES

An emergency plan's primary purpose is to prepare key personnel to initiate actions during and after any emergency. Supervisory personnel should develop and regularly review plans and procedures. The plan should incorporate contingency factors for emergencies such as power failures, severe weather conditions, tornadoes, floods, earthquakes, and so on.

The plan should include actions to safeguard systems from damage and provisions to ensure that backup copies of program software and data are available in case damage occurs. There should be a contingency plan to relocate operations or to provide alternative means to complete critical functions if a computer center is temporarily out of service or permanently damaged.

Alternative equipment should be available, either within the organization or from an outside organization, if the operation is to continue during the restoration of damaged equipment. A prearranged plan should consider and test the compatibility of backup equipment.

The plan should include local emergency personnel such as security and/or local fire response organizations and outside fire departments. Local fire departments should be invited to visit the computer and electronic equipment rooms to familiarize them with the emergency plan. It is important that they be aware of any fixed automatic fire extinguishing systems and know how they operate and what procedures to follow, for example, where to enter the building if responding to a fire alarm.

Restoration companies can successfully restore much of the hardware involved in incidents. An effective preplan includes preliminary visits by a restoration company. This familiarity will allow the company to preplan for the chemicals, labor, and equipment needed for fast and effective restoration.

The second part of the plan is an emergency personnel evacuation procedure. The primary purpose of this plan is life safety for all persons in the IT area. The procedure should be posted and updated periodically—every six months—so that all employees and others entering the area know what to do when the alarm signal sounds. The alarm signal must be audible throughout the entire area, and when it is initiated, all occupants should immediately assemble at a predesignated location, for example, a safe, interior part of an adjacent building. Employees should remain in the assembly area until all are accounted for, and they are advised otherwise. Several persons should be assigned to check their areas to make certain all persons have exited. Laboratories, washrooms, storage rooms, and so on should be checked. The plan should include provisions for those who

may need physical assistance. Visible notification appliances should be provided for people who cannot hear the alarm, in accordance with *NFPA 72*.

Emergency lighting also should be provided for the entire interior of the building that houses the computers or electronic equipment and offices. Auxiliary battery lighting packs are permitted.

SUMMARY

Given our global dependence on information technology and other electronic equipment, protection from fire must be given a high priority. A fire protection system must take into account many factors, including security measures from arson and sabotage, physical characteristics of facilities and locations, hazardous arrangements, fire alarm and suppressions systems, and emergency procedures. Information technology equipment should be installed in specifically designed areas that provide security, fire protection, and controlled environment. Such installations may be located in computer rooms adequately separated from other parts of the building or even in separate structures. Combustible materials should be kept at a minimum and preferably located outside the computer room. Fire alarm and suppression systems include smoke alarms, automatic sprinkler systems, and portable fire extinguishers. The emergency plan should include actions to safeguard systems from damage and provisions to ensure that backup copies of data/information are available in case damage occurs, as well as provide for the evacuation of personnel. Local fire departments should be invited to visit the IT and electronic equipment rooms to become familiar with the emergency plan.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on protecting the electronic equipment discussed in this chapter. (See latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

Chapter 7

Heat Transfer Systems and Fluids

John A. LeBlanc

Chapter Contents

Types of Heat Transfer Systems and Fluids
Heat Transfer System Components
Hazards of Organic Heat Transfer Fluids
Organic or Synthetic Heat Transfer Fluid System Safeguards

Key Terms

heat transfer fluid (organic), heat transfer fluid (synthetic), heat transfer oil, heater, molten salts, vaporizer

The term *heat transfer fluid* applies to a broad spectrum of liquid and vapor media used to transfer heat at a controlled rate from one place to another. There are many types of heat transfer fluids, ranging from the most common, water and steam, to molten salts. This chapter will discuss the use and hazards of organic and synthetic heat transfer fluids and the safeguards needed for them.

Heat transfer fluids have historically been associated with the chemical and petroleum industries but are now also used in industries ranging from food to plastics to paper manufacturing to commercial laundries. A clear understanding of the fire and explosion hazards that can be created by organic heat transfer liquids is needed to ensure that the plants and facilities using these liquids are adequately protected.

For additional information relevant to heat transfer systems, see Section 6, Chapter 12, "Flammable and Combustible Liquids"; Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 8, Chapter 2, "Chemical Processing Equipment"; and Section 8, Chapter 8, "Industrial and Commercial Heat Utilization Equipment."

TYPES OF HEAT TRANSFER SYSTEMS AND FLUIDS

There are two general types of heat transfer systems: liquid phase and vapor phase. Figure 8.7.1 illustrates a liquid-phase system. Figures 8.7.2 and 8.7.3 illustrate vapor-phase heat transfer systems. With liquid-phase systems, the temperature of the fluid changes as heat is transferred, resulting in nonuniform temperatures, even if circulation flow rates are high (see Figure 8.7.1). With vapor-phase systems, heat is transferred at the saturation temperature of the vapor, which affords controlled temperatures. Combinations of these systems can be used as well (see Figures 8.7.2 and 8.7.3). Types of transfer fluids include water, molten salts, and heat transfer oils and synthetic fluids.

Water

Water in either its liquid form or its vapor state is the most common heat transfer fluid. If the temperature required by the transfer process is above the freezing point of water and below about 350°F (177°C), the choice is usually between these two media. On the other hand, if the temperature needed is above or below this range, it is desirable, if not necessary, to consider other fluids. For temperatures below the freezing point of water, the most common heat transfer fluids are air; refrigerants, such as halogenated hydrocarbons or ammonia; brines; or solutions of ethylene glycol and water.

When temperatures increase above 350°F (177°C), the vapor pressure of water increases rapidly, requiring expensive high-pressure processing equipment. Therefore, a more practical and inexpensive means of heating or temperature control at higher temperatures is to use a fluid or

John A. LeBlanc is manager of special hazards at FM Global in Norwood, Massachusetts. He has a Bachelor of Science in Chemical Engineering and a Master of Science in Fire Protection Engineering. He is a member of NFPA's Flammable and Combustible Liquids Code Committee and the Technical Committee on Aerosol Products.

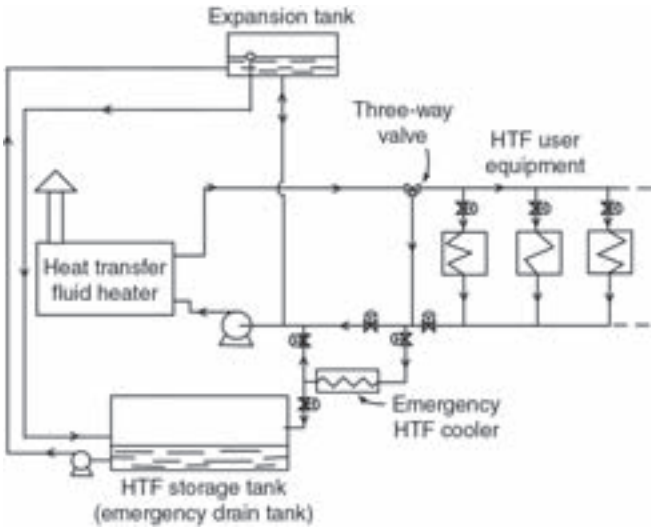

FIGURE 8.7.1 Liquid-Phase Heat Transfer System with Forced Circulation–Type Heater (Source: Reprinted with permission from FM Global)

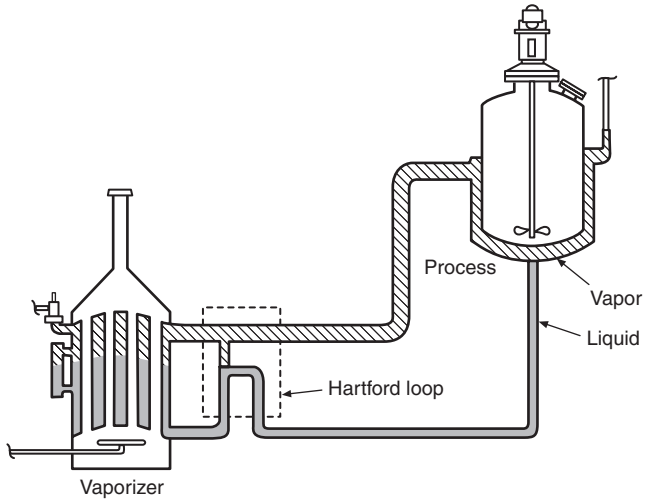

FIGURE 8.7.2 Vapor-Phase Gravity Condenser Return Heat Transfer System with a Vertical Fire-Tube-Type Vaporizer for Natural Circulation

vaporizing fluid with a high boiling temperature. Care should be taken to use high flashpoint, thermally stable, and noncorrosive fluids intended for this purpose. Liquids with a high boiling point that are commonly used can be generally categorized as molten salts, heat transfer oils, or specially formulated heat transfer media.

Molten Salts

Molten salts are generally used as heat absorbers or cooling media and thus serve to control exothermic reactions that occur in the manufacture of certain chemicals. The most frequently

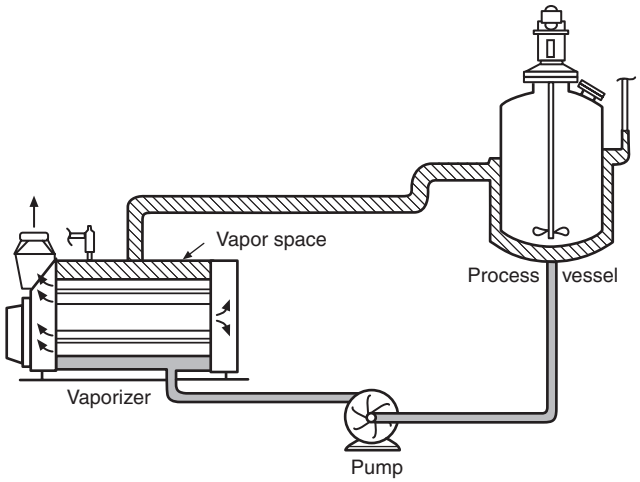

FIGURE 8.7.3 Vapor-Phase Heat Transfer System with Pumped Condensate Return and a Horizontal Fire-Tube-Type Vaporizer for Natural Circulation

used salt is a mixture of sodium and potassium salts having a relatively low melting point. Since these salts are solid at room temperature, care must be exercised to keep the temperature of the salt above its melting point to prevent solidification that can plug the system. Care also must be taken during start-up to control the heat input so the mixture will melt slowly. Many molten salts are strong oxidizers, and this factor should also be considered when the salts are used.

Heat Transfer Oils and Synthetic Fluids

Heat transfer oils and synthetic fluids are specially refined petroleum oils for use at temperatures up to approximately 600°F (315°C). At higher temperatures, the oils undergo excessive thermal cracking, which produces light hydrocarbons. Some amount of thermal cracking is common; however, certain liquids actually produce significant quantities of light hydrocarbons at normal operating temperatures. It is important to fully understand the properties of the fluids being used for heat transfer operations. The light hydrocarbons produced by this cracking process can collect in the system's expansion tank, and their presence must be considered when designing and arranging breather and emergency vents for the expansion tank. Petroleum oils are also subject to oxidation at temperatures above 392°F (200°C) and when in contact with air. These oils will provide a long service life and good heat transfer when the manufacturer's recommended guidelines are followed.

A variety of specially formulated synthetic fluids are used as heat transfer fluids. Synthetic fluids are subject to thermal cracking and oxidation as well; however, they are noncorrosive and generally thermally stable when used under the manufacturer's recommended guidelines. Table 8.7.1 gives the physical properties of some common heat transfer fluids and oils.

Some newer fluids have limited flammability and in some cases will not burn. These fluids are generally used in refrigeration processes but may have some application at elevated tem-

TABLE 8.7.1 Physical Properties Typical of Heat Transfer Fluids

	Freezing		Boiling Point		Flashpoint		Fire Point

peratures. Use of a fluid that does not burn and that does not have the limits of water would be ideal.

HEAT TRANSFER SYSTEM COMPONENTS

Heater or Vaporizer

Recirculating heat transfer systems consist of several common components. A heater or vaporizer provides the thermal energy that is carried by the heat transfer fluid to the process or piece of equipment where it will be used. When the fluid is used in the liquid state, the unit is referred to as a heater; when used in the vapor state, the unit is called a vaporizer. Two types of equipment are manufactured: (1) fuel-fired heaters, which are generally designed for heat duties in excess of about 1 million Btu/hr (290 kW), and (2) electric heaters, which are usually designed for smaller heat duties. Capacities of vaporizers and heaters range from less than a kilowatt to more than 175 million Btu/hr (50,000 kW). Figure 8.7.4 shows a typical heat transfer heater.

Piping System

The piping system allows the transport of the heat transfer fluid from the heater to the process or piece of equipment that is being heated or cooled. Piping can be arranged as a single primary loop between the heater and user equipment or it can be arranged to form primary and secondary loops. In either case, properly arranged control valves and emergency shutoff valves are necessary to ensure the proper operation of the system under normal conditions and to permit the isolation of the heat transfer fluid during a fire.

Expansion Tank

Expansion tanks are used in liquid-phase systems only. They accommodate the expansion and contraction of the heat transfer fluid as the system is heated or cooled. The expansion tank is typically located at the highest point in the system near the heater. It can be either inside or outside the building and is used to provide a constant hydraulic head on the system. In systems operating above the heat transfer fluid's boiling point, the expansion tank is normally pressurized with an inert gas blanket. Other systems operating below the fluid's boiling point may have the tank vented to atmosphere. The expansion tank is generally the point of lowest system pressure. Any light hydrocarbons

FIGURE 8.7.4 Typical Heat Transfer System Heater (Source: Courtesy of Heatec, Inc.)

produced by the degradation of the fluid will collect in the expansion tank.

Expansion tanks can be provided with a breather vent and/or an emergency overflow line. Breather vents must discharge to a safe location outside the building. Ideally, emergency overflow lines should be piped back to the system storage tank. If this procedure is not done, then this line must also discharge to a safe location outside the building.

HAZARDS OF ORGANIC HEAT TRANSFER FLUIDS

Fire and Explosion Hazards

The hazards associated with organic heat transfer fluids (hydrocarbon or synthetic) are not unexpected. These fluids are basically high-flashpoint liquids that are contained and circulated in a closed piping system while being heated above their flashpoints and sometimes above their boiling points. When these liquids are at room temperature, they are difficult to ignite. But, like any flammable or combustible liquid, when heated to or above their flashpoints, they will easily ignite and burn. Since most systems operate above the liquids' flashpoints, loss of containment can quickly produce a pool or spray fire. Containment can be compromised in the heater room (e.g., at pumps, valves, and other connection points), at the user equipment (e.g., at valves, rotary joints, and other connection points), and anywhere along the piping system if the system is exposed to potential physical damage.

If the liquids are released in the heater, they will create an uncontrolled fire within the unit, which can result in damage to the heater, excessive heating of the circulation fluid, or both. Within heaters and vaporizers precautions must also be taken to prevent the liquid level from falling below the tops of the tubes and impairing circulation. In direct-fired units, impingement of burner flames on empty tubes can produce excessive local temperatures, resulting in deposits and ultimate failure of the tubes.

The severity of the fire hazard depends on the amount of liquid in the system, the level of interlocks to shut down flow, and the surrounding occupancy. The chemical process plants where these systems originated are generally protected for large flammable liquid fires. Many of the occupancies where these systems are now found generally present a low fire hazard and are not protected against a flammable or combustible liquid pool fire.

In the case of organic heat transfer liquids that are heated above their boiling points, loss of containment can quickly produce large quantities of flammable vapor or mist that can produce a deflagration if ignited in an enclosed space. The explosion potential in the heater/vaporizer area and the use area needs to be examined closely. Depending on the amount of fluid released, the vapor/mist may spread well beyond the immediate release area.

Another problem associated with organic heat transfer fluids is the development of leaks in the piping system at points of connection. Heat transfer fluids generally have very low surface tensions and low viscosities, allowing them to escape through any small openings at pipe joints. Leaking oil can soak into common insulation materials used on piping. Oil-soaked pipe insulation can autoignite and allow fire spread along the piping system.

Loss History

For the period 1981 to 1990, loss experience from one industrial property insurance company shows 54 fire and explosion losses involving organic or synthetic heat transfer fluids. The gross total loss amount was $150,800,000. The average loss amount was $3 million, but the median loss amount was less than $300,000.[1]

Even an otherwise well-engineered and constructed system may be susceptible to leakage due to the high system temperatures and pressures and due to low fluid surface tension and viscosity. These smaller noncatastrophic leaks can result in fires, but a well-designed plant and heat transfer system will keep the loss in those fires well below a typical catastrophic or large-loss threshold.

These systems have the potential for great destruction as they involve the pumping of hot combustible liquids in conjunction with one or more unfavorable factors. Examples of unfavorable factors include the following:

- Heat transfer fluid virtually always well above its flashpoint
- Systems often having large liquid holdups and high flow rates
- Piping and user equipment located throughout the plant
- Piping and user equipment adjacent to other important equipment or nearby combustibles

Because of their inherent potential for severe fire, these systems require that all aspects of design, installation, maintenance, and operation adhere to the highest possible standards. One of the most common preventable causes of leakage and subsequent fire is the improper siting of the discharge outlet from a system breather vent or pressure relief valve. Improper siting of system discharge points, such as outlets from breather vents or pressure relief valves, has been implicated in numerous fire incidents due to the resulting discharge directly into plant areas. Any inspection or plan review of a heat transfer system should pay close attention to these easily identifiable potential danger points.

One manufacturer conducted a study of heat transfer fluids that also reveals some interesting facts. The 3-year study found 23 fire incidents among the users of its fluids and established the cause for 22 of the 23 fires. Operation/misoperation of the system was the primary cause for 5 of the fires (23 percent), system design was the primary cause for 5 of the fires (23 percent), and system maintenance was the primary cause for 12 of the fires (54 percent).[2]

The results of one loss[3] also clearly demonstrate the severe fire hazard created by heat transfer fluid systems. A 1995 fire in a sprinklered Georgia carpet mill resulted in a $400 million gross loss. The loss occurred when a rotary coupling failed, releasing the heat transfer fluid. The system was not shut down, and all heat transfer fluid pumped into fire.

ORGANIC OR SYNTHETIC HEAT TRANSFER FLUID SYSTEM SAFEGUARDS

The following recommendations for the safe design and operation of heat transfer fluid systems are based, in part, on Section 7.4, "Recirculating Heat Transfer Systems," of NFPA 30, *Flammable and Combustible Liquids Code.*

Location and Construction Considerations

Ideally the heater/vaporizer should be located at a distance from important buildings and facilities. If the heater/vaporizer needs to be located within an important building, it should be cut off from adjacent areas by a fire barrier wall having a fire resistance of at least 2 hours. If automatic sprinkler protection is provided, the fire barrier wall may have a fire resistance of 1 hour. Damage-limiting construction should be provided for rooms housing heater/vaporizers that use organic or synthetic heat transfer fluids with flashpoints below approximately 425°F (220°C), which are heated to or above their atmospheric boiling point.

Curbs, dikes, sloped floors, and drainage should be used to limit the spread of a fluid release within the heater/vaporizer room, around the expansion tank, and in utilization areas.

System Design Considerations

The following items should be considered when designing a heat transfer system:

- Providing an emergency drain line at the low points of the system and directing this drain line to a properly arranged storage tank to permit system drain down during an emergency and routine system maintenance
- Providing a low point drain line on elevated expansion tanks
- Avoiding use of organic/synthetic heat transfer fluids to provide direct building heat
- Terminating breather vent outlets from expansion tanks at a safe location so as not to expose buildings, equipment, or personnel to a potential liquid release
- Interlocking the heat transfer system to stop circulation of fluid throughout the system in the event of a fire
- Providing a well-marked manual emergency shutoff switch that is capable of safely shutting down the entire heat transfer system
- Providing a high liquid level switch on any expansion tank that can be automatically or manually filled directly from a storage tank, and arranging the switch to automatically shut down the fill pump

Fuel Burner Controls and Interlocks. Fuel burner controls and interlocks need to be considered when designing heat transfer systems. Specifically, oil- and gas-fired heaters/vaporizers should be arranged in accordance with NFPA 31, *Standard for the Installation of Oil-Burning Equipment;* NFPA 54, *National Fuel Gas Code;* or NFPA 85, *Boiler and Combustion Systems Hazards Code,* whichever is applicable. Instrumentation and interlocks also should be provided to sound an alarm and shut down the fuel supply to the heater/vaporizer when any one of the following conditions is detected:

- Low fluid flow through the heat exchanger tubes of the heater/vaporizer
- High fluid temperature or pressure at the heater/vaporizer outlet
- Low system pressure with bypass for start-up sequence
- Low fluid level in the expansion tank
- Low vaporizer liquid level
- Sprinkler system flow in any area containing heat transfer system equipment or piping

Piping. Piping, which should be run underground, outside, or in floor trenches wherever practical, should be insulated with closed-cell, nonabsorbent insulation. Welded pipe connections should be used throughout the piping system. For systems operating above 15 psig (1 bar ga), pipe materials and types should be in accordance with ANSI/ASME B31, *Code for Pressure Piping.* Copper, cast iron, or plastic pipe should be avoided.[4]

Fire Protection

Automatic sprinkler protection should be provided in building areas containing a heat transfer system heater or vaporizer. The sprinkler system should be designed in accordance with NFPA 13, *Standard for the Installation of Sprinkler Systems,* for an Extra Hazard Group 1 occupancy. It is also advisable to protect all building areas that contain heat transfer system equipment or piping with a properly designed automatic sprinkler system.

When a supply of steam or inert gas is available, a manually controlled steam or inert gas smothering system for the firebox is advisable. Throughout all areas containing heat transfer system equipment or piping, portable fire extinguishers should be provided.

Operational considerations include promptly correcting all system leaks and inspecting, calibrating, and testing all safety interlocks annually. In addition, operators of heat transfer systems should be trained in the proper operation of the system and the hazards of system misoperation and in how to recognize upset conditions that can lead to dangerous situations.

SUMMARY

Heat transfer oils and specially formulated synthetic fluids are now used as heat transfer fluids. A heat transfer system comprises such fluids, together with a heater or vaporizer, a piping system, and an expansion tank (for fluid-phase systems). NFPA 30 addresses the safe design and operation of recirculating heat transfer systems. Considerations for safe design and operation include location and construction, fuel burner controls and interlocks, and piping.

Heat Recovery
Lumber Kilns
Dehydrators and Dryers

Key Terms

furnace (class A), furnace (class B), furnace (class C), furnace (class D), heat exchanger, heat recovery, heat transfer fluid, heat utilization equipment, heating equipment, oven

Heat utilization equipment has potential hazards involving both heat generation and the process materials. Fuel-fired systems, electrically heated systems, and heat transfer systems all have their individual hazards. The hazards of exposure of adjacent materials and overheating are common to any type of heating system. The hazards and control methods are discussed in subsequent sections of this chapter.

The process hazards within the equipment can involve combustible materials, flammable liquids, or flammable gases; such hazards would occur in the curing of solvent-based coating materials, roasting or drying of combustible agricultural products, or heat treating in a flammable special atmosphere. The principal method of fire or explosion prevention is to prevent overheating or an accumulation of a gas or vapor-air mixture in the explosive range. Subsequent paragraphs in this chapter describe the various classes of ovens, furnaces, and dryers and present general process hazards. The prevention and protection methods that usually are applied to those processes and devices are also described.

Guidelines, rules, and methods applicable to the safe operation of such equipment are covered by NFPA standards and those of other organizations. These should be referred to for details that could not be included in this text.

Additional information is available in this handbook in the following chapters: Section 6, Chapter 10, "Gases," and Section 6, Chapter 12, "Flammable and Combustible Liquids." The grading of heat-producing appliances is discussed in these chapters: Section 8, Chapter 7, "Heat Transfer Systems and Fluids"; Section 10, Chapter 2, "Heating Systems and Appliances"; and Section 10, Chapter 6, "Boiler Furnaces."

Heat utilization equipment is so varied in size, complexity, location, and use that it has been difficult to develop rules that can apply to every type of oven, furnace, or dryer. Users and designers must use engineering and supervisory skills to bring together the proper combination of controls, protective devices, and operator training necessary for proper equipment operation.

Heat utilization equipment failures have resulted because someone either ignored safety procedures and designs or was unaware they existed, due to inadequate training of operators and maintenance technicians. Other reasons include faulty equipment design, complacency on the part of users, or improper selection of combustion safeguards.

This chapter is not a guide to solving all of these problems. However, if the guidelines and principles it presents are used, a number of problems will be either mitigated or solved.

INDUSTRIAL HEAT UTILIZATION EQUIPMENT

Types of Industrial Heat Utilization Equipment

Industrial heat utilization equipment includes a variety of forges, furnaces, kettles, kilns, ovens, and retorts that are heated by gas, oil, solid fuels, or electricity. They can be fired directly, with the products of combustion entering the process space, or indirectly, with radiant tubes or other heat

Raymond Ostrowski is a consultant for Ostrowski Consultants, Cave Creek, Arizona. He is a member of NFPA's Technical Committee on Ovens and Furnaces and chairman of the NFPA 86C committee.

exchanger methods. Heat transfer media, such as organic fluids, are also used where steam or hot water does not provide the temperature or thermal efficiencies desired for the equipment. Figures 8.8.1 and 8.8.2 illustrate typical industrial heat utilization equipment.

Industrial ovens and furnaces, special atmosphere furnaces, vacuum furnaces, afterburners and catalytic combustion systems, dehydrators, dryers, and lumber kilns are discussed in this chapter.

Fire and Explosion Problems

When heat utilization equipment is installed, the following factors need to be considered: (1) the proximity and combustibility of the contents of the building where the equipment is located; (2) construction of the building; (3) setting; (4) ventilation; (5) location within the building; (6) removal of waste heat, gas, and smoke; (7) maximum temperature required; and (8) handling of heated materials in connection with equipment. Fire in combustibles can be prevented by insulation or by separating them from the source of heat. Overheating can be prevented by temperature controls.

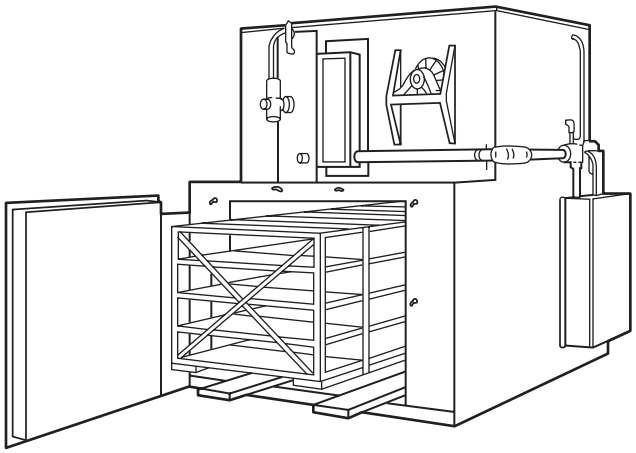

FIGURE 8.8.1 Typical Industrial Oven (Source: Fireye, Inc.)

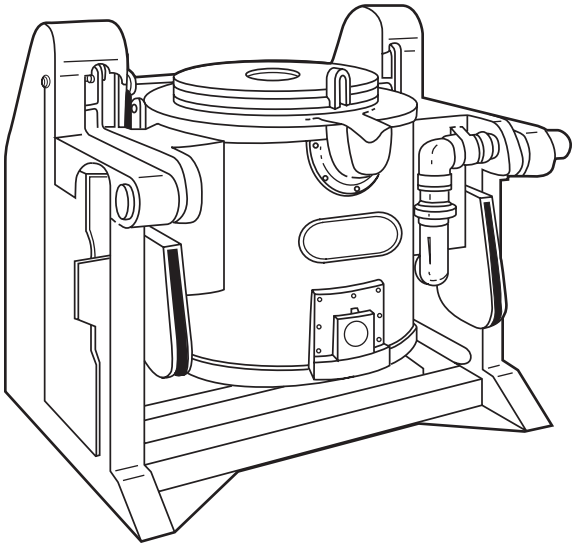

FIGURE 8.8.2 Fuel Fire Melting Furnace (Source: Fireye, Inc.)

Explosion hazards exist where there are flammable vapor-air mixtures from gas or oil fuel or from volatiles released from the material being dried. Explosions or fires can be prevented by ventilation and controls that keep the flammable vapor content below 25 percent of the lower flammable limit (LFL) of the vapor-air mixture.

Some special process ovens and furnaces contain hydrogen or other flammable gases for such purposes as annealing copper and heat treating other metal shapes. To operate these devices safely, it is necessary to prevent air from entering the processing enclosure under normal operating conditions. Both normal and unscheduled starts and stops of these devices require special safety procedures that depend heavily on a skilled operator and adequate control equipment.

OVENS AND FURNACES

This discussion covers the location, design, construction, operation, protection, and maintenance of the industrial heating enclosures known as ovens or furnaces. It does not cover small-cabinet or stove-type ovens for domestic use. The source of heat for industrial heating can be gas burners, oil burners, electric heaters, infrared lamps, induction heaters, or steam radiation systems. In practically all cases, there are fire or explosion hazards from either the fuel used, volatiles produced by material in the oven, or by a combination of both.

There is no clear distinction between an oven and a furnace. The dictionary definition of an *oven* is "a compartment or receptacle for heating, baking, or drying by means of heat"; a *furnace* is "an enclosed chamber or structure in which heat is produced for heating a building, reducing ores and metals, baking pottery, etc." It has been an industry rule of thumb to classify heating devices that do not "indicate color" (i.e., operate at temperatures of less than approximately 1000°F [540°C]) as ovens. This rule does not always apply. For example, coke ovens operate at temperatures in excess of 2000°F (1093°C), and some furnaces operate at temperatures below 1000°F (540°C).

NFPA Classification of Ovens and Furnaces

The classification system for heat processing equipment as set forth in NFPA 86, *Standard for Ovens and Furnaces,* is as follows:

> *Class A* ovens or furnaces are heat utilization equipment operating at approximately atmospheric pressure wherein a potential explosion and/or fire hazard may be occasioned by the presence of flammable volatiles or combustible material processed or heated in the oven.

Such flammable volatiles and/or combustible material may, for instance, originate from paints, powder, or finishing processes including dipped, coated, or sprayed-on impregnated materials; or wood, paper and plastic pallets; or spacers; or packaging materials. Polymerization or similar molecular rearrangements and resin curing are processes that may produce flammable residues and/or volatiles. Potentially flammable materials, such as quench oil, waterborne finishes, cooling oil, and so on, in sufficient quantities to present a hazard, are ventilated according to Class A standards. Ovens may also utilize a low-oxygen atmosphere to evaporate solvent.

Class B ovens or furnaces are heat utilization equipment operating at approximately atmospheric pressure wherein there are no flammable volatiles or combustible material being heated.

Class C furnaces are those in which there is a potential hazard due to a flammable or other special atmosphere being used for treatment of material in process. This type of furnace may use any type of heating system and includes the special atmosphere supply system(s). Also included in the Class C standards are integral quench and molten salt bath furnaces.

Class D furnaces are vacuum furnaces that operate at temperatures above ambient to over 5000°F (2760°C) and at pressures below atmospheric using any type of heating system. These furnaces may include the use of special processing atmospheres. During gas quenching, these furnaces may operate at pressures from below atmospheric to over 100 psig (7 bar).

Classification by Type of Handling System

Ovens and furnaces may be further classified according to the way a material is handled. The two principal types are (1) the batch oven or furnace, sometimes referred to as "in and out," "intermittent," or "periodic" type; and (2) the continuous oven or furnace.

Batch Oven or Furnace. In the batch oven or furnace the temperature is practically constant throughout the interior. The material to be heated is placed in a predetermined position and remains there until the process is complete. Material is then removed, generally through the opening by which it entered. Figures 8.8.3 and 8.8.4 are examples of a batch-type furnace and oven, respectively.

Continuous Oven or Furnace. In the continuous oven or furnace, the material moves through the furnace while being heated. The straight-line furnace is probably the most common of this type. The material passes through a continuous oven or furnace on a conveyor or on rollers. The oven or furnace might operate at a constant temperature throughout, or it might be divided into zones maintained at different temperatures. Figure 8.8.5 is an example of a continuous-type furnace.

A common variation of the continuous-type oven or furnace is one known as a rotating hearth or rotating table furnace. In it, the material is placed on the hearth and is removed after the hearth has completed one revolution. Another design feeds the material being processed through the revolving hearth furnace or tube by means of a stationary internal screw thread.

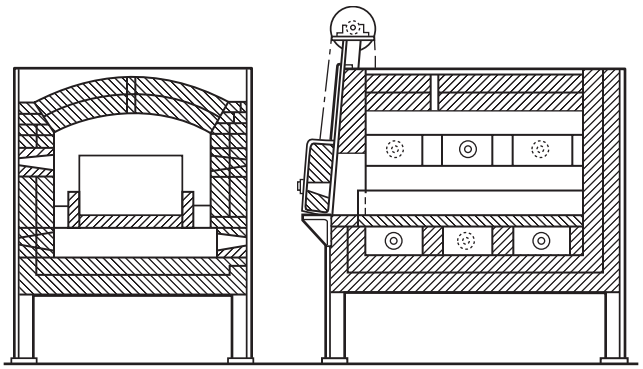

FIGURE 8.8.3 Large Batch-Type, Under- and Overfired, Semimuffle, Heat Treating Furnace

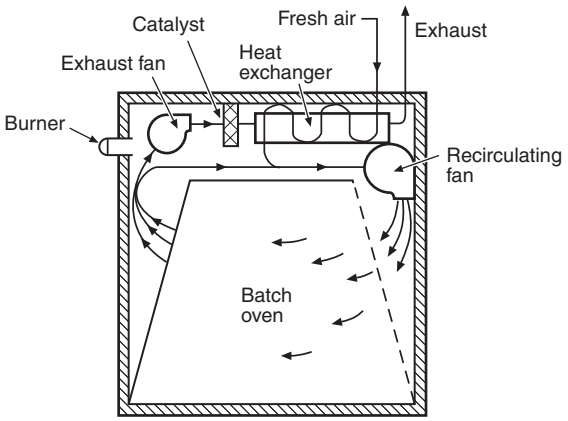

FIGURE 8.8.4 Batch Oven with a Catalytic Heater for Air Pollution Control

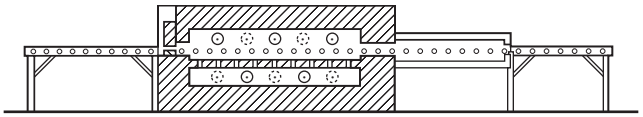

FIGURE 8.8.5 Continuous Roller Hearth Furnace

Location and Construction of Ovens and Furnaces

Ovens and furnaces should be located where they will present the least possible hazard to life and property. To prevent or minimize damage from a fire or explosion, they might need to be surrounded by walls or partitions and located either at or above grade, because basements below grade are difficult to ventilate and offer severe obstacles to proper explosion release.

The oven or furnace and the building that houses it need to be of noncombustible construction, and explosion-relief venting should be provided where required. Combustibles in the vicinity of the oven should be adequately separated or properly insulated and each oven or furnace should have its own venting facilities. When gas or oil fuel is used, the heater and the oven or furnace should have separate venting unless the products of combustion discharge directly into the oven. Except in special cases, separate mechanical means are needed to provide air for the combustion and ventilation; natural draft is usually inadequate.

Furnaces that exhaust directly outdoors are sometimes necessary, depending on the heating process, type of combustion, and the hazard to personnel. If a furnace exhausts directly into a room, the room must have a balanced mechanical ventilation system to bring in fresh air and carry the exhaust outdoors. The supply inlets and exhaust outlets should be arranged to provide a uniform flow of air throughout the area without any dead-air pockets. The system should also remove any toxic contaminants at their maximum anticipated rate of release and keep concentrations below the established maximum allowable concentration (MAC) values.

Some furnaces are made of metal with a brick or masonry covering; some are made of metal with metal supports but no covering; and others have an inner lining of ceramic fibers or fire clay products. Occasionally furnaces have air spaces or noncombustible fillers between the outer and inner walls.

Ovens and furnaces should be well separated from valuable stock, important power equipment, machinery, and automatic sprinkler risers, so there will be minimal interruption to production and protection if there are accidents to the oven or furnace. They should be readily accessible with adequate space above them for automatic sprinklers, the proper use of hose streams, the proper functioning of explosion vents, and routine inspection and maintenance. Roofs and floors of ovens should be insulated. The space above and below the ovens should be ventilated to keep temperatures at combustible ceilings and floors below 160°F (71°C).

Oven and Furnace Heating Systems

For the purpose of this chapter, the term "furnace heating system" includes the heating source, associated piping and wiring used to heat the furnace, auxiliary quenches, and the work therein. Please note the following:

1. For the protection of personnel and property, careful consideration should be given to the supervision and monitoring of conditions that could cause, or could lead to, a real or potential hazard on any installation
2. The presence of safety equipment on an installation cannot, in itself, ensure absolute safety of operation
3. There is no substitute for a diligent, capable, well-trained operator
4. Highly repetitive operational cycling of any safety device can reduce its life span

The three most common methods of transferring heat to materials in ovens or furnaces are (1) direct contact with the products of combustion, (2) convection and direct radiation from the hot gases, and (3) reradiation from the hot walls of the furnace. In muffle furnaces, the products of combustion are separated from the material being heated by a metal or refractory muffle, and heat transfer occurs by radiation (see Figure 8.8.3). In liquid bath furnaces (i.e., salt baths or molten metal used for tempering, hardening, galvanizing, tinning, etc.), a metal pot containing a liquid is heated and the heat is transferred through the liquid to the material placed in the pot.

Oven Heaters. The two general types of oven heaters are (1) direct fired and (2) indirect fired. In direct-fired heaters, the products of combustion enter the work chamber and contact the work in process; this is not the case in indirect-fired oven heaters. Instead, heating comes from radiation from tubes or from air passing over tubes and into the oven. Dangerous fuel-air mixtures cannot readily fill the work space of an indirect-fired oven. Nevertheless, explosions may still occur from vapors given off by a flammable liquid drying process.

There are several arrangements of these two types of oven heaters—direct-fired internal, direct-fired external, indirect-fired internal, and indirect-fired external heaters. Figure 8.8.6 shows three variations of direct-fired external heaters, two of indirect-fired internal heaters, and three of indirect-fired external heaters, with the advantages and disadvantages for each type. The exhaust ventilation arrangements in these designs provide for air movement through the oven with no recirculation through the exhaust fan. The direct-fired external-type oven can have a single burner or a relatively small number of burners that simplify the completing of automatic safety controls.

Furnace Heaters. Furnace heaters are usually arranged like ovens—direct-fired internal, indirect-fired external, and so on, though sometimes the terms are different. If products of combustion are under a hearth and then carried up and into the heating chamber, the furnace is said to be underfired. When the same thing occurs in a chamber at one side of the furnace and passes over a bridge wall into the heating chamber, the furnace is referred to as side-fired. A furnace in which the products of combustion are produced in a space above the heating chamber and pass through a perforated arch into the heating chamber is called an overfired furnace. If combustion occurs at some distance above the heating chamber and hearth, and the products of combustion are deflected onto the hearth by an arched roof, the furnace is called a reverberatory furnace. A radiant-tube-heated furnace is an arrangement for indirect firing (Figure 8.8.7).

Sources of Heat

Heat for an oven or furnace can be provided by gas-fired burners, oil-fired burners, electric heating systems, steam heating systems, or thermal heat transfer fluid systems. It is important that flames, heating surfaces, or other possible sources of ignition be located where drippings or dust cannot fall or accumulate on them.

Gas-Fired Burners. Gas fuel is any type of gas in common industrial use. It is important that the burner, its adjustment, and the means of combustion be suitable for the type of gas to

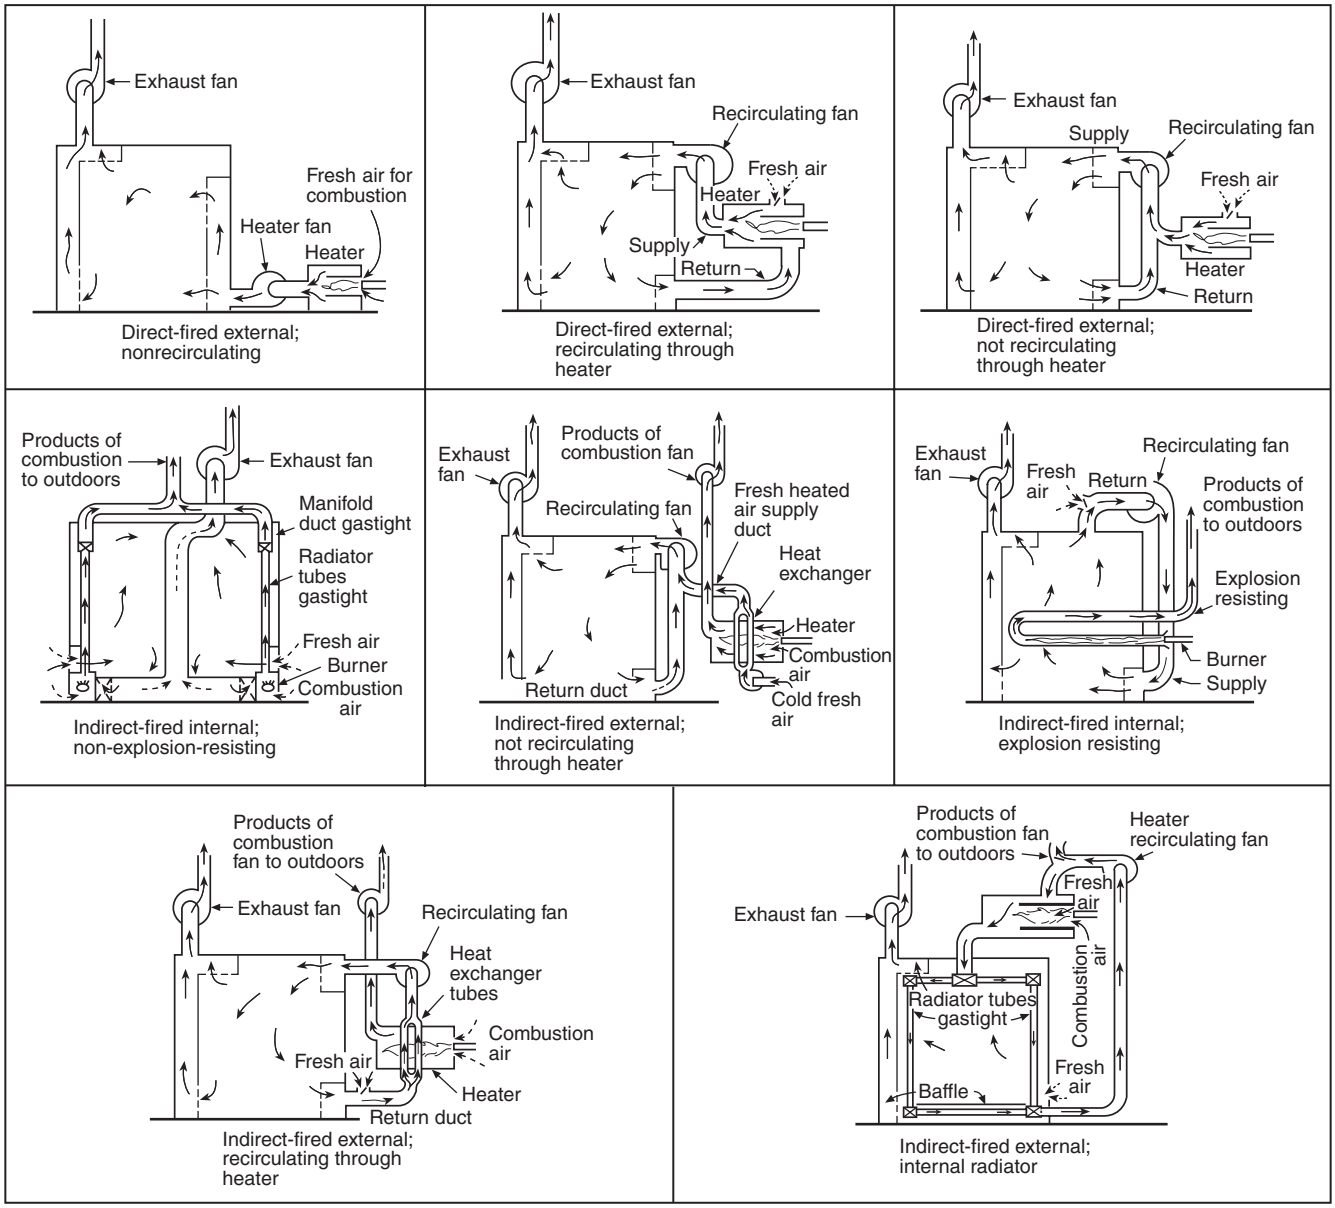

FIGURE 8.8.6 Types of Oven Heating Systems

be burned. The burner can have a single nozzle, with burners located singly or in groups, or it can have multiple nozzles in perforated-pipe, ribbon, or slot burners. Burners must light easily, have a stable flame at all ports, and not have the tendency to flash back or blow off over the entire range of turndown under all draft conditions in the oven. A supply of air adequate for complete combustion may be premixed with the gas, nozzle-mixed at the burner, or otherwise provided.

Oil-Fired Burners. Oven heating systems can be fired with fuel oil. Oil must be vaporized before it can be burned. Most oven and furnace burners atomize and then vaporize oil while mixing it with combustion air. Heat for vaporization is generated by the flame. Atomization can be effected by pressure, mechanical spraying into fine droplets, sonic vibration, low-pressure air, high-pressure air, or steam.

Combination gas- and fuel-oil fired systems use either separate gas and oil burners or configurations where an oil-atomizing nozzle is centered on a gas burner and arranged to use a common combustion air source.

Electric Heating Systems. There are five types of electric heating systems for ovens and furnaces: (1) resistance, (2) infrared, (3) induction, (4) arc, and (5) dielectric.

Resistance heat is produced by current flow through a resistive conductor. Resistance heaters can be "open," with bare

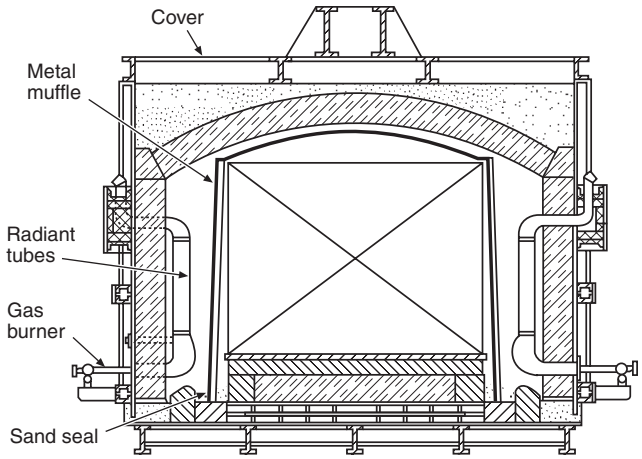

FIGURE 8.8.7 Annealing Muffle Furnace

heating conductors, or "insulated sheath," with heater conductors covered by a protective sheath that may be filled with electrical insulating material (Figure 8.8.8).

Infrared heat is transmitted as electromagnetic waves from incandescent lamps with filaments that operate at temperatures lower than the filament temperature of ordinary incandescent lamps, so that most of the radiation occurs in the infrared part of the spectrum. These waves pass through air and transparent substances but not opaque objects and release their heat energy to these objects.

Induction heat is developed by electric currents induced in the charge by an externally applied alternating magnetic field. Induction heaters have an electric coil surrounding the oven space, and heating is by electric currents induced in the work being processed.

Arc heat is caused by an electric current that passes between either a pair of electrodes or between electrodes and the work, causing an arc that releases energy in the form of heat.

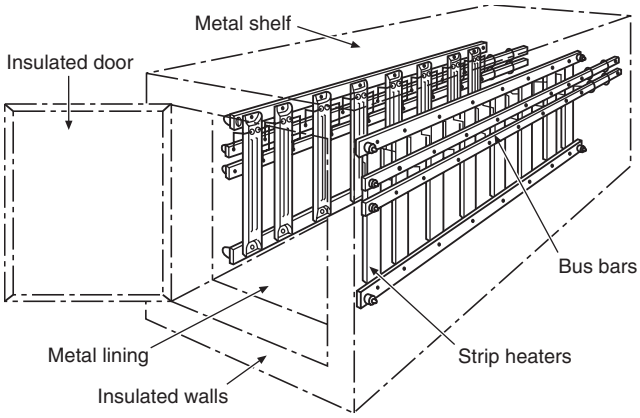

FIGURE 8.8.8 Strip Heaters Mounted in a Small Oven

Dielectric heat occurs when dielectric materials are exposed to an alternating electric field. The frequencies are generally 3 MHz or more—higher than those in induction heating. This type of heater is useful for heating materials that are commonly considered nonconductive.

Electric systems can be arranged so that processing does not require an oven enclosure. "Ovenless," that is, unenclosed heating systems, can employ lamps, resistance-type electric elements, or infrared heaters to vaporize flammable, toxic, or corrosive liquids and their residues. Enclosures around ovenless systems are advisable to prevent flammable, toxic, or corrosive vapors from escaping into the general area and to help provide better ventilation and safeguards for personnel. However, heating systems with energy input of under 100 kW may be excluded if adequate area ventilation is provided. (NFPA 70, *National Electrical Code®*, gives guidance for electrical installations in hazardous locations.)

All parts of heaters that operate at elevated temperatures within an oven or furnace and all other energized parts must be protected to prevent contact by persons and to prevent accidental contact with materials being processed and with drippage from the materials.

Steam Heating Systems. In steam heating systems, the steam pressure in heat exchanger coils must be regulated at the minimum required to provide the proper drying temperatures. This avoids unnecessarily high temperatures at coil surfaces. The coils must not be located on the floor of the oven or anywhere that paint drippings or other combustibles, such as recirculated lint, can accumulate on them.

Thermal Heat Transfer Fluid Systems. As with steam heating systems, the heat exchanger should be kept free of combustibles, such as lint. The heat exchanger may be located outside the work chamber and a recirculating heated air system may be used.

Fuel Hazards

Gas or vapors from unburned or incompletely burned fuel might, when mixed with air, be within the explosive range. These hazards develop during lighting off, firing, and shutting down the oven or furnace; therefore, it is necessary to treat each operation as a separate condition requiring certain specific operating procedures to avoid mishaps.

Lighting Off. Before torches, sparks, or other ignition sources are introduced, and until all burners are properly lighted, the operator must take every precaution, using all practical automatic safety controls, to avoid producing dangerous unburned fuel accumulations. The following precautions should be followed:

1. Purging possible accumulations of unburned fuel
2. Igniting burners promptly with substantial igniters
3. If another ignition attempt is necessary, purging before introducing the ignition source and fuel again

Firing. In the firing phase, safety requires continuous ignition and complete burning of the fuel before it passes beyond its

normal combustion zone. To maintain this, the mixer and burner assembly must proportion fuel and air properly throughout the combustion zone, and the mixture velocity in the combustion zone must be neither too high, causing extinguishment by blow-off, nor too low, causing the flame to flashback or "go out." Thus, good burner mixer design will be one of the main factors in safety during firing.

Air for combustion is obtained from the primary and secondary air supplied at the burner. Partial or total failure of the combustion air supply can cause an unstable flame, which in turn can lead to flame failure and the introduction of unburned fuel into the combustion chamber. When too little air is supplied, the result is an overrich mixture and incomplete combustion. Ignitable incomplete products of combustion that leave the burner at concentrations too high for prompt ignition can later, within the oven or ductwork, become diluted by air into the flammable range and ignite, causing an explosion. Overrich combustion can also produce rapid smothering and extinguishment of the burner flame. The flammable products of incomplete combustion followed by raw fuel likewise can become explosive when later diluted by air in another part of the system. Therefore, precautions must be taken to shut off the fuel and to require manual reset in the event that the air supply for combustion fails.

Liquid fuel, like fuel oil, must be atomized so that it will ignite easily and burn quickly. This can be accomplished by injecting the liquid fuel at high pressure, or by directing a steam or air jet into the oil stream. Improper oil temperature or high viscosity can prevent proper flow and can create partial obstructions in burner tips and loss of oil or atomizing medium pressures, causing improper atomization. Failure to atomize properly will usually result in an unstable flame, which in turn can lead to flame failure. Other conditions that cause flame failure are stoppage of fuel supply by an improperly closed fuel valve or other pipe obstruction and the presence of water in a fuel oil line.

Shutting Down. Following a shutdown, a dangerous accumulation of unburned fuel might occur in an oven and heating system if any manual fuel valves are left open or are leaking and/or safety shutoff valves are not tight-closing. If the leaking fuel subsequently is ignited by hot refractory material or by another ignition source when starting up, an explosion is possible.

Supervisory Controls for Ovens and Furnaces

It is essential that all ovens and furnaces processing flammable materials involving flammable vapors or heated with combustible fuels be provided with adequate supervisory devices that ensure sufficient preventilation, adequate ventilation during operation, and proper operating conditions that will not permit fires or explosions to develop. All safety devices must be listed for the service intended. Although it is true that a competent operator is essential, it is also true that assistance is needed because the operator cannot continually supervise everything. The operator is, however, responsible for the proper maintenance and testing of the oven's operating and control equipment.

The type of supervisory control equipment used with oven or furnace assemblies depends on the requirements of the particular operation. A list of the principal types of supervisory controls is given in Table 8.8.1. Figure 8.8.9 shows a typical arrangement of the devices for a gas-fired unit. Most of these units are tested by testing laboratories and listed according to the appropriateness of the devices for varying situations.

Equipment for Ovens and Furnaces

Full supervisory control of a gas- or oil-fired oven, especially one that is direct-fired, might require the following: (1) determining that all fuel valves are closed and not leaking, (2) establishing and maintaining required ventilation, (3) turning on and igniting the gas pilot only at the conclusion of a required preventilation period, and (4) opening the fuel valves (including the safety shutoff valve) that supply the burner only after the combustion safeguard shows that the pilot flame has been ignited and that fuel and air (or other atomizing agent) pressures are correct. If the burner flame is not promptly established, the safety shutoff valve will close and the entire cycle must be repeated, starting from the beginning. Once started, operation continues only as long as the supervisory controls indicate normal conditions; failure in any respect shuts down the entire system, and the full cycle must begin again.

NFPA 86 specifies in considerable detail the safeguards needed for different types of ovens and furnaces.

TABLE 8.8.1 Supervisory Control Equipment for Ovens and Furnaces

Ventilation controls
Airflow switches
Pressure switches
Fan shaft rotation detectors
Dampers
Position limit switches
Electrical interlocks
Preventilation time-delay relays

Fuel supervisory controls
Safety shutoff valves
Supervising cock (FM cock)
Flame detection units (combustion safeguards)
Flowmeters
Firechecks
Reliable ignition sources
Pressure switches
Program relays

Temperature controllers
Excess temperature limit controller
Continuous vapor concentration indicators and controls
Conveyor interlocks (with steam and electric-resistance heating equipment)
Electrical overload protection (with resistance and induction heating equipment)
Low oil-temperature limit controls (on oil-burner equipment using heavy residual fuel oil, such as No. 5 and No. 6, which require preheating)

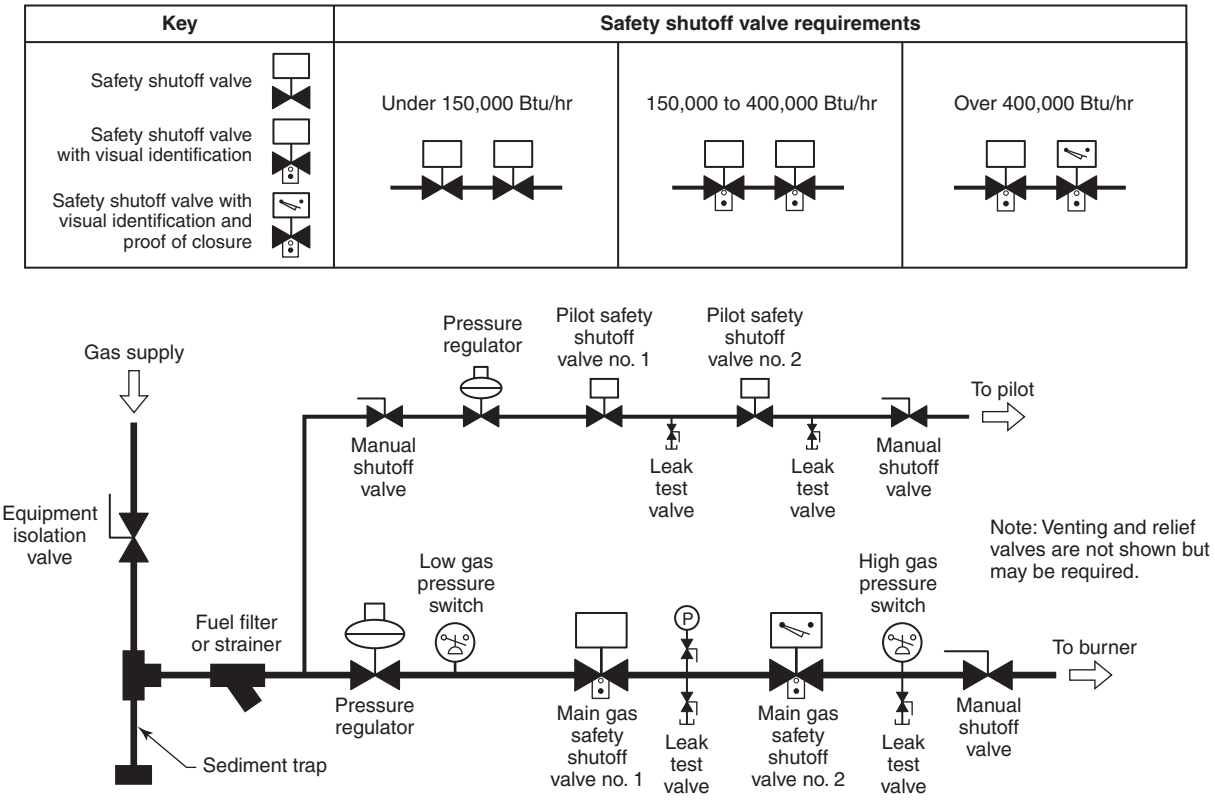

FIGURE 8.8.9 Typical Piping Arrangement Showing Fuel Gas Safety Shutoff Valves
(Source: NFPA 86, *Standard for Ovens and Furnaces,* 2003 ed., Figure A.7.7.2)

When installations contain a large number of burners, the usual supervisory controls for each pilot and each burner might not be considered practical; in such cases, special devices and arrangements might have to be employed. A special continuous line pilot for multiple burners is illustrated in Figure 8.8.10.

Controls for a large number of cup burners with flame propagation between individual burners can be provided as shown in Figure 8.8.11.

Multiburner combustion safeguards are now available, making it possible to install flame supervision for each burner,

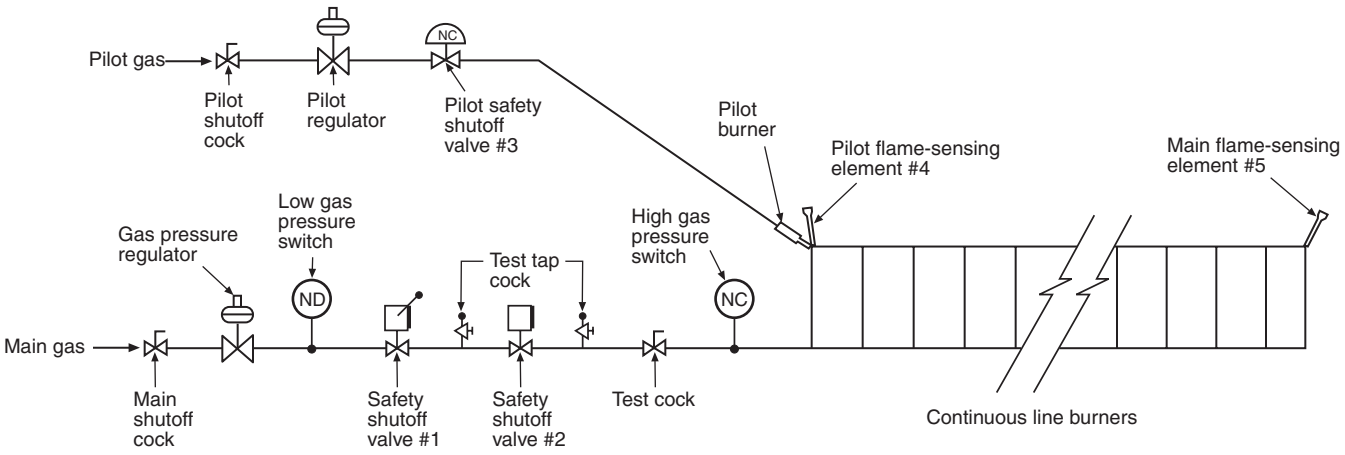

FIGURE 8.8.10 Approved Combustion Safeguard Supervising a Pilot for a Continuous Line Burner During Lighting-Off and the Main Flame Alone During Firing

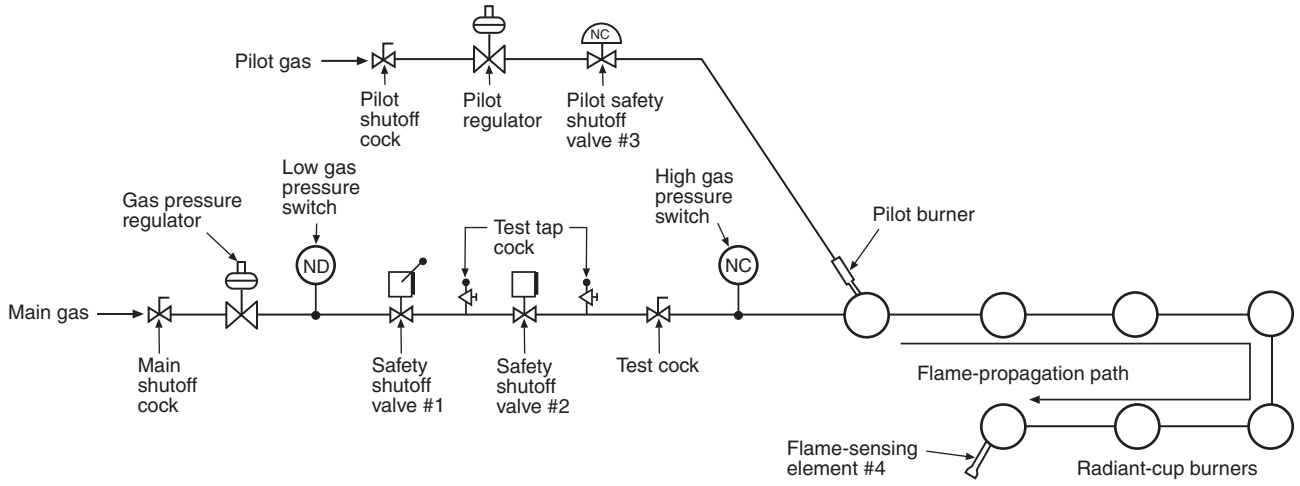

FIGURE 8.8.11 Approved Combustion Safeguard Supervising a Group of Radiant-Cup Burners Having Reliable Flame-Propagation Characteristics from One to the Other by Means of Flame-Propagation Devices

where previously the supervisory cock system was the only safeguard available.

When the capacity of a gas-fired burner system exceeds 400,000 Btu/hr (117 kW), two safety shutoff valves are required. A manually operated plug cock and test tap must be provided downstream of the safety valves. This arrangement ensures positive fuel shutoff when testing the valves for leakage.

Safety ventilation is not needed in an oven that never contains flammable or noxious vapors, and it is unnecessary to guard against flammable fuel-air mixtures in an electric or steam-heated oven.

Operator Training

Alert and competent operators are essential to safe operations. New operators should be thoroughly trained and tested in the use of the equipment. Regular operators should be retrained at intervals to maintain proficiency and effectiveness. Operators must have access to operating instructions at all times.

Operating instructions should be provided by the equipment manufacturer. These instructions should include schematic piping and wiring diagrams, as well as (1) light-up procedures, (2) shutdown procedures, (3) emergency procedures, and (4) maintenance procedures.

Operator training should include information on (1) combustion of air-fuel mixtures, (2) explosion hazards, (3) sources of ignition and ignition temperature, (4) atmosphere analysis, (5) handling of flammable atmosphere gases, (6) handling of toxic atmosphere gases, (7) functions of control and safety devices, and (8) purpose and basic principles of the gas atmosphere generators.

Testing and Maintenance for Ovens and Furnaces

The operating and supervisory control equipment of each oven should be checked and tested regularly, preferably once a week. At less frequent intervals, probably annually, a more comprehensive test and check must be performed by an expert. All deficiencies must be corrected promptly and a regular cleaning program followed to cover all portions of the oven and its attachments. Access openings for cleaning the oven enclosure and the connecting ducts must be provided.

A program for inspecting and maintaining oven safety controls is given in the appendices of NFPA 86.

CLASS A OVENS AND FURNACES

Adequate ventilation must be provided in the operation of Class A ovens and furnaces where there is an explosion potential because of the presence of flammable vapors or fuel-air mixtures. Such fires or explosions can generally be prevented by good ventilation and supervisory controls that keep the flammable vapor content well below the LFL.

Ventilation

Ventilation is required while an oven is in operation and flammable vapors are given off. Control devices ensure that the ventilating and preventilating systems are operating. Failure of the ventilating fan causes shutdown of the heating system and the conveyor that carries material into a continuous oven. The following discussion refers only to that ventilation required for safe operation and not that required for combustion and recirculation. It also does not apply to ovens operating in conjunction with solvent recovery systems, which sometimes use a low-oxygen atmosphere.

Proper ventilation includes a sufficient supply of fresh air, proper exhaust to outdoors, and properly distributed air circulation sufficient to ensure that the flammable vapor concentration throughout the oven is safely below the LFL at all times. The quantity of fresh air required for safe ventilation is determined by the amount of vapor released during the process.

In general, mechanical ventilation to outdoors is required on all ovens in which flammable or toxic vapors are liberated, as well as for ovens heated by direct-fired gas or oil heaters.

Ovens in which flammable or toxic vapors are never released do not require ventilation for safety, if heated by steam or electric energy or by gas- or oil-fired indirect heating equipment. On new ovens of every size, ventilation provided by a separate exhauster is advisable whenever appreciable amounts of flammable vapors are given off by the work.

Continuous Conveyor Ovens. The general rule for ventilating continuous conveyor–type ovens is to provide not less than 10,000 cfm (283 m^3/min) of fresh air at 70°F (21°C) for each 1 gal (3.79 L) of common solvent introduced into the oven. The basis for this rule is that 1 gal (3.79 L) of common solvent produces a quantity of flammable vapor that will diffuse in air to form roughly 2500 ft^3 (71 m^3) of the leanest explosive mixture. Because a considerable portion of the ventilating air might pass through the oven without completely traversing the zone in which vapors are given off, the ventilation air might be distributed unevenly. To provide a margin of safety, four times this amount of air, or 10,000 ft^3 (283 m^3) at 70°F (21°C) is required for each 1 gal (3.79 L) of solvent evaporated. In certain solvents, however, the volume of air rendered barely explosive exceeds 2500 ft^3 (71 m^3), and the safety factor decreases proportionately.

When a continuous-type oven is designed to operate with a particular solvent and the ventilating air can be accurately controlled, the required ventilation can be determined by calculation. (See NFPA 86 for information on how to calculate the volume of vapor produced by various solvents and the volume of air required to provide sufficient dilution to prevent an ignitable mixture.) As with the general rule for oven ventilation, the calculated rate of air change includes a factor of safety four times the volume of air required to prevent an ignitable mixture.

Batch Process (Box) Ovens. The nature of the work being processed is the basis for determining the ventilation rate in batch process ovens. Because of the wide variations in the materials, rate of evaporation, and coating thickness, it is preferable to make tests and calculations to figure the proper ventilation rate. However, years of testing and experience have shown that approximately 380 cfm (10.7 m^3/min) (at 70°F [21°C]) of ventilation for each 1 gal (3.79 L) of flammable volatiles released from a batch of sheet metal or metal parts being baked after dip coating is a reasonably safe rate of air change.

For other types of work, the figure of 380 cfm (10.7 m^3/min) (at 70°F [21°C]) is also used, unless the required ventilation rates can be calculated from reliable previous experience or the maximum evaporation rate is determined by tests run under actual operating conditions. In the latter case, a safety margin requires a rate of air change equaling four times the volume of air needed to produce an ignitable mixture. In any event, caution is needed when applying this estimating method to work of low mass (e.g., paper, textiles, etc.), which will heat quickly, or work coated with materials containing highly volatile solvents. Either condition can give too high a peak evaporation rate for the estimating method.

Temperature Correction. Temperature corrections must be made when using the preceding rules, since the volume of a gas varies in direct proportion to its absolute temperature (0°F is equivalent to approximately 460° abs, and 0°C is equivalent to approximately 273 K).

For example, to supply 10,000 ft^3 of fresh air at 70°F (530° abs) to an oven operating at 300°F (760° abs), it is necessary to exhaust:

$$\frac{760}{530} \times 10{,}000 = 14{,}320 \text{ ft}^3 \text{ of } 300°\text{F air}$$

To supply 283 m^3 of fresh air at 21°C (294 K) to an oven operating at 149°C (422 K), it is necessary to exhaust:

$$\frac{422}{294} \times 283 = 406 \text{ m}^3 \text{ of } 149°\text{C air}$$

In some cases, process requirements call for more ventilation than needed to maintain safe conditions in an oven. When this is true, an approximate method of figuring ventilation might be adequate for checking safety requirements. Except in these cases, all factors, including solvent characteristics, type of oven, material being processed, oven temperatures, and effect of temperature on the LFL, must be carefully considered so that an adequate safety factor is ensured.

Low-Oxygen Ovens. Low-oxygen ovens are used for evaporating solvent in an atmosphere where the oxygen concentration is below that required for combustion. For some solvents this operating value would be approximately 8 percent oxygen, which includes a safety factor of approximately 3 percent. There is a need for oxygen analysis to verify the low-oxygen concentrations. Inert gas is used to displace the oxygen (air) during startup and combustible gas or vapor during shutdown. These systems are used for solvent recovery from the coating cure process in the oven as shown in Figure 8.8.12. The treated product

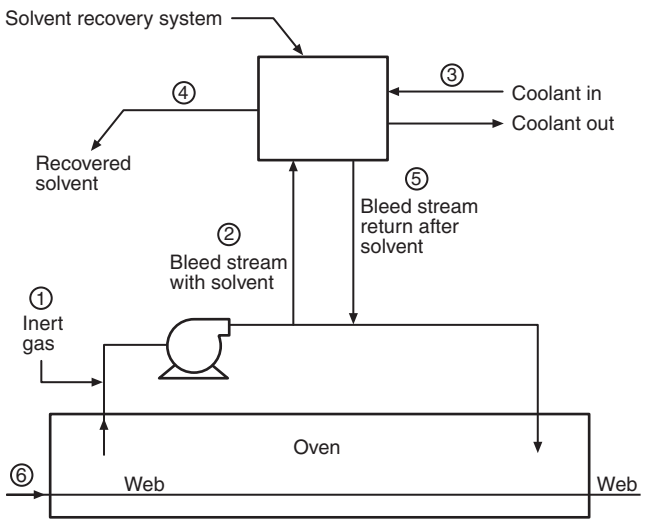

FIGURE 8.8.12 Low-Oxygen Oven with a Solvent Recovery System

passes into and out of the oven enclosure through the oven openings. The oven atmosphere consists of an inert carrier gas that is continuously recirculated through the oven enclosure (line 1). Solvents evolve from the treated product and build up to an equilibrium vapor level that is much higher than the allowable levels in an air atmosphere. A bleed stream (line 2), which is typically 1 percent of the recirculation flow, is processed by a solvent recovery system. A liquid (line 3), which provides cooling through vaporization, acts to condense the solvents that are pumped to storage (line 4). After solvents are stripped from the inert gas stream, it is returned directly to the oven enclosure (line 5) to resume its role as a solvent vapor carrier.

Fire and Explosion Protection

Automatic sprinklers and water spray systems should be considered for heat processing equipment that contains or processes sufficient combustible materials to sustain a fire. The amount of protection required depends on the construction and arrangement of the oven and the materials handled in it. If combustible material is processed, or if trucks or racks are combustible (or subject to loading with excess finishing material), fixed protection must extend as far as necessary into the enclosure and exhaust ducts. It also should be present where an appreciable amount of flammable drippings from finishing materials accumulates within the oven. If desired, supplementary carbon dioxide, foam, dry chemical, or halon protection can be permanently installed, but such protection is not a substitute for automatic sprinklers.

The use of steam for fire protection in ovens and dryers generally is not recommended. However, when there is no alternative, steam-smothering systems may be allowed when oven temperatures exceed 225°F (107°C) and large supplies of steam are available at all times. Complete standards have not been developed for the use of steam as an extinguishing agent. Steam is not as dependable as water, carbon dioxide, dry chemical, halon, or foam.

Portable extinguishers are needed near the oven, oven heater, and related equipment, including dip tanks or other finishing processes operated in conjunction with the oven. Small-hose stations with combination nozzles also should be provided so all parts of the oven structure can be reached.

Ovens that might contain flammable gas or vapor mixtures must be equipped with unobstructed relief vents to release internal explosion pressures. These vents, panels, or doors are secured with explosion-relieving hardware or gravity-retained panels that provide adequate insulation and possess the necessary structural strength. The weight of the panel should be minimal to permit movement at the lowest practical pressures. Explosion-relief panels must be proportioned according to the ratio of area to the explosion-containing volume of the oven, with due allowance made for openings or access doors equipped with approved explosion-relieving hardware. The preferred ratio is 1 ft^2 (0.09 m^2) of relief panel area to every 15 ft^3 (0.42 m^3) of oven volume.

CLASS B INDUSTRIAL FURNACES

In many ways, Class B furnaces are similar to Class A ovens and furnaces. However, because no flammable volatiles or residues are present, there is nothing combustible in the construction or contents of the Class B furnace.

In many Class B furnaces, little or no effective explosion-relief venting can be provided because of the weight and strength of the walls. Preventilation is important before a source of ignition is introduced into the furnace. In some cases, completely automatic purging might be practical; in others, purging might be partly manual. In either case, supervisory controls are needed to interlock the ventilation, fuel supply, combustion air, safety shutoff valve, and flame failure devices.

In multiburner installations, combustion safeguards with flame supervision should be applied. When furnaces have zones operating at different temperatures, the zones might have to be treated as separate units.

Changes in the usual safety requirements may be permitted in some ovens or furnaces, but if there is any possibility of explosion from unburned fuel, adequate safeguards should be provided. An audible alarm can be installed to indicate unsafe conditions.

CLASS C INDUSTRIAL FURNACES USING A SPECIAL PROCESSING ATMOSPHERE

Special atmosphere furnaces are used to improve the quality of metals and metal alloys by heating them in an atmosphere in which air has been replaced by other gases, some of which are combustible. In most cases, the gas is used to prevent oxidation of the metal during heating, but it can also prevent the removal or addition of carbon. Some processes that use atmospheric gases are bright annealing of copper and steel, scale-free hardening and annealing of castings, brazing, and sintering. Examples of protective gases used in these processes are hydrogen, charcoal gas, and dissociated ammonia. Also used are various hydrocarbon gases produced by equipment that processes the gas used for firing, generally in the presence of a catalyst. During the past few years, synthetic atmospheres that include methanol and other stored gas components have been used.

Some heat-treating furnaces contain an inert atmosphere (carbon dioxide, helium, argon, nitrogen) so they present no special fire hazard; however, these gases could present a health hazard. Other gases produce a flammable atmosphere (hydrogen, dissociated ammonia, incompletely burned hydrocarbon gas, carbon monoxide, and methane), which presents an explosion hazard; therefore, their use requires special safeguards. Atmosphere furnaces are not limited to flammable gases but also include acid gases, such as chlorine and anhydrous hydrochloric acid. When the latter are used in a special atmosphere, extreme care must be taken to keep air from entering the furnace. Regardless of the type of special atmosphere, Class C furnaces have fuel hazards similar to those of the Class A and B ovens and furnaces discussed earlier (although most Class C units are indirectly fired or electrically heated). The hazards in Class C furnaces exist chiefly at three times: (1) before the process starts and the flammable atmosphere is replacing air in the furnace; (2) when the process is finished and air is being readmitted; and (3) when, for some reason, the special atmosphere supply is interrupted and air is permitted to enter. If at each of these times sufficient inert gas can be introduced into the furnace to prevent

a combustible mixture, there is no danger of an explosion. Automatic introduction of inert gas on failure of the special atmosphere supply is desirable; at the least, an audible alarm should notify the oven operator of atmosphere supply failure or other upset conditions.

Inert Gas Purge Procedure

Begin by verifying the adequacy of the inert gas supply. After all doors (if any) are closed, make sure that the flammable atmosphere gas, flame curtain, and other valves are closed. The furnace may then be heated to operating temperature. If so, introduce the inert gas at a rate capable of maintaining a positive pressure in the furnace. Sample the furnace atmosphere until two consecutive readings indicate the oxygen content is below 1 percent. With at least one furnace zone above 1400°F (760°C), ignite the pilots at the outer doors and effluent vents. The flammable special atmosphere then may be introduced. When the flammable atmosphere is flowing, the inert gas should be turned off immediately. When flames appear at the vestibule effluent ports, the atmosphere introduction has been completed. The curtain burners then may be ignited.

To remove the flammable atmosphere with the furnace at operating temperature, the doors (if any) should remain closed, the inert gas purge actuated, and a positive furnace pressure maintained. Shut off the special atmosphere, flame curtain, and other valves, and sample the atmosphere until two consecutive analyses indicate the atmosphere is below 50 percent of its lower explosive limit (LEL). The furnace is then purged and the doors may be opened and the inert gas turned off.

The normal procedure for startup or shutdown of most Class C furnaces when the temperature is above 1400°F (760°C) is to burn out the air at the start of the process and the flammable atmosphere at the finish. In furnaces with an operating temperature above 1400°F (760°C), burning may be performed at the start by bringing the temperature up to 1400°F (760°C) before the special atmosphere is introduced. Automatic means are required to prevent the introduction of flammable fluids into a furnace before the furnace temperature has risen to 1400°F (760°C). At this temperature the flammable gas will burn in the oven until the oxygen is used up and the hazard removed, allowing the operation to be started. At the end of the process, the heating should be continued so the temperature stays above 1400°F (760°C); then the flammable gas supply is shut off and air gradually admitted. When burning stops, the flammable gas has been consumed. When an alarm indicates failure of the flammable gas supply or of the heating system, the oven operator must immediately initiate an inert gas purge or start the admission of air to burn the flammable gas in the furnace. This must be done before the furnace cools to below 1400°F (760°C). Where operators are not present and flammable gas flow is interrupted because of insufficient temperature inside the furnace, a flow control unit should automatically admit a flow of inert gas that will restore positive pressure without delay.

Special Atmosphere Generators

Special atmosphere generators are a source for the atmospheric gases used in some Class C furnaces. One type of generator (i.e., exothermic) produces the atmospheric gas by completely or partially burning fuel gas at a controlled ratio, usually at 60 to 100 percent aeration, whereas another type (i.e., endothermic) produces the atmosphere at a controlled ratio of less than 50 percent. Atmospheres from an exothermic generator are either inert or flammable, depending on the generator design and operating range, whereas those from endothermic generators are always flammable.

Another type of generator is an ammonia dissociator, which, by temperature reaction with a catalyst in an externally heated vessel, produces dissociated ammonia (25 percent nitrogen and 75 percent hydrogen) from ammonia.

The special atmosphere generator must be provided with adequate supervisory controls. These would normally include interlocking of raw gas, air (if needed), burners for heating or processing, feed and discharge pressures, and so on. Safety shutoff valves are usually provided in feed and discharge piping, and devices are also provided to indicate the pressure or rate of flow of processed gas to the furnace and its analysis. This can vary. The operator is thus assisted in his or her efforts to supply the furnace with the desired special atmosphere.

The best location for the generator and its auxiliary equipment, such as surge tank, compressor, aftercooler, storage tank, and so on, is in a separate, detached building of light, noncombustible construction.

CLASS D VACUUM FURNACES

Vacuum furnaces are used for heat treating metals; they are not, however, limited to this industry. In a vacuum furnace a vacuum pump is used to displace oxygen and, in most cases, to reduce the water vapor content or dew point as well.

Vacuum furnaces are usually batch furnaces. Batch furnaces are further classified into hot-wall and cold-wall furnaces; the latter are in greater use at the present time. Examples of hot-wall and cold-wall vacuum furnaces are shown in Figures 8.8.13 and 8.8.14, respectively. In the hot-wall furnace, the entire vacuum vessel is heated, though usually not above 1800°F (982°C) because of the reduction in the strength of materials at elevated temperatures. However, installation of a second vacuum vessel outside the vacuum retort (within which a roughing vacuum is maintained during the heating cycle) permits construction of larger hot-wall furnaces with higher operating temperatures.

Cold-wall furnaces consist of a water-cooled vacuum vessel. Usually the heating elements are inside the vacuum vessel. The walls can be maintained at near ambient temperature during high temperature operations; thus, large units operating at high temperatures (4000 to 5000°F [2204 to 2760°C]) can be constructed. The two most common methods of heating cold-wall furnaces are by resistance and induction, with the heating elements located within the vacuum vessel. The heating elements are usually water cooled, though occasionally they are air cooled. Insulation can be affected by radiation shields constructed of low-emissivity, oxidation-resistant metals with proper vapor pressure characteristics. Refractory insulation can be used in some instances, but this is difficult due to outgassing of entrapped air in the refractory.

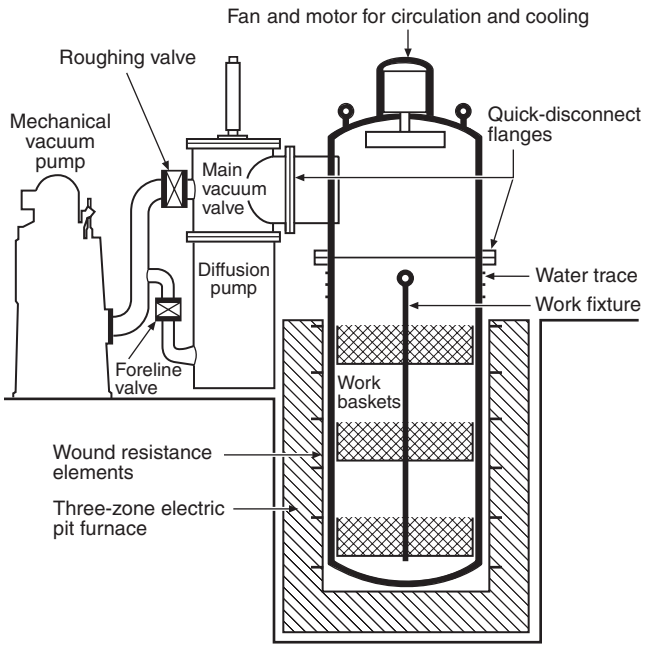

FIGURE 8.8.13 Hot-Wall, Single-Pump Retort Vacuum Furnace

Mechanical-type pumps may achieve vacuum pressures of 10^{-3} to 10^{-2} torr. (Torr is a unit of pressure equal to 1/760 of an atmosphere.) For greater vacuum, booster oil-diffusion pumps are used to achieve pressures in the range of 10^{-5} to 10^{-7} torr; they must be "backed" by a supplementary pump.

Fractionating oil-diffusion pumps also are used and should always be backed by a rotary pump, or rotary and mechanical booster combination. They produce pressures from below 10^{-3} torr down to about torr. The accidental admission of air into a heated diffusion pump has resulted in an explosion of the pump fluid. The explosion forces damaged both the pump and the furnace hot zone.

Vacuum furnaces have the same hazards as most Class C furnaces. Besides those hazards associated with the heat sources, the additional hazards of vacuum furnaces are the following:

1. Water leaks in either heating elements or vessel jackets can cause explosions; if water enters the furnace at operating temperatures, it will cause more than just a steam explosion
2. Collapse of the furnace wall if a relief valve on the water jacket fails
3. Collapse of the vacuum retort in a hot-wall furnace, if the vessel uses materials that have inadequate strength at high temperatures; if this occurs in a gas-fired unit, the flame can be pulled into the vacuum pump and ignite the oil in the pumps
4. Vacuum pumps that pull fluids (water or oil) from hydraulic seal pots
5. The condensed metallic vapors on electrical insulators, which can cause short circuiting, because this kind of furnace operates at pressures that can vaporize metals
6. Short circuiting, if improperly supported heat shields sag at high temperatures and contact heating elements
7. Hot spots on furnace walls that can weaken the furnace wall, if heat shields sag
8. Temperature control problems not present in other types of furnaces and ovens; optical pyrometers must have a line of sight to the work and their accuracy can be seriously impaired by gases, smoke, or discoloration of the sight glass
9. Heat transfer—unless the thermocouple is actually attached to the part being measured, the heat transfer is based

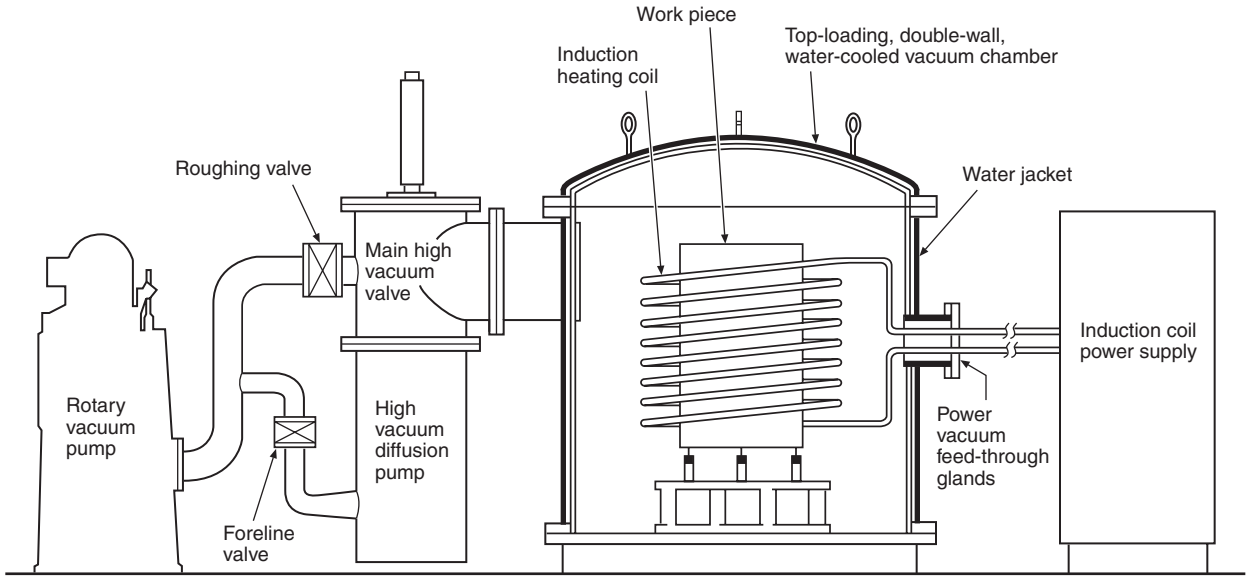

FIGURE 8.8.14 Cold-Wall, Induction-Heated Vacuum Furnace

wholly on radiation. In air, a thermocouple receives heat by conduction and convection; therefore, with no air (or gas) in the furnace, the thermocouple response is slower. A gap of as little as 0.001 in. (0.025 mm) between the thermocouple and part or surface being measured can change significantly the response time of the thermocouple. A thermocouple on the heating element could mean that the parts would not reach the desired temperatures because the heating elements would of necessity have a temperature higher than the part (center of furnace), at least until equilibrium has been reached.

10. Induction heating—keeping piping conduits, building columns, beams, and so on, out of the induction field, if the furnace is heated by induction. Any one of these items near an improperly shielded furnace can be heated by the induction coil inside the furnace. For instance, a steel bar placed so that it touches the furnace and a metal floor will be visibly hot in a matter of minutes. Of course, this also can happen on a Class B induction furnace.

AFTERBURNER AND CATALYTIC COMBUSTION SYSTEMS

Vapor incinerators are combustion oxidation chambers designed to destroy process exhaust vapors by heat. Both direct flame and catalytic oxidation are used to reduce odors, vapors, and gases to acceptable exhaust products, such as carbon dioxide and water vapor. Exhaust that contains something besides plain hydrocarbons and oxygenated species might require additional special treatment, scrubbing, and filtration to remove particulate matter as well as halogens, hydroxides, sulfur oxides, and nitrogen oxides.

The advantages of vapor incinerators can include reduced cleaning costs, reduced equipment downtime, reduced fire and explosion hazards, compliance with federal, state, and local pollution regulations, and savings in plant heating costs. Process fuel consumption can be reduced by the heat recovery of the burned exhaust fumes.

Installations have been damaged by fires in ducts between the process units and the incinerator, explosions of accumulated vapors in the ducts before or during startup, improper operation of gas-fired incinerators, and overheating of the catalytic element or combustion chambers. The causes of these fires have been inadequate duct cleaning; inadequate duct design; incomplete prepurging of the ducts, process unit, and incinerator; failure by the operator to follow proper operating procedures; and malfunction of burner and temperature controls.

Afterburner (Direct-Flame) Incineration

Direct-flame incinerators can be used for a wide range of organic solvent vapors, organic dusts, and combustible gases. In order to burn, the fumes must be heated to their autoignition temperatures with sufficient oxygen present to complete the chemical reaction. Quenching the burner flame might occur if the burner capacity is insufficient or the flame pattern and mixing are inadequate. The material being incinerated must reach the autoignition temperature and remain there long enough (dwell time) for the chemical reaction to occur (the dwell time is usually 0.4 to 0.8 sec). Ample oxygen, more than 16 percent, is necessary for complete combustion. The step sequence for successful incineration is shown in Figure 8.8.15.

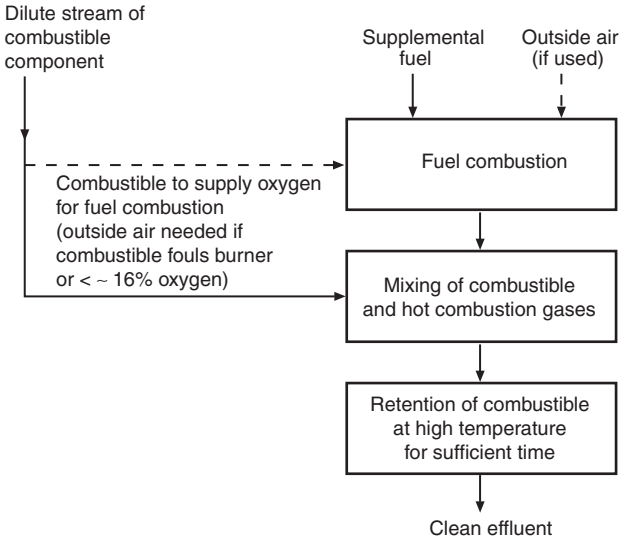

FIGURE 8.8.15 Steps Required for Successful Incineration of a Dilute Stream of Combustible Dust, Gas, or Vapor

Operating temperatures in the combustion chamber are usually designed for a range of 1200 to 1500°F (650 to 816°C). Tests on some units have reported approximately 92 percent conversion efficiency to CO_2 at 1300°F (704°C) and 96 percent conversion efficiency at 1450°F (788°C). These conversion percentages to CO_2 are frequently required by air pollution codes. In any case, complete combustion requires that the combustion component have sufficient air, proper mixing with the air, adequate dwell time, and adequate combustion chamber temperature.

Direct-flame combustion chambers are usually heavy refractory lined with external burners, such as tunnel burners, or light refractory with sectional line burners or line burners with mixing plates (Figure 8.8.16).

When metal construction is used, the design must take into account high thermal stresses and possible overheating of the metals. The combustion chambers, kiln, and boiler burner flames sometimes are used as fume incinerators.

Contaminated process waste streams might be inert gases with a low combustible hydrocarbon content. This mixture can be mixed with sufficient air to ensure combustion, then oxidized in a direct-flame or catalytic incinerator.

Special precautions must be taken where a concentrated combustible stream is exhausted from the process. For safety, the stream is usually diluted with air to below 50 percent LEL for transfer to the incinerator.

Concentrated combustibles above the LEL are normally burned in flare stacks or as fuel in various types of heating equipment. The latter requires special burner design and combustion control supervision.

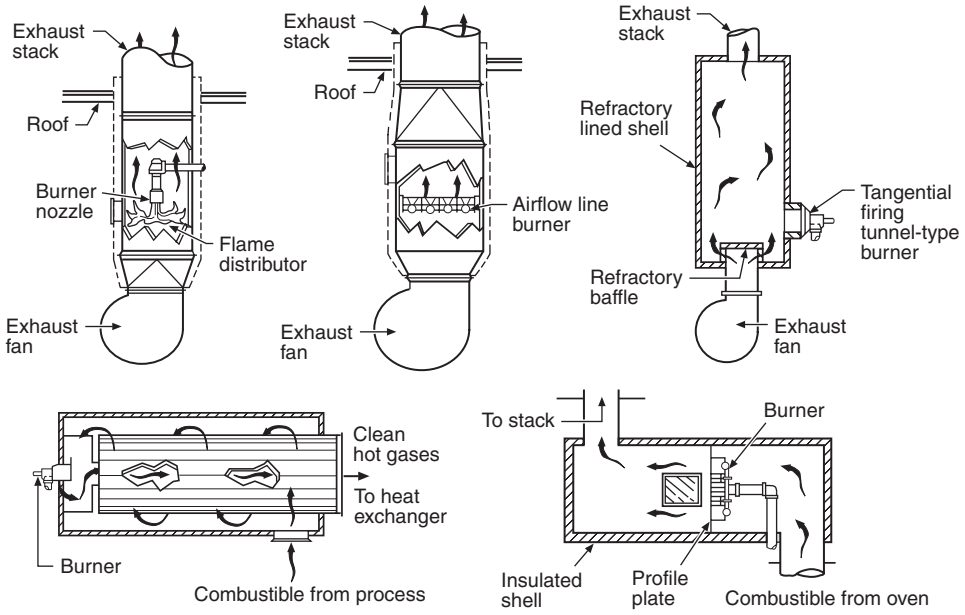

FIGURE 8.8.16 Typical Direct-Flame Dilute Stream of Combustible Component Incinerators (Source: Maxon Corp.)

Catalytic Combustion Systems

Air pollution from furnace exhaust often is removed or reduced by catalytic combustion systems. A catalytic heater employs catalysts to accelerate the oxidation or combustion of air-fuel mixtures, including waste streams, for eventual release of heat to an oven or other process. Catalytic heaters can be used to burn a fuel gas, with substantial portions of the energy released as radiation to the processing zone. Alternately, catalytic heaters can be installed in the oven exhaust stream to release heat from evaporated oven byproducts, with available energy returned by a heat exchanger for recirculation through the oven processing zone.

Three types of catalytic combustion elements are available. The first is an all-metal mat used either as a fuel-fired radiant heater or alternately to oxidize combustible materials in an exhaust stream. The second type is of ceramic or porcelain construction arranged in various configurations for gas fuel or vapor oxidation with catalyst media, including a variety of "rare earth" elements (e.g., platinum or metallic salts). Both types of these elements are classified as "fixed-bed" catalysts since they are normally held rigidly in place by clamps, cement, or other means. A third type of element consists of a bed, pellets, or granules supported or retained between screens in a fixed position but with the individual members free to migrate within the bed.

Heating systems that employ catalysts are widely used to conserve oven fuel and control air pollution emissions (Figures 8.8.17 and 8.8.18). Catalytic heaters cannot, however, oxidize or consume silicones, chlorine compounds, and metallic fumes as from tin, mercury, and zinc; these elements and various inorganic dusts can retard or paralyze the catalysts.

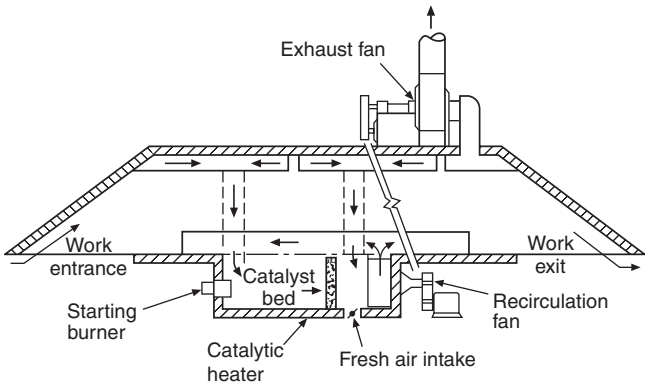

FIGURE 8.8.17 Direct-Type Catalytic Oven Heater for Partial Air Pollution Control

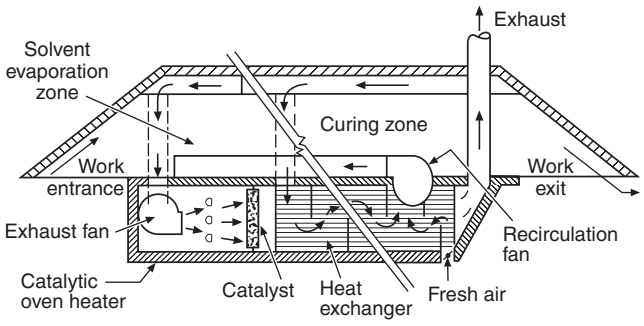

FIGURE 8.8.18 Indirect-Type Catalytic Oven Heater for Full Air Pollution Control

Installation

All components of the afterburners and catalytic combustion system, related process equipment, and interconnecting ducts must be provided with controls and safeguards to supervise conditions during startup, operation, and shutdown. In some installations, many different concentrations of the combustible stream develop. Collection and delivery of this stream to the incinerator is an important part of the system. A careful investigation must be made for the incinerator and the associated equipment, including the appropriateness of the design and operating procedures.

HEAT RECOVERY

Heat exchangers and direct recirculation methods of heat recovery are often used to make process and waste system incineration more economical. Some plants have calculated that if heat recovery methods are applied to heat generating processes, including incineration, the recovered heat can supply a substantial portion of the entire plant's heat or process demands (Figure 8.8.19).

Recovered heat can be used for (1) the process as either a sole or supplementary heat source, (2) the process for some zones in a multizone unit, (3) other nearby processes, (4) preheating the stream entering incinerator, (5) heating plant makeup air, and (6) a waste heat boiler serving multiple plant services. However, dirty stream deposits in the heat exchanger can make it inoperable. Combustible deposits and flammable liquids heated to high temperatures within the heat exchanger could cause a fire or explosion.

LUMBER KILNS

Drying lumber to a predetermined moisture content is accomplished in a variety of structures called kilns. Kilns make it possible to turn freshly cut, green wood into dry, accurately dimensioned lumber in a much shorter time than seasoning wood in open air. Because large quantities of combustible material are exposed to temperatures that can approximate ignition temperatures, kilns present a high degree of fire hazard.

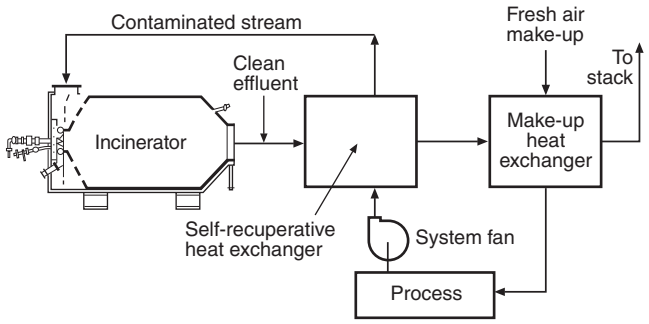

FIGURE 8.8.19 Typical Incineration System Incorporating Waste Heat Recovery with Fume and Process Air Preheating

Although called dry kilns, wood dryers usually employ moisture to maintain a uniform content within the wood during the drying, thus eliminating warping, checking, and splitting. The amount of moisture will vary with the species; significant variations are found within trees of the same species. The length of time required to bring the moisture content down to an optimum of about 2 percent depends on the species, its original moisture content, the dimensions of the pieces being seasoned, the type of kiln, and the volume of material.

Types of Kilns

A dry kiln is basically an oven with controlled heat and humidity. It can be either a batch dryer or a progressive dryer. The wood being dried in a batch or compartment kiln remains stationary throughout the process. Temperature and humidity in all parts of the kiln are maintained as uniformly as possible and are adjusted as the wood dries.

Progressive kilns permit green lumber to be introduced in one end while dried lumber is being removed from the other end. Such kilns are designed so that somewhat higher temperatures are maintained at the dry, or discharge, end rather than at the loading end.

In natural circulation kilns, heated air rises up through the stacked lumber by convection (Figure 8.8.20). Losing its heat, air travels down to the heating device and is reheated. During the first part of the drying cycle, the air flows up along the sides, over the stacked lumber, and down through air passages in the stack. When the moisture content has been reduced to somewhere between 20 and 10 percent, heated air is directed up through the center of the stack to equalize the drying. Vents in the walls or roof of the kiln exhaust the hot, moisture-laden air.

Forced circulation kilns move air through the stacked lumber by either internal or external blowers (Figure 8.8.21). Figure 8.8.22 shows an internal fan kiln with fans located beneath the

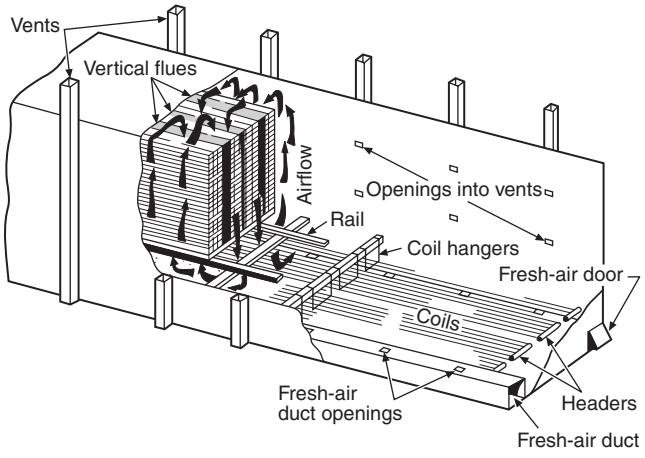

FIGURE 8.8.20 Natural Circulation, Steam-Heated Compartment Kiln. Arrows indicate air movement during the early stages of the drying cycle.

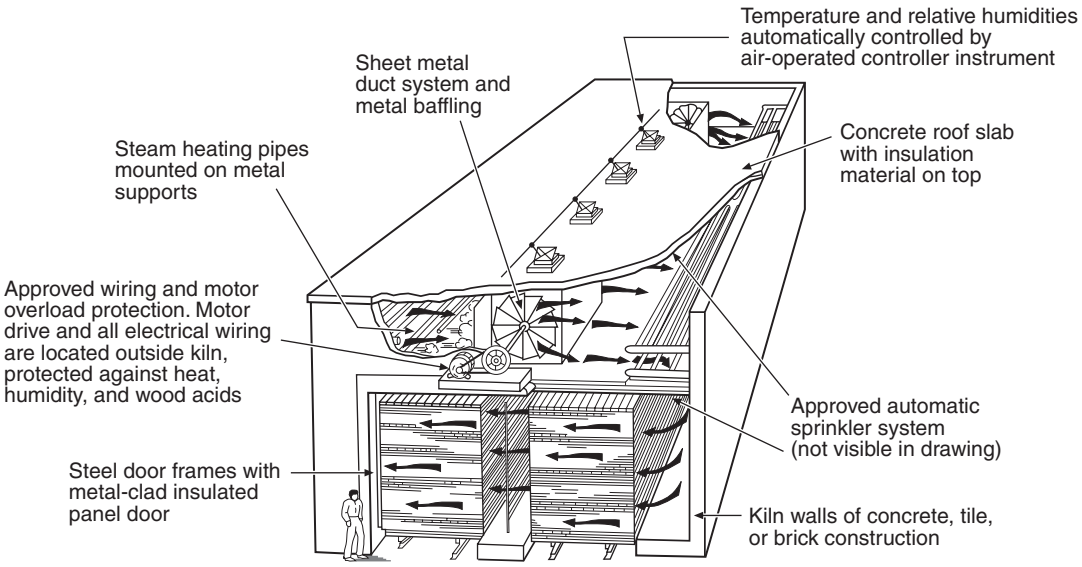

FIGURE 8.8.21 Forced Circulation Double-Track Compartment Kiln. Note that automatic sprinklers are installed above and below the platform between the kiln and the overhead fan room.

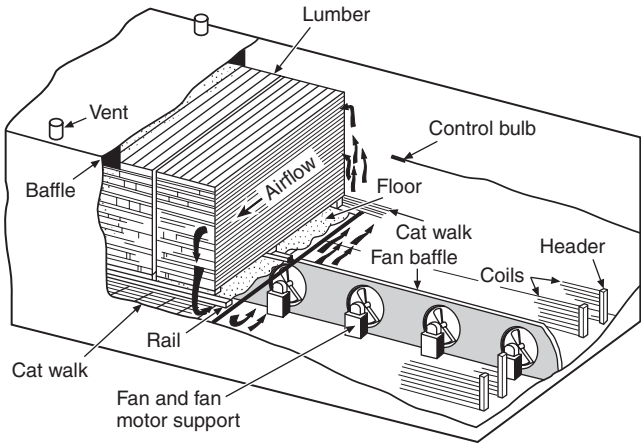

FIGURE 8.8.22 Compartment Kiln with Internal Fans and Steam Coils Located under Grating at Floor Level. Broken pieces of stickers and sawdust can fall through the grates and collect around the coils and fan motors to become a hazard, particularly if high-pressure steam coils are used.

floor. Internal fans are reversible, changing the airflow for optimum drying. Internal fan kilns normally require cloth or metal baffles to eliminate turbulence and keep the air flowing in the desired direction.

Much the same airflow systems are used in both batch and progressive kilns. There are some minor differences, however. In progressive kilns, the air flows through the length of the chamber and is discharged at the green end. Because the air has picked up moisture and is cooler by the time it reaches the loading end of the kiln, the drying rate there is much slower.

Kiln Construction

Unlike most other buildings, kilns are subjected to extreme variations in internal temperature and humidity. Such variations cause unusual expansion and contraction that reduce structural integrity of the kiln and increase heat loss. Untended structural defects can also lead to premature failure of the structure. To reduce the fire hazard, kilns should be of fire-resistant or heavy-timber construction.

Heat Sources

Dry kilns require a constant source of heat, provided either directly or indirectly, to vaporize the water content of the wood. Direct heating is accomplished by circulating hot gases (produced by burning gas, oil, sawdust, or other fuels) through the stacked lumber. It also can be done by heating large metal surfaces with an open gas or oil flame as in Figure 8.8.22. Air circulated by internal fans passes over the metal, which acts as a heat exchanger, then flows over the lumber, carrying off moisture vapor.

Steam is a common source of heat for indirectly heated kilns, but hot gases and electrical resistance heaters are also used. Steam is circulated through pipes and hot gases through ducts.

Fire Hazards

Lumber kilns present high fire hazards. This is especially true when direct-heat systems or high-pressure steam systems are used and in those instances where the structure itself is of combustible materials.

Direct-fired kilns present the greatest hazard because open ignition sources are close to the wood (Figure 8.8.23). The kilns should be considered analagous to Class A ovens in that they

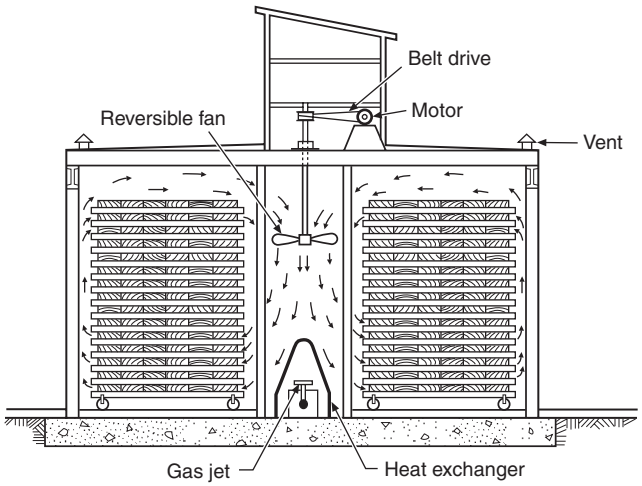

FIGURE 8.8.23 Double-Track, Internal Fan Compartment Kiln Heated Directly by a Gas Burner

should be equipped with all the combustion controls normally required for drying ovens where the heating fuel is introduced into the heating enclosure itself. Indirectly heated kilns utilizing steam coils as heat exchangers and having controlled humidity are usually considered to be of low hazard.

Safeguards

The important requirements for fire safety are automatic sprinkler protection, sound construction, good housekeeping, automatic humidity control, good air circulation, and proper ventilation. Kilns should be situated at safe distances from storage yards, sheds, and mill buildings. Ideally, they should be of fire-resistant construction and equipped with a complete automatic sprinkler system connected to an adequate water supply. The sprinkler protection should extend to fan houses and control rooms. Hydrants or hose connections should be located on the exterior for manual fire fighting.

DEHYDRATORS AND DRYERS

Dehydrators and dryers for agricultural products, commonly referred to as dryers, use heat to reduce the moisture content of products. The hazards of dryers are (1) the possibility of igniting combustible materials near them, (2) the use of fuel or electricity as a heat source, and (3) the ignition of stock being dried.

Types of Dehydrators and Dryers

The three types of agricultural product dryers are (1) continuous, (2) batch, and (3) bulk. They differ in the arrangement and operation of the drying chamber.

Continuous dryers include the following types:

1. Drum dryers for milk, puree, and sludges
2. Spray dryers for milk, eggs, and soup
3. Flash dryers for chopped forage crops
4. Gravity dryers (can also be batch type) for small grains, beans, and seeds (Figure 8.8.24)
5. Tunnel dryers (also batch type and can be further classified according to airflow and whether or not intermediate heat-

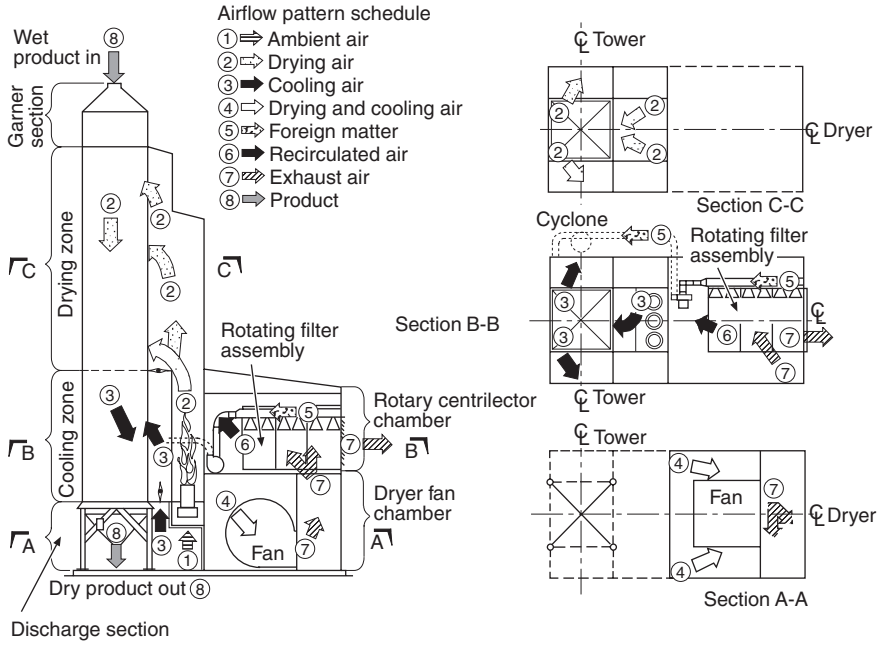

FIGURE 8.8.24 Tower-Type Gravity Dryer (Source: Aeroglide Corp., http://www.aeroglide.com)

ing is used) for fruits, vegetables, grains, seeds, nuts, fibers, and forage crops (Figure 8.8.25)
6. Rotary dryers for milk, puree, and sludges (Figure 8.8.26)

Batch dryers can be either fixed or portable and include pan dryers for sugar, puree, sludges, and other products (Figure 8.8.27).

Bulk dryers dry the product in a bin, crib, or compartment in which it is to be stored. They are used to dry seeds, grains, nuts, tobacco, hay, and forage (Figure 8.8.28).

Methods of Heating

Dryers for agricultural products can be direct-fired (where products of combustion contact the material being dried) or indirect-fired. The heaters can be oil-fired, gas-fired, solid-fuel-fired, electrical, or heated by a heat transfer medium, such as steam. In general, the requirements for burner installation and fuel storage are the same as those for other heat-producing devices.

If gas-fired infrared heaters or lamps are used, their focal length should be ample so the surface of the drying product does not reach unsafe temperatures. If electrical infrared lamps are used in dryers, the lamps should be located where they cannot collect combustible dust.

Solid-fuel furnaces (other than those burning coke and anthracite coal) should not be used where the products of combustion can enter the drying chamber. Indirect solid-fuel dryers need temperature-controlled heat relief openings to the outside.

Dryer Controls

Some suggested controls for dryers, except those on the heating equipment, include the following:

1. A method for automatically shutting down the dryer in the event of fire or excessive temperature
2. A thermostat in the exhaust air when the product is fed automatically from the dryer to a storage building; in the event of excessive temperature, the thermostat
   (a) shuts off heat to the dryer and stops airflow (except when the product being dried is in suspension)

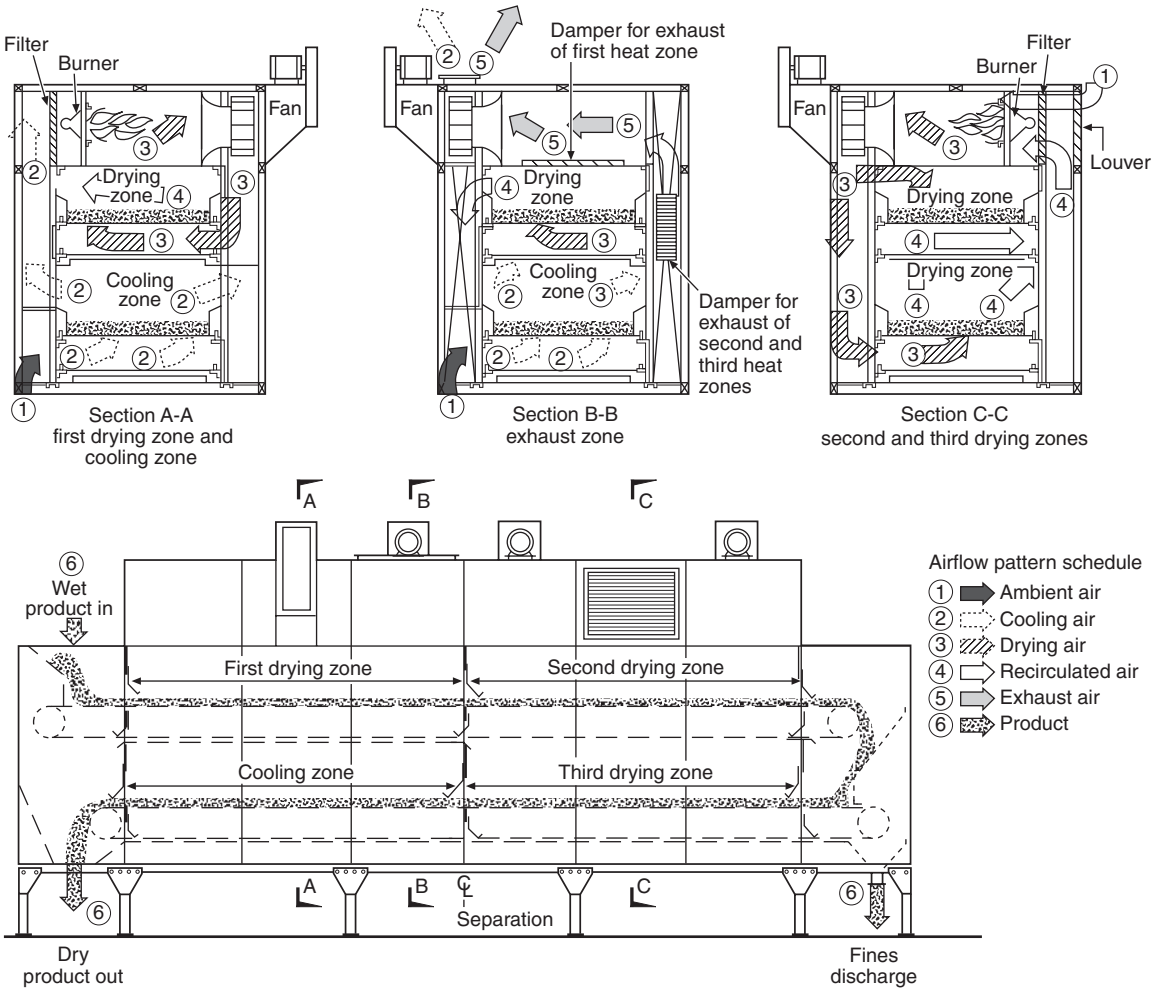

FIGURE 8.8.25 Tunnel Dryer (Source: Aeroglide Corp., http://www.aeroglide.com)

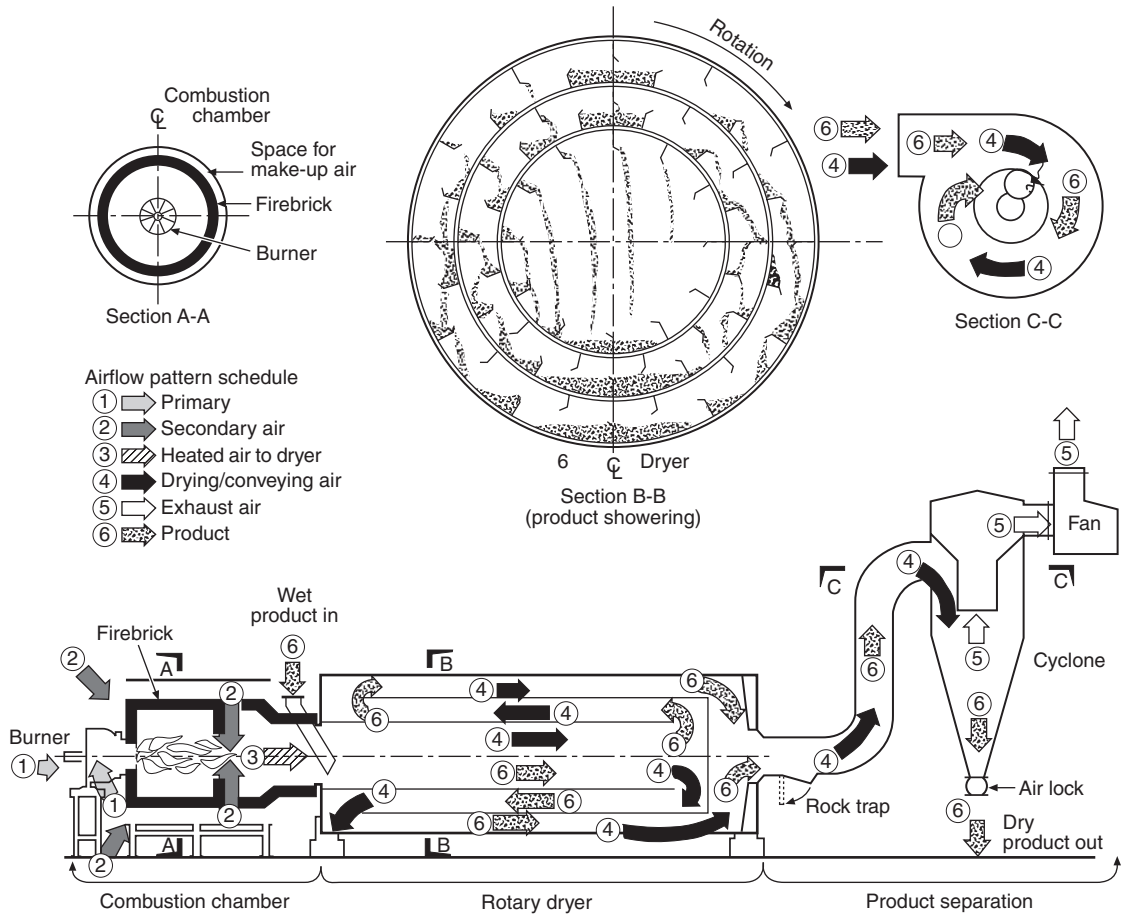

FIGURE 8.8.26 Rotary Dryer (Source: Aeroglide Corp., http://www.aeroglide.com)

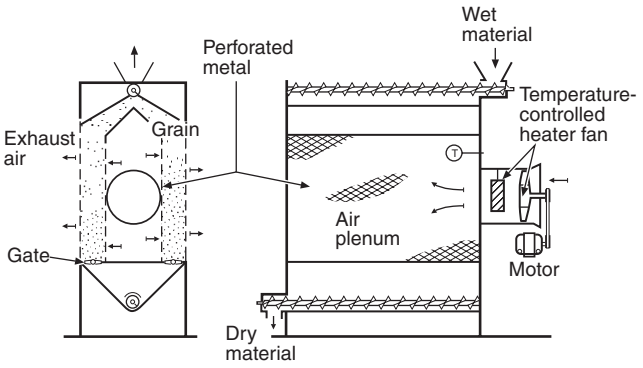

FIGURE 8.8.27 Batch-Type Grain Dryer

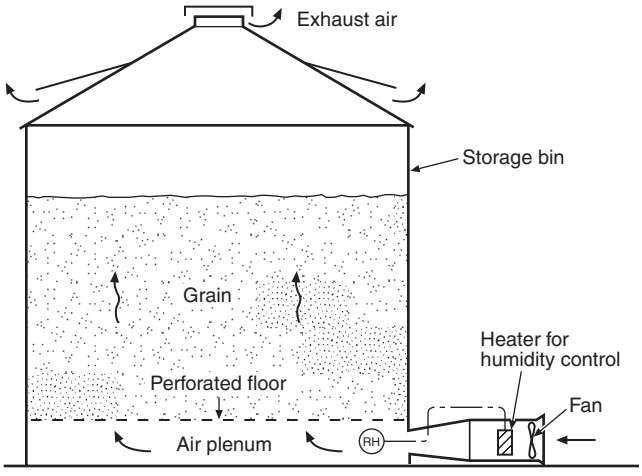

FIGURE 8.8.28 Bulk-Type Grain Dryer

(b) stops the flow of the product
(c) sounds an audible alarm

3. A thermostat in combustible dryers that, when the temperature of the combustible reaches 165°F (74°C), shuts off heat to the dryer but permits unheated air to pass through and activates an audible alarm
4. A device to shut off heat to the dryer if air movement through the dryer stops
5. A high-limit thermostat located between the heat-producing device and the dryer

Burner Controls

In general, the burner controls for dryers are the same as those for other automatically fired devices. A manual, quick-closing shutoff valve should be installed in the supply line of gas- and oil-fired burners and controls should be arranged so that, following automatic shutdown, manual restart will be necessary. Other control safeguards include flame failure protection and preventilation of the combustion chamber. All safety devices must be listed for the service intended.

Construction and Installation of Dryers

Because dryers operate at elevated temperatures, they should be made of fire-resistant or noncombustible materials. If combustible materials must be used, dryers must not be subjected to sustained temperatures in excess of approximately 165°F (74°C). Expansion joints should be provided to prevent damage from expansion and contraction.

Secondary air openings for direct-fired dryers are screened with ½-in. (12.7-mm) mesh screen so materials cannot enter the combustion chamber. Primary air openings require screens with mesh ¼ in. (6.4 mm) or smaller. An ample supply of easily opened access panels is necessary for inspection, cleaning, and fire fighting.

When stock is moved through the dryers in a way that generates static electricity, all conductive parts of the dryers should be electrically bonded and grounded.

Like any heat-producing device, a dryer must have adequate clearance from nearby combustibles to prevent overheating. If there is a combustible dust hazard in the same building as the dryer, the heating device and blowers are installed in a dust-free room or area separated from the rest of the building. Ducts to convey heated air to the dryer and exhaust air from the dryer to the outside should be noncombustible.

Extinguishing Equipment

The best way to protect a dryer enclosure is to install a water spray or automatic sprinkler system within the enclosure where possible. An exception to this is the direct-fired rotary dryer, which can be damaged by the internal application of water. A carbon dioxide system is satisfactory protection for this type of dryer.

Fire protection might be needed in the product and exhaust dust-collecting system, bins, chutes, ducts, cyclone collectors, and dust collectors. In addition to automatic sprinkler or deluge systems, high-speed infrared detectors with water spray might be needed to extinguish ignition sources, sparks, or embers in the ducts and to prevent propagation to the bins or dust collectors.

To extinguish small fires in and around most dryers, standpipe hoses are most useful, though water-type portable fire extinguishers also may be used.

Cooling of Dehydrated Products

A product being dried requires adequate cooling before it is packaged or stored. The amount of cooling required to prevent subsequent ignition will depend on the properties of each material and how it is to be packaged or stored.

SUMMARY

This chapter is meant to increase the awareness of designers, end users, and operators of industrial and commercial heat utilization equipment of the hazards involved with this type of equipment. The potential hazards involve both heat generation and the process materials.

Because heat utilization equipment is so varied in size, complexity, and location, developing rules that fit every type of oven, furnace, or dryer is difficult. Proper equipment operation depends on the right combination of controls, protective devices, and operator training. The best design and installation still require the competent and well-trained operator who is thoroughly familiar with the equipment, its hazard potential, and its maintenance requirements.

For additional requirements, the reader is directed to NFPA 86.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on industrial and commercial heat utilization equipment discussed in this chapter. Chapter Contents

Oil and Polymer Quenching
Quench Tanks
Material Transfer
Oil Temperature Control
Central Oil System
Safety Considerations
Molten Salt Baths

Key Terms

controlled cooling, hardening processes, heat-treating operations, molten salt bath operations, oil (quenching), oil quenching operations, quenching (polymer), salt bath furnace, tempering processes

Oil-quenching operations are heat treatment processes that both harden and temper metals. Molten salt baths are used for heat treatment of metals, ceramics, or polymers to increase their hardness.

The first part of the chapter addresses the various elements of oil quenching, safeguards, and fire protection. The second part of the chapter describes salt bath types and applications, hazards, and safeguards.

Additional hazard and protection information relevant to oil quenching can be found in Section 8, Chapter 11, "Fluid Power Systems." Fire suppression information can be found in Section 15, "Water Supplies for Fixed Fire Protection"; and Section 17, "Fire Suppression Systems and Portable Fire Extinguishers."

Additional information on molten salt baths can be found in Section 7, Chapter 4, "Storage and Handling of Chemicals"; and Section 8, Chapter 8, "Industrial and Commercial Heat Utilization Equipment."

OIL AND POLYMER QUENCHING

One process in the heat treatment of metals is a controlled cooling or quenching of heated materials by immersion in a liquid-quenching medium. This process hardens and tempers the metal by imparting metallurgical changes to its surface. Due to the combustible nature of quench oils, the process presents serious fire hazard potentials.

Contributing to the hazards of oil quenching are the following:

1. Requirements for a special atmosphere (a flammable gas blanketing the surface of the oil)
2. Temperature requirements of the quench medium
3. Physical properties of the quench medium
4. Volume limitations of the quench medium
5. Size and configuration of process materials
6. Locations of furnaces and quench tanks
7. Mutual exposure between quenching and other processing or storage facilities

Whether the quenching is automatic and continuous, semiautomatic, or a batch operation, it will involve elevators, conveyors, hoists, and cranes, either individually or in combination, to immerse the work in, move it through, and remove it from the oil bath (Figure 8.9.1). Although all three steps are important to the process, the one that is critical to safety is the entrance of the work into the quench.

Quenching Oils

In most cases, mineral oils are used for quenching, but specific metallurgical requirements sometimes dictate the use of mixtures with animal or vegetable oils. In addition, wetting agents might

Raymond Ostrowski is a consultant for Ostrowski Consultants, Cave Creek, Arizona. He is a member of NFPA's Technical Committee on Ovens and Furnaces and chairman of the NFPA 86C Committee.

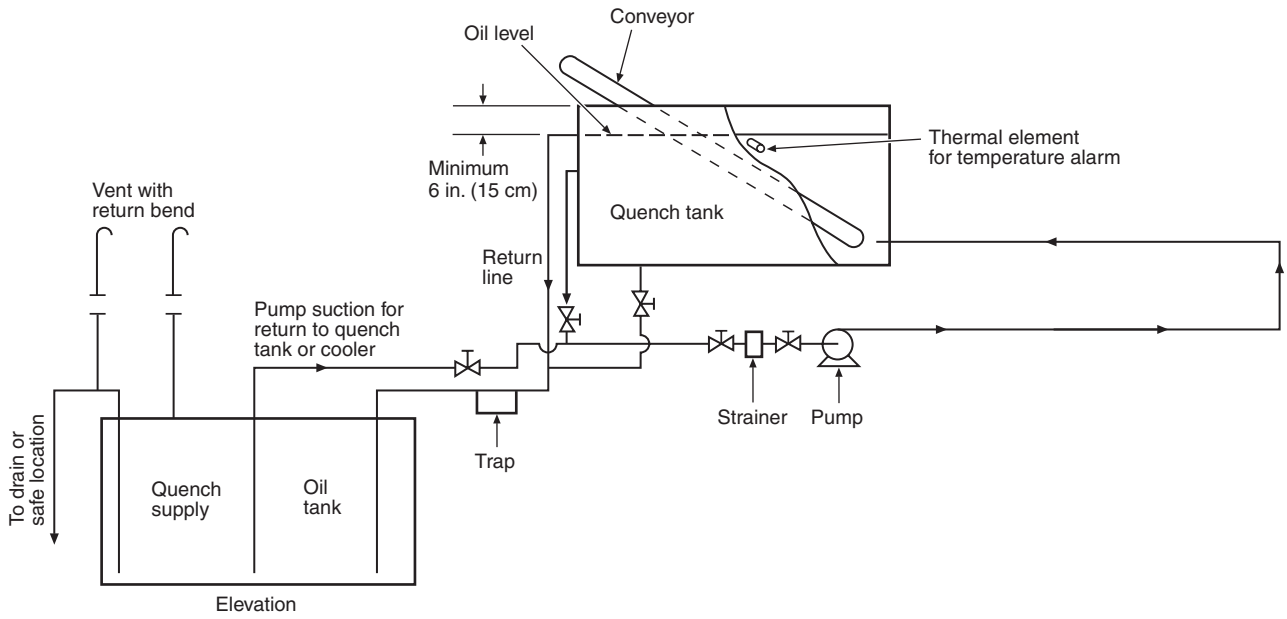

FIGURE 8.9.1 Typical Continuous-Type Oil Quench Tank

need to be blended with certain oils or oil mixtures. In any case, it is important to use a quenching oil with a low viscosity.

Essential quench oil properties include the ability to remain stable over periods of extended usage and to retain fluidity. For unheated quenching, operating temperatures between 100 and 200°F (38 and 93°C) are considered normal. Standard quench oils for use in this temperature range usually have flashpoints somewhat above 300°F (149°C). For heated quenching, operating temperatures between 200 and 400°F (93 and 204°C) are common. Quench oils used at these temperatures generally have a flashpoint above 500°F (260°C).

Polymer Quenching

A rather recent development is the use of polymer quenchant in integral quench furnaces. A furnace designed for oil is not designed for a quick change to polymer quenching. Caution should be observed and the original furnace manufacturer should be contacted prior to changing from oil to polymer quenchant.

QUENCH TANKS

A quench tank should allow proper quenching under normal conditions and provide for minor variations in equipment control functions and operator error. The designs of the tank freeboard, overflow drains, and liquid level control are all critical. A fire that is confined to the liquid surface within a tank is much more readily controlled and extinguished than a fire involving quench oil that has overflowed the tank.

The distance from the quench surface to the top of the tank, with the tank loaded to capacity, is known as the freeboard. Freeboard should take into account the splashing to be expected when the maximum workload is immersed with maximum speed. The distance between the liquid level with the workload submerged and any openings in the tank wall should be not less than 6 in. (152 mm) below the door or any opening into the furnace.

Adequately sized, fully trapped overflow drains are important safety features for all oil quench tanks. They should direct the overflow to a safe location outside of buildings or into special tanks. As a practical matter, small quench tanks frequently can be installed without overflow drains. However, quench tanks with a liquid capacity of 150 gal (570 L) or a liquid surface area of 10 ft^2 (0.93 m^2) or larger should be provided with overflow drains.

Although overflow drains should be specifically designed for each tank, certain minimum sizes have been established and accepted (Table 8.9.1). For large quench tanks, multiple overflow pipes are preferable to a single large pipe, provided the

TABLE 8.9.1 Quench Tank Overflow Drains, Minimum Pipe Sizes

Liquid Surface Area		Minimum Pipe Diameter (I.D.)	
ft^2	m^2	*in.*	*mm*
10–75	0.93–6.7	3	76
75–150	6.7–14	4	101
150–225	14–21	5	127
225–325	21–30.2	6	152
325+	30.2+	8	203

aggregate cross-sectional area is equivalent to that of a single pipe. Piping connections on drains and overflow lines must be designed to permit ready access for inspection and cleaning.

Emergency Drains

Under serious fire conditions, it might be necessary to empty a quench tank in order to reduce the amount of quench fluid available. This can be performed readily through adequately sized, fully trapped and valved bottom drains directed to safe locations. Where gravity drainage is not possible, special pumps can be provided for oil removal. Drains and pumps should be sized so that the quench oil can be removed within 5 minutes. Gravity drains should be sized according to the tank capacities and drain diameters given in Table 8.9.2.

Emergency drains must be used only under the guidance and control of well-trained and experienced personnel, as improper usage can result in greater hazards. Whenever a flammable gas processing atmosphere is maintained above the quench oil, removal of the oil can create a negative pressure that can result in explosion, an increase in fire severity, or both.

Tank Location

Heat-treating operations involving combustible quench oils should be housed in fire-resistive buildings and should be well separated from exit areas, combustible materials, valuable stock, power equipment, and important process equipment.

The safest location for quench tanks is at grade level. Boilover from tanks above grade can be expected to spread fire to floors below, thereby making fire control more difficult and significantly increasing the potential fire loss. Fires in below-grade locations will make manual fire fighting difficult and result in a significant increase in fire loss.

Hoods

Tanks should be provided with noncombustible hoods and vents or other equally effective means to facilitate removal of vapors from the process and to prevent condensate from forming on roof structures. All such vents and ducts should be treated as flues and should be kept well separated from combustible roofs or materials. Hoods and ducts should be protected with an approved automatic extinguishing system and should be located so as not to interfere with fire protection systems that protect the quench tank.

TABLE 8.9.2 Gravity Drain Pipe Diameters, I.D.

Tank Capacity		Pipe Diameter (I.D.)	
gal	m^3	*in.*	*mm*
500–750	1.9–2.8	3	76
750–1000	2.8–3.8	4	101
1000–2500	3.8–9.5	5	127
2500–4000	9.5–15	6	152
Over 4000	Over 15	8	203

MATERIAL TRANSFER

Rapid and complete immersion of the work in process is essential to safe and proper heat-treating metallurgical processes. The method of immersion must result in minimal splashing and no overflow of the quench oil outside of the tank. It is also essential that the possibilities for partial immersion be eliminated or minimized. Partial immersion of the work is the most common cause of quench oil fires.

Chutes

Many furnaces are designed so that the work in process drops off the end of a conveyor, through a chute, and into the quench oil. The chute design and construction must allow the work to fall freely under all normal furnace feed conditions. This will involve proper chute sizing to accommodate the work, proper pitch to ensure continued stock motion, and smooth surfaces to prevent the work from being stuck in the chute (Figure 8.9.2).

Elevators

When stock in process is handled on trays or in baskets, elevators are commonly used to immerse the work in the quench oil (Figures 8.9.3 and 8.9.4). Partial immersions are caused more

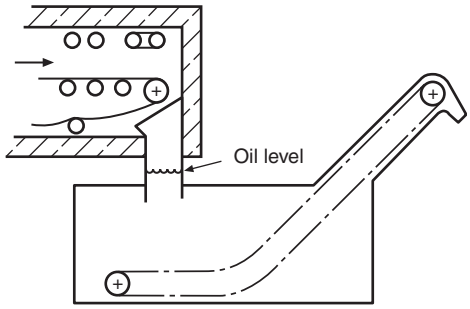

FIGURE 8.9.2 Bottom Chute-Type Quench

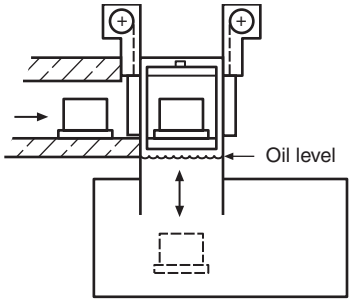

FIGURE 8.9.3 Dunk-Type Elevator Quench

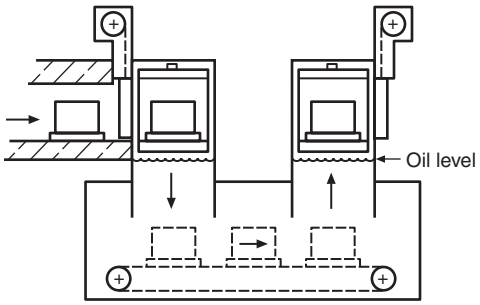

FIGURE 8.9.4 Transfer-Type Elevator Quench

by trays or baskets and elevators than by any other method. The following are three critical concerns:

1. The elevating mechanism must be adequately supported by structural members to prevent its falling unevenly.
2. Adequate guides must be provided to ensure uniform movement within the quench tank and to prevent an elevator from being wedged, as this could result in partial immersion.
3. Suitable guides and stops must be provided to prevent shifting of the workload, as this can cause elevator jamming and partial immersion.

Hoists and Cranes

A hoist or crane is usually required for moving large, specialized workloads into and out of the quench tank. Proper positioning of this equipment can be accomplished by stops and/or limit switches. Mechanical guides might be required to ensure that the work is properly positioned as it enters the quench tank.

Unless the oil drains off the work at the end of the quench period, an excessive amount of oil will be lost. Usually the work will still be warm at this time and some oil might vaporize. Any ignition source can produce a fire at this point in the process. Oil vapors will condense on cool surfaces above the drain area and, thus, contribute significantly to the potential fire loss.

OIL TEMPERATURE CONTROL

The control of quench oil temperature within specified design limits is essential to the heat-treating process as well as for safety. Failure of a cooling system can cause the oil to overheat. What is more hazardous, however, is a cooling system failure that allows water to enter the quenching oil. An excessive amount of water can produce a boilover when a hot workload is immersed in the quench. The exact critical water volume varies somewhat with the specific oil or oil mixtures being used, but if the water content reaches 0.50 percent by volume, the oil is no longer considered safe to use.

Cooling Methods

Quench oil can be cooled by water circulating through coils in the quench tank, by external heat exchangers, or by water jackets for the quench tank. Water jackets and internal water coils *must not* be used with combustible quenching oils. In these designs, any mechanical failure of the coil or the quench tank shell will result in water entering the quench medium. Such failures are not readily detectable; the first indication may be a boilover or a steam explosion when a hot workload is immersed in the quench.

If an external heat exchanger is used, quench oil must be circulated through the exchanger at a higher pressure than the exchange medium (water). If a leak should develop, oil will enter the water and be wasted. If the water pressure is higher than the oil pressure, such a leak would result in water entering the oil, creating a potential for boilover or steam explosion.

The continuous flow of cooling water is essential for temperature control. This can be properly supervised by observing the discharge from an open drain on the water side of the heat exchanger. Waterflow indicators are needed where a completely closed system must be used.

Safety Measures

An oil quench tank is built as an integral part of many special atmosphere furnaces. In these cases, the vestibule above the quench tank is water cooled, usually by water jackets. Many failures of the interior jacket walls have released cooling water into the quench tank below. As a result, safety considerations have dictated the use of special materials for vestibule jackets or the use of external coils. With special atmosphere furnaces, the use of a combustible gas for the atmosphere also will result in moisture development when the exit door is opened and the atmosphere is burned out.

If the oil level is too low and a large workload is immersed in the quench, the oil can overheat. Therefore, low-oil-level detectors should be used to sound an alarm and shut down quenching operations before overheating occurs.

Agitation is critical to maintaining safe quench oil temperature and uniformity of temperature throughout the bath. If the agitation mechanism fails, localized overheating will occur, which could cause a fire at the surface. Agitation failure and subsequent overheating can cause excessive vaporization, which could raise the pressure inside an enclosed special atmosphere furnace. Gas and oil vapor might then be forced out of the chamber around doors and through vents. Frequently, these escaping gases ignite, damaging the facilities. Agitation systems should be supervised automatically and their failure should result in the safe shutdown of operations.

Where the process requires that the quench be heated, fuel fired, electrically heated, or steam heated, immersion units are used as the heat source. All three methods of heating will create excessive temperatures at the interface of the heating unit and the quenching oil. A quench heating system should be prevented from operating if the oil level is too low, the agitation equipment is not functioning, or the oil temperature is too high. Where combustible oils are used, a separate excess high-limit temperature controller should be interlocked in the system to prevent quenching and to shut off the oil-heating system when the oil temperature exceeds a specified maximum limit.

CENTRAL OIL SYSTEM

Many heat-treating plants utilize a quenching oil that is common to several operations. Properly designed central oil systems can contribute to the maintenance of reasonably dependable and problem-free oil-quenching operations. A proper design includes filtering to remove particulate contamination, water removal for safety of operations and prevention of boilover, and cooling to deliver the quenching medium at an acceptable temperature.

Water separation can be accomplished by settling and the use of centrifuges. However, these systems are not dependable enough to eliminate the need for the oil in quench tanks to be tested periodically.

Since central systems involve a constant removal and replacement of oil from the quench tanks, it is essential for safety that oil flow be supervised. To avoid foaming and boilover, replenishment oil should not be added while the quench temperature is 212°F (100°C) or higher. Regardless of the oil being used, the temperature must never be permitted to rise to a value that is less than 50°F (10°C) below its flashpoint.

SAFETY CONSIDERATIONS

Safety Controls

All automatic shutdowns of quenching operations should result in the workload being completely immersed in, or removed from, the quench. Partial immersion always must be considered hazardous.

Whenever movement of the workload into, or out of, the quench has been stopped by a malfunction, qualified operating personnel must be permitted to override the safety interlocks so that manual attempts can be made to complete immersion or remove the workload. If exit doors must be opened, a fire condition should be anticipated. Extinguishing means adequate to protect the operator and prevent property damage should be available.

All safety controls and their interlocking functions should be tested on a regular schedule. The time interval between tests should not exceed six months. Refer to manufacturers' guidelines.

Hydraulic control systems add to the fire hazard in the vicinity of high-temperature equipment. Fire-resistant hydraulic fluids should be used. When combustible hydraulic oils must be used, proper maintenance of the hydraulic equipment is vital to safety. See NFPA 86, *Standard for Ovens and Furnaces.*

Fire Protection

Fire protection for combustible oil-quenching operations requires a detailed evaluation of the inherent fire potentials. One of the most effective forms of area protection is automatic water spray. Experience has shown that ceiling-mounted sprinkler systems will limit building and equipment damage from quench oil fires whether they are confined to the quench tank surface or spread over a large area by a quench oil boilover.

Specific protection for open quench tank surfaces and oil drainage areas is also important. Most oil fires can be extinguished by fixed carbon dioxide or dry chemical systems. In some operations, foam fire-fighting systems can also be effective. However, the suitability of foam will be determined by the quenching oil used and the temperatures involved. These systems are designed to operate automatically, well in advance of any potential sprinkler system discharge.

Those situations that require operating personnel to manually release jammed workloads and close furnace doors will dictate the provision of fire control and/or extinguishing facilities for the protection of the operator. In these instances, carbon dioxide or fixed water spray systems are the most effective. The most important fire protection features in every heat-treatment shop are the manual fire-extinguishing and control equipment and plant personnel properly trained in its use. In addition to an adequate supply of portable, hand-carried fire extinguishers, the larger, wheeled extinguishers should also be available.

Appropriately spaced hose connections with water fog or water spray nozzles should be considered an essential part of all heat-treating area fire protection. These can provide prolonged periods of fire control and life safety beyond the limited supplies of portable extinguishers.

MOLTEN SALT BATHS

Molten salt baths have become increasingly popular for the heat treatment of metals, ceramics (e.g., glass), or polymers (e.g., Teflon®) because they provide rapid and precise heat transfer and the required equipment is relatively inexpensive. A molten salt bath is defined as any heated container that holds a melt or fusion of one or more chemical salts in a fluid state. The work to be treated is immersed in the bath. There are many kinds of salt baths that use various salts and salt mixtures and that operate at various temperatures, depending on the results required.

As work is immersed fully into a salt bath, the salt serves as a protective environment. Heat is transferred more rapidly than by any other type of furnace heating. Moreover, because of the constant convection currents in the heated liquid medium, uniform temperature distribution is more easily attained.

Types of Salt Baths

The various types of salt baths available today can be classified by the heating method, application, or the particular salt mixture utilized.

Salt baths can be electrically heated or fuel fired. Electrically heated baths have electrodes introduced through the top surface of the molten salt or through the sides of the furnace below the salt surface (Figures 8.9.5 and 8.9.6). In some instances, ribbon-type resistance elements are used around a metal pot or container (Figure 8.9.7).

There are two types of fuel-fired salt baths. In one, the burners are fired directly outside a retort containing the salt. In some instances the burners are fired in metal tubes, known as radiant tubes, and the tubes are immersed in the molten salt (Figure 8.9.8).

Applications

Major uses of molten salt baths are descaling, liquid carburizing (case hardening), cyaniding and nitriding, neutral hardening,

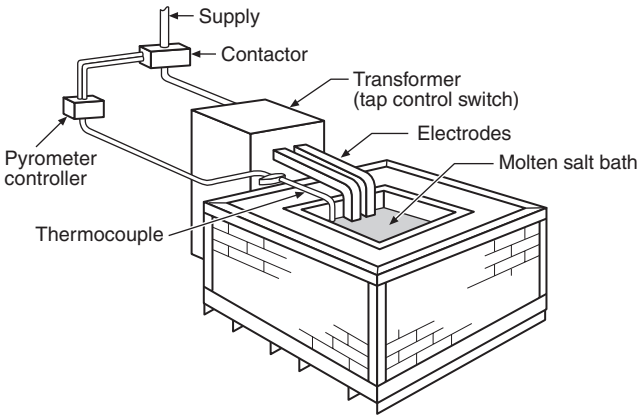

FIGURE 8.9.5 Typical Electrode Immersion–Type Electrical Heating Arrangement

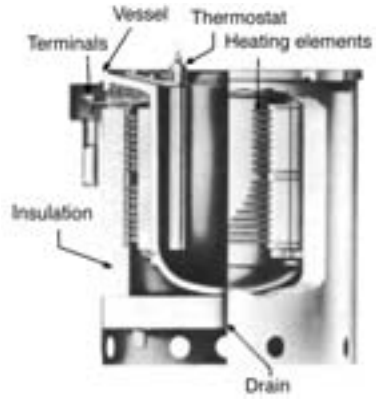

FIGURE 8.9.7 Resistance Heated Salt Bath with Pot (Source: SECO/WARWICK Corp.)

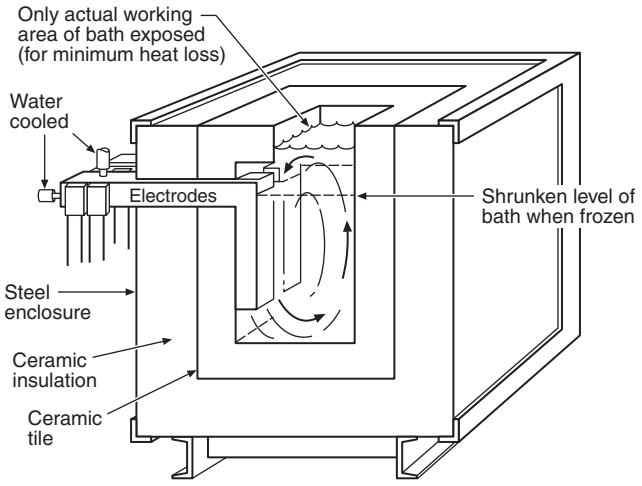

FIGURE 8.9.6 Submerged Electrode-Type Salt Bath

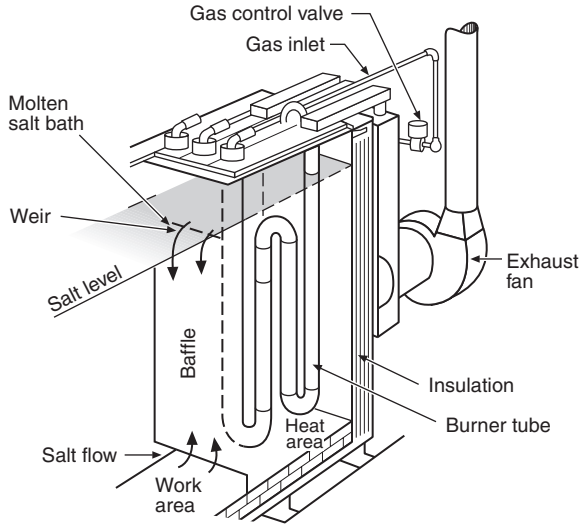

FIGURE 8.9.8 Gas-Fired Radiant Tube Salt Bath Heating Section

tool steel hardening, annealing, brazing tempering, and isothermal quenching. Each of these operations requires a different salt or salt mixture at different temperatures.

Descaling. For the removal of oxides that are difficult to remove by normal means (e.g., pickling, grit blasting, polishing, etc.), there are three different descaling processes. These processes are (1) the reducing sodium hydride process, (2) the oxidizing sodium hydroxide process, and (3) the electrolytic process. In the reducing sodium hydride process, a fused melt of sodium hydroxide and sodium hydride at temperatures between 650 and 780°F (343 and 415°C) is used. For oxidizing, a melt of sodium carbonate, sodium chloride, and sodium hydroxide is used at temperatures from 700 to 950°F (371 to 510°C). In the electrolytic process, a fused melt of sodium carbonate, sodium chloride, and sodium hydroxide is used at about 900°F (482°C). Electrolytic oxidation reduction is accomplished by passing direct current through the work. A reversing switch changes the polarity of the work from positive to negative, which effectively cleans the surfaces.

Liquid Carburizing. Case hardening is accomplished by diffusing carbon and small amounts of nitrogen into steel surfaces. The salts used are molten mixtures of sodium cyanide, sodium chloride, and barium chloride at temperatures between 1450 and 1750°F (788 and 955°C), depending on the depth of case required (Figure 8.9.9).

Cyaniding and Nitriding. These two operations are also performed with either sodium or potassium cyanides as the chief ingredient. Usually the operating temperatures are lower, typically 950 to 1050°F (510 to 566°C), for nitriding.

Neutral Hardening. The hardening of ferrous alloys without harmful surface effects is performed in mixtures of sodium,

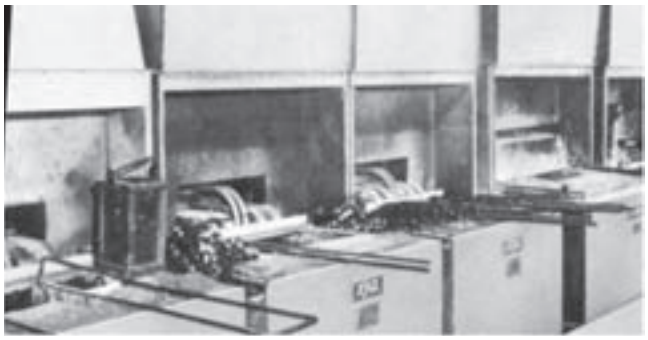

FIGURE 8.9.9 Liquid Carburizing and Isothermal Heat-Treating Line (Source: Ajax Electric Co.)

potassium, and barium chlorides. Operating temperatures may range from 1400 to 2350°F (760 to 1288°C).

Hardening of High-Speed Tool Steels. High-speed tool steels are hardened in a series of molten salt baths at various temperatures. A preheat bath at approximately 1400°F (760°C) might be followed by a high-heat bath at 2350°F (1288°C), which in turn is followed by a quench bath at 1100°F (593°C). All of these baths are mixtures of barium, sodium, and potassium chlorides (Figure 8.9.10).

Isothermal Quenching. To achieve various levels of physical properties in the heat treatment of steels, isothermal quenching rapidly cools metal parts in a molten salt bath. The three major types of isothermal quench are (1) austempering, (2) martempering, and (3) cyclic annealing. Each produces different hardness properties in metal alloys. Bath temperatures vary from 400 to 1300°F (205 to 704°C). The salts used are nitrate/nitrite salts for the lower temperatures and neutral chloride types for the higher temperatures.

FIGURE 8.9.10 Salt Bath for Hardening of High-Speed Tool Steel (Source: Ajax Electric Co.)

Annealing. Process annealing of carbon steels is usually carried out in carbonate and chloride salts at a temperature of 1250 to 1300°F (677 to 704°C). For stress relief of carbon steels, the melt is usually a nitrate salt at approximately 1000°F (538°C). Chloride salts are used to anneal stainless steel products as well as nickel-chrome alloys at temperatures of 1550 to 2150°F (843 to 1177°C).

Brazing. Salt bath brazing of ferrous and nonferrous alloys with silver and aluminum alloys, brass, and copper is another popular application for molten salt baths. Depending on the alloy and type of brazing, temperatures and salt mixtures vary considerably. For aluminum dip brazing, the salt is a mixture of chlorides with smaller percentages of sodium and/or aluminum fluorides, which act as fluxes. In copper brazing, barium chloride mixtures are used. Chlorides of sodium and potassium are used for silver alloy and brass brazing applications. Carburizing salts are used for a combination of brass brazing and carburizing.

Salt Bath Hazards

The hazards common to salt bath furnaces can be divided into the following three types:

1. Fire caused by contact of molten salt with combustibles
2. Explosion of the salt mixture due to physical or chemical reaction
3. The danger to operating personnel

Since salts are used at temperatures from 300 to 2400°F (149 to 1316°C), the ejection of salt by popping, spattering, or spilling will create a fire hazard if it comes in contact with anything combustible, including wood floors. Since molten salts have relatively little surface tension and low viscosities, any minor physical disturbance or chemical reaction can result in salt being ejected. When liquids (water, oil, etc.) or materials reactive to the particular salt utilized penetrate the surface of the salt bath, a violent ejection can result. Table 8.9.3 lists common salts and their melting points. Table 8.9.4 lists common salt mixtures and their melting points. Proprietary mixtures of these salts are formulated for specific applications and temperatures. Intermixing of certain salts is hazardous (e.g., nitrates and cyanide). Consult suppliers for recommendations.

Nitrates are particularly hazardous due to their ability to start and support combustion. When nitrates are overheated to temperatures in excess of 1100°F (593°C), rapid dissociation with the release of nitrous oxide fumes occurs. These fumes are injurious to operating personnel and are corrosive to the adjacent equipment. Explosions can occur if nitrate salt leaks from an externally heated container (pot) into a superheated combustion chamber. The overheating of nitrates can be caused by temperature controls that malfunction, an accumulation of sludge in the bath, or by operator errors.

If the operating temperature of a nitrate or nitrite bath exceeds the maximum limit, the following emergency action should be taken:

1. Shut off the heat supply.
2. Remove all work from the bath.
3. Move employees to a safe location.

TABLE 8.9.3 Melting Points of Common Chemical Salts

Salt	Melting Point °F	Melting Point °C
Barium chloride*	1764	963
Barium fluoride	2336	1280
Boric oxide (anhydride)	1071	578
Calcium chloride*	1422	773

Sodium tetraborate	1366	741
Strontium chloride	1603	873

*Most common salts.

Heated nitrate salts will react strongly with carbonaceous materials, such as oil, soot, tar, graphite, and cyanides—all of which might be utilized in some other metal-treating process. Accidental mixing of cyanides with molten nitrates can cause explosions of considerable magnitude.

The introduction of aluminum parts into a nitrate bath approaching or exceeding the melting points of these metals can cause fire and explosion. Magnesium alloys should never be immersed in a nitrate salt.

The storage of salts can cause serious problems. Chemicals, such as nitrates and cyanides, might mix and interact. Many salts are hydroscopic and, when stored in damp areas, will absorb moisture. When these salts are subsequently heated, moisture will be released below the surface and an explosion will ensue.

Intensive external reheating and remelting of a solidified salt bath might result in sufficiently rapid expansion to bulge or rupture the container. Such reheating can generate enough pressure to fracture the surface crust of the salt and scatter hot salts over a wide area.

When exposed to air having even a slight moisture content, the fumes from many salt baths become corrosive because chlorides, fluorides, and other salts will form acids by hydrolysis. These fumes are highly corrosive to adjacent building structures, wiring, and equipment and are, of course, detrimental to the bath operator.

Safety Control Equipment

A molten salt bath furnace must be equipped with control instrumentation and interlock systems that provide protection against the various and known types of potential equipment malfunctions.

Gas- and oil-fired salt bath furnaces must be provided with an approved flame safeguard device for each burner and must be interlocked to (1) shut off the fuel supply to the affected burner(s) and (2) activate an alarm.

An excess temperature control instrument must be provided that (1) has its own temperature-sensing element, (2) can be interlocked to shut off the heating system, and (3) activates an alarm when an excess temperature condition is detected.

When nitrate salts are used (regardless of the type of heating system), a "heat rate" controller should be installed to prevent a too-rapid heatup, thus preventing localized overheating and ignition of the salt.

The Safeguards

Although there appear to be many hazards connected with the operation of molten salt bath furnaces, fire, explosion, and injury can be prevented by the constant observance of ordinary precautions.

Clean dry sand can be used for diking purposes to confine and prevent the spread of the escaped melt. Carbon dioxide or dry chemical extinguishers can be used to extinguish burning carbonaceous material in the immediate vicinity of the salt bath.

The preferred location for a salt bath is a noncombustible area. The bath should be housed in a cement-lined pit or curbed area large enough to contain the contents in case of leakage or spill. It should be protected against leakage of liquids from other sources and be provided with baffles to prevent splashover from one tank to another. Salt bath furnaces provided with steel enclosures greatly reduce risks of leakage.

All salts should be shipped and stored in tightly covered containers designed to prevent the absorption of liquids or moisture. Nitrate salts should be stored in a fire-resistive, damp-free room and separated a reasonable distance from heat, liquids, and reactive chemicals. Nitrate and/or nitrite salts should never be stored in the vicinity of cyanide salts. Only the actual amount required to recharge the bath should be removed from the storage area and this amount should be melted immediately. Salts should be transported from the storage area to the furnace in suitable containers to prevent loss during transport.

The safety precautions that apply to the heating systems of salt baths are identical to those for the heating systems of other industrial furnaces. Some additional safety measures are necessary. Flame should be tangential to the wall of a salt pot or container when a gas- or oil-fired heating system is used. The products of combustion should be vented. Radiant tubes and electrodes should be of materials resistant to the corrosive action of the salts used.

TABLE 8.9.4 Melting Points of Common Salt Mixtures[a]

Mixture and Proportion	Melting Point *°F*	*°C*
Lithium nitrate 23.3, sodium nitrate 16.3, potassium nitrate 60.4	250	121
Potassium hydroxide 80, potassium nitrate 15, potassium carbonate 5	280	138

[a]Lowest constant melting points given; proportions are percentages by weight.
[b]Most common salt mixtures.

The buildup of sludge in any type of salt bath should be avoided and the sludge periodically removed. Sludge is caused by the deterioration of salt, the introduction of foreign material into the bath, the dropping of small parts into the bath, or the freezing of salt due to a cold furnace bottom. Several methods of removing sludge and foreign objects are available. Some equipment has been designed to alleviate the buildup problem. Properly applied mechanical agitation greatly aids in the elimination and/or removal of the contaminants. Agitation prevents temperature stratification and freezing on the furnace bottom. Agitation also suspends and directs the contaminating particles into a settling pan or through a filter basket (Figures 8.9.11 and 8.9.12).

Two thermocouples properly located in the bath will provide safe control and protection from overheating. An overtemperature control should be arranged to automatically shut off the heat source and actuate visual and audible alarms in the event of a malfunction of the normal operating controls. All sensing couples must be protected from the corrosive effects of the particular salt used.

For the removal and control of any toxic, corrosive, or heated fumes, all salt bath furnaces should be equipped with hoods made of material that will not be affected by the corrosive nature of such fumes. In many cases, chemical scrubbers or suitable filters should be installed to remove the particulates (Figure 8.9.13). Removal or neutralization of fumes may require special equipment.

All fixtures used for dipping parts in baths, such as hooks, ladles, or baskets, should be of a solid, closed design without corners that could retain water. Parts, such as closed piping or other hollow metallic articles in which air or moisture can be trapped, should not be inserted into a molten bath without making provisions for venting the heated, expanded air or moisture. Immersion of hollow parts in salt baths should be very gradual. Any fixture used in one salt bath should be thoroughly cleaned and dried before it is immersed in another bath. When electrodes are water cooled, an instrument should be provided to detect failure of the water-cooling system.

If a salt bath is used as an internal quench in a furnace with a combustible atmosphere, measures should be provided

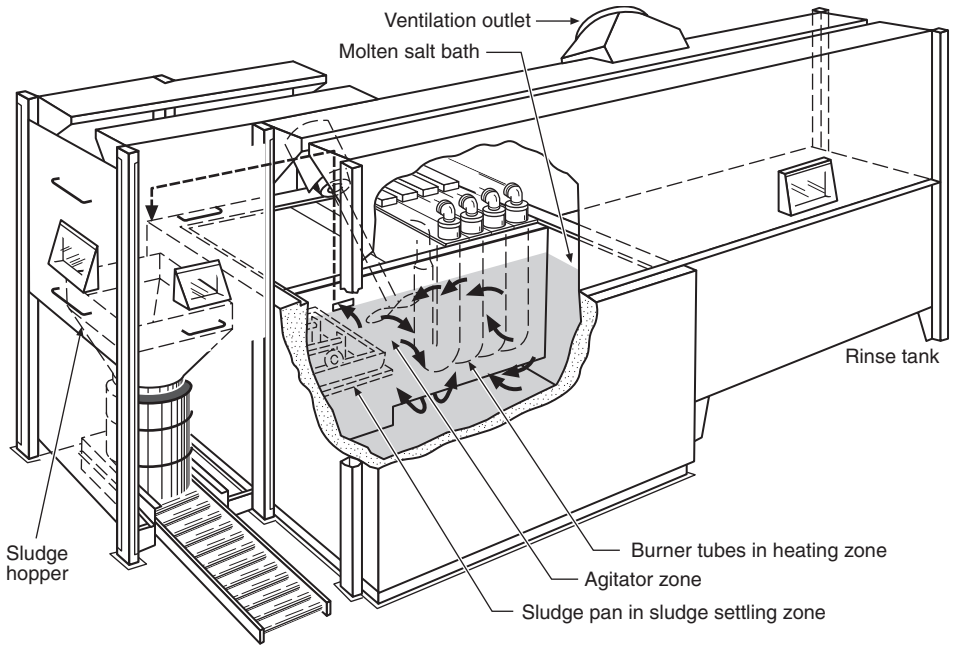

FIGURE 8.9.11 Descaling Salt Bath Showing Sludge Pan Construction (Source: Kolene® Corp.)

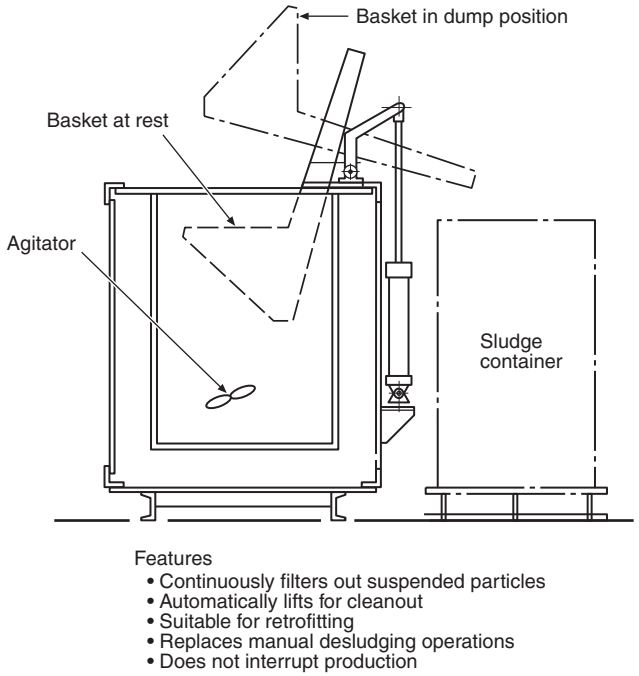

FIGURE 8.9.12 Automatic Basket Dumper

FIGURE 8.9.13 Typical Hooded Enclosure, Overhead Hoist, and Work Platform. These features greatly improve safety as well as productivity and ease of maintenance.

to prevent carbon precipitation onto the salt surface. In addition, adequate salt circulation should be provided to prevent localized hot spots whenever the salt is exposed to furnace temperatures.

A cold salt bath that has frozen over should be remelted or liquefied by applying initial heat as near to the top as possible. The application of heat to the external bottom surfaces will cause melting near the bottom and leave the top solidified. Expanding volume causes excessive pressure and failure of the container, with the subsequent ejection of hot salts. Breaking the surface crust will result in an explosive ejection of the salt. This hazard can be avoided by inserting a tapered solid bar in the molten salt

adjacent to the immersed electrodes. After the salt has frozen, the bar is removed. The cavity created by the removal of the bar will serve as a vent duct for the escape of the gases formed. Gas burners that heat the top layers and gradually heat downward can be used if they are used carefully. For the submerged type of electrodes, a resistance heating coil set in between electrodes is recommended. Pumps are available to remove salt while it is in the molten state. Considerable care should be exercised in removing any molten salt; it should be pumped directly into steel drums where it can freeze over immediately. Salt and drums can then be properly discarded. For all types of heating, a "soft start" with reduced power input is recommended until melting is established from top to bottom.

All operators and workers in the vicinity of molten salt baths should be provided with corrosion-resistant and heat-resistant shoes, gloves, aprons, hard hats, and face shields. Solutions for cleansing eyes and supplies for treating minor burns should be available at all times. Breathing apparatus should also be provided for emergency use against oxides of nitrogen or corrosive fumes, such as chlorides and fluorides.

Constant vigilance with safety in mind and good housekeeping by intelligent and well-trained personnel can keep a salt bath operation as safe as any other metallurgical process conducted in an industrial furnace.

SUMMARY

This chapter focused on two heat-treatment processes: oil-quenching operations, which harden and temper metals, and molten salt baths, which harden metals, ceramics, or polymers. In oil-quenching operations, the heated metal is cooled by immersion in a liquid-quenching material, which hardens and tempers the metal by imparting metallurgical changes to its surface. In molten salt bath operations, the metal, ceramic, or polymer work to be treated is immersed in a container that is either electrically heated or fuel fired and that holds a fusion of one or more chemical salts in a fluid state. Heat transfer is rapid and precise. Because quench oils are combustible, the oil-quenching process is inherently hazardous. Salt bath hazards include fire caused by contact of molten salt with combustibles, explosion of the salt mixture due to physical or chemical reaction, and danger to operating personnel, for example, from the fumes. After having described the two heat-treatment operations, the chapter discussed the hazards and the safeguards for both processes.

Chapter 10

Stationary Combustion Engines and Fuel Cells

James B. Biggins

Chapter Contents

Stationary Combustion Engines
Fuel Cells

Key Terms

flammable liquid, fuel cell, gas turbine engine, gaseous fuel, hydraulic oil, lubricating oil, reciprocating engine, stationary combustion engine

Stationary combustion engines are prime movers (e.g., as internal combustion engines, external combustion engines, gas turbine engines, rotary engines, and free piston engines) that are installed for use in a location as permanent equipment. Many codes and standards also treat portable engines that remain connected for use in the same location for a period of one week or more as stationary combustion engines.

Stationary engines are used for a number of applications in industry. The most common use is in tandem with a generator for the production of electricity in commercial and emergency situations. Larger engines are frequently used to drive large pumps and compressors, such as those used in the petrochemical and gas-pipeline transmission industries. Engine-driven pumps and compressors handle a variety of fluids, including flammable liquids and gases.

Fuel cells are an environmentally clean and highly efficient means for generating electricity. They differ from other power generation systems in that fuel cells are electromechanical devices that convert the energy of a chemical reaction directly into heat and energy without combustion as an intermediate step. Because the fuel is not burned, but electrochemically oxidized, fuel cells are not constrained by the same efficiency limitations that apply to engines.

Fuel cells are similar to batteries in that both convert energy that is stored in chemical form into direct current (DC) electricity. Also, like batteries, fuel cells can be combined into groups, called stacks, to obtain usable power outputs and voltages.

This chapter discusses the potential fire hazards associated with stationary engines and fuel cells and addresses the location, installation, and protection of both.

More in-depth discussions of the hazards that can be associated with the use and storage of fuels used in engines can be found in Section 6, Chapter 10, "Gases"; Section 6, Chapter 12, "Flammable and Combustible Liquids"; Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; and Section 7, Chapter 3, "Storage of Gases." Additional information on engines used to drive fire pumps is provided in Section 15, Chapter 7, "Fire Pump Controllers and Power Supply Arrangements for Motor-Driven Fire Pumps."

STATIONARY COMBUSTION ENGINES

Engine Types

The various types of engines noted above can be grouped into two primary types: (1) reciprocating engines and (2) gas turbine engines.

Reciprocating Engines. Reciprocating engines can range in size from small portable gasoline engines to very large diesel engines used for power generation. These engines are typically of two main types: (1) otto cycle engines, which use a spark plug to ignite a fuel-air mixture, and (2) diesel cycle engines, in which high-pressure compression raises the air temperature to the

James B. Biggins, P.E., C.S.P., is senior consultant and vice-president with Marsh Risk Consulting in Chicago, Illinois. He is former chair of NFPA's Technical Committee on Internal Combustion Engines.

ignition temperature of the injected fuel oil. The characteristics of and hazards associated with all reciprocating engines are similar.

Gas Turbine Engines. The first patent for a gas turbine was granted in 1884, but it was not until about 1940 that the development and design of turbines reached the point where the machines were economically viable. The initial turbines were developed for aircraft applications, with the first commercial industrial unit placed in service in the late 1940s.

Gas turbine engines are typically larger engines, ranging in size from 100 to 100,000 hp (75 to 75,000 kW). Stationary gas turbine engines are used mainly for power generation and gas-pipeline transmission. Gas turbine engines are either open or closed cycle.

In an open cycle, the working fluid passes through the engine only once. In a closed cycle, the working fluid is continually recycled through the engine. The majority of gas turbine engines currently in use are of the open cycle design.

Potential Fire Hazards

The fire hazards associated with stationary combustion engines include (1) combustible liquids and flammable gases that are used as fuel, hydraulic fluids, lubricants, and in some cases, the material being pumped or compressed; (2) the temperature of exposed engine parts, particularly exhaust manifolds and pipes, which can be hot enough to ignite flammable or combustible materials; (3) the potential arcing of electrical components, such as starters, generators, distributors, and magnetos, which can ignite flammable vapors; (4) combustible materials stored within the engine room or used in the engine installation, such as air filters; and (5) engine disintegration.

Engine Installations

NFPA 37, *Standard for the Installation and Use of Stationary Combustion Engines and Gas Turbines,* and local codes provide minimum requirements for the safe installation of engines, and include specifications for the engine installation, engine room compartmentation, fuel supply piping, room ventilation, and engine exhaust systems (Figure 8.10.1).

Engine Locations. Stationary combustion engines can be located outdoors, inside structures, or on the roofs of structures. The selection of an engine location should consider the distance from combustible walls and ceilings, exterior wall openings, and the availability of sufficient air for combustion and ventilation. Engine room compartmentation should comply with applicable standards and local codes, which might specify minimum fire resistance ratings.

Combustible materials should not be stored in rooms containing stationary engines or within the compartments of a gas turbine.

Engines should be isolated from locations where combustible dust or airborne flyings can be produced. Engine exhaust manifolds and piping can reach high temperatures, and combustible dusts and flyings deposited on these surfaces could ignite. For ignition to occur, conditions must be favorable for prolonged contact between the combustible material and the hot surface. A good maintenance and housekeeping program will lessen the chance of such an occurrence.

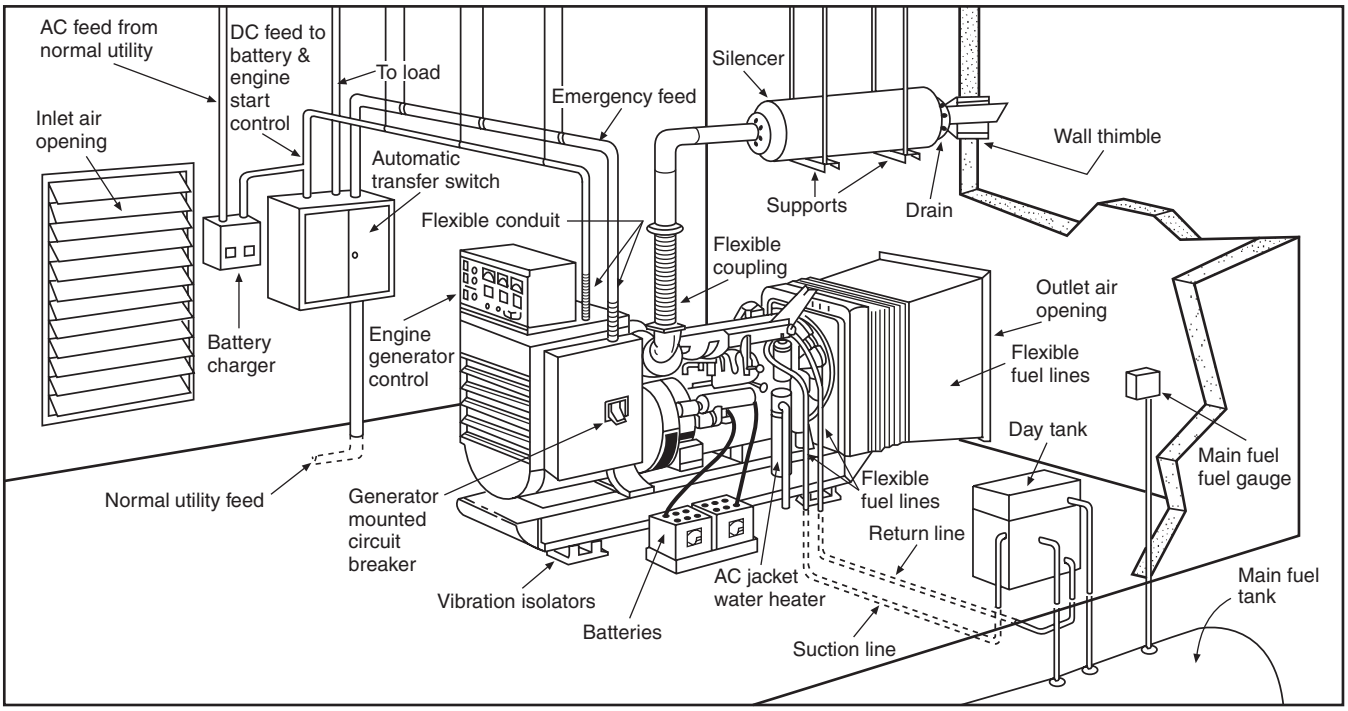

FIGURE 8.10.1 A Typical Generator Installation Used to Supply Emergency Power

Exhaust Systems. Fires can be caused by failure to allow sufficient clearance between exhaust piping and combustible walls, ceilings, or roofs. Engine exhaust systems (e.g., manifolds, mufflers, exhaust piping, etc.) can reach temperatures in excess of 1000°F (538°C), and special precautions are needed when these items penetrate combustible construction.

Engine exhaust systems should be designed based on the expected flue gas temperatures, which will typically vary with the size and type of engine. Exhaust pipes should be constructed of sufficient strength to withstand the pressures and temperatures developed by the exhaust system. Provisions are needed in the exhaust system to prevent damage from the ignition of unburned fuel. Low points, with suitable means to allow drainage of condensation, should also be incorporated into the system design.

It might be necessary to install a flexible connector from the engine to the exhaust pipe to minimize the potential for a break in the exhaust system due to engine vibration or heat expansion.

Exhaust systems should maintain a minimum clearance of 9 in. (229 mm) from combustible materials. Special precautions, such as a wall thimble, are required for cases where it is necessary to pass the exhaust system through walls or roofs of combustible construction. The exhaust system should terminate outside the structure at a point where the hot gases or sparks will be discharged harmlessly and not come in contact with combustible material.

Electrical Installations. The electrical installation for the engine should comply with NFPA 70, *National Electrical Code®*. Engine rooms or other locations are not to be classified as hazardous locations, as defined in the *NEC,* solely by reason of the engine fuel. Arcing electrical engine components should be safeguarded by flashover shielding, flame arresters, purging, or ventilation, if flammable liquids or gases are being pumped or compressed.

Fuel Supplies

Stationary combustion engines have been designed to operate with a number of different fuels. The two most common types are (1) flammable and combustible liquids, such as gasoline or diesel fuel, and (2) flammable gases, such as propane or natural gas.

Many engine applications require on-site fuel supplies of sufficient size for multiple hours of operation for reliability. The fuel supply can be stored either outdoors or within a building. Local codes and standards may restrict fuel tank size, construction, and location and should be consulted.

Liquid Fuels. Diesel fuel and gasoline are the two most widely used liquid fuels for stationary engines. Gasoline, due to its low flashpoint (–45°F [–43°C]), presents a greater fire hazard than other liquid fuels. Gasoline storage in buildings is limited to the capacity of the tank mounted on the engine, but NFPA 37 sets a limit on this amount at not more than 25 gal (95 L). When larger quantities of liquid fuel are required in buildings, a diesel-fueled engine generally is used.

Liquid fuel systems should be designed to minimize the potential for an accidental release of fuel into a structure. Alarms, float-controlled valves, gauges, and sight glasses should be installed to aid personnel in operating the fuel system. Diking, or some other method of spill containment, should be considered for fuel storage tanks installed either inside structures or aboveground outdoors.

Liquid fuels are supplied to engines by pumps. The exception is that gravity feed is permitted from an engine mounted tank. The fuel supply to tanks located above the lowest level of a building should be pumped to the tank in a manner acceptable to the authority having jurisdiction.

An overflow line, high-level alarm, and high-level automatic shutoff should be provided for all tanks that are filled by pumps. Care should be taken to avoid locating fuel lines, vents, and overflow lines near the engine combustion air intake.

Gaseous Fuels. Gas-fueled engines should be installed in accordance with applicable codes and standards, such as NFPA 54, *National Fuel Gas Code,* or NFPA 58, *Liquefied Petroleum Gas Code.*

Some gas fuels, such as propane, are heavier than air and will collect in low-lying areas. Special precautions need to be taken to ensure proper ventilation is provided, particularly with respect to the location of the supply and exhaust openings, when using these fuels. Gas pressure regulators located inside a structure should be provided with a vent to outdoors, discharging a minimum of 5 ft (1.5 m) from the structure. An alternative is to provide a listed vent limiting device.

Gas piping to engines should be provided with a shutoff valve located remote from the engine, preferably outside the structure for those engines located indoors. Each gas-fueled engine should be provided with a means to automatically shut off the flow of gas to the engine, in case the engine stops from any cause.

Lubrication and Hydraulic Systems

Engine lubrication and hydraulic systems for stationary combustion engines generally utilize a combustible oil. In some larger gas turbine units, the combustible oil may be replaced with a synthetic, fire-resistant fluid. This type of lubricating fluid has a higher flashpoint than lubricating oil. The use of a fluid with a higher flashpoint decreases the potential for ignition of a spill from a heat source, such as hot engine parts.

An oil mist is often present in the crankcases of large reciprocating engines, which, on ignition, can result in a combustion explosion within the crankcase. As a result, many such engines are equipped with crankcase explosion vents. In other cases, the crankcase is maintained under a nonflammable atmosphere.

Glass gauges and sight glasses should be protected against physical damage, if their breakage could permit the escape of oil.

Instrumentation and Control

Total mechanical failure or disintegration of a reciprocating engine occurs very infrequently. Gas turbines are at greater risk to this phenomenon than reciprocating engines, because of the turbine's very high rotational speeds.

This hazard is controlled by the provision of automatic engine speed governors. An overspeed shutdown device should be provided on large engines (greater than 100 hp [75 kW]) of both types. Furthermore, the design of gas turbines for stationary installations usually incorporates construction features to contain the compressor, turbine blades, and rotor parts in the event of mechanical failure.

Controls should be provided on all engines greater than 10 hp (7.5 kW) to shut down the engine for high jacket water temperature, high cylinder temperature, or low lubricating oil temperature. Additional shutdowns should be provided for high oil temperature on larger engines. Gas turbines should also be arranged to shut down on high exhaust temperatures.

The starting sequence for gas turbines should incorporate a purge cycle of adequate duration to ensure that a nonflammable atmosphere is present in the turbine and exhaust system prior to ignition.

Installation Safeguards

Larger engine installations should have provision for a remote emergency shutdown of the engine. Most installations also should have a remote means of shutting down fuel and lubricating oil pumps that are not directly driven by the engine.

Care should be taken in the selection of inlet air filters, particularly for larger gas turbine installations. Whenever possible, filters should be of materials that will not burn freely when exposed to fires.

Diesel engines installed in hazardous locations, as defined by the *NEC,* should be installed such that the engine is shut down by isolating both the fuel and combustion air supplies. This installation will prevent the diesel engine from "running on," utilizing the hazardous atmosphere as the fuel source.

Backfires through gas-air mixers and carburetor air intakes occur as a result of engine malfunction. These backfires can ignite grease and oil deposits on and around the engine. Flame arresting equipment should be provided at these points if flammable liquids or gases are being pumped or compressed.

Operating Instructions

Instructions for normal starting, stopping, operation, and routine maintenance procedures should be posted near the equipment.

Emergency procedures for the safe shutdown of the engine should be developed. These instructions typically include location and operation of remote shutdown stations, procedure for the shutdown of lubricating oil and hydraulic oil pumps, and closing of the fuel shutoff valve.

Fire Protection

Manual fire protection equipment, such as portable fire extinguishers, should be provided in accordance with applicable standards and codes. Larger installations, particularly those utilizing an appreciable amount of lubricating or hydraulic oils and those utilizing liquid fuel, should be protected by automatic fire suppression systems. Sprinkler systems are typically the protection provided for reciprocating engines installed within structures.

Gas turbine installations can be protected by a number of different system applications, dependent on the preference of the engine's manufacturer, operator, or both. Fire protection system options include preaction waterspray systems, carbon dioxide systems, clean agent systems, and water mist extinguishing systems. Dry chemical extinguishing systems are sometimes utilized to protect the exhaust compartments of these engines. The interlocking of fire protection system operation with the automatic closing of the fuel valves can be of assistance in limiting the size of a fire.

Emergency Planning

Emergency operating and shutdown procedures should be developed for each engine installation. Where fuel valves are not clearly identified, a diagram should be posted conspicuously near the engine, indicating the location of the fuel shutoff valves. Emergency procedures should be located where they are readily accessible to personnel operating or maintaining the engine. Individuals responsible for the operation and maintenance of the engine must be trained in operating and maintenance procedures, including emergency shutdown procedures.

FUEL CELLS

Characteristics

Fuel cells are similar to a battery, as two electrodes, an anode and a cathode, are separated by an electrolyte. However, in fuel cells, the fuel and oxidant are stored externally. This setup allows the fuel cell to continue operating as long as the fuel and oxidant are replenished. Direct current electricity is produced by a chemical reaction between a hydrogen-based fuel and an oxidant (usually oxygen) within the fuel cell, as shown in Figure 8.10.2. The hydrogen passes over the anode and is split into positively charged hydrogen ions and negatively charged electrons. The electrons then flow over an external circuit as electrical energy. Both the electrons and the protons, which pass through the electrolyte, eventually return to the cathode, where they combine with the oxidizer to produce water and heat.

The first fuel cell was built in 1839, but the first practical application was to provide electric power for NASA's Gemini and Apollo spacecraft. The industrial use of fuel cells has not been widespread, due to both the demanding technology associated with the design and operation of the fuel cells and the fact that other less expensive technologies have dominated the market. In recent years, the use of fuel cells for power generation is gaining favor due to the efficiency of the power production and the minimal impact on the environment.

The most efficient fuel cells use hydrogen and oxygen as the fuel and oxidizer. In conventional fuel cells, a carbon-rich fuel is reformed to produce hydrogen, which is then introduced into the fuel cell and electrochemically oxidized. In many cases, this reforming process is accomplished internally due to the very high temperatures (1382 to 1652°F [750 to 900°C]) encountered.

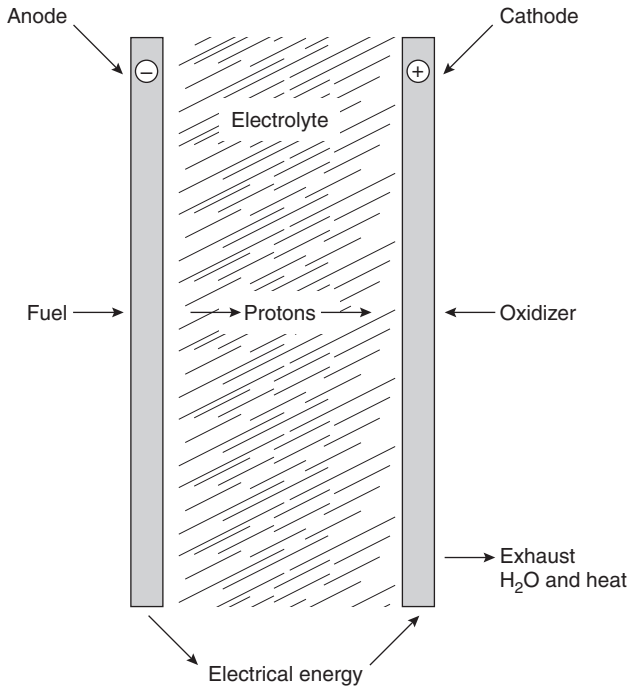

FIGURE 8.10.2 Typical Fuel Cell

Types

All fuel cells have an electrolyte that separates the two electrodes. Several different types of electrolytes are used in fuel cells, each having very different properties. The fuel cells are typically named after the electrolyte used and operate at different temperatures and supply varying amounts of heat. A brief discussion of some common fuel cell types follows.

Phosphoric Acid Fuel Cells. The phosphoric acid fuel cell is one of the oldest types of fuel cell and is the type that is most readily available commercially. Phosphoric acid fuel cells are presently used in a number of power generation projects. The fuel cell uses phosphoric acid as the electrolyte and is able to reform methane to a hydrogen-rich gas for fuel and also produces waste heat, which can be used for other purposes. This type of fuel cell operates at temperatures of 393°F (approximately 200°C).

Solid Oxide Fuel Cells. The electrolyte in this type of fuel cell is typically zirconia, which is sandwiched between the anode and cathode. Solid oxide fuel cells can operate on a number of different fuels ranging from hydrogen to methane to carbon monoxide. These fuel cells are being studied for their potential use as power generation units. Additionally, as the cells operate at extremely high temperatures of 1832°F (approximately 1000°C), the waste heat produced can be used in a cogeneration process.

Polymer Electrolyte Fuel Cells. These fuel cells use an electrolyte that is made up of a layer of solid polymer material, which allows protons to be transmitted from one face to the other. These fuel cells operate at lower temperatures of 309°F (around 154°C) and are primarily being used for mobile applications at this time.

Alkaline Fuel Cells. These are the best developed and most widely known type of fuel cell, due to their use in spacecraft. Alkaline fuel cells use a solution of either potassium hydroxide or lithium hydroxide as the electrolyte. The advantage of these fuel cells is that they operate at ambient temperatures.

Potential Fire Hazards

The fire hazards associated with fuel cells begin with the high temperatures at which several types of fuel cells operate, which in many cases can be sufficient to ignite nearby combustible materials. Additionally, the fuel used in the fuel cell is often a flammable gas or liquid, which presents fire protection concerns with respect to its handling and storage.

Fuel Cell Installations

Local building codes provide limited information on fuel cell installations, relying on the judgment of the local authorities having jurisdiction to address the installations as they arise. NFPA 853, *Standard for the Installation of Stationary Fuel Cell Power Systems,* was developed in 2000 and provides minimum requirements for the installation of fuel cell power plants with ratings of 50 kW or greater.

The selection of the fuel cell location should consider such items as the distance from combustible walls and ceilings and the distance to wall openings. Fuel cells and their related equipment can be located outdoors, inside structures, or on building roofs. Each of these installations has specific issues that need to be addressed for the installation. However, many common practices need to be considered for all fuel cell installations.

A fuel cell and its associated equipment, components, and controls should be placed on a firm foundation that is capable of supporting the equipment or components. The foundation and access to the fuel cell and its components should be located above the base flood elevation of the site. The fuel cell should also be anchored, located, and protected so that the plant and equipment will not be adversely affected by rain, snow, ice, freezing temperatures, wind, seismic events, or lightning.

The installation should be protected against access by unauthorized persons, commensurate with the location and installation environment. However, a means should be provided for fire department access. The fuel cell and related equipment installation should not affect required building exits during normal operations or fire emergencies.

Care should be taken to locate fuel cells outside of potentially hazardous atmospheres, as defined by the *NEC* and NFPA 496, *Standard for Purged and Pressurized Enclosures for Electrical Equipment,* unless listed and approved for the specific installation. The installations should also be located away from combustible materials, hazardous chemicals, high-piled stock, and other fire hazards.

Additionally, the vent or exhaust terminations should be separated from doors, windows, outdoor air intakes, and other openings into a building. Noncombustible materials should be used where vent pipes pass through roofs, walls, or other building features.

It is also suggested that the fuel cell installations be located in a manner that will readily permit service, maintenance, and emergency access to the fuel cell and associated equipment.

Outdoor. When an outdoor location is chosen, the fuel cell and its related components need to be specifically designed and constructed for outdoor installation. Security barriers, fences, landscaping, and other enclosures must not affect the required airflow into or exhaust out of the fuel cell or its components.

Fuel cell installations should not be located in areas that are used or are likely to be used for combustible, flammable, or hazardous materials storage. Air intakes to a fuel cell installation should be located so that the intake is not adversely affected by other exhausts, gases, or contaminants. The vent or exhaust terminations should not be directed onto walkways or other paths of travel for pedestrians.

Indoor. A fuel cell installation and its associated components not located in areas designed for industrial uses should be located in a room that is separated from the remainder of the building by floor, wall, and ceiling construction that meets the approval of a local authority having jurisdiction.

Rooftop. Where fuel cells are installed on roofs, in addition to addressing the issues associated with the outdoor installation of the fuel cell, the roofing material directly below and within a 1 ft (0.3048 m) horizontal distance should either be noncombustible or have a Class A rating.

Fuel Supplies

Fuel cells can be designed to use both gaseous and liquid fuels. Fuel cells typically require on-site fuel storage for reliability of the installation. These fuel supplies can be stored either outdoors or within a building. Local codes and standards might place restrictions on the fuel storage arrangement.

Gaseous Fuels. Fuel cells have been designed to utilize many types of gaseous fuels, including natural gas, compressed natural gas (CNG), liquefied petroleum gas (LP-gas), biogas, and hydrogen. Piping, valves, and fittings from the outlet of the supplier's piping to the outlet of the fuel cell power plant's shutoff valve should be in accordance with applicable codes and standards, such as NFPA 55, *Standard for the Storage, Use, and Handling of Compressed Gases and Cryogenic Fluids in Portable and Stationary Containers, Cylinders, and Tanks;* NFPA 52, *Vehicular Fuel Systems Code;* NFPA 54, *National Fuel Gas Code;* and NFPA 58, *Liquefied Petroleum Gas Code.*

The use of hydrogen as a fuel presents special concerns, as hydrogen is a colorless, odorless, highly flammable gas or liquid. The flammable range in air at atmospheric pressure is 4 to 75 percent by volume and it has a vapor density of 0.1. When hydrogen is used as a fuel, the installation of vapor detection devices is recommended.

Some of the gas fuels such as propane are heavier than air and will collect in low-lying areas. Special precautions need to be taken to ensure that proper ventilation is provided when using these fuels.

Liquid Fuels. Diesel fuel, JP-4, JP-5, ethanol, methanol, and naphtha are some of the liquid fuels that are used in fuel cell installations. The design of liquid fuel piping systems and the location and storage of liquid fuels should be in accordance with NFPA 30, *Flammable and Combustible Liquids Code.*

Liquid fuel systems should be designed to minimize the potential for the accidental release of fuel. Devices such as level alarms and float devices should be installed to aid personnel in operating the fuel system. Additionally, diking or some other means of spill containment should be considered for fuel storage installed either indoors, on roofs, or outdoors in aboveground tanks.

Fuel storage tanks should be provided with level alarms. Those tanks that are filled by pumps should also be provided with a high-level automatic shutoff.

Ventilation

The ventilation and exhaust system for fuel cells installed within a structure should be designed to provide a negative or neutral pressure in the room. A separate mechanical ventilation system should be provided for the area inside a structure where a fuel cell power plant is located, unless it can be verified that natural ventilation can provide all required ventilation and makeup air. The inlet air vent should be designed to prevent foreign matter from entering.

Pressure tanks and piping intended to be purged, pressure regulators, relief valves, and other potential sources of combustible gas should be vented to a safe location outside the building. The vent should be designed to prevent entry of water or foreign objects.

Exhaust Systems

The exhaust system for a fuel cell should be designed such that all emissions are exhausted to a safe location. An effective rate from a room inside a structure is typically considered to be a minimum of 1 cfm/ft^2 (0.3 m^3/min m^2) of floor area and not less than 150 cfm (45 m^3/min) for the total floor area.

If a mechanical exhaust is provided, the system design should incorporate the use of a control interlock to shut down the unit on loss of exhaust ventilation. The exhaust outlet shall be located away from the HVAC air intakes for the building.

Fire Protection

A combustible gas detection system should be provided in the enclosure, in the exhaust system, or in the room that encloses indoor or enclosed fuel cell installations. The combustible gas detection system should be arranged to alarm at 25 percent of the lower flammable limit (LEL) and be interlocked to shut down the fuel supply at 60 percent of the LEL. The LEL used should be the lowest of the gas or gas mixtures used. Additionally, a

combustible gas detector should be provided for all indoor or separately enclosed gas compressors.

Fuel cell enclosures should be provided with an automatic fire detection system that transmits the alarm to a constantly attended location. The room in which the fuel cell and its associated components are located should be provided with an automatic fire suppression system that is in accordance with applicable NFPA standards.

Indoor liquid fuel pumping should be protected by an automatic wet pipe sprinkler system. It is recommended that the sprinkler system be designed in accordance with the applicable requirements of NFPA 13, *Standard for the Installation of Sprinkler Systems*. An automatic safety shutoff valve is normally provided and interconnected to shut off the fuel supply when the sprinkler system is activated.

Emergency Planning

A written emergency plan should be developed for each fuel cell installation. The depth and details of the plan will vary, based on the size and location of the fuel cell installation. The plan should include the following:

- Information on emergency alarms, including responses to alarms and notification of personnel
- Evacuation of employees and visitors not directly involved in fire-fighting activities for the fire area
- Coordination with security forces or other designated personnel to admit public fire department and control traffic and personnel
- Fire extinguishment activities and identification of fire water application concerns on operating equipment
- Operator activities during fire emergencies
- Listing of frequency and requirements for periodic inspection, testing, and maintenance of the fuel cell power system emergency systems
- Posting of the location of the operating instructions and the location of the emergency controls

The plan should also include provisions for periodic training and drills to verify viability of the plan.

SUMMARY

Stationary combustion engines and fuel cells are two means of generating energy. In the case of stationary combustion engines, combustion generates energy; fuel cells generate energy electrochemically (i.e., without combustion). Stationary combustion engines are typically used in industrial settings, whereas the use of fuel cells, once limited to aerospace, is being extended to industry.

This chapter has described the characteristics, potential fire hazards, installation considerations, fuel supplies, and emergency planning for stationary combustion engines and fuel cells.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on the safeguards for stationary combustion engines and fuel cells discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 13, *Standard for the Installation of Sprinkler Systems*
NFPA 30, *Flammable and Combustible Liquids Code*
NFPA 37, *Standard for the Installation and Use of Stationary Combustion Engines and Gas Turbines*
NFPA 52, *Vehicular Fuel Systems Code*
NFPA 54, *National Fuel Gas Code*
NFPA 55, *Standard for the Storage, Use, and Handling of Compressed Gases and Cryogenic Fluids in Portable and Stationary Containers, Cylinders, and Tanks*
NFPA 58, *Liquefied Petroleum Gas Code*
NFPA 68, *Standard on Explosion Protection by Deflagration Venting*
NFPA 70, *National Electrical Code®*
NFPA 99, *Standard for Health Care Facilities*
NFPA *101®*, *Life Safety Code®*
NFPA 211, *Standard for Chimneys, Fireplaces, Vents, and Solid Fuel-Burning Appliances*
NFPA 220, *Standard on Types of Building Construction*
NFPA 496, *Standard for Purged and Pressurized Enclosures for Electrical Equipment*
NFPA 850, *Recommended Practice for Fire Protection for Electric Generating Plants and High Voltage Direct Current Converter Stations*
NFPA 853, *Standard for the Installation of Stationary Fuel Cell Power Systems*

Chapter 11

Fluid Power Systems

Paul K. Schacht

Chapter Contents

Fluids Under Pressure and Fluid Leakage
Fire Characteristics
Less Hazardous Hydraulic Fluids (Fire-Resistant Fluids)
Environmentally Acceptable Fluids
International Fluid Designations

Key Terms

biodegradable fluid, hydraulic fluid, oil (pressurized), synthesized hydrocarbon fluids (SHF)

Fluid power systems are used for transmitting power or motion to various parts of equipment and machines. The function of the fluid is power multiplication as in a hydraulic press, actuation of automatic equipment as in die casting, or remote actuation or pressure control of machines or instruments. Hydraulic fluids are generally petroleum based and present fire hazards.

For additional information on allied topics, consult the following chapters: Section 6, Chapter 12, "Flammable and Combustible Liquids"; and Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids."

Early fluid power systems used water as the hydraulic medium. Because of its corrosive effect on the metal parts of the machine and lack of lubricity, it was replaced by petroleum oil. Except for its fire hazard, oil is an ideal hydraulic fluid. It is noncorrosive, compatible with a wide variety of materials of construction, readily available, relatively inexpensive, and can be recycled. Flashpoints range from 300 to 600°F (148 to 316°C), and autoignition temperatures range from 500 to 750°F (260 to 399°C).

Although petroleum oils are by far the most commonly used hydraulic fluids, synthetic lubricants are being used more frequently in industrial and mobile applications. There are several classes of synthetic lubricants. The most common are synthesized hydrocarbon fluids (SHF), such as polyalphaolefins (PAO) and dialkyl benzenes. Flashpoints of these fluids range from about 225 to 500°F (106 to 260°C).

Seals and hoses made from nitrile or fluorocarbon polymers are commonly used with petroleum oils, synthetic hydrocarbons, polyol esters, biodegradable fluids, and water-containing fluids such as water-glycols and water-in-oil emulsions. Phosphate esters require the use of fluorocarbons. The use of nitrile with phosphate esters will cause seals and hoses to soften and swell, resulting in failure and loss of fluid.

FLUIDS UNDER PRESURE AND FLUID LEAKAGE

Pressurized petroleum-based lubricants or synthesized hydrocarbons present a considerable fire hazard, particularly when ignition sources are constantly present, such as in die casting, plastic molding, automatic welding, heat treating of metals, molten glass, hot forgings, steel production, and the engines of mobile equipment (Figure 8.11.1). Other sources of fire are oil-impregnated floors, oil-saturated insulation in sound barriers, and external system leakage being ignited by cutting torches, sparks from a welder, and other human carelessness.

Fires in coal mines continue to be a common problem, particularly in some parts of the world. This is primarily the result of extremely hard usage of the hydraulically actuated equipment, without proper maintenance. Despite the known hazards of using oil as the hydraulic medium, because of increased fluid costs and fluid maintenance costs, many systems have not been converted to safer fluids.

High-pressure pipe with welded and threaded joints, steel tubing, and metal reinforced rubber hose is used to conduct oil at pressures ranging up to 10,000 psi (68,950 kPa). Failure of piping, particularly at threaded sections; failure of system components, gaskets, or fittings; tubing pulling out

Paul K. Schacht is consultant for Bosch Rexroth, Racine, Wisconsin, and chairman of the fluids coordinating committee for the National Fluid Power Association.

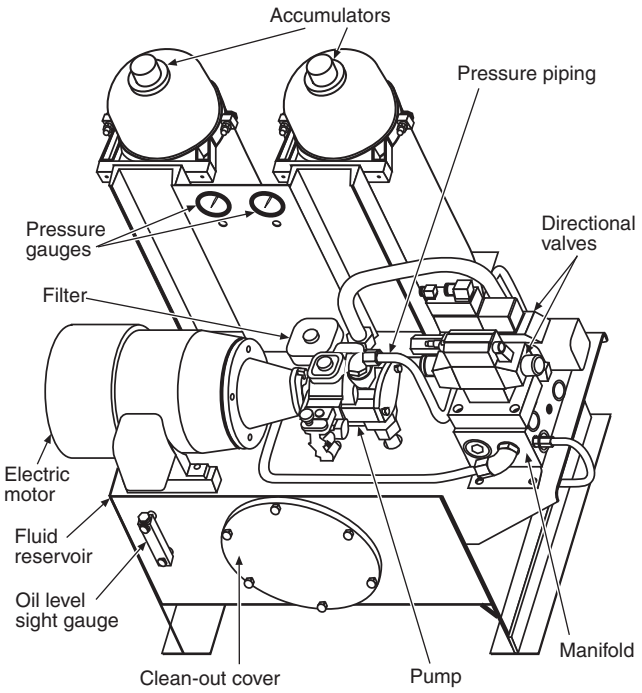

FIGURE 8.11.1 A Nonspecific Power Unit That Might Be Used to Run Any of a Variety of Machines

of fittings; and rupture of flexible hose are considered principal causes of oil being released from a fluid power system. Lack of adequate supports or anchorage to prevent vibration or movement of piping has also been a factor in these failures. Repeated flexing and abrasion of rubber hose against other hoses or parts of a machine can create weak spots that eventually fail. Tubing under pressure can fail due to being accidentally cut by torches, hit by a fork lift truck, or stepped on during maintenance procedures.

Even though a system is shut down, high-pressure fluid may be contained in accumulators and released for some of the previously mentioned reasons covering the loss of fluid. Guidelines to be followed when selecting tubing and burst pressure ratings of components can be found in the National Fluid Power Association and Society of Automotive Engineers (SAE) standards listed in the bibliography.

FIRE CHARACTERISTICS

When oils, synthesized hydrocarbons, or biodegradable fluids under pressure are released by failure of equipment, the usual result is an atomized spray of mist or oil droplets, which, depending on pressure, may encompass large areas. The oil spray is readily ignited and the resulting fire is usually torchlike with a very high rate of heat release.

If systems contain oil, the following recommendations should be met in addition to those recommended for less hazardous fluids:

1. Automatic sprinklers should be provided over areas where an oil-containing hydraulic system is located. Due to the type of fire associated with a high pressure (atomized oil) fire, the sprinkler system design area is often 5000 to 7500 ft^2 (465 to 697 m^2).

2. Automatic or remote manual switches should be provided to shut off the hydraulic pumps in the event of fire if over 100 gal (378 L) of fluid are involved. Automatic shutoff of hydraulic systems can be accomplished in several ways. Most commonly, heat detectors are placed over the areas where hydraulic fluids are present. This would include the hydraulic system reservoir, pump, and the associated piping to the equipment where the pressurized fluid is used. The heat detectors are interlocked to the hydraulic oil pump and arranged to shut it off when a heat detector is activated.

Another method of automatic shutoff of the hydraulic oil system is by the use of fusible links attached to cables at ceiling level, laced over the hydraulic fluid reservoir, pump, and other components, such as cylinders, fluid motors, and the associated piping. The cable under tension is secured to a building component at one end and to a microswitch at the oil pump controller at the other end. The microswitch, when activated by the fusible link, trips the switch on the controller to the off position, thus shutting off the flow of pressurized oil.

A third way to arrange for automatic shutoff is to provide a low level indicator in the fluid reservoir that, when activated, shuts off the pump. This method is less likely to stop the flow of pressurized oil as quickly as other methods discussed but can be acceptable under some conditions, such as in outdoor locations and in buildings of fire-resistive construction.

3. Fire extinguishers should be provided that are suitable for a Class B fire.

4. Threaded piping should be avoided. Where present, the fittings should be seal welded.

5. Machines should be isolated from positive ignition sources such as metal castings and open flames.

6. When rubber or synthetic hose is used, it should be of the armored type or enclosed in a metallic tube to contain escaping fluids.

7. Hydraulic oil systems should be inspected regularly for impending failures.

LESS HAZARDOUS HYDRAULIC FLUIDS (FIRE-RESISTANT FLUIDS)

Test Methods

For many years several different types of test methods have been used to evaluate the degree of fire resistance of less hazardous hydraulic fluids. Typical procedures were linear flame propagation, autoignition temperature, high-pressure spray flammability, flashpoint, and the Factory Mutual hot channel ignition test. Unfortunately, none of these tests individually, or sometimes collectively, reflect the degree of fire resistance achieved under various conditions encountered in industrial and mobile applications. Inability to agree on a standardized test procedure was of concern to industry, insurance underwriters, and the fluid suppliers.

Spray Flammability Parameter (SFP)

Perhaps the most respected certification of fire resistance is by Factory Mutual Approvals, which is a business unit within FM Global, one of the world's largest property insurers and risk management organizations. Factory Mutual Approvals certification is required by many industrial facilities. Additionally, in order to obtain insurance, some property insurance underwriters require that the fire-resistant fluid being used has received Factory Mutual Approvals certification.

Through Factory Mutual Approvals continual testing and research efforts, a revised standard, CN 6930, was introduced early in 2002. This standard defines the test that is commonly known as the spray flammability parameter (SFP). The SFP value is determined by measuring various parameters during fluid ignition testing. These data are used in an equation that calculates the SFP value. Fluids are classified by the SFP number, which is an indication of their degree of fire resistance. The SFP number is an important criterion when selecting the hydraulic medium, because some fluids offer a much greater margin of safety than others. The Factory Mutual Approvals test has been used quite extensively, although there are still some unresolved issues pertaining to the test, which is prompting revisions to CN 6930.

It is perhaps a bit unrealistic, at this point, to believe that in the near future there will be a single test method to determine fluid fire resistance that will be universally accepted throughout the world. Some fluids that pass the Factory Mutual Approvals test will, with use, lose their fire resistance due to fluid degradation. It is also not uncommon for oil, solvents, or process fluids to enter the system or to be added to the system accidentally or through carelessness or improperly marked storage containers. A very common problem is poorly maintained fluids, primarily the loss of water in water-containing fluids. A decrease in water level through evaporation will seriously affect level of fire resistance of the fluids.

Water-Glycol Fluids

Water-glycol fluids normally consist of 35 to 50 percent water, and ethylene or propylene-glycol, thickeners, and additives. Recommended temperature limits are 0 to 150°F (–18 to 66°C), with normal operating temperatures of 120 to 130°F (49 to 54°C). At higher temperatures, the rate of water evaporation is such that addition of makeup water is frequently required. As the water evaporates, the viscosity increases and the fire resistance decreases.

Water-glycol fluids are compatible with most types of seals, gaskets, and hoses made from nitrile, fluorocarbon, butyl, or ethylene-propylene but are incompatible with certain types of leather, cork, and paper. These fluids generally have a solvent action on most petroleum-compatible paints and coatings.

Synthetic Fluids

Synthetic fluids are non-water-containing man-made materials, such as phosphate esters, blends of phosphate esters with petroleum oil, and polyol esters. Recommended temperature limits are 20 to 150°F (–7 to 66°C), with normal operating temperatures of 120 to 130°F (49 to 54°C).

Phosphate esters and phosphate ester blends are not compatible with seals, gaskets, or hoses made from nitrile, neoprene, or natural rubber, and these elements must be replaced with fluorocarbon or other compatible materials.

Polyol esters are compatible with seals, gaskets, or hoses made from nitrile or fluorocarbon.

All synthetics typically attack paints, coatings, and electrical insulation.

Water-in-Oil Emulsions

Water-in-oil emulsions consist of 35 to 40 percent water, petroleum oil, emulsifiers, and additives. The water is dispersed in fine droplets in the oil phase. Recommended temperature limits for the emulsion are 50 to 150°F (10 to 66°C), with normal operating temperatures of 120 to 130°F (49 to 54°C). At higher temperatures, frequent addition of water is required. Loss of water tends to reduce viscosity and increase flammability. Water-in-oil emulsions are compatible with most seals and gaskets and with hoses made from nitrile, fluorocarbon, or neoprene. Seals or gaskets made from cork, paper, leather, or butyl are unacceptable. These fluids generally have a solvent action on most petroleum-compatible paints and coatings.

ENVIRONMENTALLY ACCEPTABLE FLUIDS

Currently there are four major classes of environmentally acceptable fluids. They are vegetable-based oils, polyglycols, synthetic esters, and synthetic hydrocarbons. Although these fluids are typically used in equipment such as turf maintenance and tree harvesting equipment, man lifts, as well as in off-road construction equipment, they are on occasion used in hydraulically actuated elevators, presses, cranes, winches, and other machinery that may cause ground contamination. In general, these fluids have flashpoints ranging from 410 to 480°F (210 to 249°C).

INTERNATIONAL FLUID DESIGNATIONS

Fluids experts from other countries who represent ISO (International Standards Organization) often attend meetings of the Fluid Power Association's Fluid Standards Committee. Through the input of these experts, the committee prepares standards that can be applied internationally. Some types of hydraulic fluids, such as phosphate esters, are not used extensively throughout the world because of degradability and disposability problems.

All categories of hydraulic fluids have been assigned symbols by the International Standards Organization, which identify the fluid as to type. This coding is now being used on storage containers and product data sheets. The ISO designation and matching fluid description can be found in Table 8.11.1.

SUMMARY

Fluid power systems are used to transmit power or motion to equipment and machinery. Although petroleum oils are the most commonly used hydraulic fuels, synthetic lubricants are used

TABLE 8.11.1 Classification of Hydraulic Fluids

Symbol ISO-L	*Composition*
HH	Refined mineral oils with no additives
HL	Refined mineral oils with antirust and antioxidation properties
HM	HL type with antiwear properties
HV	HL type with improved viscosity/temperature properties
HS	Synthetic with no specific fire-resistant properties
HETG	Vegetable-based oil
HEPG	Polyglycols
HEES	Synthetic esters
HEPR	Synthetic hydrocarbons
HG	Hydraulic slide way oils
HFAE	Oil-in-water emulsions—typically more than 80% water (coolants)
HFAS	Chemical solutions—typically more than 80% water (coolants)
HFB	Water-in-oil emulsions
HFC	Water-glycol fluids
HFDR	Phosphate esters
HFDU	Polyol esters

more frequently in industrial and mobile applications. Pressurized oils or synthesized hydrocarbons in fluid power systems present a considerable fire hazard, especially where ignition sources are constantly present. Less hazardous hydraulic fluids, referred to as fire-resistant fluids, represent a lower fire hazard than petroleum oils or synthesized hydrocarbons, but all will ignite under certain conditions.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on the safeguards for fluid power systems discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

Chapter 12

Refrigeration Systems

Henry L. Febo, Jr.

Chapter Contents

Effects of Regulatory Changes
Applications, Classifications, and Basic Operating Principles
Types of Systems and Their Basic Hazards
Hazard Control and Emergency Response

Key Terms

azeotropic, chlorofluorocarbons (CFCs), Clean Air Act, halogenated agents, heat transfer fluid, oxygen depletion potential (ODP), refrigerant, refrigeration systems, zeotropic

Industrial refrigeration systems are usually designed to provide a means for cooling specific locations to temperatures below ambient. Although there are many types of refrigeration systems, they are all heat exchangers, differing only in mechanical and thermal design, employing different fluids for refrigerants. This chapter outlines regulatory changes affecting refrigeration systems and reviews the refrigerant identification and hazard classification schemes. It discusses basic operating principles and identifies some of the more common types of refrigeration systems and associated hazards. Although it does not address the distribution aspects of refrigeration systems used for heating, ventilation, and cooling (HVAC) systems, the machinery room is similar whether the goal is building cooling or process and food refrigeration.

For related topics, see Section 10, Chapter 4, "Air-Conditioning and Ventilating Systems."

EFFECTS OF REGULATORY CHANGES

In 1978 chlorofluorocarbons (CFCs) were banned from use in nonessential aerosols by the United States in an effort to reduce depletion of the ozone layer. However, increased use of CFCs in manufacturing operations resulted in a continuation rather than a reduction of the problem of ozone depletion.

Montreal Protocol (1987) and the Clean Air Act of 1990

The United Nations began to address the problem and called a conference, the Vienna Convention for the Protection of the Ozone Layer (1985), which led to the adoption of the "Montreal Protocol on Substances That Deplete the Ozone Layer" (1987). The protocol became effective worldwide in 1989, which led the United States to enact the Clean Air Act of 1990 that required the total phaseout of CFC production by the year 2000. Later, this date was revised to January 1, 1996. At this time, recycled and reclaimed stocks are the only source of CFC refrigerants. The Clean Air Act also mandated reduction of CFC emissions to the "lowest achievable levels," including a ban on intentional venting and limitations on purge units expelling CFCs into the atmosphere.

Alternative Refrigerants

Alternative refrigerants have been developed and commercialized. Centrifugal chillers that air condition buildings and use R-11, R-113, R-114, and R-12 (CFCs) can be substituted with R-123, R-134a, R-124, and R-22 (HCFCs), depending on whether the chiller is replaced or retrofitted. Reciprocation chillers using R-12 (CFC) can be substituted with R-134a and R-22, again, depending on whether the chiller is replaced or retrofitted. R-13B1 (fluorine/bromine hydrocarbon) and R-503 (a blend of CFCs) are being recommended for industrial process refrigeration applications. These are not "drop-in" replacements. There *could* be incompatibilities with lubricants and residual refrigerant in existing equipment. The issue of incompatibility needs to be properly addressed on any changeover. Further, the regulations require that all personnel handling refrigerants be certified, including service, operating, and installation personnel.

Henry L. Febo, Jr., P.E., is an assistant vice-president and senior engineering technical specialist at FM Global in Norwood, Massachusetts.

Beijing Amendment (1999)

The United Nations has continued to modify and update the protocol during a series of subsequent meetings, the last held in Beijing, China, in 1999. The latest accepted amendments to the protocol have adopted new controls on the production of hydrochlorofluorocarbons (HCFCs). HCFCs have been promoted as substitutes for CFCs but they also contribute to ozone depletion. The Beijing amendment mandates production of HCFCs be halted in developed countries by 2020 and developing countries by 2040.

Kyoto Protocol (1999)

An additional international agreement, the Kyoto Protocol (1999), seeks to control the release of greenhouse gases to the environment. Greenhouse gases contribute to global warming. Some alternative refrigerants are covered by this agreement. Since it does not prohibit the use or manufacture of these gases but only controls their release, the impact on refrigeration applications is less severe. Two included classes in the refrigeration area are HFCs (hydrofluorocarbons) and PFCs (perfluorocarbons).

CFC Substitutes

Presently the United States requires CFC substitutes be authorized for use by the Environmental Protection Agency (EPA). This process is administered under the Significant New Alternatives Policy (SNAP) published in the Final Rulemaking (59 FR 13044) on March 18, 1994. It continues to list HCFCs as acceptable CFC substitutes. The EPA continues to expand the list of acceptable substitutes under the SNAP guidelines with the latest rulemaking, Notice 19, in October 2004.

Available alternatives to the use of halogenated refrigerant systems include the following:

1. Ammonia systems
2. Absorption systems
3. Steam-jet systems
4. Systems employing CFC substitutes
5. Hydrocarbon refrigeration systems

The use of ammonia as a refrigerant is affected by a number of regulations of the U.S. Occupational Safety and Health Administration (OSHA) and the EPA. Application of these various regulations is based on specific quantity limits, typically 500 to 1000 lb (227 to 454 kg). One regulation in particular that might have to be considered is OSHA's 29 CFR 1910.119, "Process Safety Management Standard." This regulation applies to any system with over 10,000 lb (4540 kg) of ammonia, quite common in industrial systems.

Facilities should consult a regulatory specialist prior to proceeding with a new or modified installation.

APPLICATIONS, CLASSIFICATIONS, AND BASIC OPERATING PRINCIPLES

Applications

The following brief outline includes many of the principal applications of refrigeration systems:

1. Industrial, refining, and chemical
   a. Controlling vapor pressure of volatiles during distillation, separation, or processing
   b. Shifting solubility relationships to permit segregation and removal of undesired constituents, such as asphalt or wax, in lubricating oils
2. Manufacture, freezing, preservation, and distribution of food products
3. Air conditioning
4. Manufacture, preservation, and distribution of medicine and drugs
5. Environmental testing chambers
6. Cold treatment of metals
7. Industrial testing
8. Miscellaneous
   a. Cold storage of flowers and furs
   b. Ice making and skating rinks

Refrigerant Classifications

Numerical Designation. One does not usually associate low temperatures with fire hazards, but refrigeration systems are of concern for two reasons: (1) some of the fluids used as refrigerants are flammable and (2) some are explosive in critical combination with air. Other refrigerants are toxic and, if they escape during a fire, can cause injury or death or interfere with fire-fighting operations.

Refrigerants are identified by a numerical designation as specified in ANSI/ASHRAE 34, *Number Designation and Safety Classification of Refrigerants.* The number can be up to four digits, with each representing the number of fluorine, hydrogen, and carbon atoms as well as the number of unsaturated carbon-carbon bonds, respectively. The number of chlorine atoms can be inferred, and the number of bromine atoms is designated by an uppercase "B" in the numerical designation.

Commercialized refrigerant blends are designated in either the 400 or 500 series. The 400 series is for zeotropic* blends, with the number identifying the compounds in the blend but not the amount of each. The 500 series is for azeotropic† blends, with the number indicating both the compounds and, by definition, the amounts of each. The 600 series has been assigned to miscellaneous organic compounds and the 700 series to inorganic compounds.

Safety Designation. ANSI/ASHRAE 34 also assigns safety groups to the various refrigerant compounds. The classification consists of two alphanumeric characters (e.g., A2 or B1). The capital letter indicates toxicity, and the arabic numeral indicates flammability. The safety group classification can be represented

*Zeotropic: These blends comprise multiple components of different volatilities that, when used in refrigeration cycles, change volumetric composition and saturation temperatures as they evaporate (boil) or condense at constant pressure.

†Azeotropic: These blends comprise multiple components of different volatilities that, when used in refrigeration cycles, *do not* change volumetric composition and saturation temperatures as they evaporate (boil) or condense at constant pressure.

as in Figure 8.12.1. Complete details of the classification criteria and methods can be found in ANSI/ASHRAE 34.

The safety class changed with the 1992 edition of ANSI/ASHRAE 34. The pre-1992 system evolved over the years and attempted to classify these two independent parameters, that is, toxicity and flammability, with a simple (or modified single) designator (i.e., Group 1, 2, 3a, 3b, 4a, and 4b). The new system is less arbitrary in assignment of the letter for toxicity and number for the flammability index.

A list of the more commonly used refrigerants, some selected properties, and their safety class can be found in Table 8.12.1. The table has been expanded with the addition of several new refrigerants that can serve as replacements for existing high ODP (oxygen depletion potential) materials. Some of the blends have a potential for flammability when mixed with air or enriched oxygen concentrations at temperatures above 212°F (100°C) and elevated pressures even though rated as Safety Class A1. This situation may occur when they are used as a leak testing agent. Several industrial explosions have occurred under these conditions with R-22. To identify those compounds with special flammability considerations that are not included in this document, see the MSDS or the agent supplier. For a complete listing of the covered compounds, refer to the latest edition of ASHRAE 34.

Basic Operating Principles

All refrigeration systems take heat from one space or medium and transfer it to another. To accomplish the transfer, fluids are used that will readily absorb, transport, and release heat under controlled conditions. These fluids used as refrigerants perform in both the liquid and gaseous states. When a refrigerant in a liquid state changes to a gas, it absorbs heat from its surroundings.

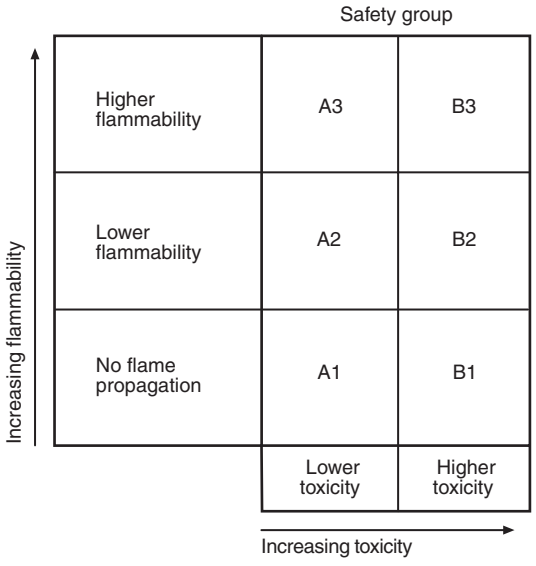

FIGURE 8.12.1 Refrigerant Safety Group Classification (Source: ANSI/ASHRAE 34-2004, *Designation and Safety Classification of Refrigerants*)

Conversely, when a refrigerant in a gaseous state condenses back to a liquid, it releases heat to its surroundings. The most effective refrigerant is a material that can vaporize and condense at the desired temperatures and pressures.

The unit of refrigeration in the United States is known as the ton. It is historically developed from the heat required to melt 1 ton (2000 lb [907 kg]) of ice at 32°F (0°C) during a period of 24 hours. Since the heat of fusion of water is approximately 144 Btu/lb (3.4×10^5 J/kg), a U.S. ton of refrigeration equals 12,000 Btu/hr (3.5 kW).

A refrigeration system consists of a circulating refrigerant, condenser and receiver, a control device, an evaporator, and a compression device (Figure 8.12.2). At the start of a cycle, the refrigerant passes from the receiver at high pressure to the control device, which is an expansion valve where the high-pressure liquid is allowed to expand (thus reducing its pressure and temperature), and then to the evaporator with many coils or tubes that will remove heat from the area or secondary fluid. The compression device, where an outside energy source is used for operation, takes the low-pressure gas, increases its pressure, and then discharges the hot, high-pressure gas into a condenser. Here the gas gives up the heat obtained in the evaporator and compressor and condenses into a liquid, returning to the receiver where the cycle repeats.

TYPES OF SYSTEMS AND THEIR BASIC HAZARDS

Refrigeration systems are classified in two ways: (1) by the type of compression system (mechanical, absorption, steam-jet ejectors) and (2) by the method of cooling the space or substance (direct or indirect).

Mechanical System

Description. A mechanical refrigeration system, where the compression step is achieved by a mechanical compressor, is probably the most common refrigeration system type in use.

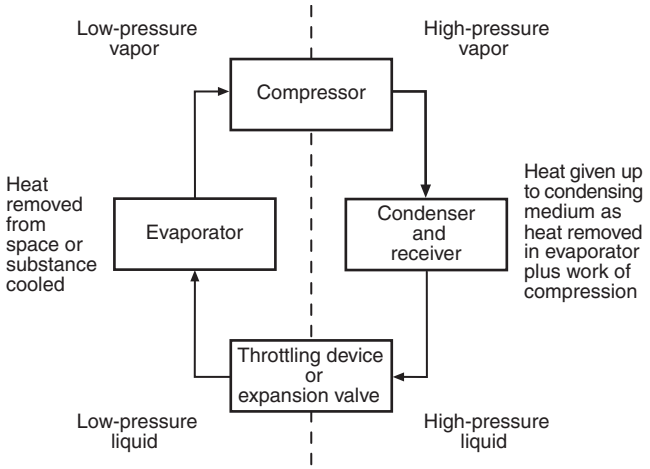

FIGURE 8.12.2 Basic Mechanical Refrigeration System

The compressor types include reciprocating (horizontal, vertical [Figure 8.12.3], or "V" design), centrifugal (Figure 8.12.4), or rotary screw type. Refrigerants can include any of the fluids shown in Table 8.12.1. Figure 8.12.5 illustrates a typical ammonia refrigeration system, showing the relationship of the major components, such as the compressor, expansion valve, and evaporator.

Hazards. The hazards are primarily related to the refrigerant fluid. Refrigerants with a flammability rating of 1 present no fire hazard but, if released into a confined space, present oxygen depletion hazards to personnel, as would those rated 2 or 3.

Refrigerants with a flammability rating of 2 pose limited fire and explosion hazard, according to the ANSI/ASHRAE 34 classification method. The potential fire and explosion hazards of these fluids should be evaluated before any installation decision is made.

Refrigerants with a flammability rating of 3 are highly flammable. These are used primarily in the petroleum refining and petrochemical industries. Use of these refrigerants requires special design and construction to control the fire and explosion hazards and to minimize the consequences of an unexpected release.

Refrigerants carrying a B toxicity rating present additional personnel hazards that must be recognized and addressed in design and emergency planning.

The equipment used for the compression step will present various hazards not directly addressed in this chapter. These hazards, which include potential for overspeed, overpressure,

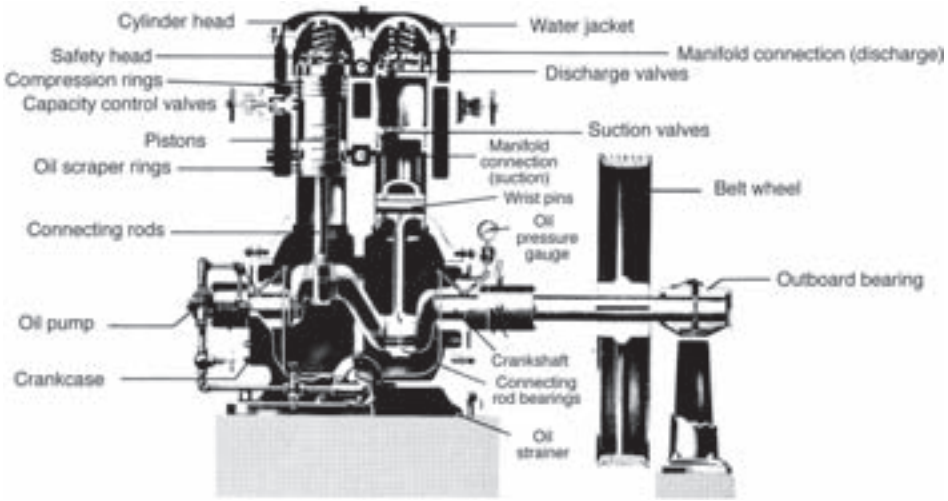

FIGURE 8.12.3 Reciprocating Compressor, Vertical Single Acting (Source: FM Global)

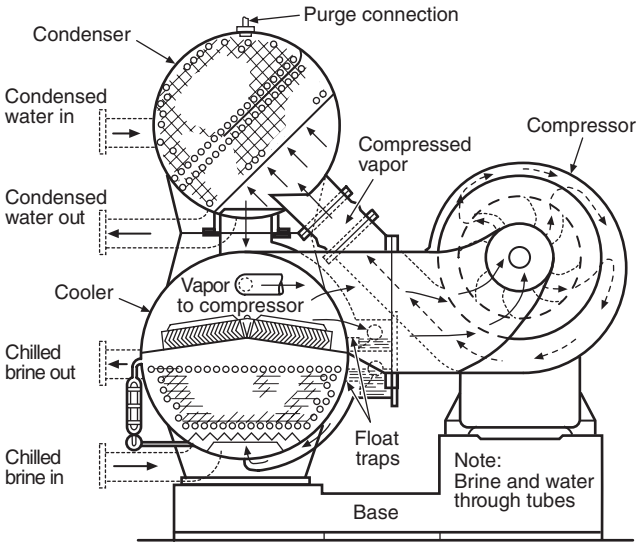

FIGURE 8.12.4 Cross Section of Centrifugal Refrigeration System Showing Refrigeration Cycle (Source: FM Global)

leakage of refrigerants or lubricants, and personnel safety issues, should be recognized in the design and installation phase and addressed in a preventive maintenance program.

Absorption System

Description. The absorption cycle is the oldest known for producing a refrigeration effect. Mechanically, it is the simplest of the systems in common use today. The simple absorption system consists of the basic components shown in Figure 8.12.6, with the absorber, heat exchanger, and generator system serving as the compression step.

The absorption cycle uses an absorbent as a secondary fluid to absorb the primary fluid, which is a gaseous refrigerant that has been vaporized in the evaporator. The evaporation process absorbs heat, providing the needed refrigeration.

The absorption and mechanical compression cycles have in common the evaporation and condensation of a refrigerant liquid, occurring at two pressure levels within the unit. The two cycles differ in that the absorption cycle uses a heat-operated generator to produce the pressure differential, whereas the mechanical compression cycle uses a compressor. Both cycles require energy for operation, that is, heat and a small amount of mechanical energy (a pump) in the absorption cycle and mechanical energy in the compression cycle.

The two most common working fluids presently in use are (1) water-lithium bromide (H_2O-LiBr) and (2) ammonia-water

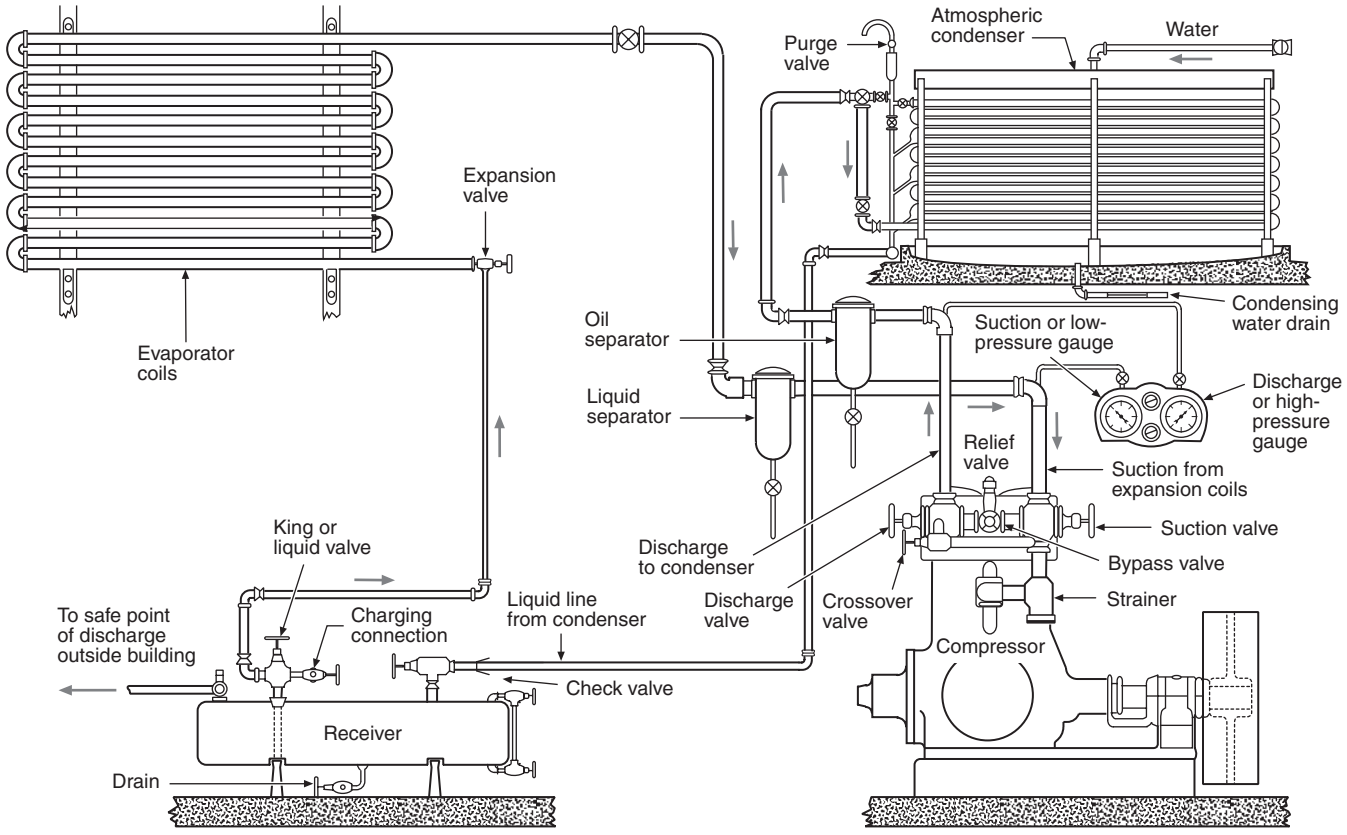

FIGURE 8.12.5 Typical Ammonia Refrigeration Plant (Source: FM Global)

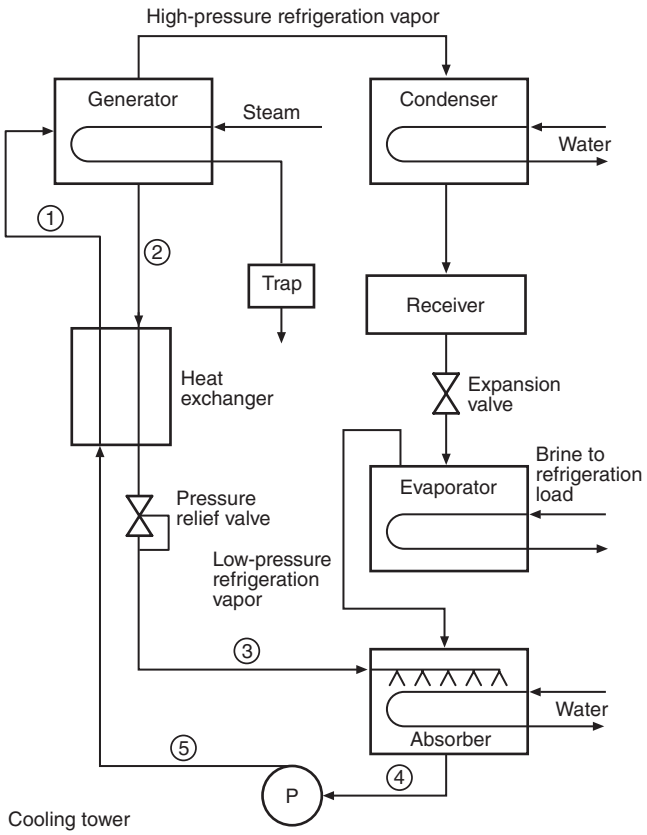

FIGURE 8.12.6 Basic Absorption Refrigeration System (Source: FM Global)

(NH_3-H_2O), where the components are given as refrigerant, then absorbent. Note that in one system water is the refrigerant, whereas in the other it is the absorbent.

The water-lithium bromide is used primarily for air-conditioning applications, whereas the ammonia-water is used for large tonnage industrial applications requiring low temperatures for process cooling.

Water-lithium bromide is a brine that has a subatmospheric vapor pressure at typical cycle conditions. Machines that use water-lithium bromide operate under a vacuum. Conversely, ammonia-water solutions have vapor pressures up to 295 psi (2030 kPa) at cycle conditions. As a result, equipment used for ammonia-water systems requires much stronger vessels.

The heat energy for the generator can come from various sources. These include steam or hot fluids (called indirect fired); clean, hot waste gases (heat recovery, also indirect fired); or flame (direct fired).

Hazards. Lithium bromide is a relatively stable compound (nontoxic, nonflammable, and nonexplosive). If contaminated, it can generally be reclaimed.

Ammonia systems have inherent hazards, as described in the section entitled "Hazard Control and Emergency Response." Similar safeguards in that section would apply.

Steam-Jet Ejector System

Description. The steam-jet (also known as the steam vacuum or steam-ejector) refrigeration cycle has been used for almost 100 years, yet it is one of the least common refrigeration cycles in use today. Its lack of popularity stems, at least in part, from some inherent performance limitations. Several hundred of these units are still in use in such industries as pulp and paper, petrochemical, food processing, and pharmaceuticals, where they are used for air conditioning and process cooling.

The steam-jet refrigeration cycle is similar to the more conventional refrigeration cycles having basic system components, such as an evaporator, compression device, condenser, and refrigerant. Instead of a mechanical compressor, the steam-jet system employs a steam ejector or booster to compress the refrigerant to the condenser pressure level. In the steam-jet refrigeration cycle, water is used as the refrigerant and the cooling effect is produced by the continuous vaporization of a part of the water in the evaporator at a low absolute pressure level.

Figure 8.12.7 shows a simple open, chilled-water refrigeration system. In this open system, refrigerant water is circulated directly to the cooling load. It is possible to have a closed chilled-water system in which a secondary fluid, usually water or brine, is used to serve the cooling load.

Hazards. Due to the simple nature of this system, no unique hazards are presented. Because water is the refrigerant, care is needed to prevent freezing in the evaporator, including operational controls and low-refrigerant-temperature alarms.

Direct Method of Cooling System

In addition to being classified according to the type of compression stage employed, refrigeration systems are further differentiated by how the heat is removed from the cooling load. In direct systems, the evaporator is in direct contact with the product or space to be cooled, or it is in air-circulating passages connected to the area or product. A household refrigerator is an example of a direct system.

Indirect Method of Cooling System

An indirect system uses an intermediate heat transfer fluid, which is first cooled by the refrigerant and then circulated to the material or space. The intermediate fluid is called "brine," because early refrigerating systems used a mixture of sodium or calcium salt and water. Brine has been defined as any liquid cooled by a refrigerant and used for the transmission of heat energy without a change in state. Organic chemical solutions, such as ethylene glycol, as well as brine, are employed in indirect systems.

HAZARD CONTROL AND EMERGENCY RESPONSE

Detailed criteria for installation and arrangement of refrigeration systems are addressed in various national standards and

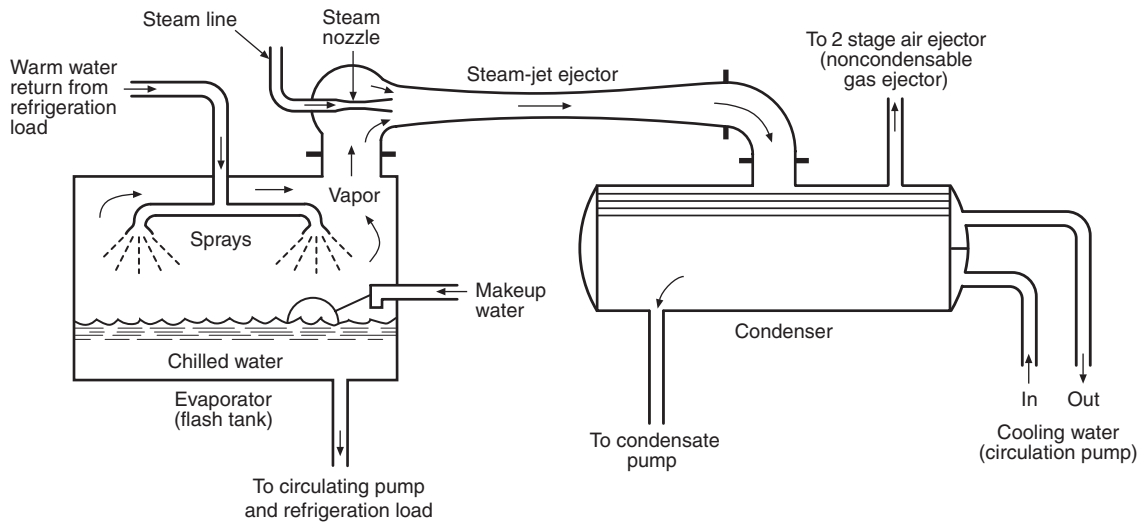

FIGURE 8.12.7 Open, Chilled-Water Steam-Jet Refrigeration System with Surface Condenser (Source: FM Global)

codes (see bibliography). This section summarizes some basic considerations and safeguards. Some of the following criteria might not be practical where small quantities of refrigerants are involved.

Location and Construction

The choice of refrigerant type is limited by some codes, depending on the occupancy of the area where the system is to be installed. Indirect systems can sometimes be used with toxic refrigerants when the machine room can be safely located away from normally occupied areas.

Refrigeration machinery is best located in a separate room, cut off from any adjoining occupancy. In most cases, this room should be limited to containing the refrigeration machinery and controls. Electric switchgear, boilers, fuel fire equipment, and so on should be located in other rooms. Even the noncombustible refrigerants (Classes A1 and B1) can be decomposed by arcs, flames, and hot surfaces, possibly releasing corrosive chlorides and fluorides.

The room construction should be noncombustible. Cutoffs should be 1-hour fire rated for flammability Class 1 and 2 refrigerants, and 2-hour fire rated where flammability Class 3 refrigerants are used.

Where flammability Class 2 and 3 refrigerants are used, the potential for room explosion must be considered. Outdoor locations or rooms of damage-limiting construction (see NFPA 68, *Standard on Explosion Protection by Deflagration Venting*) should be used to minimize damage from an explosion caused by release of these refrigerants.

Ammonia, a flammability Class 2, is often considered exempt from these criteria due to the exemption from using hazardous location electrical equipment (see below). This exemption has proved ill-considered in a number of explosion incidents involving ammonia refrigeration systems.

Electrical Equipment

For flammability Class 1 refrigerants, the major concern for electrical equipment is potential corrosion issues. Best practice is to locate all electrical equipment not directly associated with the refrigeration system to areas other than the machine room. For flammability Class 2 and 3 refrigerants, the machine room should conform to NFPA 70, *National Electrical Code*®. For ammonia, a flammability Class 2 refrigerant, some codes and authorities having jurisdiction allow use of ordinary electrical equipment under either of the following conditions:

1. The machine room is continuously ventilated and failure of the ventilation system sounds an alarm
2. The machine room is equipped with a vapor detector that will automatically start the ventilation system and sound an alarm at a detection level at or below 1000 ppm

Ventilation

For Class A1 refrigerants, natural or mechanical ventilation is necessary for equipment cooling and personnel comfort only. For all other refrigerants, mechanical ventilation is needed. Where the hazard is only toxicity, appropriate guidelines should be followed. Where refrigerant flammability is an issue, continuous mechanical ventilation of 1 $ft^3/min/ft^2$ (0.3 $m^3/min/m^2$) of floor area will minimize the possibility of developing an explosive concentration in the event of normal or minor leakage.

Fire Protection

Control of fire emergencies generally consists of reducing the heat of the fire with water and, if possible, shutting off the gas supply. Water should be applied as a spray from hoses or fixed nozzles.

Where the construction is combustible, or flammable refrigerants are used, automatic sprinklers provide the best and most reliable form of fire protection.

All machine rooms should be provided with portable extinguishers suitable for at least Class B and C fires.

Miscellaneous

To minimize refrigerant release from equipment and piping, a high level of maintenance should be provided, especially where refrigerants are flammable or toxic. In addition, the initial installation should ensure that piping and components are compatible with the refrigerant and installed according to appropriate codes. ANSI/ASHRAE 15, *Safety Code for Mechanical Refrigeration,* details the requirements for piping, pressure relief, and so on. Special care should be taken to protect refrigerant piping from mechanical damage. For large ammonia-based systems (over 10,000 lb [4540 kg]) and those using flammability Class 3 refrigerants, the requirements of the OSHA Process Safety Management standard may apply.

Control of the nonfire emergency is accomplished by directing, diluting, and dispersing the gas to prevent it from coming in contact with people or goods. Simultaneously, steps should be taken to stop the flow of gas. Air, water, and steam are practical media for accomplishing dilution and dispersion. Water, in the form of a spray from hoses or fixed nozzles, is most commonly used for this purpose.

Ammonia presents hazards of fire, explosion, toxicity, and contamination of goods. It can be most severe in the refrigerated area and machine room but can spread to adjoining areas. Emergency planning should address control of the release, protection of personnel, and decontamination or preservation of the stored commodity.

SUMMARY

Industrial refrigeration systems are designed to cool specific locations to below-ambient temperatures by taking heat from one space or medium and transferring it to another. Principal applications of such systems include use in industrial, refining, and chemical processes; in the manufacture, freezing, preservation, and distribution of food products, medicine, and drugs; in air conditioning; in environmental testing chambers; in the cold treatment of metals; in industrial testing; in the cold storage of flowers and furs; and in ice making and skating rinks.

Refrigeration systems are classified by the type of compression system (mechanical, absorption, or steam-jet ejectors) and by the method of cooling (direct or indirect). The hazards of these systems center on the fluids used as refrigerants, some of which are flammable and explosive in critical combinations with air, and some of which are toxic and could cause injury or death during a fire or accidental release.

Basic considerations and safeguards include (1) location, that is, placing refrigeration machinery in a separate room and locating all electrical equipment not directly associated with the refrigeration system elsewhere than in the machinery room; (2) ventilation; (3) fire protection, such as automatic sprinklers and portable extinguishers; and (4) a high level of maintenance.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on the safeguards for refrigeration systems discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

This chapter discusses electrical systems and appliances. Specific topics include origins of electrical fires; codes and standards; building wiring, design, and protection; electrical household appliances; industrial and commercial equipment; electrical equipment for outdoor use; locations exposed to moisture and dust; signaling and communications systems; emergency systems; and special occupancy installations.

Other chapters in this handbook address related building services, most notably Section 10, Chapter 2, "Heating Systems and Appliances," and Section 10, Chapter 4, "Air-Conditioning and Ventilating Systems." Special considerations for the installation of electrical systems can be found elsewhere in this handbook. See Section 4, Chapter 3, "Concepts of Egress Design"; Section 6, Chapter 11, "Medical Gases"; Section 8, Chapter 8, "Industrial and Commercial Heat Utilization Equipment"; and Section 11, Chapter 6, "Lightning Protection Systems."

If properly designed, installed, and maintained, electrical systems are both convenient and safe; otherwise they can be a source of both fire and personal injury. Electricity can cause a fire if an arc occurs or if electrical equipment overheats and can cause injury or death through shocks and burns.

All references to the *National Electrical Code*® (*NEC*®) in this chapter are to the 2005 edition.

ARCING AND OVERHEATING IN ELECTRICAL SYSTEMS

When an electric circuit carrying a current is interrupted either intentionally, as by a switch, or unintentionally, as when a connection at a terminal becomes loosened, arcing at the switch contacts or heating from the high-resistance connection at the terminal is produced. The intensity of the arc and the energy released depend largely on the current and resistance of the contact at the terminal, as well as the voltage and inductance of the circuit load. The temperature may easily be high enough to ignite any combustible material in the vicinity.

An electric arc may not only ignite combustible material in its vicinity, for example, the insulation and covering of the conductor, but may also melt the metal of the conductor. Embers from burning combustible material and splatters of hot metal may fall on combustible material, setting it on fire.

When an electrical conductor carries current, heat is generated in direct proportion to the resistance (ohms) of the conductor and to the square of the current (amperage). The resistance of conductors used to convey current to the location in which it is used or to convey it through the windings of a piece of apparatus (except resistance devices and heaters) should be as low as practical. Metals, such as copper and aluminum, are used for this purpose. In other instances, such as in electric heaters, electric cooking equipment, and soldering irons, the heat from the current serves a useful purpose.

The heating of electrical conductors is almost never a fire hazard under design conditions. NFPA 70, *National Electrical Code*®, specifies the *ampacity,* or the maximum safe current a

conductor can carry without overheating (Tables 8.13.1 through 8.13.8). Ampacity depends on size of the conductor; temperature of the environment in which the equipment is installed; type of insulation; and location where the conductors are installed, such as in a raceway, in a cable, in the earth, or in free air. Where the specified current is exceeded, the generation of heat causes deterioration of the electrical insulation and may ignite combustibles in contact with or close to the conductors. Apparatus or appliances that use electric conductors as heating elements or use an electric arc to generate heat (e.g., arc welders) can also be fire hazards if improperly installed and used.

The risk of an electrical fire can be reduced by using the proper size conductor for the load, suitable insulation for the environment, and the correct size overcurrent protection (fuse or circuit breaker). Where heat-generating equipment is utilized, the risk of fire can be further reduced by ensuring that sufficient clearances and air circulation are provided to prevent unsafe

temperatures and premature breakdown of electrical insulation or ignition of nearby combustibles.

All standards governing electrical equipment include requirements intended to prevent fires caused by arcing and overheating and to prevent accidental contact, which may cause an electric shock. These primary sources of electrical hazards should be kept in mind whenever any work is being done on electric equipment.

ORIGINS OF ELECTRICAL FIRES IN BUILDINGS

Table 8.13.9 provides an overview of structure fires reported to U.S. fire departments from 1994 through 1998 that were coded as caused by electrical failure. This table is limited to fires coded as involving a short circuit, a ground fault, or another electrical failure, so some relevant incidents are likely not counted. Other causes, some of which may include a mix of electrical failures with other fires, are not included. Also, these statistics reflect cause determinations by fire officers on the scene, so some errors of inclusion or exclusion may have occurred.

Electrically powered equipment is involved in several times this number of fires each year (Table 8.13.10, for example, shows total fires involving electrical distribution equipment), including nonelectrical-failure scenarios, such as installing or using equipment with hot surfaces too close to combustibles. Some of these nonelectrical-failure scenarios involve mechanical failure or some other type of equipment failure. But, in fact, even when equipment failure is a proximate cause, nearly all fires involving electrically powered equipment stem from foreseeable or avoidable human error, such as the following.

Improper Installation

Failure to follow manufacturer's installation instructions or to observe all provisions of the *NEC,* including the workmanship provisions, can result in equipment being installed in ways that will lead to overloading, damage to equipment, or excessive heating of nearby combustibles. Mismatching of wire gauge size with equipment wattage or overfusing (using a fuse of too high an amperage rating) are examples.

Lack of Maintenance

Equipment wears out in service. An example is the deterioration of electrical insulation over time. Deterioration can accelerate due to improper installation, excessive heat, adverse environmental conditions, or physical damage. Even when equipment and systems are properly installed, aging can cause deterioration; therefore, periodic inspection and maintenance of electrical equipment should be performed.

Improper Use

Listed equipment that is not installed in accordance with the manufacturer's instruction for its intended use and for the conditions under which it is used can cause fires or injure personnel.

TABLE 8.13.9 Structure Fires Due to Electrical Failure (Annual Average of 1994 Through 1998 Reported Fires)

Equipment Involved in Ignition	*Average Number of Fires per Year*
Heating Equipment	
Central heating unit	1,930
Water heater	1,280
Fixed space heater	1,110
Portable space heater	850
Cooking Equipment	
Stove	1,970
Oven	910
Portable cooking or warming unit	600
Air-Conditioning or Refrigeration Equipment	
Central air-conditioning or refrigeration equipment	940
Refrigerator	960
Fixed local air-conditioning unit	560
Portable air conditioning or refrigeration unit	540
Electrical Distribution Equipment	
Fixed wiring	15,030
Transformer	750
Meter or meter box	890
Power switch or overcurrent protection device (e.g., fuse, circuit breaker)	2,520
Switch, receptacle, or outlet	4,430
Light fixture, lampholder, ballast, or sign	4,890
Cord or plug	6,360
Lamp or lightbulb	740
Unclassified electrical distribution equipment	3,370
Appliance or Tool	
Television, radio, or phonograph	1,440
Dryer	2,310
Washing machine	750
Separate motor or generator	690
Portable appliance designed to produce controlled heat (e.g., iron, electric blanket)	1,120
Portable appliance not designed to produce controlled heat (e.g., can opener, electric razor)	550
Unclassified appliance or equipment	2,500
Special Equipment	
Electronic equipment (e.g., telephone, computer, x-ray)	620
Other	
Vehicle	450
No equipment involved	9,770
Other known equipment involved	5,270
Unknown equipment involved	5,580
Total	81,670

Notes: These are fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. Statistics include a proportional share of fires with ignition factors unknown or unreported. "Electrical failure" defined as Ignition Factor 54 (short circuit or ground fault) or 55 (other electrical failure). Numbers rounded to nearest ten. Sums may not equal totals because of rounding error. Individual types of equipment are shown if they accounted for at least 450 fires per year.

Source: National estimates based on NFIRS and NFPA survey.

TABLE 8.13.10 Structure Fires Originating with Specified Electrical Distribution Equipment (Annual Average of 1994 Through 1998 Reported Fires)

Equipment Involved in Ignition	*Average Number of Fires per Year*
Fixed wiring	17,800
Transformer	1,100
Meter or meter box	1,300
Power switch gear or overcurrent protection device (e.g., fuse or circuit breaker)	3,000
Switch, receptacle, or outlet	5,700
Light fixture, lampholder, ballast, or sign	8,900
Cord or plug	8,000
Lamp or lightbulb	3,900
Total	49,700

Notes: These are fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. Statistics include a proportional share of fires with equipment involved in ignition unreported or unknown. Numbers rounded to nearest hundred.

Source: Kimberly D. Rohr, *The U.S. Home Product Report (Appliances and Equipment Involved in Fires),* NFPA Fire and Analysis Division, Quincy, MA, Jan. 2002.

Use of equipment listed for dry locations, but installed in damp or wet locations, or general-purpose equipment installed in locations where flammable liquids are used can be sources of ignition. Cords installed in traffic areas or pinched against a wall can be damaged and lead to overheat fires. Lightbulbs with higher wattage than the fixture is rated for can overheat and ignite lamp shades. Many other examples exist.

Carelessness or Oversight

Even momentary lapses of caution in the use of equipment can cause fires. Failure to turn off devices (e.g., space heaters) when no longer needed, dropping combustible objects into equipment, and draping combustible materials over operating equipment (e.g., clothes on a lamp) are all examples.

Some special studies provide additional insights that go beyond the level of detail in Table 8.13.9, although no other sources of representative national fire statistics exist. These studies include the annual tabulations by the International Association of Electrical Inspectors (IAEI) of fire and shock incidents that come to their attention and the several field studies done by the U.S. Consumer Product Safety Commission (CPSC). These studies appear to support a few qualitative observations:

- Many electrical cord fires involve extension cords, as opposed to lamp or other appliance power cords. This fact indicates that extension cords are probably overused as semipermanent extensions of building wiring systems.
- Overcurrent protection device fires appear to involve circuit breakers more often than fuses, both overall and relative to

the degree of use of each type of device. This is notable given that fuses are used primarily in much older homes, where deterioration due to age or damage due to system alterations would be more likely, and that fuses are more susceptible to tampering.

- Color televisions pose a greater fire hazard than black-and-white televisions due to differences in the energy usage of the two types.

CODES AND STANDARDS

All electrical installations in the United States should be made, used, and maintained in accordance with the *NEC* and other National Fire Protection Association (NFPA) standards that apply in special situations—for example, NFPA 70E, *Standard for Electrical Safety in the Workplace;* NFPA 75, *Standard for the Protection of Information Technology Equipment;* NFPA 79, *Electrical Standard for Industrial Machinery;* and NFPA 99, *Standard for Health Care Facilities.* There are also special standards for electrical installations on marine vessels, on aircraft, in hazardous (classified) locations, and in other locations.

National Electrical Code (ANSI/NFPA 70)

The *NEC* provides for the practical safeguarding of persons and property from hazards arising from the use of electricity. The *NEC* was first issued under its present name in 1897. It is revised every three years by the National Electrical Code Committee.

National Electrical Safety Code (ANSI C2)

As interest increased in electrical safety in the United States, a need arose for a code to cover the practices of public utilities and others when installing and maintaining overhead and underground electric supply and communications lines. Accordingly, the first edition of the *National Electrical Safety Code* (*NESC*) was completed in 1916. This code is updated and published by the Institute of Electrical and Electronics Engineers (IEEE).

Canadian Electrical Code

CSA International (CSA) sponsors and publishes the *Canadian Electrical Code (CEC).* This code establishes essential requirements and minimum standards for the installation and maintenance of electrical equipment in Canada. It can be adopted and enforced by electrical inspection departments throughout Canada and was prepared with due regard for the *NEC* and the *NESC.* Its several parts are the Canadian equivalent of the *NEC,* the *NESC,* and the standards of Underwriters Laboratories Inc. (UL) in the United States.

The *National Electrical Code® Handbook*

Although not itself a code or standard that can have the force of law, the *National Electrical Code® Handbook* is a valuable resource in implementing provisions of the *NEC.* The *NEC Handbook* contains the entire text of the *NEC,* supplemented by comments, diagrams, examples, and illustrations that are intended to clarify and explain some of the intricate requirements of the *NEC.* The *NEC Handbook* is published by the NFPA; a new edition is published with each new edition of the *NEC.*

Listed and Labeled Electrical Equipment Manufacturers

Publications are available that list the names of companies making electric appliances and materials that have been listed or labeled by nationally recognized testing laboratories, such as UL, Intertek Testing Services, and other testing laboratories. Devices and materials in the product categories listed have been tested for actual field use in accordance with the *NEC* and against other American National Standards Institute (ANSI) safety standards. The lists are published so that the names of manufacturers of devices that meet test criteria may be readily obtained. UL publishes the *Hazardous Location Equipment Directory,* the *Electrical Appliance and Utilization Equipment Directory,* and the *Electrical Construction Materials Directory.* UL also publishes the *Fire Resistance Directory,* which includes a number of listed methods of protecting penetration of building assemblies, such as walls or floors. They are all published annually by UL with six-month supplements. Certain types of electrical equipment are covered in other testing laboratory directories, such as the *Marine Products Directory.*

There are sections of the *NEC* that influence the design and construction of electric equipment. Most testing labs have complete published standards for most electric fittings, materials, and equipment, including specifications for performance under test conditions and in actual service and further details of design and construction. Other testing laboratories in the United States and Canada that test electric equipment include Factory Mutual Research Corporation (FMRC); U.S. Testing; Applied Research Laboratories; Dash, Straus, and Goodhue; and CSA. Some laboratories stipulate compliance with the *NEC* in testing equipment. (Where no published standards are available for special equipment, arrangements usually can be made with testing laboratories for field testing on an individual basis.)

BUILDING WIRING, DESIGN, AND PROTECTION

This section contains information on various types of building wiring and electrical equipment, including panelboards and overcurrent protection; types of electric conductors; identification of conductors, terminals, and so on; how to calculate loads; and similar subjects.

Service Entrance

Good practice requires that service entrance conductors comply in all respects with the detailed requirements of Article 230 of the *NEC.* Figure 8.13.1 provides typical arrangements of service entrance conductors.

The basic requirement is that a building or other structure can be supplied by only one service. Where more than one service is allowed, however, a permanent plaque or directory that describes all the other services to the building and the area served by each is required to be installed at each service drop

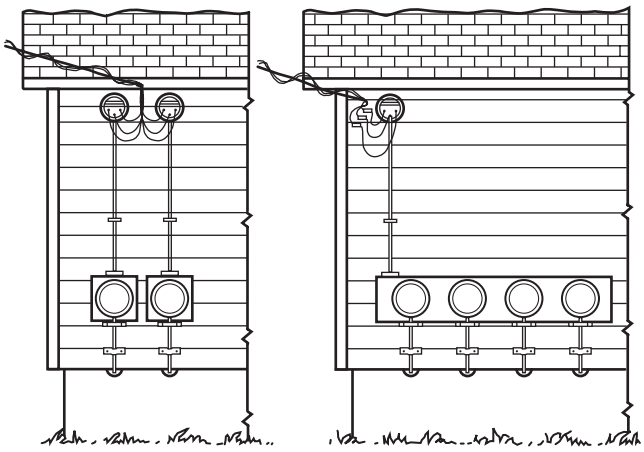

FIGURE 8.13.1 (a) Two Sets of Service Entrance Conductors Tapped from One Service Drop, with Meters Mounted on Outside of Building; (b) Set of Main Service Entrance Conductors Connected to Service Drop and Carried Through a Trough and Through Four Sets of Subservice Entrance Conductors to Each Service Equipment, with Meters Mounted on Outside of Building

or lateral or at each service equipment location. This plaque or directory should be sufficiently durable to withstand the ambient environment.

Where separate services are permitted, such as for fire pumps, emergency or legally required standby electrical systems, optional standby electrical systems, or parallel power production systems, six additional switches or circuit breakers are allowed, in addition to the six service disconnects normally allowed. The intent here is that a disruption of the main building service will not interfere with the operation of fire pump equipment, emergency or legally required standby electrical systems, optional standby electrical systems, or parallel power production systems.

Special permission is required for the installation of more than one service. Expansion of buildings, shopping centers, or industrial plants often necessitates the addition of one or more new services. It may, for example, be impractical or impossible to install one service for an industrial plant with capacity requirements to compensate for any and all future load requirements. It is also impractical to run feeders for extremely long distances, because of high costs and voltage drop problems.

More than one service is allowed for different characteristics, such as different voltages, frequencies, single-phase or three-phase services, or different utility rate schedules. For example, different service characteristics exist between a three-wire, 120/240-V single-phase service and a three-phase, four-wire, 480Y/277-V service. For different rate schedules, a second service is allowed to supply a second meter for specific equipment, such as an electric water heater.

Parallel underground conductors, 1/0 AWG or larger that are connected together at their supply end and at their load end, are considered to be *one* service lateral. These conductors are permitted to supply up to six service disconnecting means installed at one location in a group, as required by *NEC* Section 230.71(A).

All feeder and branch-circuit conductors must be separated from service conductors. Service conductors are not provided with overcurrent protection where they receive their supply; they are protected against overload conditions at their load end by the service disconnect fuses or circuit breakers. The amount of current that could be imposed on feeder or branch circuit conductors, should they be in the same raceway and a fault occurs, would be much higher than the ampacity of the feeder or branch-circuit conductors.

The *NEC* requires that means be provided for disconnecting all conductors in the building from the service entrance conductors. The object is to permit disconnection of all conductors of the service at that location with no more than six operations of the hand (Figure 8.13.2). This requirement applies to all of the service disconnecting means located, or grouped, in one place and each disconnect must be marked to indicate the load served. It does not include service disconnecting means for fire pumps, legally required standby services, or optional standby services, which the *NEC* recognizes as being separate services for specific purposes. These must be sufficiently remote from the one to six service disconnecting means for normal service to minimize the possibility of simultaneous interruption of supply to the building or structure.

The disconnecting means can be either outside or inside the building served and must be at a readily accessible location nearest the point of entrance of the service entrance conductors. It cannot be in a bathroom. A remote-control device may be used to actuate the service disconnecting means, if it is located in a readily accessible location. Service entrance conductors must be of sufficient size to carry the calculated load.

No maximum distance is specified from the point of entrance of the service conductors to the service disconnecting means. The authority enforcing the *NEC* has the responsibility for, and is charged with, deciding how far inside the building the service entrance conductors are allowed to travel before reaching the main disconnecting means.

The length of service entrance conductors should be kept to a minimum inside buildings, because power utilities provide limited overcurrent protection and, in the event of a "fault," the

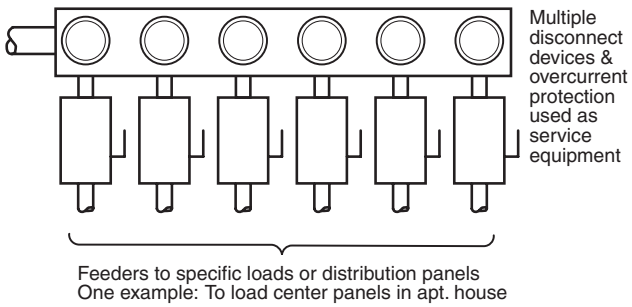

FIGURE 8.13.2 Typical Layout for Multiple Disconnecting Means

service conductors could ignite nearby combustible materials. Some local jurisdictions have ordinances that allow service entrance conductors to run within the building up to a specified length to terminate at the disconnecting means. The authority having jurisdiction (AHJ) may permit service conductors to pass by fuel storage tanks or gas meters to permit the service disconnecting means to be located in a readily accessible location. However, if the authority judges the distance to be excessive, the disconnecting means may be required to be located on the outside of the building or near the building at a readily accessible location that is not necessarily nearest the point of entrance of the conductors.

One set of service entrance conductors, either overhead or underground, is permitted to supply two to six service disconnecting means in lieu of a single main disconnect. A single-occupancy building can have up to six disconnects for each set of service entrance conductors. Multiple-occupancy buildings (residential or other than residential) can be provided with one main service disconnect or up to six main disconnects for each set of service entrance conductors.

Multiple-occupancy buildings may also have service entrance conductors run to each occupancy, with each such set of service entrance conductors having from one to six disconnects.

Where service entrance conductors are routed outside the building, each set of service entrance conductors is permitted to supply not more than six disconnecting means at each occupancy of a multiple-occupancy building. Conductors are considered outside a building where installed under not less than 2 in. (50 mm) of concrete beneath a building or in a raceway encased by 2 in. (50 mm) of concrete or brick within a building. They are also considered outside the building where installed in a transformer vault (Figure 8.13.3).

Service entrance conductors, overhead or underground, are the supply conductors between the point of connection to the service drop or service lateral conductors and the service equipment. Service equipment is intended to constitute the primary means of controlling and disconnecting the electrical supply to the premises' wiring system. At this point, an overcurrent device, which usually consists of circuit breakers or a set of fuses, is required to be installed in series with each ungrounded service conductor.

The service overcurrent device will not protect the service conductors under conditions of short circuit or ground fault on the line side of the disconnect. A degree of protection under these overcurrent conditions is provided by the special requirements applicable to locating and physically protecting the service conductors.

Figure 8.13.4 illustrates the wiring and components of a fire pump circuit designed to comply with the *NEC* and NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection.* Note that the service head protects the conductors

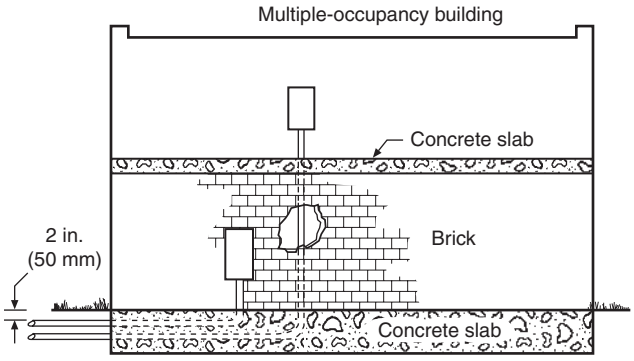

FIGURE 8.13.3 Conductors Installed Under Concrete Beneath a Building or in a Raceway of Concrete or Brick Within a Building

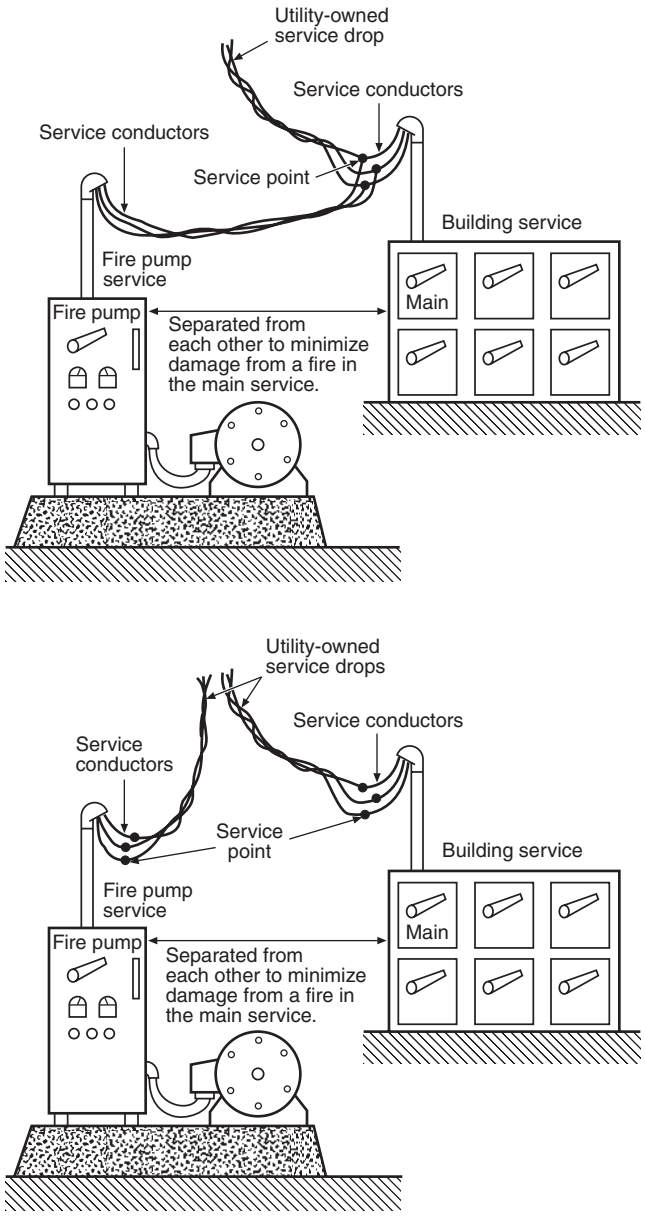

FIGURE 8.13.4 Methods of Connecting Utility-Owned Service Drop Conductors to the Service Entrance Conductors Supplying the Building and Fire Pump Services

against the entrance of water and that the point of connection of the service entrance conductors is below the level of the service head. The pump motor represented is a 100-hp, 460-V, three-phase, squirrel-cage induction type, and its full-load current, taken from *NEC* Table 430.250, is 124 A.

The service conductors, feeder conductors, and branch-circuit conductors are sized for 125 percent of the motor's full-load current rating (124 A at 125 percent = 155 A). According to *NEC* Table 310.16, the appropriate copper wire size for 155 A is a 2/0 AWG, XHHW conductor, which has an allowable ampacity of 175 A; therefore, all the conductors would be sized at not less than 2/0 AWG, XHHW copper. Where the voltage drop at the controller under starting conditions exceeds 15 percent, conductors with an ampacity greater than 155 A are necessary. The locked-rotor current of the motors in the installations illustrated in Figure 8.13.4 is 725 A, derived from *NEC* Table 430.51(B). The power supply protection may consist of either fuses or circuit breakers sized to carry locked-rotor current. In either case, the next standard ampere rating for fuses or circuit breakers is 800 A. Most fire pumps rated 100 hp and over would require a disconnecting means rated at 1000 A or more. However, due to the emergency nature of their use, fire pumps are exempt from the following ground-fault provisions.

Ground-Fault Protection for Equipment (GFP)

Ground-fault protection of equipment (GFP) should not be confused with ground-fault circuit-interrupter protection for personnel (GFCI). Ground-fault protection of equipment on services rated 1000 A or more, operating at 480Y/277 V, was first required in the 1971 *NEC* because of the unusually high number of burndowns that were reported for this type of service. Alternating current, due to its sine wave characteristics, can be a dangerous source of ignition that can ignite combustibles and start a fire. Where the voltage is greater than 250 V to ground, even though the voltage sine wave decreases to zero, the voltage can cause a restrike of the arc, causing continuation of burning at the ground-fault location.

Ground-fault protection of services will not protect the conductors on the supply side of the service disconnecting means, but is designed to provide protection from line-to-ground faults that occur on the load side of the service disconnecting means. An alternative to installing ground-fault protection may be to provide multiple disconnects rated less than 1000 A. For instance, up to six 800 A disconnecting means may be used, and, in this case, ground-fault protection would not be required. The second fine print note (FPN) in *NEC* Section 230.95(C) recognizes that ground-fault protection may be desirable at lesser amperages on solidly grounded systems for voltages exceeding 150 V to ground, but not exceeding 600 V phase-to-phase.

The maximum setting for ground-fault sensors is 1200 A; however, there is no minimum, and it should be noted that setting at lower levels increases the likelihood of nuisance tripping. The *NEC* requirements place a restriction on fault currents greater than 3000 A and limit the duration of the fault to not more than 1 second. This limit will minimize the amount of damage done by an arcing ground fault, which is directly proportional to the time it is allowed to burn.

Where interconnection is made between multiple-supply systems or multiple buildings, care should be taken to ensure that the interconnecting of different systems or buildings does not negate the proper ground-fault sensing by the ground-fault protection equipment. A careful engineering study should be made to ensure that fault currents do not take parallel paths back to the supply system, thereby bypassing the ground-fault detection device.

Physical Protection

Underground service conductors must be protected against physical damage (Figure 8.13.5). Tables 8.13.11 and 8.13.12 give minimum cover requirements for underground installations. (Cover is defined as the shortest distance in millimeters measured between a point on the top surface of any direct buried conductor, cable, conduit, or other raceway and the top surface of finished grade, concrete, or similar cover.)

For circuits over 600 V, there are variations in burial depths shown in Table 8.13.12, under certain circumstances. For example, the burial depth beneath areas subject to vehicular traffic is 24 in. (600 mm). Under airport runways and adjacent areas, the burial depth must be a minimum of 18 in. (450 mm). Lesser burial depths are permitted where access is necessary, or where termination or splicing points are located.

Lightning (Surge) Arresters—Building Wiring

Lightning and surge arresters are not required but may be used, particularly where buildings are supplied by an overhead service and where thunderstorms are prevalent in the area. (See NFPA

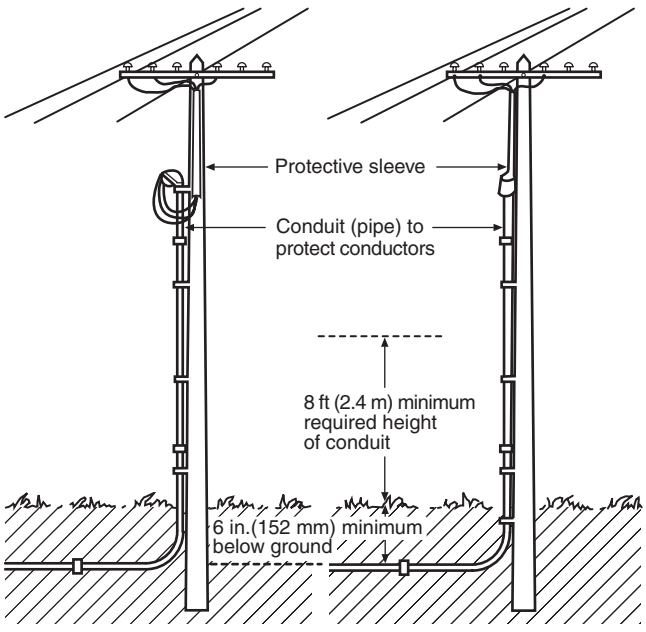

FIGURE 8.13.5 Two Different Configurations Permitted for Connecting to Electric Utility–Owned Service Drops

TABLE 8.13.11 Minimum Cover Requirements, 0 to 600 V, Nominal, Burial in Inches (Millimeters)

	Type of Wiring Method or Circuit									
	Column 1 Direct Burial Cables or Conductors		Column 2 Rigid Metal Conduit or Intermediate Metal Conduit		Column 3 Nonmetallic Raceways Listed for Direct Burial Without Concrete Encasement or Other Approved Raceways		Column 4 Residential Branch Circuits Rated 120 Volts or Less with GFCI Protection and Maximum Overcurrent Protection of 20 Amperes		Column 5 Circuits for Control of Irrigation and Landscape Lighting Limited to Not More Than 30 Volts and Installed with Type UF or in Other Identified Cable or Raceway	
Location of Wiring Method or Circuit	*in.*	*mm*	*in.*	*mm*	*in.*	*mm*	*in.*	*mm*	*in.*	*mm*
All locations not specified below	24	600	6	150	18	450	12	300	6	150
In trench below 2-in. (50-mm) thick concrete or equivalent	18	450	6	150	12	300	6	50	6	50
Under a building	0 (in raceway only)	0	0	0	0	0	0 (in raceway only)	0	0 (in raceway only)	0
Under minimum of 4-in. (102-mm) thick concrete exterior slab with no vehicular traffic and the slab extending not less than 6 in. (152 mm) beyond the underground installation	18	450	4	100	4	100	6 (direct burial) 4 (in raceway)	150 100	6 (direct burial) 4 (in raceway)	150 100
Under streets, highways, roads, alleys, driveways, and parking lots	24	600	24	600	24	600	24	600	24	500
One- and two-family dwelling driveways and outdoor parking areas, and used only for dwelling-related purposes	18	450	18	450	18	450	12	300	18	450
In or under airport runways, including adjacent areas where trespassing is prohibited	18	450	18	450	18	450	18	450	18	450

Notes:
1. Raceways approved for burial only where concrete encased shall require concrete envelope not less than 2 in. (50 mm) thick.
2. Lesser depths shall be permitted where cables and conductors rise for terminations or splices or where access is otherwise required.
3. Where one of the wiring method types listed in columns 1–3 is used for one of the circuit types in columns 4 and 5, the shallower depth of burial shall be permitted.
4. Where solid rock is encountered, all wiring shall be installed in metal or nonmetallic raceway permitted for direct burial. The raceways shall be covered by a minimum of 2 in. (50 mm) of concrete extending down to rock.

780, *Standard for the Installation of Lightning Protection Systems*). Surge arresters are required to be installed on electric and telephone services and on radio and television antenna lead-ins. Installation of such devices serves to minimize damage to solid-state electronic equipment, because such equipment is very sensitive to voltage surges.

Each lead-in from an outdoor antenna to a radio or television set or to an amateur radio transmitting station needs protection from lightning. Antenna discharge units should be installed to provide lightning protection for the equipment. Additional protection from power line surges or from connected communications equipment may also be desirable.

Grounding Requirements—Building Wiring

Dangerous voltages that constitute a fire hazard and a personal injury (shock) hazard can be imposed on electric distribution systems and equipment by lightning, inadvertent contact between low-voltage conductors and a high-voltage primary system, breakdown of insulation in transformers, surface leakage due to dirt or moisture, or by a wire coming loose from its connection.

Grounding one conductor of the electrical system and then grounding all exposed noncurrent-carrying metal parts of the electrical installation that might accidentally come in contact with an ungrounded circuit conductor ensures that a low-resistance path is provided for fault current to actuate the fuse or circuit breaker. The fault current finds a path through the equipment grounding conductor and can cause the operation of an overcurrent device (fuse or circuit breaker) in the ungrounded circuit conductor, thereby eliminating the dangerous condition. The impedance of the fault path must be low enough to permit sufficient current flow to cause the overcurrent device to operate quickly.

The metal enclosures of conductors (metal armor of cables, metal raceways, boxes, cabinets, and fittings) must be grounded. (Article 250 of the *NEC* contains general requirements for grounding electrical installations.) The *NEC* also requires

grounding of exposed noncurrent-carrying metal parts of equipment likely to become energized, where the equipment is operated by persons standing on the ground or on metal surfaces, or where it is operated at more than 150 V to ground. In some cases, the metal frames of electrically heated appliances should also be grounded. The *NEC* also specifies grounding of cord- and plug-connected appliances. These appliances include refrigerators, freezers, air conditioners, clothes washers and dryers, dishwashers, sump pumps, electric aquarium equipment, and portable handheld motor-operated tools—for example, hedge clippers, lawn mowers, snow blowers, and wet scrubbers. Appliances may be exempt from grounding if equivalent protection via double insulation is provided.

If available on the premises at each building or structure served, each item in *NEC* Section 250.52(A)(1) through (A)(6) must be bonded together to form the grounding electrode system. Where none of these electrodes is available, one or more of the electrodes specified in *NEC* Section 250.52(A)(4) through (A)(7) must be used.

A metal underground water pipe with at least 10 ft (3.0 m) of pipe in direct contact with the earth can be used as the grounding electrode (including any metal well casing effectively bonded to the pipe). Interior metal water piping more than 5 ft (1.5 m) from the point of entrance to the building is not allowed to be used as part of the grounding electrode system or as a conductor to interconnect electrodes that are part of the grounding electrode system. However, a metal underground water pipe grounding electrode must be supplemented by an additional electrode of the type specified in *NEC* Section 250.52(A)(2) through (A)(7), in the event that the metal water pipe is replaced by a nonmetallic pipe, thereby maintaining the integrity of the grounding electrode system.

Electrodes permitted for grounding are listed in the *NEC,* Section 250.52(A), and they are (1) metal underground water pipe, (2) metal frame of the building or structure, (3) concrete-encased electrode, (4) ground ring, (5) rod and pipe electrode, (6) plate electrode, and (7) other local metal underground systems or structures.

An example of a grounding electrode is shown in Figure 8.13.6. Piping should be inspected to ensure that there are no intervening insulating joints that might isolate it from the earth. Effective bonding jumpers must be provided around any insulated joints and sections and around any equipment that is likely to be disconnected for repairs or replacement.

Figure 8.13.6 shows an electrical system service neutral conductor grounded by connection to a metal water pipe and supplemented with a driven ground rod. The metal parts of the service equipment are allowed to be grounded by bonding to the neutral (grounded) conductor. The service enclosure is bonded to the grounded neutral conductor at point "B." This connection is often a removable strap or green-colored screw. The service raceway (conduit) is grounded through the metal of the panelboard. Because service equipment is not protected by an overcurrent device, a bonding jumper is one of the methods employed to ensure electrical continuity at service equipment; this electrical connection is indicated at "A." The meter box on the line side of the service equipment is usually grounded by means of the neutral terminal being bonded directly to the meter box and would be required where service-entrance cable is used. The upper portion of the service raceway or cable is grounded through threaded connections to the meter box where metal conduit or electrical metallic tubing is used. The conduit between the meter and panelboard may be grounded by bonding to the meter enclosure or bonding to the panelboard. The branch circuit equipment grounding conductor is connected to ground through the equipment grounding terminal block, which is grounded at point "C." This connection is commonly the mounting screw for this terminal block. The grounding connection shown is an underground water piping system. The connection should be as required by the *NEC.*

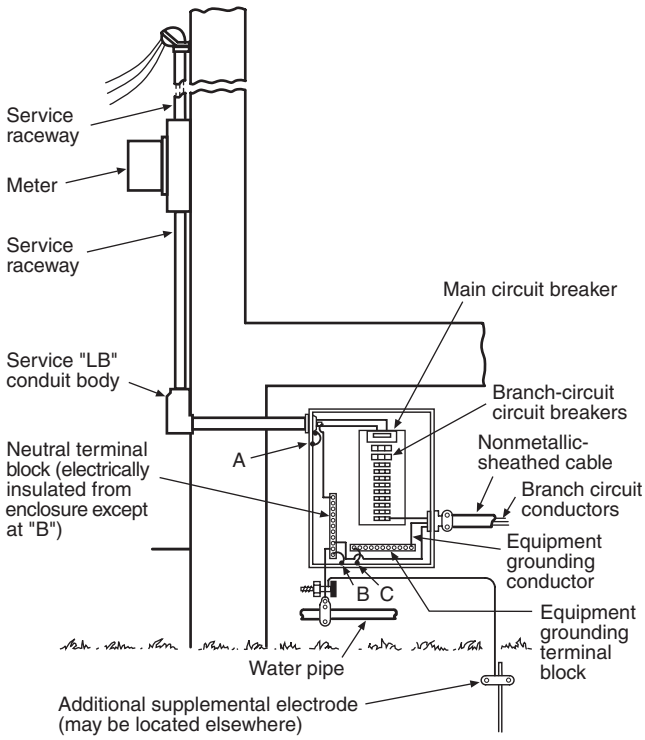

FIGURE 8.13.6 Grounding at a Typical Small Service (ac, Single-Phase, Three-Wire [120/240 V])

Panelboards and Overcurrent Protection—Building Wiring and Equipment

Panelboards. A panelboard consists of an assembly that may include switches, fuses, or circuit breakers that are mounted on copper or aluminum bus-bars, whose function is the control and protection of light, heat, or power circuits. The buses are mounted in a cabinet or cutout box, which may be placed in or on a wall and is accessible only from the front.

The *NEC* does not allow a lighting and appliance branch-circuit panelboard to have more than 42 overcurrent devices installed in any one cabinet or cutout box. Lighting and appliance panelboards are not allowed to have more than two main circuit breakers or two main sets of fuses to protect the buses in a lighting and branch-circuit panelboard (Figures 8.13.7 and 8.13.8). Figures 8.13.9 and 8.13.10 show exceptions to the general rule

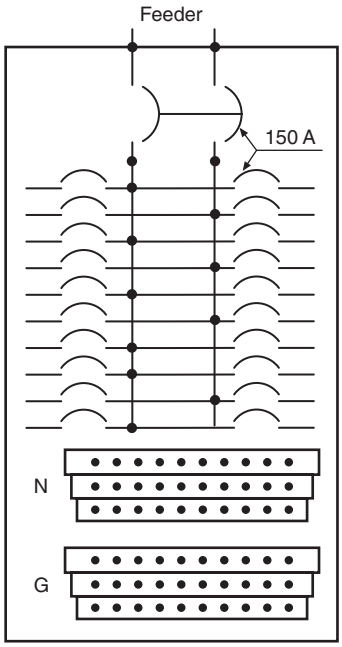

FIGURE 8.13.7 One Main Provided (Two Permitted). Grounding terminal block may not be required, depending on wiring system used.

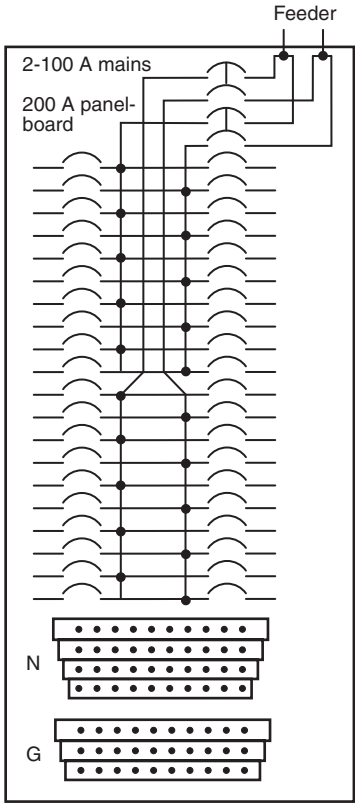

FIGURE 8.13.8 Two Mains Required. Grounding terminal block may not be required, depending on wiring system used.

for individual protection of panelboards. The arrangement shown in Figure 8.13.10 is acceptable only for the service to an existing individual residential occupancy where the panelboard was installed prior to application of the 1981 *NEC* requirements.

Panelboards installed in wet locations need weatherproof cabinets and must be mounted so that there is at least ¼ in. (6 mm) of airspace between the cabinet and the wall or other

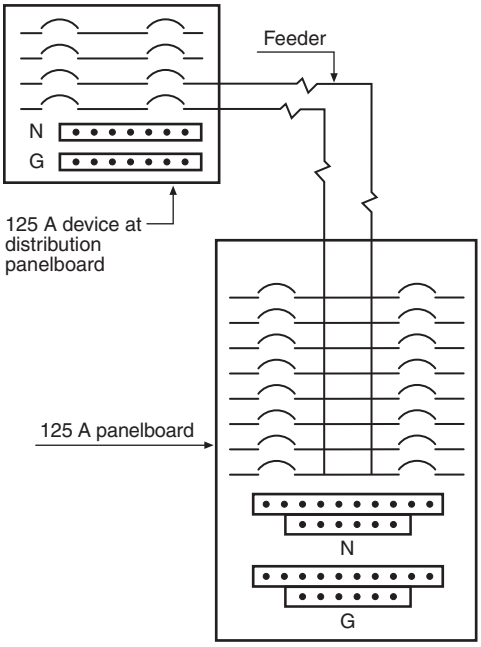

FIGURE 8.13.9 No Mains Required. Grounding terminal block may not be required, depending on wiring system used.

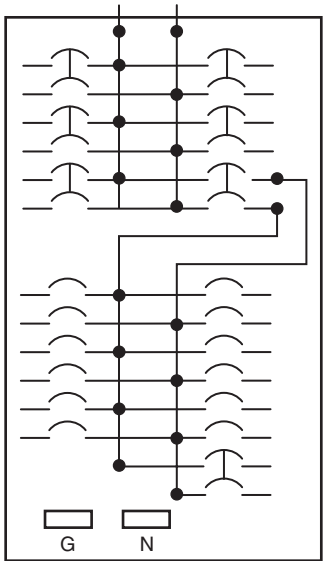

FIGURE 8.13.10 One Service Circuit Breaker in Upper Section Serving as the Main for Lower Section Buses Supplying Branch Circuits

supporting surface. Where located in corrosive atmospheres, equipment must be suitable for the conditions. Special requirements in Chapter 5 of the *NEC* govern installation of panelboards in hazardous (classified) locations.

Overcurrent Protection. Conductors are provided with overcurrent protection to open the circuit, if the current is greater than the value that will cause the conductor's temperature to exceed the temperature of its insulation. Equipment also needs overcurrent protection to minimize the effects of an electrical fault within the equipment, thereby reducing the amount of arcing and ejection of hot metal. No feature of an electrical installation deserves more careful attention and supervision. In general, overcurrent devices should be rated or set in accordance with the tables for conductor ampacity, as shown in Tables 8.13.1 through 8.13.8. They should be installed in each ungrounded conductor of each circuit and feeder, at the point where the conductor to be protected receives its supply. Fixture wires, cords, taps, motor circuits, remote-control circuits, and fire-protective signaling circuits are covered in Articles 240, 430, 725, and 760 of the *NEC*.

Overcurrent Protective Devices

The most commonly used overcurrent protective devices for feeders, circuits, and equipment are fuses and circuit breakers. (Overcurrent and undervoltage relays, and so on, are used on high-voltage, high-current systems.) Thermal motor running overload sensing devices are not considered to be overcurrent protection but are used in the same manner.

Plug Fuses. There are two basic types of plug fuses: (1) the ordinary Edison-base type and (2) the Type S. Either of these may incorporate time delay. An Edison-base fuseholder will take an Edison-base fuse of any size up to a maximum 30 A rating. Plug fuses of the Edison-base type are allowed only for replacements in existing installations where there is no evidence of tampering.

The Type S fuse is designed to minimize tampering or bridging. Adapters are available that fit the Edison-base fuseholders and that, once properly installed, cannot be removed without damaging the fuseholder. The adapters are designed to prevent the use of Edison-base fuses in the fuseholder and to prevent the use of a higher rated Type S fuse in an adapter designed for a lower rating. They also prevent the use of pennies and other common bypassing schemes.

Time-Delay Plug Fuses. Whether of Type S or Edison-base design, time-delay fuses permit short-time current surges, such as motor starting currents, without interruption of the circuit. These momentary surges are harmless unless repeated a number of times at short intervals. This function makes it possible to use Type S fuses in sizes small enough to give better protection than a non-time-delay type, which must be oversized to allow for such surges. In the case of a short circuit or a high-current fault, however, the time-delay type will operate and open the circuit as rapidly or even more rapidly than the non-time-delay type. A representative plug fuse is shown in Figure 8.13.11. The

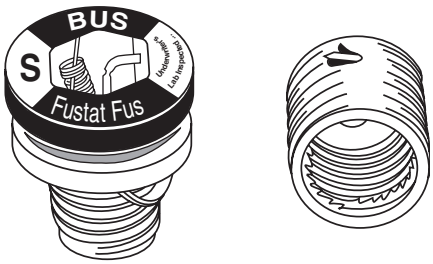

FIGURE 8.13.11 Type S Nonrenewable Fuse (Source: Cooper Bussman)

time-lag type of fuse shown in Figure 8.13.11 is acceptable but not required by the *NEC*. These fuses have been designed to minimize tampering or bridging. The *NEC* specifies that fuseholders for plug fuses of 30 A or less must not be used unless they are designed to accept a Type S fuse or to accept a Type S fuse through use of an adapter.

Cartridge Fuses. Cartridge fuses are of both the time-delay and the non-time-delay types. They are also of the one-time and the renewable link types. When a one-time fuse opens, the entire fuse must be replaced. But when a renewable link fuse opens, the fuse link can be replaced inside the same cartridge unless the cartridge has also been damaged.

Renewable link fuses have two disadvantages: (1) the links can be doubled, tripled, and so on, thereby defeating their purpose and usefulness; and (2) the links, on replacement, can be left with loose connections. A representative cartridge fuse is shown in Figure 8.13.12.

Circuit Breakers. There are two basic types of breakers: (1) adjustable trip and (2) nonadjustable trip. The adjustable-trip type may be of either the air- or oil-immersed type. The setting of the trip point is adjustable between a minimum and a maximum range. This type is usually used only on large installations having qualified operators and maintenance personnel. They are designed to trip when the current reaches that of the setting. The nonadjustable-trip type comes in a molded case, making it extremely difficult or impossible to change its rating. A

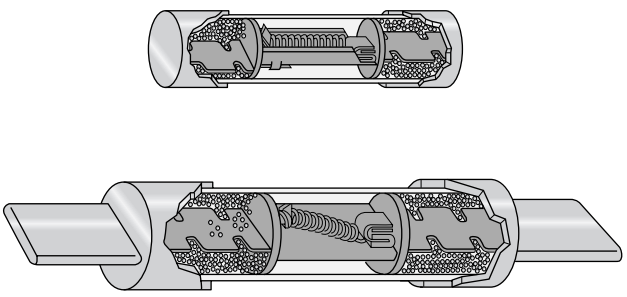

FIGURE 8.13.12 A Fusetron Cartridge-Type Fuse (Source: Cooper Bussman)

molded-case breaker can be of the inverse-time thermal-magnetic type or of the magnetic-only inverse-time type. Inverse-time thermal-magnetic breakers consist of two elements: (1) an electro-magnetic trip element that trips quickly on high fault current and (2) a bimetallic trip element that provides a time delay. Molded-case circuit breakers are designed so that the current has to exceed the rating (as is also true with all types of fuses) before it will trip. Unless it is the thermally compensated type, high ambient temperatures can reduce the current required to trip the circuit breaker (or fuse). A representative nonadjustable circuit breaker is shown in Figure 8.13.13.

Thermal Devices. These are not intended for protection against short circuits, but only for the protection of overload currents of a comparatively lower magnitude unless otherwise designed. An example is overload protection for a motor where short-circuit and ground-fault protection is provided by the branch-circuit fuses or circuit breakers and motor running overload protection is provided by the thermal relay. Another thermal device is the type used in recessed luminaires (lighting fixtures), which temporarily opens the circuit when the luminaire (fixture) exceeds a predetermined temperature. For detailed requirements for motors and other equipment, see Articles 410 and 430 of the *NEC*.

Current-Limiting Overcurrent Protective Devices. These devices are provided in some installations where high current (more than 10,000 A) is available under short-circuit conditions. They are designed so that, when interrupting a specified current, they will consistently limit the short-circuit current in that circuit to a magnitude substantially less than that obtainable in the same circuit if the device were replaced with a solid conductor having comparable impedance (Figure 8.13.14). Fuseholders for current-limiting fuses are designed to make it difficult to install a noncurrent-limiting fuse.

Ground-Fault Circuit Interrupters (GFCI)

Circuit breakers and fuses open a circuit and stop the flow of electricity when the current flow exceeds their ratings. Lighting and receptacle circuits are usually rated 15 or 20 A. Under certain conditions, as little as 20 mA can kill a normal healthy adult; thus, the rating of lighting and receptacle circuits is high, relative to the amount of current that could kill a person.

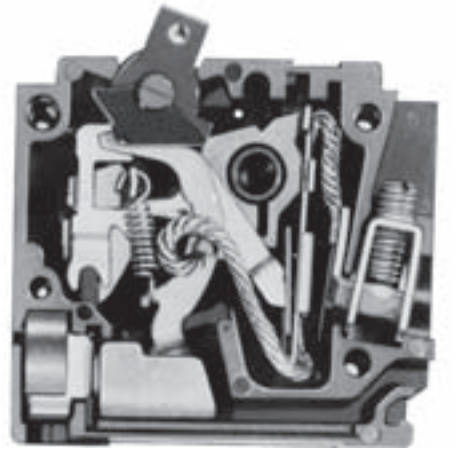

FIGURE 8.13.13 15-A, Single-Pole, 120-V Branch-Circuit Breaker (Source: Eaton's Cutler-Hammer Business)

FIGURE 8.13.14 Class R Current-Limiting Fuses with Rejection Feature to Prohibit Installation of Non-Current-Limiting Fuses (Source: Cooper Bussman)

Ground-fault circuit interrupters (GFCIs) are devices that sense when even a small amount of current passes to the ground through any path other than the proper conductor. When this condition exists, the GFCI trips almost instantly, stopping all current flow in the circuit, including through a person who might be in contact with it.

Simplicity of design is one reason for the reliability of the GFCI. Figure 8.13.15 shows a typical circuit arrangement of a GFCI for personnel protection. Figure 8.13.16 shows types of GFCI units and a GFCI tester.

Currently available GFCIs are set to operate when line-to-ground currents exceed 5 mA. Evaluation standards permit a differential of 4 to 6 mA. Even at trips of 5 mA, it should be clearly understood that the instantaneous current will be higher and any shock during the time the fault is being cleared will be

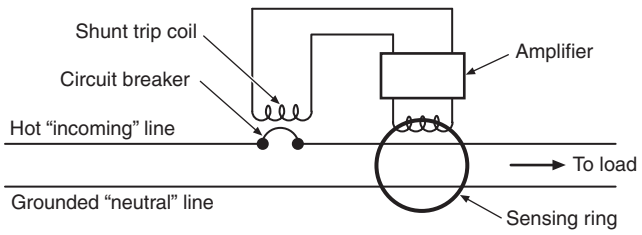

FIGURE 8.13.15 Circuit Arrangement for a Typical Ground-Fault Circuit Interrupter for Personnel Protection

(b)

(c)

FIGURE 8.13.16 (a) Portable Plug-In Type of GFCI; (b) Raintight GFCI with Open Neutral Protection for Use on Line End of a Flexible Cord; (c) 15 A Duplex Receptacle with Integral GFCI That Also Protects Downstream Loads (Source: Pass & Seymour/Legrand®)

uncomfortable. The key to the ground-fault circuit interrupter is its time-current characteristic. Trip-out time is about ¼₀ of a second (25 msec) when the fault reaches or exceeds 6 mA.

There are two classes of GFCIs—Class A and Class B. The Class A GFCI trips at not more than 6 mA. The Class B GFCI trips when the current exceeds 20 mA and is for use only with swimming pool underwater lighting fixtures that were installed prior to local adoption of the 1965 edition of the *NEC*. The Class A GFCI is used where personnel protection against ground fault is required or desired.

GFCIs at Construction Sites. All 125 V, single-phase, 15-, 20-, and 30-A receptacle outlets must have GFCI protection for personnel or an assured equipment grounding conductor program. Precautions must be taken to aid the efficient operation of GFCIs on construction sites. Most laboratory-tested 120 V appliances have 0.5 mA leakage or less under normal operating conditions. However, moisture and improper maintenance on portable handheld tools, which is common at construction sites, can create conditions under which GFCIs can be expected to trip. Flexible cords with standard attachment plug cap and connector, when dropped in water (e.g., puddles), can be expected to cause leakage currents of 100 to 300 mA or greater, far in excess of GFCI trip currents. Motors with dirty brushes, carbon tracking on commutators, or moisture in the windings contribute to leakage current. A commonsense approach to installing, using, and maintaining GFCI circuits goes a long way toward eliminating nuisance tripping at construction sites. (Actually, tripping under any of the conditions mentioned is not nuisance tripping, but merely a device performing its intended function.)

Moisture is the major culprit in current leakage on wiring and equipment. Panelboards, receptacles, and cord caps and connectors intended for dry locations must not be subjected to wet conditions.

GFCIs in Residential and Commercial Occupancies. The *NEC* requires ground-fault protection for personnel (i.e., a GFCI) on all 125 V, single-phase 15- and 20-A receptacles installed in the following locations in dwelling units: bathrooms, garages and accessory buildings that have a floor at or below grade level not intended as habitable rooms and limited to storage areas, work areas and areas of similar use, the outdoors, unfinished basements, crawl spaces that are at or below grade level, boathouses, receptacles that are installed to serve kitchen countertop surfaces, and receptacles that are located within 6 ft (1.8 m) of the outside edge of a wet-bar sink.

A single or duplex receptacle does not need GFCI protection if (1) it is located within a dedicated space for an appliance that is not easily moved from one location to another and is cord- and plug-connected or (2) it is not readily accessible and supplied by a dedicated circuit for snow-melting or de-icing equipment. In other than dwelling units, receptacles that are installed must have GFCI protection for personnel in all bathrooms and rooftops.

All 125 V receptacles, whether of the parallel blade or twist locking type, that are located within 20 ft (6 m) of a swimming pool, fountain, or outdoor spa or hot tub are required to be GFCI protected. Where spas or hot tubs are installed indoors, receptacles that provide power to the spa or hot tub must be GFCI

protected. Hydromassage bathtubs and their associated equipment are required to be GFCI protected, as well as any receptacles within 5 ft (1.5 m) of the tub. In addition, in all occupancy types, non-GFCI-protected receptacles that are replaced due to damage or other causes that were not previously required to be GFCI protected under previous *NEC* editions must be GFCI protected if the present *NEC* requires it.

Arc-Fault Circuit Interrupters (AFCIs)

Fixed wiring in homes accounted for 13,000 reported structure fires in 1998, with associated losses of 96 civilian deaths and 293 civilian injuries.[1] As early as the mid- to late 1980s, when home wiring fires were averaging 17,000, with more than 150 deaths a year, the U.S. Consumer Product Safety Commission (CPSC) identified arc-fault detection as a promising new technology. Since then, CPSC electrical engineers have tested arc-fault circuit interrupters (AFCIs) and found these devices to be effective.

AFCI Defined. An arc fault is an unintentional electrical discharge characterized by low and erratic current that is capable of igniting combustible materials. Although standard circuit breakers provide overload protection, short circuit protection, and (when specified) ground-fault protection for personnel, they do not provide protection against potential fire hazards that can result from low-level arcing faults.

An AFCI is a safety device that uses electronics to recognize the current and voltage characteristics of arcing faults and interrupts the circuit when the arcing fault occurs. The AFCI is expected to provide enhanced protection from fires resulting from these unsafe wiring conditions. AFCI technology was first used to protect the areas surrounding downed utility lines. Advances in electronic technology make arc-fault protection available for use on 125-V, 15- or 20-A branch circuits.

AFCIs are already recognized for their effectiveness in preventing fires. The current edition of the *NEC* will contain updated AFCI requirements.

Short Circuits and Arcing Faults. Short circuits, also known as faults, are usually high and rapid current flows. Conventional circuit protective devices quickly detect these short circuits. Arcing faults are characterized by low and erratic current flow. Due to these characteristics, arcing faults in damaged cords or cables can continue undetected by conventional circuit protective devices, thus creating hazardous situations such as ignition of nearby combustive materials.

There are three types of arc faults:

- A *parallel arc fault* is an arc resulting from direct contact of two conductors with opposite polarity (e.g., damaged extension cord).
- A *ground arc fault* is an arc between a single conductor and ground (e.g, improperly installed wall receptacle).
- A *series arc fault* is an arc across the break in a single conductor (e.g., cable pierced by a nail).

Arcing can occur and lead to fire in these and the following common situations:

- Deterioration of the insulation due to aging
- Extension cords caught in a doorjamb or crimped between a piece of furniture and a wall
- Deterioration of the cord's insulation by exposure to sunlight or a hot air duct
- Frayed appliance extension cords
- Appliances where the insulation of the internal wires are impaired
- Appliance wire damaged by constant use, bending, and abuse
- Wire stapled too tightly against a stud, severing or damaging insulation
- Overheated cords or wires
- Exposed stranded wiring on an old style plug caps, including frayed and loose wiring
- Receptacles that have loose connections

When unwanted arcing occurs, it generates high temperatures that can ignite nearby combustibles such as wood, paper, and carpets. The AFCI uses unique current sensing circuitry to discriminate between normal and unwanted arcing conditions. Once an unwanted arcing condition is detected, the control circuitry in the AFCI trips the internal contacts, thus de-energizing the circuit and reducing the potential for a fire to occur. An AFCI should not trip during normal arcing conditions, such as those that occur when a switch is opened or a plug is pulled from a receptacle. The AFCI circuit breaker provides protection for the branch-circuit wiring as well as power cords, extension cords, and internal wiring of equipment.

AFCIs can be installed in any single-pole 125 V, 15 or 20 A branch circuit and are currently available as built-in features to circuit breakers. In the near future, other types of devices with AFCI protection will be available. In homes equipped with conventional circuit breakers rather than fuses, an AFCI circuit breaker can be installed in the panel box in place of the breakers. Homes with fuses are limited to receptacle or portable-type AFCIs, which are expected to be available in the near future.

AFCI and GFCI Combination Devices

The AFCI should not be confused with the ground-fault circuit interrupter (GFCI). The GFCI is designed to protect people from severe or fatal electric shocks whereas the AFCI protects against fires caused by arcing faults. The GFCI also can protect against some electrical fires by detecting arcing and other faults to ground but cannot detect hazardous across-the-line arcing faults that can cause fires. Based on U.S. Consumer Products Safety Commission reports, combination devices that include both AFCI and GFCI protection in one unit will become available soon.

Leakage Current Detection and Interruption (LCDI)

The leakage current detection and interruption (LCDI) device is a protective device that is similar to an AFCI and is usually provided, by the manufacturer, in the power supply cord of a piece of equipment. The LCDI is designed to sense any damage in a power supply cord or cord set; if the cord or cord set is

damaged, current begins to leak from the conductor to the shield and interrupts the circuit at a predetermined level of leakage current. The plug-mounted electronics sense the current on the shield and disconnect power in less than 25 milliseconds, faster than a blink of the eye.

Electrical cord fires are a leading cause of residential fires in the United States. Extension cord fires have been and continue to be a major problem. There are many causes of cord fires, including consumer misuse, overload (which damages the insulation of the extension cord), overheating, and aging of the cord.

Consumer misuse is the most common and occurs in an assortment of ways, including leaving the cord to be crushed by pedestrian traffic or by furniture or other heavy items placed on top of the cord, stapling the cord to baseboards, running the cord under the carpet, or leaving it coiled for aesthetic reasons. When the cord is used as a permanent extension of premises wiring, as in the case of the overload condition, the insulation is damaged from the inside out.

Circuit breakers and fuses are designed to protect the fixed wiring. Breakers and fuses allow an overload to exist for a period of time, depending on its inverse-time trip curve; they do not provide overload protection for extension cords.

There are two primary types of cord faults. Series faults (the fault is in series with the load) are partially or completely severed conductors within the cord set. A parallel fault, either line to neutral or a ground fault, is typically caused by damaged insulation. Both of these faults will lead to carbon tracking within the cord set, leakage current, arcing, and then combustion.

Types of Wiring Methods and Materials

The *NEC* recognizes a number of standard wiring methods, some of which are suitable for general use whereas others are suitable only for special purposes. In some localities, regulations restrict the use of some of the wiring methods recognized by the *NEC*. The most widely used wiring methods are rigid metal conduit, rigid nonmetallic conduit, intermediate metal conduit (IMC), electrical metallic tubing (EMT), metal-clad cable (MC), armored cable (AC; trade name "BX"), nonmetallic sheathed cable (NM, NMC, NMS; trade name "Romex"), surface metal and nonmetallic raceways, wireways, busways, underfloor raceways, and cellular metal floor raceways (Figures 8.13.17 through 8.13.20). In some areas of the country, flexible metal conduit (trade name "Greenfield") is used for complete wiring systems. None of these wiring methods should be used for either temporary or permanent work where they do not fully conform to *NEC* safety requirements.

FIGURE 8.13.17 Type UF Sheathed Cable. The insulated conductors are jacketed in parallel and the overall covering must be flame retardant, moisture resistant, fungus resistant, corrosion resistant, and suitable for direct burial in the earth.

Identification of Conductors, Terminals, Circuits, and Branch Circuits

With few exceptions, all interior wiring systems have a grounded circuit conductor that is continuously identified throughout. The identification for conductors of 6 AWG or smaller (except for Type MI cable) should consist of an outer white or natural gray colored insulation. Insulated conductors larger than 6 AWG should have similar identification or be identified by distinctive white markings at their terminations during installation. The grounded conductors of Type MI cable

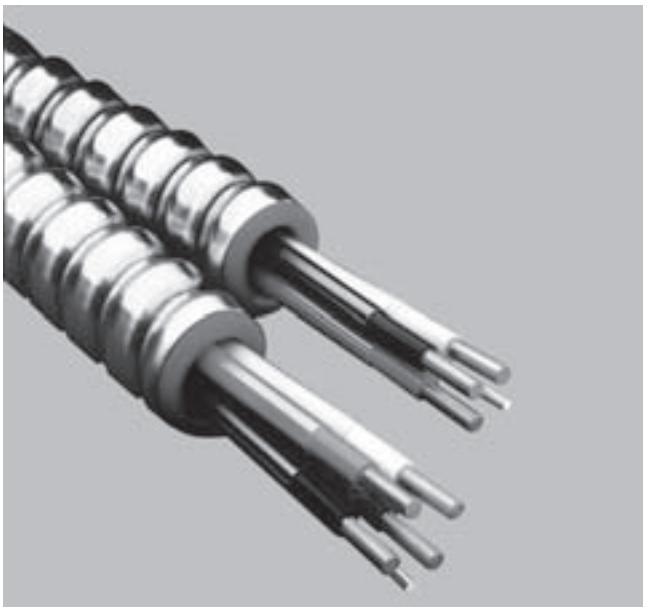

FIGURE 8.13.18 Type AC Cable (Source: AFC Cable Systems, Inc.)

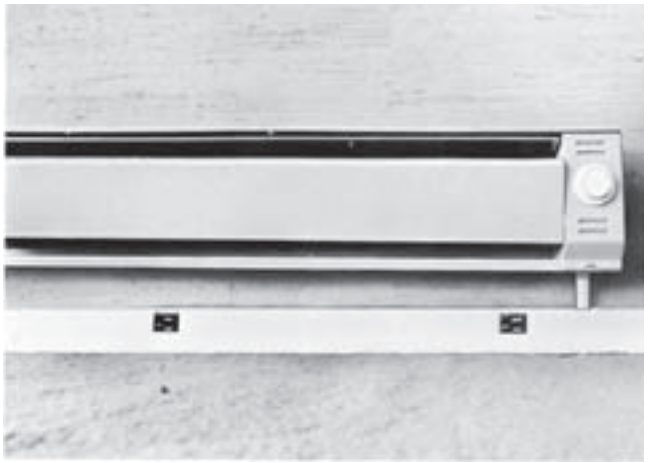

FIGURE 8.13.19 Installation of a Typical Metal Raceway System Showing an All-Steel Baseboard and a Multi-Outlet System (Source: The Wiremold Co.)

FIGURE 8.13.20 Multi-Outlet Assembly Installed to Serve Countertop Appliances (Source: The Wiremold Co.)

are also identified by distinctive markings at their terminations during installation.

In general, the terminals of electrical devices to which a grounded conductor is to be connected are identified by being made of metal substantially white in color, having a metallic plating substantially white in color, or having the word *white* located adjacent to the terminal. If the terminal is not visible, the conductor entrance hole may be colored white. In the case of screw-shell-type lampholders, the (white) terminal is the one that is connected to the screw shell.

Where a terminal is provided for the connection of an equipment grounding conductor, it must be designated by a green-colored hexagonal-head screw or nut, or, if the terminal is not visible, the conductor entrance hole must be marked with the word *green,* or the letter *G* or *GR,* or the grounding symbol (⏚).

Lighting and Appliance Branch Circuits

A branch circuit is that portion of a wiring system extending between the final overcurrent device protecting the circuit and the outlets on the circuit. Branch circuits are further defined as (1) a small-appliance branch circuit supplying one or more outlets to which appliances are to be connected that has no permanently connected luminaires (lighting fixtures) other than those that are part of the appliance, (2) a general-purpose branch circuit supplying two or more outlets for lighting and appliances, and (3) an individual branch circuit supplying only one utilization equipment.

The equipment grounding conductor of a circuit can be bare or insulated. Where it is insulated, it must be identified by a continuous green color or green with one or more yellow stripes. Conductors larger than 6 AWG that are insulated or covered must be identified by stripping the insulation from the exposed length, coloring the insulation green, or covering it with green tape or green adhesive labels.

Ungrounded conductors of different voltages are permitted to be of any color other than green, white, or natural gray. In some special applications, for example, isolated (ungrounded) power systems used in hospital operating rooms, the circuits are identified as follows: isolated conductor No. 1—orange; isolated conductor No. 2—brown.

Lampholders, where connected to branch circuits having a rating in excess of 20 A, must be of the heavy-duty type with a rating of not less than 660 W if of the admedium type, and not less than 750 W if of any other type.

Receptacles, when connected to circuits having two or more receptacles or outlets, must not supply loads greater than the values given in Table 8.13.13. They must not be supplied by circuits of ratings greater than the values listed in Table 8.13.14. Where larger than 50 A, the receptacle rating is not permitted to be less than the branch-circuit rating, except for motor loads.

Individual branch circuits may supply any loads. Branch circuits having two or more outlets may supply only loads as follows.

Branch circuits rated at 15 and 20 A are for lighting units or appliances. The rating of any one cord- and plug-connected appliance must not exceed 80 percent of the branch-circuit ampere

TABLE 8.13.13 Maximum Cord- and Plug-Connected Load to Receptacle

TABLE 8.13.14 Receptacle Ratings for Various Size Circuits

Circuit Rating (A)	*Receptacle Rating (A)*
15	Not over 15
20	15 or 20
30	30
40	40 or 50
50	50

Source: NFPA 70, *National Electrical Code,* 2005 edition.

rating. The total rating of fixed appliances must not exceed 50 percent of the branch-circuit ampere rating when lighting units or other appliances are also supplied.

Branch circuits rated at 40 and 50 A are permitted to supply fixed lighting units with heavy-duty lampholders, infrared heating units, or other utilization equipment in other than dwelling units. Branch circuits rated larger than 50 A may supply only nonlighting loads.

Receptacle outlets in dwelling occupancies, including guest rooms in hotels and motels, should be installed in every kitchen, family room, dining room, living room, parlor, library, den, sunroom, bedroom, recreation room, or similar room or area of dwelling units. Insofar as practical, the outlets should be spaced equal distances apart (Figure 8.13.21). Receptacles should be installed so that no point along the floor line is more than 6 ft (1.8 m), measured horizontally, from an outlet so as to permit a lamp or appliance equipped with a 6 ft (1.8 m) cord to be located anywhere along the wall, in the room.

In guest rooms of hotels, motels, and similar occupancies, the *NEC* allows the receptacle outlets to be located conveniently for permanent furniture layout, with at least two receptacle outlets in a readily accessible location. The total number of receptacle outlets cannot be less than the minimum number that would comply with the provisions of Section 210.52(A) of the *NEC*. Where receptacles are installed behind the bed, the receptacle must be located so that the bed does not contact any attachment plug that may be installed, or it must be provided with a suitable guard. (See the *NEC Handbook* for a better understanding of this requirement.)

Most appliances and portable lamps are provided with flexible cords at least 6 ft (1.8 m) in length. Countertop appliances for use in the kitchen are usually supplied with 2 ft (600 mm) cords. Therefore, the *NEC* requires receptacles to be installed so that no point along the wall is more than 2 ft (600 mm), measured horizontally, from a receptacle. All receptacles that serve countertop spaces are required to be GFCI protected (Figure 8.13.22).

Receptacles installed on 15- and 20-A branch circuits must be of the grounding type and must be effectively grounded. This does not mean that all cord- and plug-connected equipment must be of the grounded type. (See the current *NEC* for specific details on grounding.)

Calculation of Loads

The methods specified in the *NEC* provide a basis for calculating the expected branch circuit and feeder loads and for determining the number of branch circuits required. Where in normal operation the maximum load of a branch circuit will continue

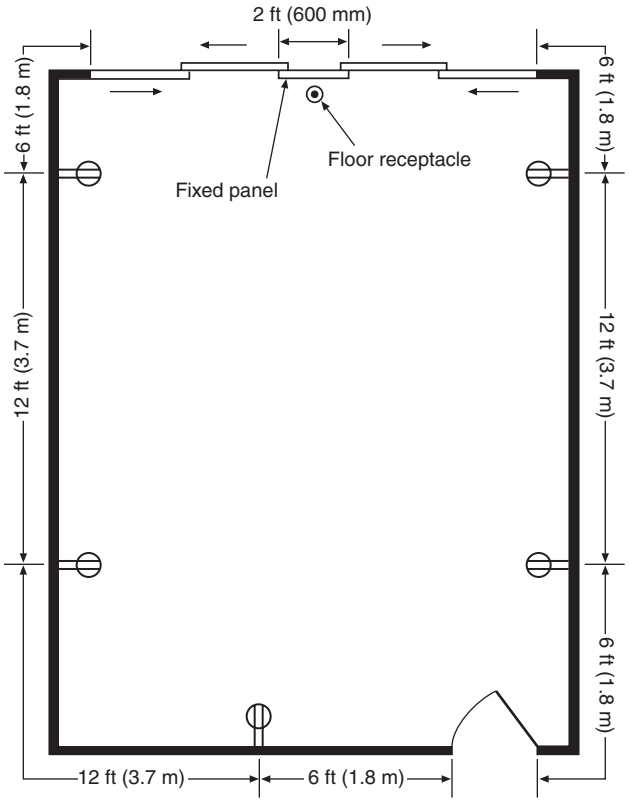

FIGURE 8.13.21 *NEC* Requirements on the Placement of Receptacles in Dwelling Occupancies

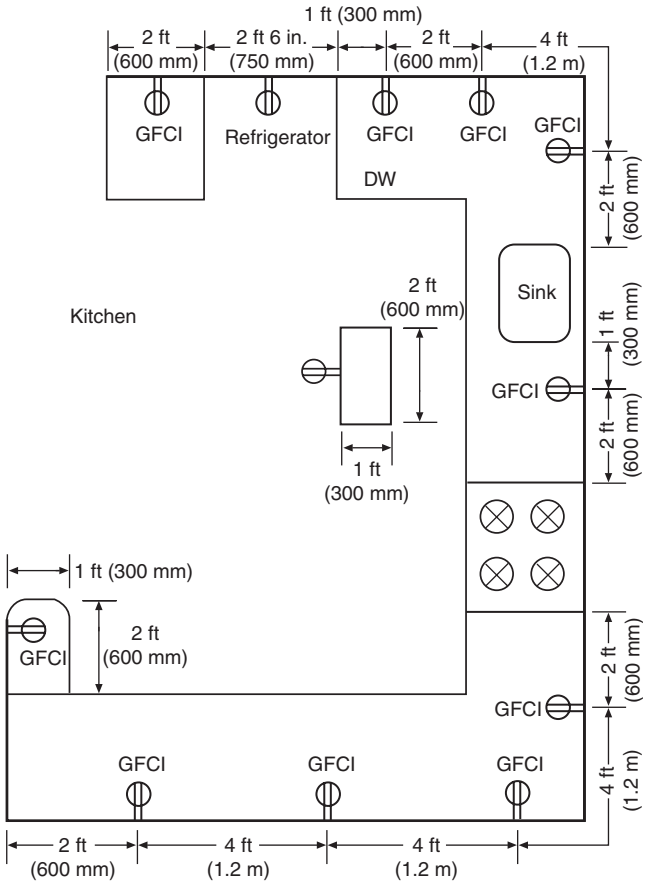

FIGURE 8.13.22 *NEC* Requirements on the Placement of Receptacles at Countertops and Islands in Kitchens and Dining Areas of Dwelling Units

for 3 hours or more, such as store or office lighting, the loads specified must be increased by 25 percent.

The minimum unit lighting loads in volt-amperes (VA) per square foot for various types of occupancies are given in Article 220 of the *NEC*. In determining the load, open porches and garages in connection with dwelling occupancies are not included. Unfinished and unused spaces in dwellings need not be included unless adaptable for future use.

For other than general illumination lighting, general-use receptacles, appliances, and loads other than motor loads, the following minimum unit load should be included for each outlet:

1. Outlets supplying specific appliances and other loads—ampere rating of appliance or load served
2. Outlets supplying heavy-duty lampholders—600 VA
3. Other outlets—180 VA (This does not apply to the small-appliance branch circuit.)

Feeder Loads

Feeder conductors must have sufficient ampacity to supply the load served. The computed load of a feeder must not be less than the sum of all branch-circuit loads supplied by the feeder, subject to the demand factor provisions of the *NEC*. Tables of demand factors for general illumination, electric ranges and other cooking appliances, and for clothes dryers are found in the *NEC*. Table 8.13.15 lists the demand factors that may be applied to that portion of the total feeder load computed for general illumination.

TABLE 8.13.15 Lighting Load Feeder Demand Factors

Type of Occupancy	*Portion of Lighting Load to Which Demand Factor Applies (VA)*	*Demand Factor Percent*
Dwelling units	First 3000 or less at	100
	From 3001 to 120,000 at	35
	Remainder over 120,000 at	25
Hospitals*	First 50,000 or less at	40
	Remainder over 50,000 at	20
Hotels and motels—including apartment houses without provision for cooking by tenants*	First 20,000 or less at	50
	From 20,001 to 100,000 at	40
	Remainder over 100,000 at	30
Warehouses (storage)	First 12,500 or less at	100
	Remainder over 12,500 at	50
All others	Total volt-amperes	100

*The demand factors of this table shall not apply to the computed load of feeders to areas in hospitals, hotels, and motels where the entire lighting is likely to be used at one time, as in operating rooms, ballrooms, or dining rooms.

Source: NFPA 70, *National Electrical Code,* 2005 edition.

An optional method of calculating the load for a single-dwelling unit served by a 120/240 V or 208/120 V system, with feeder or service conductors rated 100 A or greater, is to use the percentage values provided in Table 8.13.16.

Examples of branch-circuit and feeder calculations for other buildings and occupancies are given in Annex D of the *NEC*.

These calculations are not applicable to receptacle outlets required by the *NEC* for dwelling units. The 20 A small-appliance branch circuits and laundry branch circuits in dwelling units are calculated at 1500 VA per circuit. Other receptacle outlets rated 20 A or less in dwelling units are considered part of the general lighting load, based on the area and calculated at 3 VA per ft^2. For receptacle outlets in other than dwelling units, each single or multiple receptacle on a single yoke or strap is considered at not less than 180 VA.

An example from the *NEC* of how to calculate the load in a single-family dwelling is presented to illustrate the principles involved.

For a dwelling that has a floor area of 1500 ft^2 (457 m^2) (exclusive of an unoccupied cellar, unfinished attic, and open porches), a 12 kW range, and 5 kW clothes dryer, the load may be computed as follows:

General Lighting Load: 1500 ft^2 at 3 VA per ft^2 = 4500 VA.

Number of Branch Circuits Required

General Lighting Load:

4500 ÷ 120 = 37.5 A; 37.5 ÷ 15 = 2.5 or three 15 A, 2-wire circuits; or two 20 A 2-wire circuits.

Small-Appliance Circuit: Two 20 A, 2-wire circuits.

Laundry Circuit: One 20 A, 2-wire circuit.

TABLE 8.13.16 Optional Calculation for One-Family Dwelling Unit

Largest of the Following Five Selections

(1) 100 percent of the nameplate rating(s) of the air conditioning and cooling, including heat pump compressors.
(2) 100 percent of the nameplate ratings of electrical thermal storage and other heating systems where the usual load is expected to be continuous at the full nameplate value. Systems qualifying under this selection must not be figured under any other selection in this table.
(3) 65 percent of the nameplate rating(s) of the central electric space heating including integral supplemental heating in heat pumps.
(4) 65 percent of the nameplate rating(s) of electric space heating if less than four separately controlled units.
(5) 40 percent of the nameplate rating(s) of electric space heating of four or more separately controlled units.

Plus: 100 percent of the first 10 kVA of all other load. 40 percent of the remainder of all other load.

Source: NFPA 70, *National Electrical Code,* 2005 edition.

Minimum Size Feeders Required

Computed load	
General lighting	4500 VA
Small-appliance load	3000 VA
Laundry	1500 VA
Total (without range and dryer)	9000 VA
3000 VA at 100 percent	3000 VA
9000 – 3000 = 6000 VA at 35 percent =	2100 VA
Net Computed (without range and dryer)	5100 VA
Range load	8000 VA
Clothes dryer	5000 VA
Net Computed (with range and dryer)	18,100 VA

For 120/240 V system feeders 18,100 ÷ 240 = 75 A. Therefore, feeder size for total load may be selected on the basis of 75 A load. Net computed load exceeds 10 kVA, so service conductors must have a rating of 100 A.

Flexible Cords and Cables

Flexible cords are made for various kinds of service, ranging from wiring for portable lamps to elevator cables. Article 400 of the *NEC* gives a description, the ampacities, and the intended use of the various flexible cords now available. The ampacity of flexible cords is limited by type and gauge of wire used. They must not be overloaded nor their size reduced where the gauge is intended for mechanical strength.

Flexible cords are frequently subject to physical damage and rapid wear. Ground faults or short circuits may occur if the insulation is damaged and the resulting arc may ignite the insulation or nearby combustible material. Replacement of flexible cords as soon as they show damage or appreciable wear is of utmost importance.

Under present labeling practices, only replacement nondetachable power supply cords; range and dryer power supply cords; and cord sets, such as extension cords, carry the label on the product itself. Formerly, the original cords and power supply cords were labeled, and some consumers may have thought a label on the cord of an electrical appliance signified the appliance itself was investigated for safety. Nondetachable cords on new appliances no longer carry a label, so the consumer cannot be misled into assuming that the appliance itself has been tested, which may not be the case.

Flexible cords are not considered by the *NEC* as a wiring method. They are covered in Chapter 4 of the *NEC,* "Equipment for General Use." Flexible cords, including extension cords, are not acceptable as a substitute for the fixed wiring of a structure, but they are acceptable for use in extending the length of a cord on a portable lamp or on cord- and plug-connected appliances. The appliance should be used in accordance with any instructions included with the listing or labeling and the flexible cord itself should be used in accordance with Article 400 of the *NEC.* Flexible cords are not limited solely to "temporary wiring."

Switches

Switches are required for the control of lights and appliances and as the disconnecting means for motors and their controllers. Switches may be of either the air-break or the oil-break type. In the oil-break type, the interrupting device is immersed in oil.

A chief fire hazard in switches is the arcing produced when the switch is opened. This hazard is somewhat greater with oil-break switches. If operated much beyond their rated capacity or if the condition of the oil is poor or its level is not properly maintained, the arc can vaporize the oil, rupture the case, and cause a fire. However, the amount of oil is comparatively small (except in high-voltage equipment) and these switches present no hazard if properly used and maintained.

ELECTRICAL HOUSEHOLD APPLIANCES

Electric Heating Equipment

Electric heating equipment is used widely and it is important that all such devices be tested and listed by qualified electrical testing laboratories. Some fixed spaceheating equipment covered in Article 424 of the *NEC* is acceptable for installation in direct contact with combustible material. Baseboard heaters, for example, have been tested and found to incorporate suitable safeguards against fire hazards that might result from contact with draperies, furniture, carpeting, bedding, and so on, although discoloration or scorching (but no glowing embers or flaming) is possible on adjacent materials. Other electric air heaters, however, may present fire hazards if they come in contact with combustible materials or if they are covered or blocked in any manner. Space heating systems must not be installed where exposed to severe physical damage unless adequately protected, nor in damp or wet locations unless approved for such locations.

A heater installed in an air duct or plenum must be of a type suitable for that purpose. Article 424 of the *NEC* covers installation of heaters for ducts and plenums and such items as airflow reliability, problems of condensation, fan circuit interlock, limit controls, and location of disconnecting means. NFPA 90B, *Standard for the Installation of Warm Air Heating and Air-Conditioning Systems,* also contains details on central systems.

Electric Ranges, Wall-Mounted Ovens, and Counter-Mounted Cooking Units

Each of these devices needs a means for disconnection from all ungrounded conductors of the supply circuit. A separable connector or a plug and receptacle may serve as the disconnecting means for free-standing household ranges. A plug and receptacle connection at the rear base of the range, if accessible from the front by removal of a drawer, is considered satisfactory. Grounding requirements for ranges are covered in Article 250 of the *NEC.*

In new installations, the grounded conductor (neutral) is not allowed as a means of grounding the frame of an electric range or counter-mounted cooking unit. Therefore, the flexible power cord must contain four conductors and a four-blade plug. Where there is an existing branch circuit containing only three conductors supplying a three-wire receptacle, the grounded conductor (neutral) is allowed to be used for grounding the frame of the appliance.

The *NEC* gives the methods for calculating feeder loads for household electric ranges and other cooking appliances.

Refrigerators

Fire problems with refrigerators can include deterioration in service of the fractional horsepower motors used and the possibility of overheating. Refrigerant coils and motors are susceptible to accumulations of lint and oily deposits, so cleanliness is a primary consideration in fire prevention. New devices have sealed motors not requiring oiling or maintenance, but overheating can result from improper use or inefficient cooling of the refrigerant due to coil dirt or damage. Ordinary household or commercial refrigerators must not be used to store flammable liquids. (Refrigerators listed for use in Class I hazardous [classified] locations and for flammable materials storage in laboratories, in accordance with Chapter 10 of NFPA 99 and NFPA 45, *Standard on Fire Protection for Laboratories Using Chemicals,* are available.) Exposed noncurrent-carrying metal parts of refrigerators and freezers that are likely to become energized need to be grounded under provisions of the *NEC.*

Room Air-Conditioning Units

Room air-conditioning units have the same fire hazards as other motor-operated appliances. The exposed noncurrent-carrying metal parts must be grounded as required by Article 250 of the *NEC.*

Properly designed portable room air conditioners are protected by an LCDI provided with the cord. The protection is an integral part of the attachment plug or is located in the power supply cord within 12 in. (300 mm) of the attachment plug.

Incandescent Lamps

Because incandescent lamps produce considerable heat, they inherently possess a fire hazard and can ignite combustible material in contact with them. Under normal conditions, with the lamp in an approved lampholder and the fixture properly guarded, the heating hazard is negligible, but ignition of combustible material may result if lamps are surrounded by or laid on such combustible material. Table 8.13.17 presents information on surface and base temperatures of standard lamps in open sockets. The temperature measurements are all taken at an ambient temperature of 77°F (25°C). In most instances where lamps are incorporated in various kinds of lighting equipment, the ambient temperature at which the lamps operate is higher; thus, the surface temperatures of the bulbs are also higher. The bulb temperatures may be further increased if the lamp is in other than a vertical, base-up position. Figure 8.13.23 shows surface temperatures of 100 W A-19 and 500 W PS-35 lamps in various positions but, again, these temperatures were measured in an ambient temperature of 77°F (25°C); so where enclosed in fixtures, the temperatures will be higher. The older style conventional Christmas tree lamps of U.S. manufacture have approximate average bulb surface temperatures at the hottest spot of approximately 260°F (127°C) for the blue and green colors, and somewhat lower for the white, red, and yellow colors.*

*The data in Table 8.13.17 was extracted from the *IES Handbook,* 5th ed., of the Illuminating Engineering Society, and is used here with the permission of the society. The reader is asked to keep in mind the above comments in the text regarding use of data in Table 8.13.17 and Figure 8.13.23.

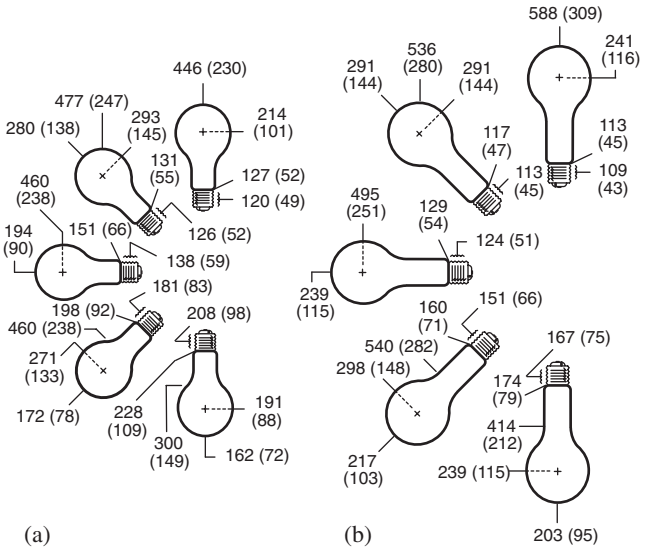

FIGURE 8.13.23 Surface Temperatures of Lamps in Various Positions: (a) 100 W, A-19 Lamp; (b) 500 W PS-35 Lamp

In clothes closets, an open, partially enclosed, pendant, or lampholder with incandescent lamp in a luminaire (fixture) is not permitted to be installed.

In locations where there are flammable vapors or gases, combustible dusts, or readily ignitable fibers or flyings, lamps in fixtures specially approved for the location must be used. Luminaires (lighting fixtures) approved for Class I, Division 1 locations must be marked to indicate the maximum wattage of the lamps for which they are approved, and they must be protected against physical damage by a suitable guard or located beyond the area of potential damage.

Fixed luminaires (lighting fixtures) in Class I, Division 2 locations must be protected from physical damage by a suitable guard or located out of the area of potential damage. Where there is the potential for sparks or hot metal falling from the lamps and igniting localized concentrations of flammable vapors or gases, suitable enclosures or other means must be provided. Where lamp size might be increased so that, under normal operating conditions, the surface temperature of the luminaire (fixture) could exceed 80 percent of the ignition temperature (°C) of the gas or vapor involved, the fixture must be of a type that has been tested for the marked temperature operating range.

Electric Discharge (Fluorescent) Lamps

The operating temperature of a fluorescent tube is lower than that of the glass envelope of the incandescent lamp, but high voltage is often used to start the lamp. This requires the use of transformers, reactors, capacitors, and switches. The heat produced by this equipment must be taken into account, and the equipment properly safeguarded.

Bulb temperatures on the surface of fluorescent lamps average between 100 and 110°F (38 and 43°C) over most of their length, because this is a requirement for efficient light production.

[a]Lamp burning base up in ambient temperature of 77°F (25°C).
[b]At junction of base and bulb.
[c]For 120 V lamps.
[d]Percent initial light output at 70 percent of rated life.
[e]Lumen and lumen per watt values of white lamps are generally lower than for inside frosted.
[f]Used mainly in Canada.

There is a small area of higher bulb temperature directly above the cathode at each end of a fluorescent lamp that ranges from 120 to 250°F (49 to 121°C), depending on the type involved.

Where fluorescent lamps having an open circuit voltage of more than 300 V are installed in dwelling occupancies, they must have no exposed live parts when lamps are in place and when being inserted or removed.

Extreme care is required in mounting fluorescent lamp luminaires (fixtures) containing a ballast on combustible, low-density, cellulose fiberboard. In this case, low-density refers to combustible low-density, cellulose fiberboard tiles or sheets that have a density of 20 lb/ft^3 (320 kg/m^3) or less, and are formed of bonded plant material. It does not include solid or laminated wood or fiberboard that has a density in excess of 20 lb/ft^3 (320 kg/m^3). Luminaires (fixtures) containing ballasts should not be mounted in contact with low-density, cellulose fiberboard, unless specifically listed by a qualified electrical testing laboratory for mounting in that manner. If not so listed, they should be spaced not less than 1½ in. (38 mm) from the surface of the combustible material. A principal hazard is ignition of the fiberboard, which under some conditions can ignite at relatively low temperatures. Integral thermal ballast protection is now provided for fluorescent luminaires (fixtures) installed indoors to protect against ballast overheating as a result of failure of capacitors, lamps, ballast winding shorts, and so on.

Electric (High-Intensity) Discharge Lamps

The operating temperature of a high-intensity discharge lamp, such as a mercury vapor lamp, is usually much higher than the operating temperature of either Edison-base incandescent or fluorescent lamps, exceeding 550°F (288°C) in some sizes. Extreme care is therefore necessary where such lamps are encountered to prevent their contacting combustible material. Although such lamps were at one time used primarily for street lighting and other outdoor lighting applications, their higher lighting efficiency and new designs providing good color correction and lower wattages have resulted in increased use indoors. Such lamps usually require ballasts (transformers), sometimes capacitors, and are designed to fit into Edison-base lampholders. There are, however, self-ballasted lamps that can be substituted directly for incandescent lamps. High-intensity discharge lamps should be used only in luminaires (fixtures) listed by a qualified electrical testing laboratory for their use, as indicated on the luminaire (fixture).

Portable Handlamps

Metal-shell, paper-lined lampholders are not designed to be used as portable handlamps. A fire hazard may result from a defective or worn cord or from the breaking of a lamp. A personnel hazard may result from personal contact with bare spots on the cord or by contact with a live metal lamp socket. Portable handlamps must have a handle of molded composition or other insulating material and a substantial guard attached to the lampholder or handle. Metallic guards must be grounded by means of an equipment grounding conductor that runs with the circuit conductors within the power supply cord. Portable handlamps are not required to be grounded where supplied through an isolating transformer with an ungrounded secondary of not over 50 V.

Portable handlamps used in hazardous (classified) locations must be suitable for the purpose (Figures 8.13.24 and 8.13.25).

FIGURE 8.13.24 Explosionproof Handlamp for Use in Class I Locations (Source: Appleton Electric LLC, EGS Electrical Group)

FIGURE 8.13.25 Portable Handlamp with Grounded Metal Guard and Reflector and Swivel-Type Hook (Source: Daniel Woodhead Co.)

Home Entertainment Equipment

Outdoor antennas and lead-in conductors must be of corrosion-resistant material and securely supported (Figure 8.13.26). They must not be attached to poles or similar structures carrying electric light or power wires or trolley wires, nor should they cross over or be near electric light or power circuits (to avoid accidental contact). Where antennas or lead-in conductors are in proximity of outdoor electric light or power circuits operating at less than 250 V, they must have at least 2 ft (600 mm) of clearance, and at 250 V or more, 10 ft (3.0 m) clearance. Lead-in conductors also must be kept at least 6 ft (1.8 m) from any conductor forming a part of a lightning protection system. The metal sheath of the coaxial cable used for cable television systems must be grounded in accordance with Article 820 of the *NEC,* to avoid electric shock and fire hazards. The sheath must be electrically bonded to the electrical system power ground. Where a separate ground rod is installed for the cable television ground, it must be bonded to the electrical system grounding electrode system or to the electrical service equipment.

Masts and metal structures supporting antennas must be well grounded, and each conductor of a lead-in from an outdoor antenna must be protected by an approved antenna discharge unit. Metal masts on buildings are required by NFPA 780 to be bonded to the nearest lightning conductor (where available). This bonding is normally done with standard lightning conductors.

FIGURE 8.13.26 Dangerous Arrangement of a Lightly Supported Television Antenna in Proximity of Power Lines

Radio interference eliminators and noise suppressors connected to power supply leads and devices, intended to permit an electric supply circuit to be used in lieu of an antenna, should be listed for the purpose by a qualified electrical testing laboratory.

Operating television sets, even solid-state sets, can develop considerable heat, so most cabinets housing such equipment are provided with ventilation openings at the rear and bottom. It is important not to install television receivers so that the desired ventilation is cut off or significantly reduced (e.g., by recessing the set in a wall, bookcase, etc.), unless the receiver is designed for such use.

Clothes Washers and Dryers

These appliances are required to have a means for disconnecting all ungrounded conductors from the supply circuit. A separable cord connector or an attachment plug and receptacle may serve as the disconnecting means.

Electric clothes washers and dryers and similar appliances are usually installed within reach of a person who can make contact with a grounded surface or object. Consequently, the exposed, noncurrent-carrying metal parts of these machines must be grounded to remove the danger of electric shock. Accumulations of lint in dryers and in lint traps also present a potential fire hazard if not periodically cleaned.

Flatirons

These appliances intended for use in residences are required by the *NEC* to be equipped with approved means to limit the temperature. Even with the widespread use of automatic irons, some hazard still remains because satisfactory ironing of many fabrics requires a degree of heat sufficient to cause ignition if the iron is left in contact with some combustible materials for a considerable period of time.

Electrically Heated Pads and Bedding

The user must be warned by means of a marking on the appliance and by instructions packed with it against the common possible abuses that would increase the fire or shock hazard.

Because many fabrics readily absorb moisture, listed pads (unless of the waterproof type) are provided with moisture-resistant envelopes. This envelope should be examined frequently for signs of deterioration. Blankets are normally designed so that they may be laundered; some cannot be dry cleaned (as with Stoddard solvent or perchloroethylene) and are normally labeled "Do Not Dry Clean."

INDUSTRIAL AND COMMERCIAL EQUIPMENT

Furnaces

Industrial furnaces generally employ transformers, which may be either the dry type, askarel-insulated type, oil-insulated type,

or insulated with a less flammable fluid (e.g., dimethyl silicone). Although new transformers are no longer made with askarel (a material containing polychlorinated biphenyl, or PCB), many such transformers are still in use. The *NEC* requires oil-insulated transformers of a total rating exceeding 75 kVA to be located in a fire-resistant vault. Electric furnace transformers that have a total rating not exceeding 75 kVA are permitted to be installed without a vault in a building or room of fire-resistant construction, provided suitable arrangements are made to prevent a fire involving the transformer oil from spreading to other combustible material.

Oil-filled circuit breakers that control arc furnaces are subject to unusually severe duty and, unless frequently inspected and properly maintained, may fail with disastrous results. Circuit breakers on circuits operated at more than 600 V and that are used to control oil-filled transformers must be located outside the transformer vaults. Vents on high-voltage circuit breakers must be piped outdoors. Electric arc furnace circuits, due to the nature of the operation, are also subject to high surge voltages that can cause failure of the arc circuit breakers used. In these cases, shunt capacitors are installed in the circuit to prevent these high-voltage surges.

Inductive and dielectric heat-generating equipment employing high-frequency alternating currents is used in many heat-treating processes. To eliminate both the personnel hazards and fire hazards of such equipment, construction and installation should comply with the special requirements of the *NEC.*

Other hazards of electric furnaces are similar to those of furnaces employing other means of heating.

Motors

Ignition of motor insulation or nearby combustible material can be caused by sparks or arcs when the motor winding short circuits or grounds or when brushes operate improperly. Bearings may overheat because of improper lubrication and sometimes excessive bearing wear allows the rotor to rub on the stator. The individual drives of machines of many different types sometimes make it necessary to install motors in locations and under conditions that are injurious to motor insulation. Dust that can conduct electricity may be deposited on the insulation, or deposits of textile fibers and so on may prevent the normal dissipation of heat. Motors should be cleaned and lubricated regularly. All motor installations should comply with the requirements of the *NEC,* which includes special rules for motors in hazardous (classified) locations.

Machine Tools

The electrical equipment of a modern machine tool or plastics processing machine may vary from a simple single-motor drill press or extruder to a large complicated multimotor automatic machine involving highly complex control systems and equipment. This latter type is generally custom designed and factory wired. Machine tools incorporate many devices and safeguards to provide safety to life, safety from fire, reduction of machine lost time due to replacement of parts, safety to the machine itself, and safety to the work in process.

NFPA 79 covers the specific electrical equipment, apparatus, and wiring furnished as a part of an industrial machine, starting at the electrical supply connection, provided that it is 600 V or less. The *NEC* contains requirements for general application, particularly for protection of several motors on one branch circuit.

Electrical equipment is subject to damage by oil, metal chips, coolants, and moving parts. The fixed wiring to the machines specified in the *NEC* should generally be conductors in conduit, tubing, or Type MI cable. Exceptions are connections to continuously moving parts, which can be extraflexible, multiconductor cable. For flexible connections where small or infrequent movement is involved, as at motor terminals, flexible metal conduit, liquid-tight flexible metal conduit, or liquid-tight flexible nonmetallic conduit is permitted.

Motor Control Center Rooms

Automation of production machinery has greatly increased the use of motors and their related control circuits, resulting in grouping the motor control equipment in relatively large, compartmented metal enclosures. These are specially designed, factory-built equipment, commonly referred to as "motor control centers." They are usually located in large rooms, sometimes referred to as "motor control center rooms." Electrical failures or fires in motor control centers can result in the destruction of the equipment in many compartments of the control center due to rapid temperature rise.

A serious fire hazard can be created if multiconductor circuits are installed stacked one above the other in cable trays. Heat from arcing or a fire in the control center can raise the temperature in the control center room to a point where normally slow-burning cables become readily combustible. A fire in such cables can shut down a process or an entire plant for weeks or months. The *NEC* covers the use and construction of cable trays, and should be strictly followed where this type of support is used.

The number of motor control centers in one room should be limited or arranged so that exposure of a large number of circuits or equipment to any one fire is avoided. Motor control center rooms should be of noncombustible construction, with a roof or ceiling not readily weakened by a major electrical disturbance or fire. In addition to normal ventilation, the room should be provided with emergency ventilation for removal of heat and smoke in event of a severe fire.

Suggested fire protection for motor control center rooms may consist of preaction sprinkler systems or fixed water spray protection to cover exposed cables, fire detectors to initiate an alarm at a central point in the event of abnormally high temperatures or smoke conditions, total flooding carbon dioxide or other gaseous agent system, portable Class C fire extinguishers located at each entrance to the control room, and small hose connections with suitable hose and adjustable spray nozzles readily available near the control room.

Switchboards

Ideally, switchboards are installed in clean, dry locations. They should be under competent supervision and accessible only

to qualified persons. Switchboards operating at voltages over 600 V must be provided with protection to avoid damage from condensation leaks and breaks in piping. Piping for fire suppression is allowed within the electrical room for the protection of the electrical installation. Where it is necessary to install a switchboard in a wet location or outside a building, the enclosure must be weatherproof. Ample space must be provided for maintenance operations, as stipulated in the *NEC*.

Insulated conductors grouped within switchboards, as well as the instrument and control wiring, should have a listed flame-retardant outer covering.

Circuit breakers and switches must have ample ratings for the maximum loads and sufficient interrupting capacity for the maximum short-circuit currents. Contacts of switches and circuit breakers should be kept in good condition and the oil in oil circuit breakers renewed periodically and kept at the proper level.

Capacitors

Capacitors may be insulated with a combustible or a nonflammable liquid. Capacitors containing more than 3 gal (11 L) of flammable liquid must be enclosed in vaults or outdoor fenced enclosures. These safeguards prevent persons from coming into accidental contact or bringing conducting materials into accidental contact with exposed energized parts, terminals, or buses.

Capacitors must have a means of draining the stored energy, such as through a suitable resistance. The residual voltage of a capacitor must be able to be reduced to 50 V, nominal, or less, within 1 minute after the capacitor is disconnected from the source of supply. The discharge circuit must be either permanently connected to the terminals of the capacitor or capacitor bank, or provided with automatic means of connecting it to the terminals of the capacitor bank on removal of voltage from the line. Manual means of switching or connecting the discharge circuit cannot be used. If no means were provided for draining off the charge stored in a capacitor after it is disconnected from the line, a severe shock might be received by a person servicing the equipment, or the equipment might be damaged by a short circuit.

Resistors and Reactors

Except when installed in connection with switchboards or control panels whose locations are suitably guarded from physical damage and accidental contact with live parts, resistors should always be completely enclosed in properly ventilated metal boxes. A resistor is always a source of heat and, when mounted on a combustible wall, a thermal barrier should be required if the space between the resistors or reactors and any combustible material is less than 12 in. (305 mm).

Large reactors are commonly connected in series, with the main leads of large generators or the supply conductors from high-capacity network systems assisting in limiting the current delivered under short-circuit conditions. Small reactors are used with lightning arresters to offer a high impedance to the passage of a high-frequency lightning discharge and aid in directing the discharge to ground. Another type of reactor, having an iron core and closely resembling a transformer, is used as a remote-control dimmer for stage lighting in some of the older installations. Reactors are sources of heat and therefore should be mounted in the same manner as resistors.

Motion Picture Projection Rooms

The provisions of *NEC* Article 540 apply to motion picture projection rooms, motion picture projectors, and associated equipment of the professional and nonprofessional types using incandescent, carbon arc, xenon, or other light sources that develops hazardous gases, dust, or radiation. (For further information, see NFPA 40, *Standard for the Storage and Handling of Cellulose Nitrate Film.*)

All professional projectors should be operated by qualified personnel. A professional projector is a type that uses 35- or 70-mm film that has a minimum width of 1⅜ in. (35 mm) and has on each edge 5.4 perforations per in., or that uses carbon arc, xenon, or other light source equipment that develops hazardous gases, dust, or radiation.

Motor generator sets, transformers, rectifiers, rheostats, and similar equipment for the supply or control of current to projection or spotlight equipment must be located in a separate room, if cellulose nitrate film is used. When placed in the projection room, cellulose nitrate film must be located or guarded so that arcs or sparks cannot come in contact with film. The commutator end or ends of motor generator sets must comply with one of the conditions in *NEC* Section 540.11.

Switches, overcurrent devices, or other equipment not normally required or used for projectors, sound reproduction, flood or other special effect lamps, or other equipment cannot be installed in projection rooms. There are exceptions: (1) In projection rooms approved for use only with cellulose acetate (safety) film, the installation of appurtenant electrical equipment used in conjunction with the operation of the projection equipment and the control of lights, curtains, audio equipment, and so on is permitted. In such projection rooms, a sign reading "Safety Film Only Permitted in This Room" must be posted on the outside of each projection room door and within the projection room itself in a conspicuous location. (2) Remote-control switches for the control of auditorium lights or switches for the control of motors operating curtains and masking of the motion picture screen are permitted to be installed in projection rooms.

Approved projectors of the nonprofessional or miniature type, when employing cellulose acetate (safety) film, may be operated without a projection room. Special rules are also given in the *NEC* to cover electrical installations in motion picture studios, factories, laboratories, stages, or areas of buildings in which work is done on cellulose nitrate film. Provisions include wiring on stages, sets, dressing rooms, viewing, cutting, and patching tables, and film storage vaults.

Cranes and Hoists

Wiring methods and installation of electrical equipment for cranes and hoists are covered in Article 610 of the *NEC*. Where bare contact conductors are objectionable because of the presence of easily ignitable material, current may be conducted to

a crane or hoist via a multiple cable on a cable reel or suitable takeup device.

Where a crane operates over combustible material, the resistors must be placed in either (1) a well-ventilated cabinet of noncombustible material that will not emit flames or molten metal, or (2) a cage or cab constructed of noncombustible material that encloses the sides of the cage or cab from the floor to a point at least 6 in. (152 mm) above the top of the resistors.

Collectors must be designed to reduce sparking between them and the contact conductors to a minimum. When operated in rooms where easily ignitable fibers or materials producing combustible flyings are handled, manufactured, used, or stored, the installation must comply with the special requirements of Section 503.155 of the *NEC*.

All exposed metal parts of cranes, monorail hoists, hoists, and accessories (including pendant controls) should be metallically joined together into a continuous electrical conductor so the entire crane or hoist will be grounded.

Elevators, Dumbwaiters, Escalators, Moving Walks, Wheelchair Lifts, and Stairway Chair Lifts

Installation of electrical equipment and wiring used in connection with elevators, dumbwaiters, escalators, moving walks, wheelchair lifts, and stairway chair lifts are covered in Article 620 of the *NEC*. For further information, see *Safety Code for Elevators and Escalators,* ASME/ANSI A17.1-1996, and *Elevator and Escalator Electrical Equipment Certification Standard,* ASME/ANSI A17.5-1996 (CSA B44.1-1996).

All live parts of electrical apparatus in the hoistways, at landings, in or on cars of elevators and dumbwaiters, in the wellways or the landings of escalators or moving walks, or in the runways and machinery spaces of wheelchair lifts and stairway chair lifts must be enclosed to protect against accidental contact. (See *NEC* Section 110.27 for guarding of live parts [600 V, nominal, or less].) The conductors to the hoistway door interlocks from the hoistway riser must be flame retardant and suitable for a temperature of not less than 392°F (200°C). Conductors must be Type SF or equivalent. Other wiring in raceways must have flame-retardant insulation.

Bonding of elevator rails (car and/or counterweight) to a lightning protection system grounding down conductor(s) is permitted. However, the lightning protection system grounding down conductor(s) cannot be located within the hoistway. Elevator rails or other hoistway equipment cannot be used as the grounding down conductor for lightning protection systems. (See *NEC* Section 250.106 for bonding requirements. For further information, see NFPA 780.)

Traveling cables must be suspended at the car and hoistways' ends, or counterweight end where applicable, so as to reduce the strain on the individual copper conductors to a minimum and must be supported by one of the following means: (1) by its steel supporting member(s), (2) by looping the cables around supports for unsupported lengths less than 100 ft (30 m), and (3) by suspending from the supports by a means that automatically tightens around the cable when tension is increased for unsupported lengths up to 200 ft (60 m).

Unsupported length for the hoistway suspension means is that length of cable as measured from the point of suspension in the hoistway to the bottom of the loop, with the elevator car located at the bottom landing. Unsupported length for the car suspension means is that length of cable as measured from the point of suspension on the car to the bottom of the loop, with the elevator car located at the top landing.

Traveling cables used as flexible connections between the elevator or dumbwaiter car or counterweight and the raceway must be of the types listed in *NEC* Table 400.4 or other approved types.

To reduce the danger of electric shock, the following equipment must be effectively grounded in accordance with the grounding requirements of the *NEC:* (1) metal raceways, Type MC cable, Type MI, or Type AC cable attached to elevator cars; (2) the frames of all motors, elevator machines, and controllers; (3) the metal enclosures for all electric devices in or on the car or hoistway; and (4) the frames of nonelectric elevators if accessible to persons and if any electric conductors are attached to the car.

Each 125 V, single-phase, 15- and 20-A receptacle installed in pits, elevator car tops, and in escalator and moving walk wellways must be of the ground-fault circuit-interrupter type, and all 125 V, single-phase, 15- and 20-A receptacles installed in machine rooms and machinery spaces must have ground-fault circuit-interrupter protection for personnel. A single receptacle supplying a permanently installed sump pump does not require ground-fault circuit-interrupter protection. This protection does not include a GFCI circuit breaker located in a distribution panel; the intent is to allow personnel to reset the GFCI receptacle without climbing around in the dark. Receptacles installed in the machine room are allowed to be protected by either a GFCI receptacle or a GFCI circuit breaker.

Heating Cable

Recognized testing laboratories have listed a number of heating cables for use within buildings. These cables are of the resistance type, primarily designed to be used around water pipes to prevent freezing and facilitate the flow of viscous liquids. The cable is secured to the pipe with straps or wrapped around the pipe with the pitch recommended by the manufacturer. Electric heating cables are required to have a grounded metal outer covering. The pipe and heating cable are usually encased in thermal insulation.

Some units incorporate a thermostat that automatically turns on the heating cable when the temperature drops below a predetermined value. The pipe heating cables are intended to be connected to a permanent supply wiring system. Unless specifically indicated otherwise by marking on the heating cables or in the installation instructions, the heating cables are intended for use only on metallic pipes. Ground-fault protection of equipment must be provided for each branch circuit supplying electric heating equipment; this is not GFCI protection. For industrial establishments where only qualified persons will service the installation and the continued circuit operation is necessary for safe operation of the equipment or process, ground-fault protection is not required, but an alarm indication of a ground fault is required.

Electrical heating cables for outdoor ice- and snow-melting systems are covered in the *NEC* Article 426.

ELECTRICAL EQUIPMENT FOR OUTDOOR USE

Electric equipment that is installed outside of buildings must be weatherproof in design, that is, constructed such that exposure to the weather will not interfere with its successful operation; otherwise it must be enclosed in weatherproof cabinets, enclosures designed to prevent moisture or water from entering and accumulating within them. If mounted on a wall or other supporting surface, there should be at least ¼ in. (6 mm) airspace between the box or cabinet and the supporting surface.

Description of Devices

Electric equipment suitable for outdoor use is tested by recognized electrical testing laboratories. The tests encompass the following: (1) suitability of the materials used and the protective coatings for exposure to sunlight, rain, and snow; (2) effects of heat and cold; and (3) provisions for grounding. The term *raintight,* as used in the *NEC,* is applied to equipment that, on exposure to a beating rain, will not let water enter. The term *weatherproof,* as used in the *NEC,* is applied to equipment that, on exposure to the weather, will still operate successfully. Rainproof, raintight, or watertight equipment can fulfill the requirements for weatherproof equipment where varying weather conditions other than wetness—for example, snow, ice, dust, or temperature extremes—are not a factor.

Electric Signs and Outline Lighting

Electric signs and outline lighting, whether fixed, mobile, or portable, are required to be listed. Except for portable indoor signs, signs and outline lighting equipment are usually constructed of metal or other noncombustible material. The spacing between wood or other combustible materials and an incandescent or high-intensity discharge (HID) lamp or lampholder must not be less than 2 in. (50 mm). Enclosures for outside use must be weatherproof. Signs and outline lighting systems must be constructed and installed so that adjacent combustible materials are not subjected to temperature in excess of 194°F (90°C). All steel parts of enclosures must be galvanized or otherwise protected from corrosion. Signs, troughs, tube terminal boxes, and other metal frames must be grounded in the manner specified in the *NEC.*

Each electric sign (other than cord-connected) and each outline lighting installation must be controlled by an external operable switch or circuit breaker (handle on outside of switch enclosure), which will open all ungrounded conductors. The switch or breaker must be within sight of the sign or outline lighting installation unless it is capable of being locked in the open position.

Portable outdoor electric signs must be equipped with factory-installed GFCI protection. The GFCI must be an integral part of the attachment plug or located in the power supply cord within 12 in. (300 mm) of the attachment plug.

Electric Fences

Wire fences with electrical connections to produce a shock when animals come in contact with them are widely used on farms. To avoid hazard to persons and to livestock, the current and the time interval during which the current is on and off must be limited to values that will not cause fatalities or injuries to persons or animals, while still causing an unpleasant sensation of shock. Fatalities and fires can result from homemade equipment supplied from ordinary lighting circuits. The open circuit voltage need not be limited if the current is properly limited. UL Research Bulletin No. 14 and UL 69, "Standard for Safety Electric-Fence Controllers," give detailed information on these installations.

The output characteristics of some controllers are such that combustible material may be readily ignited when a grounded object occupies a position respective to the energized fence to produce an electric arc. To protect against fire from such a cause, users should determine whether the controller has been designed and tested with respect to this hazard. Electric fence controllers listed in accordance with the requirements of UL 69 have been so tested.

Marinas and Boatyards

Wiring in marinas and boatyards presents special outdoor electric equipment problems, which are covered in Article 555 of the *NEC.* Electric service equipment for floating docks or marinas must be located adjacent to, but not on or in, the floating structure. Metal raceways and metal boxes must not be depended on for grounding; a continuous insulated copper conductor, not smaller than 12 AWG, must be provided as an equipment grounding conductor from outlet boxes and receptacles to the service ground. Electrical equipment and wiring located at gasoline dispensing stations must follow the requirements in Article 514 of the *NEC* and NFPA 30A, *Code for Motor Fuel Dispensing Facilities and Repair Garages.* Wiring over and under navigable water should be subject to approval by the authority having jurisdiction.

LOCATIONS EXPOSED TO MOISTURE AND NONCOMBUSTIBLE DUSTS

Special electric equipment is required for use where moisture and noncombustible dusts might be present. For years, the *NEC* referred to such equipment as *vaportight,* but this term was dropped from the *NEC* because of confusion in the field between equipment so designated and *explosionproof* equipment. Many users assumed that vaportight equipment was safe to use in atmospheres containing flammable gases or vapors (Class I locations), combustible dusts (Class II locations), or easily ignitable fibers or flyings (Class III locations). To avoid this type of misunderstanding, the term *enclosed and gasketed* was developed for this type of equipment. Some inspection authorities permit enclosed and gasketed luminaires (lighting fixtures) in Class I, Division 2; in Class II, Division 2; and in Class III, Divisions 1 and 2 locations when marked to show the operating temperature and maximum wattage of permissible lamps. The

NEC requires luminaires (lighting fixtures) to be marked for use in wet and damp locations when so used.

SIGNALING AND COMMUNICATIONS SYSTEMS

Communications systems, including telephone, telegraph, fire and burglar alarms, and watchman and sprinkler supervisory systems, usually operate with low voltages and currents and, if kept free from accidental contacts with higher voltage systems, they present no unusual hazards. There are, however, *NEC* requirements for the wiring of these systems if the wiring is in a duct, plenum, or other space for environmental air, because of the hazard of spreading products of combustion from one location to another. There are also *NEC* requirements for separation from other systems, such as lighting and power circuits, to minimize imposing higher voltages and current on the communication equipment and conductors. Where fire-rated walls, floors, or ceilings are penetrated, the integrity of the construction assembly must be maintained by proper sealing around cables to prevent the spread of fire or smoke.

Fire alarm systems are classified as nonpower-limited or power-limited. Nonpower-limited cables (NPLFAs) must be identified and listed as NPLFP, where installed in spaces used for environmental air; NPLFR, where used as a vertical riser from floor to floor or in shafts; and NPLF, where used for general purpose in other than risers, ducts, plenums, or environmental air-handling spaces. Power-limited systems (PLFAs) must be identified and listed with the following markings: FPLP, FPLR, and FPL; these are similar to those of nonpower-limited cables.

Signaling systems and communications systems must be installed in accordance with Articles 725, 760, and 800 of the *NEC,* and *NFPA 72®*, *National Fire Alarm Code®*, which covers the proper electrical wiring and equipment for fire alarm services. *NFPA 72* has cross references to the *NEC.* Telephone communications circuits may be used for completing the fire-protective circuits between the protected premises and fire alarm headquarters.

EMERGENCY SYSTEMS

Requirements for the installation, operation, and maintenance of emergency system circuits and equipment are given in Article 700 of the *NEC.* The systems are intended to supply light and power when the normal supply fails. They are generally installed in places of assembly where artificial lighting is required, such as auditoriums, theaters, sports arenas, and so on, occupied by large numbers of persons (Figures 8.13.27 and 8.13.28). In Figure 8.13.27, the heavy lines represent walls required by typical local building codes to be of fire-rated construction. The light lines represent walls not required by typical local building codes to be of fire-rated construction.

Legally required standby systems installed to serve loads such as heating and refrigeration systems, communications systems, ventilation and smoke removal systems, sewerage disposal, lighting systems, and industrial processes, that, when stopped during any interruption of the normal electrical supply, could create hazards or hamper rescue or fire-fighting operations, are covered in Article 701 of the *NEC.* NFPA 110, *Standard for Emergency and Standby Power Systems,* covers the performance requirements for such systems.

NFPA *101®*, *Life Safety Code®*, specifies where emergency lighting is considered essential for life safety. NFPA 99 gives minimum factors governing the design, operation, and maintenance of those portions of health care facility electrical systems where any degree of interruption would jeopardize the effective and safe care of hospitalized patients. The provisions in NFPA 99 do not supersede the recommendations in NFPA *101* or the *NEC,* which both limit the type of alternative source of electrical power allowable for use to ensure electric power continuity in health care facilities. NFPA 99 recognizes the progressively greater dependence being placed on electrical apparatus for the preservation of life of hospitalized patients and is a guide in the selection of the electrical services for emergency supply to all lighting and power equipment considered essential, and for their design and maintenance in health care facilities.

The sources of electric current that can be used for emergency lighting equipment are (1) storage batteries of suitable capacity, (2) a generator driven by some form of prime mover, and (3) a second electric service separated electrically and physically from the regular service to minimize the possibility of simultaneous interruption of both services. NFPA 99 stipulates that the alternative source of power for health care facilities be prime-mover-driven generators or, where the normal source is an on-site generator, an external utility service may be the alternative source. Means must be provided for automatically energizing emergency lights on failure of the regular lighting system supply. For hospitals, the transition time from the instant of failure of the normal power source to an emergency generator source must not exceed 10 seconds.

Audible and visual signal devices are provided, where practical, to (1) warn of impairment of the emergency source, (2) indicate that the battery or generator is carrying load, (3) indicate when a battery charger is functioning properly, and (4) indicate a ground fault on large 480Y/277 volt systems.

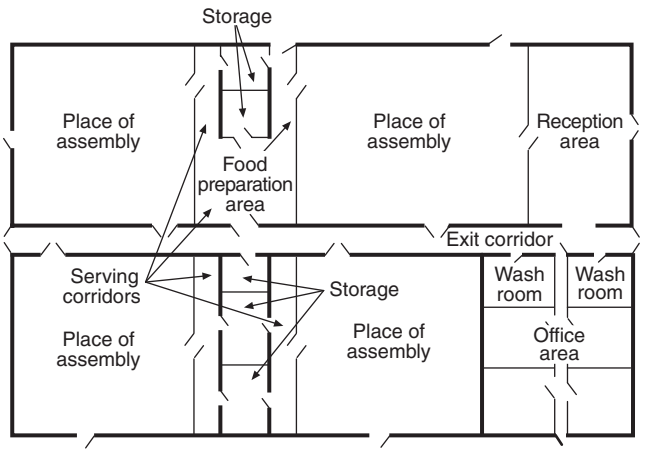

FIGURE 8.13.27 Walls in Places of Assembly Requiring (heavy lines) and Not Requiring (light lines) Fire-Rated Construction by Typical Local Building Codes

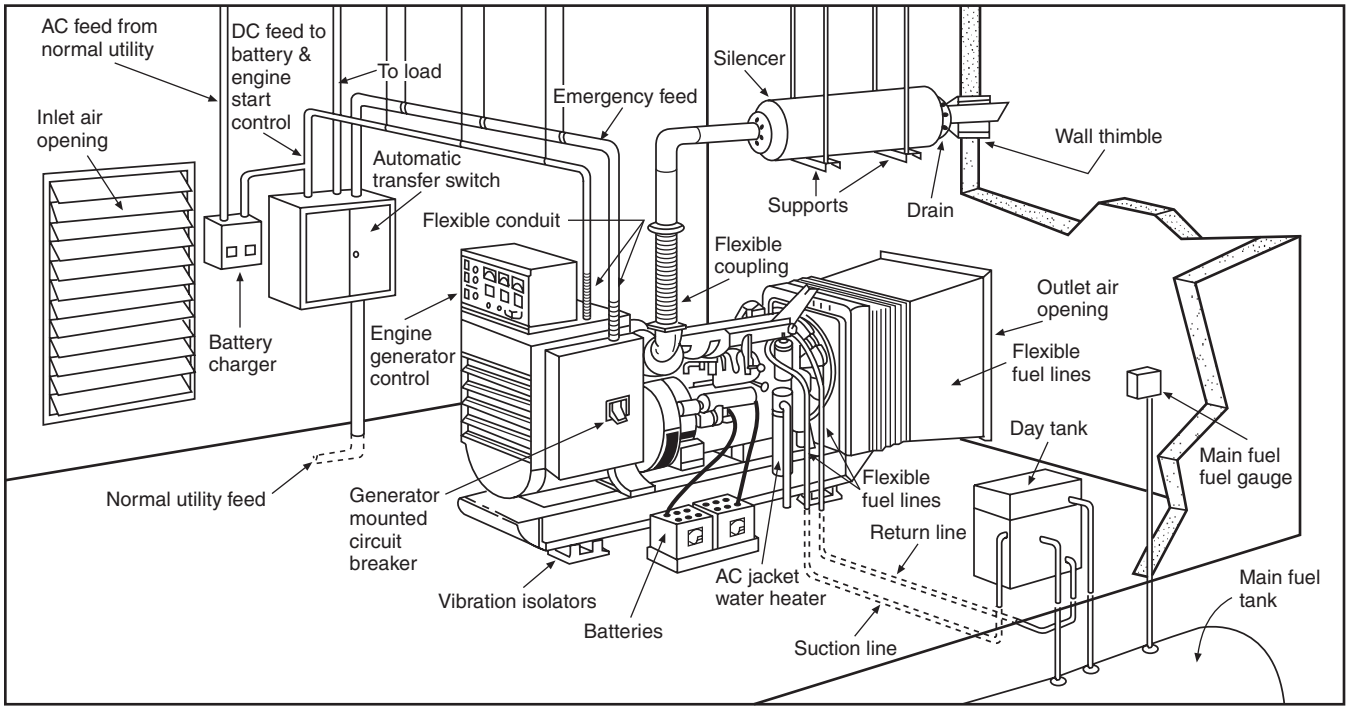

FIGURE 8.13.28 Typical Installation of a Diesel-Powered Standby Generator Such as Might Be Used for Emergency Light and Power Systems

No appliances or lamps, other than those required for emergency use, are to be supplied by the emergency lighting circuits. A good emergency lighting system is designed so that the failure of any individual lighting element, such as the burning out of a lightbulb, cannot leave any space in total darkness.

The emergency lighting circuit wiring is independent of all other wiring and equipment and must not enter the same raceway, cable, box, or cabinet with other wiring except at transfer switches and at exit lighting fixtures supplied from both the normal and the emergency sources.

A transfer switch that supplies emergency power is not allowed to also supply normal loads. Loads other than emergency loads must be supplied from a different transfer switch.

It is good practice to test the complete system on installation and periodically thereafter to ensure it is maintained in proper operating condition. A written record should be kept of such tests and maintenance.

SPECIAL OCCUPANCY ELECTRICAL PROBLEMS

Hazardous (classified) locations and other special problems require individual attention for which the *NEC* has specific recommendations.

Hazardous (Classified) Locations—General

The *NEC* recognizes an additional method of classification of hazardous locations. This method uses zones that are consistent with the rules of the International Electrotechnical Commission (IEC). The method is described in Article 505 of the *NEC.*

Electric power for lighting, motors, controls, and instrumentation, along with their associated wiring, is necessary or desirable in many hazardous locations. Due to the presence of flammable liquids, gases, vapors, combustible dusts, or readily ignitable fibers or flyings in these areas, special electrical equipment and wiring methods are necessary to prevent ignition and to minimize the occurrence of fire and explosion.

A flammable liquid, as it pertains to Article 500 of the *NEC,* is defined as follows: "A liquid having a flashpoint below 100°F (37.8°C) and having a vapor pressure not exceeding 40 psia at 100°F (37.8°C) shall be known as a Class I liquid."

Explosionproof apparatus is defined in the *NEC* as follows: "Apparatus enclosed in a case that is capable of withstanding an explosion of a specified gas or vapor that may occur within it and of preventing the ignition of a specified gas or vapor surrounding the enclosure by sparks, flashes or explosion of the gas or vapor within, and that operates at such an external temperature that a surrounding flammable atmosphere will not be ignited thereby."

In Article 500 of the *NEC,* hazardous (classified) locations are divided into three classes depending on the kind of hazardous material involved; each class is further divided into two divisions according to the likelihood of the potential hazard existing. For the purposes of testing for approval and area classification, various air mixtures (not oxygen enriched) have been grouped on the basis of their characteristics. The groups are given in Tables 8.13.18 through 8.13.21 (statistics from Section 500.3 of

TABLE 8.13.18 Group Classification and Autoignition Temperature (AIT) of Selected Flammable Gases and Vapors of Liquids Having Flashpoints Below 100°F (37.8°C)

[a]Material has been classified by test.
[b]If equipment is isolated by sealing all conduit (trade size) ½ in. or larger, in accordance with Section 501.5(A) of the *NEC,* equipment for the group classification shown in parentheses is permitted.
[c]For classification of areas involving ammonia, see "Safety Code for Mechanical Refrigeration," ANSI/ASHRAE 15, and "Safety Requirements for the Storage and Handling of Anhydrous Ammonia," ANSI/CGA G2.1.
[d]Certain chemicals may have characteristics that require safeguards beyond those required for any of the above groups. Carbon disulfide is one of these chemicals because of its low autoignition temperature and the small joint clearance to arrest its flame propagation.
[e]Petroleum naphtha is a saturated hydrocarbon mixture whose boiling range is 68 to 274°F (20 to 135°C). It is also known as benzine, ligroin, petroleum ether, and naphtha.

Sources: NFPA 497, *Recommended Practice for the Classification of Flammable Liquids, Gases, or Vapors and of Hazardous (Classified) Locations for Electrical Installations in Chemical Process Areas.* Autoignition temperatures listed above are the lowest value for each material as listed in NFPA's *Fire Protection Guide to Hazardous Materials,* which was originally NFPA 325, *Guide to Fire Hazard Properties of Flammable Liquids, Gases, and Volatile Solids,* or as reported in an article by Hilado, C. J., and Clark, S. W., *Chemical Engineering,* Sept. 4, 1972. NFPA 325 has been officially withdrawn from the National Fire Codes®; the information is still available in NFPA's *Fire Protection Guide to Hazardous Materials.*

Notes: Cl: cloud ignition temperature is shown; NL: no layer ignition temperature is available and the cloud ignition temperature is shown; M: dust layer melts before it ignites, and the cloud ignition temperature is shown; S: dust layer sublimes before it ignites, and the cloud ignition temperature is shown.

*Normally, the minimum ignition temperature of a layer of a specific dust is lower than the minimum ignition temperature of a cloud of that dust. Because this is not universally true, the lower of the two minimum ignition temperatures is listed. If no symbol appears between the two temperature columns, then the layer ignition temperature is shown.

the *NEC* and tables from NFPA 497, *Recommended Practice for the Classification of Flammable Liquids, Gases, or Vapors and of Hazardous (Classified) Locations for Electrical Installations in Chemical Process Areas*). For Group A, B, C, and D materials with flashpoints of 100°F (38°C) and higher, see NFPA 497. For a more complete table of Group G dusts and information on Group E dusts, see Table 8.13.18 and NFPA 497.

Group G includes combustible dusts, such as wood, flour, grain, corn starch, cocoa, food, chemical, and plastics dusts. Coal, coke, and carbonaceous dusts are classified in Group F. Group E includes metal dusts and other dusts of similarly hazardous characteristics.

Determining the proper group classification for flammable gases and vapors involves a determination of explosion pressures and maximum safe clearance between parts of a clamped joint under several conditions and comparison of the values obtained with those obtained for materials that have already been evaluated.

Listed equipment is marked to show the class, group, and operating temperature, or temperature range, referenced to a 248°F (120°C) ambient. The temperature range, if provided, is indicated by identification numbers, as shown in Table 8.13.22. The identification numbers are marked on equipment nameplates.

The ignition temperature of a liquid, solid, or gaseous substance is the minimum temperature required to initiate or cause self-sustained combustion, independent of the heating or heated element. The flashpoint and the ignition temperature are not the same, and the flashpoint is always lower than the ignition temperature.

Because there is no consistent relationship among explosion properties, explosion pressure, maximum experimental safe gap, minimum ignition energy, and ignition temperature, testing requirements for groups and classes are independent of each other.

TABLE 8.13.20 Selected Carbonaceous Dusts Classified as Group E—Ignition Sensitivity Equal to or Greater Than 0.2; Explosion Severity Equal to or Greater Than 0.5

Material[a]	Minimum Cloud or Layer Ignition Temperature[b] °F		°C
Aluminum, atomized collector fines	1022	Cl	550

Vanadium, 86.4%	914		490
Zirconium hydride (93.6% Zr, 2.1% H_2)	518		270

[a]Certain metal dusts may have characteristics that require safeguards beyond those required for atmospheres containing the dusts of aluminum, magnesium, and their commercial alloys. For example, zirconium, thorium, and uranium dusts have extremely low ignition temperatures (as low as 68°F [20°C]) and minimum ignition energies lower than any material classified in any of the Class I or Class II groups.

[b]Normally, the minimum ignition temperature of a layer of a specific dust is lower than the minimum ignition temperature of a cloud of that dust. Because this is not universally true, the lower of the two minimum ignition temperatures is listed. If no symbol appears between the two temperature columns, then the lower ignition temperature is shown. "Cl" means the cloud ignition temperature is shown. "NL" means that no layer ignition temperature is available and the cloud ignition temperature is shown.

Source: NFPA 497, *Recommended Practice for the Classification of Flammable Liquids, Gases, or Vapors and of Hazardous (Classified) Locations for Electrical Installations in Chemical Process Areas*.

The operating temperature markings specified in Table 8.13.22 are not to exceed the ignition temperature of the specific gas or vapor to be encountered.

For information regarding ignition temperatures of gases and vapors, see Table 8.13.18, NFPA 497, and NFPA's *Fire Protection Guide to Hazardous Materials.*

Classes on Divisions of Hazardous Locations

Complete definitions of the several classes and divisions of hazardous (classified) locations and the methods of wiring and types of electrical equipment to be used in each are covered in detail in the *NEC*. Rules applying specifically to commercial garages, aircraft hangars, gasoline dispensing facilities and service stations, bulk storage plants, finishing processes, and areas in health care facilities containing flammable anesthetics are also covered in the *NEC*.

Class I, Division 1. This division includes locations in which (1) ignitable concentrations of flammable gases or vapors can exist under normal operating conditions; (2) ignitable concentrations of such gases or vapors may exist frequently because of repair or maintenance operations or leakage; or (3) breakdown or faulty operation of equipment or processes might release ignitable concentrations of gases or vapors, and might also cause simultaneous failure of electrical equipment in such a way as to directly cause the electrical equipment to become a source of ignition. Motors and other rotating electrical machinery, luminaires (lighting fixtures), most switches, circuit breakers, and similar electrical equipment in these locations must be of the explosionproof type or purged type approved for Class I locations of the proper group (see NFPA 496, *Standard for Purged and Pressurized Enclosures for Electrical Equipment*) (Figures 8.13.29, 8.13.30, and 8.13.31). Approved intrinsically safe equipment and circuits may also be used. These are usually limited to low-energy control, signal, and instrumentation systems.

Class I, Division 2. This division includes locations (1) in which volatile flammable liquids or flammable gases are handled, processed, or used, but in which the liquids, vapors, or gases will normally be confined within closed containers or closed systems from which they can escape only in case of accidental rupture or breakdown of such containers or systems, or in case of abnormal operation of equipment; (2) in which ignitable concentrations of gases or vapors are normally prevented by positive mechanical ventilation, and that might become hazardous through failure or abnormal operation of the ventilating equipment; or (3) that are adjacent to Class I, Division 1 locations, and to which ignitable concentrations of gases or vapors might occasionally

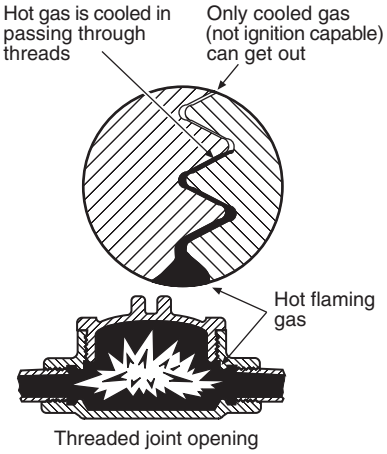

FIGURE 8.13.29 Principle of "Explosionproof" Equipment, Indicating Containment of Hot Gases Within the Enclosure

FIGURE 8.13.30 Typical Luminaire for Use in Class I, Group C and D Locations (Source: Appleton Electric LLC, EGS Electrical Group)

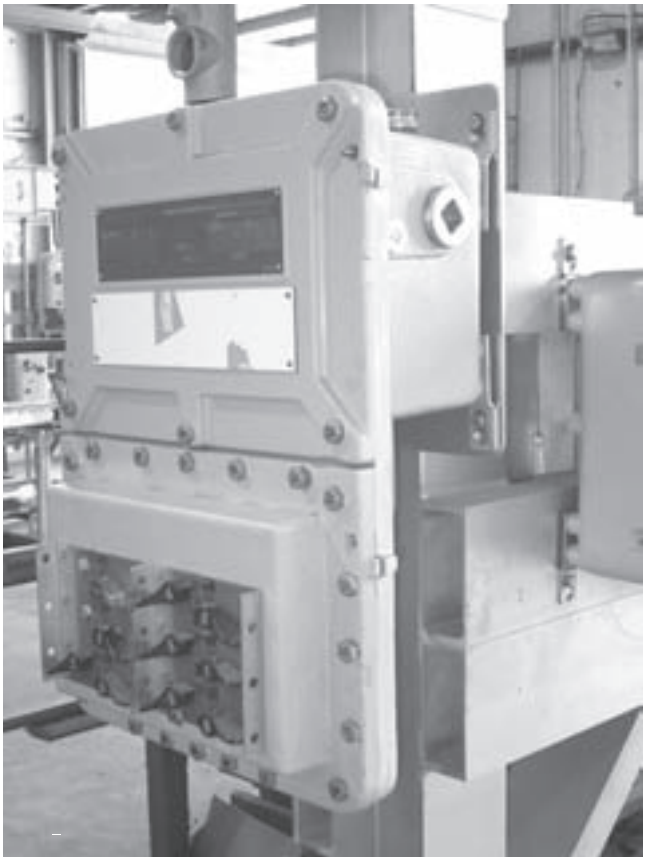

FIGURE 8.13.31 Explosionproof Panelboard (Source: Appleton Electric LLC, EGS Electrical Group)

be communicated unless such communication is prevented by adequate positive-pressure ventilation from a source of clean air, and effective safeguards against ventilation failure are provided. In general, ordinary types of motors that do not have brushes, switching mechanisms, and so on may be installed in these locations, but motors that do have sliding contacts, switches, and so on must have the switches in explosionproof or other type enclosure approved for Class I, Division 2 locations. Lamps that operate at temperatures above the ignition temperature of the gas or vapor involved must have approved explosionproof or purged enclosures. Units located where falling sparks or hot metal from broken lamps might ignite localized concentrations of flammable gases below the Division 2 location must also have suitable enclosures. Switches, circuit breakers, controllers, and other devices that create arcs or sparks and that are intended to interrupt ignition-capable energy in normal operation must either be explosionproof, have their contacts in hermetically sealed chambers, or have contacts immersed in oil. Enclosures for electrical equipment that does not interrupt ignition-capable energy or otherwise represent an ignition source under normal conditions may be of the general-purpose type. Portable lamps must be of the type satisfactory for use in a Class I, Division 1 location.

Class II, Division 1. This division includes locations (1) in which combustible dust is in the air under normal operating conditions in sufficient quantities to produce explosive or ignitable mixtures; (2) where mechanical failure or abnormal operation of machinery or equipment might cause such explosive or ignitable mixtures to be produced, and might also provide a source of ignition through simultaneous failure of electric equipment, operation of protective devices, or from other causes; or (3) in which combustible dusts of an electrically conductive nature may be present in hazardous quantities. Motors must be of an enclosed type approved as dust-ignitionproof for the proper Class II locations. Luminaires (lighting fixtures), switches, circuit breakers, controllers, and fuses that are intended to interrupt current in normal operation must be provided with dust-ignitionproof enclosures approved for the proper Class II locations. Maximum surface temperatures on equipment in Class II locations under actual operating conditions must not exceed the ignition temperature of the dust. See Tables 8.13.19 through 8.13.21 for information regarding ignition temperatures of dusts. For additional information, see NFPA 497.

Class II, Division 2. This division includes locations (1) in which combustible dust is not normally in the air in quantities sufficient to produce explosive or ignitable mixtures, and dust accumulations are normally insufficient to interfere with normal operation of electrical equipment or other apparatus, but combustible dust may be in suspension in the air as a result of infrequent malfunctioning of handling or processing equipment; and (2) where combustible dust accumulations on, in, or in the vicinity of the electrical equipment may be sufficient to interfere with the safe dissipation of heat from the electrical equipment or may be ignitable by abnormal operation or failure of electrical equipment. In general, totally enclosed motors are suitable. Under certain conditions, standard, open-type motors without sliding contacts, switches, and so on may be used in many of

these locations. Fixed lamps and lampholders must have enclosures designed to minimize the deposit of dust and prevent the escape of sparks, burning material, or hot metal. Switches, circuit breakers, controllers, and fuses should be provided with dust-tight enclosures. Division 1 temperature limits also apply to Division 2 locations.

Class III, Division 1. This division includes locations in which easily ignitable fibers or materials producing combustible flyings are handled, manufactured, or used. In general, motors in these locations must be of the enclosed type except that, where only moderate accumulations of lint are present and cleaning and maintenance are satisfactory, self-cleaning, squirrel-cage, textile motors or standard, open-type motors without sliding contacts, switches, and so on may be installed. Lamps and lampholders, switches, circuit breakers, controllers, and fuses must be dust-tight. Maximum surface temperatures under actual operating conditions must not exceed 329°F (165°C) for equipment that is not subject to overloading, and 248°F (120°C) for equipment, such as motors, power transformers, and so on, that may be overloaded.

Class III, Division 2. This division includes locations in which easily ignitable fibers are stored or handled other than in process of manufacture. Motors must be of the enclosed type. Lamps, lampholders, switches, circuit breakers, controllers, and fuses must have enclosures similar to those specified for Class III, Division 1 locations. Division 1 temperature limits apply to Division 2 locations.

Equipment for Use in Hazardous Locations

Equipment for use in Class I, Division 1 hazardous (classified) locations, as defined in the *NEC,* is sometimes referred to as *explosionproof* equipment. The two basic design criteria for explosionproof apparatus for Class I locations are that it (1) withstand internal explosions of flammable gas or vapor-air mixtures and (2) prevent propagation of the internal explosion to the surrounding flammable atmosphere. In other words, it is recognized that surrounding flammable gas or vapor-air mixtures will enter the enclosure of this equipment and the possibility exists of their ignition within the enclosure. To prevent the propagation of flame to the outside surrounding atmosphere, which may likewise contain flammable vapor-air mixtures, the enclosures of this equipment must (1) arrest flame at joints or other openings to the outside, (2) be of sufficient strength to resist (without rupture or serious distortion) the internal pressure, and (3) ensure that the external surface temperature of the enclosure is not high enough to ignite the surrounding gas or vapor. The various gas or vapor-air mixtures vary considerably with respect to (1) the propagation of flames through joints of such assemblies, (2) the pressure developed within the enclosure following ignition, and (3) the ignition temperature of the gas or vapor-air mixture. Thus, equipment should be tested and listed for use, and the various groups listed in Table 8.13.18 should be addressed, as necessary.

Equipment for use in Class I hazardous (classified) locations must also be designed to operate under full load and, in the case of equipment such as motors likely to be overloaded, must operate under overload conditions without developing surface temperatures above the ignition temperature of the flammable gas or vapor with which it is intended to be used.

As an alternative to explosionproof motors, controllers, luminaires (lighting fixtures), switches, or equipment approved for use in Class I locations, it is permissible to use either of the following two designs:

1. *Pressurizing system.* The protected enclosure must be constantly maintained at a positive pressure of at least 0.1 in. water (25 Pa) above the surrounding atmosphere during operation of the protected equipment and if a positive pressure is not maintained in a protected enclosure, a suitable device such as an indicator, alarm, cutoff, or interlock switch must warn the user to take action or must automatically de-energize power from ignition-capable equipment. The type of device should be dependent on the type of pressurization used. An alarm must be provided to indicate failure of the protective gas supply to maintain the required pressure. If Type X pressurized equipment is provided with a protective gas supply, an alarm is not required. Electric motors require at least 10 volumes of air while maintaining a positive internal pressure of at least 0.1 in. water (25 Pa), in order to accomplish proper purging of the voids between windings.

2. *Protective gas system.* The protective gas must be essentially free of contaminants or foreign matter and can contain no more than trace amounts of flammable vapor or gas. Protective gas supplies must be carefully designed to minimize chances for contamination. Air of normal instrument quality, nitrogen, or other nonflammable gas is acceptable as protective gas. Piping for the protective gas must be protected against mechanical damage. If compressed air is used, the compressor intake must be located in an unclassified location. If the compressor intake line passes through a classified location, it must be constructed of noncombustible material, designed to prevent leakage of flammable gases, vapors, or dusts into the protective gas, and protected against mechanical damage and corrosion. In addition, the electrical power for the protective gas supply (blower, compressor, etc.) must be supplied either from a separate power source or from the protected enclosure power supply before any service disconnects to the protected enclosure. When "double pressurization" is used (e.g., a Division 1 enclosed area pressurized to a Division 2 classification that contains ignition-capable equipment also protected by pressurization), the protective gas supplies must be independent.

When either of these designs is used, no external surface of the motors, generators, or other rotating electrical machinery can have an operating temperature (°C) that exceeds 80 percent of the ignition temperature (°C) of the gas or vapor involved, as determined by ASTM E659, "Autoignition Temperature of Liquid Chemicals." Appropriate devices (heat sensors) must also be provided to detect any increase in temperature of the equipment beyond its design limits and then to automatically de-energize the equipment. The detectors and control equipment used are to be suitable for the atmosphere involved without positive pressure; in other words, they must be explosionproof or intrinsically safe if the location is Class I, Division 1.

NFPA 496 provides information for the design of purged enclosures for the purpose of eliminating or reducing within

the enclosure a Class I hazardous (classified) location (gases or vapors in air in quantities sufficient to produce explosive or ignitable mixtures). Protective measures include supplying an enclosure with clean air or an inert gas at sufficient flow and positive pressure to achieve and maintain an acceptable safe level of the atmosphere.

Another alternative is the use of intrinsically safe systems, which are assemblies of interconnected intrinsically safe apparatus, associated apparatus, and interconnecting cables whose parts that are located in hazardous (classified) locations are intrinsically safe circuits. An intrinsically safe circuit is a circuit in which any spark or thermal effect is incapable of releasing sufficient electrical energy under normal or abnormal conditions to cause ignition of a specific hazardous atmospheric mixture in air under prescribed test conditions.

In many cases, the amount of explosionproof, purged, or intrinsically safe equipment required can be reduced through the exercise of ingenuity in the layout of electrical installations by locating much of the equipment in nonhazardous areas. The extent of the hazardous areas is normally defined by the codes and standards relating to the storage and handling of the specific flammable liquids, gases, or solids.

Equipment for use in Class II and Class III hazardous (classified) locations presents a somewhat different problem, because the equipment is designed to be dust-ignitionproof for Class II, Division 1 and for some Class II, Division 2 locations, and to be dust-tight or totally enclosed with telescoping covers for some Class II, Division 2 locations and for Class III locations. It is thus not intended to resist internal explosions of a dust-air mixtures. Such equipment is tested in specific dust-air mixtures to determine that the enclosures are dust-ignitionproof for Class II locations and that overheating does not occur when the device is blanketed with dust or lint and flyings.

Garages, Commercial (Repair and Storage)

The requirements of Article 511 of the *NEC* apply to locations used for the servicing and repair of passenger automobiles, buses, tractors, trucks, and so on in which flammable liquids or flammable gases are used. NFPA 30A and NFPA 88A, *Standard for Parking Structures,* should also be consulted in connection with further classifications of, and the fire protection recommendations applying to, garages. The specific hazardous (classified) areas in these garages are defined in the *NEC.*

Aircraft Hangars

Where aircraft containing gasoline, jet fuels, or other flammable liquids are stored or serviced, the specific (classified) hazardous areas are as defined in Article 513 of the *NEC.* Reference should also be made to NFPA 409, *Standard on Aircraft Hangars,* for guidance on the construction and protection of these structures.

Motor Fuel Dispensing Facilities

This occupancy group includes locations where gasoline or other volatile flammable liquids or liquefied petroleum gases are transferred to the fuel tanks or auxiliary fuel tanks of self-propelled vehicles. Reference should be made to NFPA 30, *Flammable and Combustible Liquids Code,* and NFPA 30A as well as Article 514 of the *NEC* for information on the hazardous (classified) areas and other guidance on fire safety in service stations.

Bulk Storage Plants (Flammable Liquid)

Where gasoline or other volatile flammable liquids are stored in tanks having an aggregate capacity of one carload or more and from which such products are distributed, the hazardous (classified) areas are defined in NFPA 30 and Article 515 of the *NEC.* NFPA 30 also contains many requirements for the safe construction and utilization of bulk storage plants.

Spray Application, Dipping, and Coating Processes

The *NEC* hazardous (classified) locations requirements apply to areas where paints, lacquers, or other flammable finishes are regularly or frequently applied by spraying or dipping, or by other means and where volatile flammable solvents or thinners are used, or where readily ignitable deposits or residues from such paints, lacquers, or finishes may occur. Further information regarding safeguards for finishing processes are contained in NFPA 33, *Standard for Spray Application Using Flammable or Combustible Materials,* and NFPA 34, *Standard for Dipping and Coating Processes Using Flammable or Combustible Liquids.* NFPA 33 also governs chopper-gun and hand-layup production of glass fiber reinforced plastics. Hazardous (classified) areas with respect to flammable vapors are defined in Article 516 of the *NEC.*

Chemical Plants

In chemical plants where flammable liquids or gases are processed or handled, NFPA 497 provides information on the extent of the hazardous (classified) location.

Anesthetizing Locations

The use of flammable anesthetics in health care facilities has been greatly reduced; however, there may be some older facilities that still use them. Special rules apply in hospital operating rooms and other locations where flammable anesthetics are or may be administered to patients. Article 517 of the *NEC* defines the anesthetizing location as follows: "Any area of a facility that has been designated to be used for the administration of any flammable or nonflammable inhalation anesthetic agent in the course of examination or treatment, including the use of such agents for relative analgesia."

In a flammable anesthetizing location, the entire area is considered to be a Class I, Division 1 location extending upward to a level 5 ft (1.52 m) above the floor. The remaining volume up to the structural ceiling is considered to be above a hazardous (classified) area.

Any room or location in which flammable anesthetics or volatile flammable disinfecting agents are stored shall be considered to be a Class I, Division 1 location from floor to ceiling.

For further information on the subject of flammable anesthetics, reference should be made to Chapter 3 of NFPA 99.

Places of Assembly, Theaters, Areas of Motion Picture and Television Studios, Performance Areas, and Similar Locations

In places of assembly, theaters, areas of motion picture and television studios, performance areas, and similar locations where numbers of people congregate, it is important that the electric equipment be properly designed and installed. The general rules of the *NEC,* as well as its special requirements for these occupancies, should be followed in installing the equipment. NFPA *101* should be consulted for further information on use of emergency lighting.

SUMMARY

Electricity can result in fire if an arc occurs or if electrical equipment overheats, potentially causing injury or death through shock and burns. The risk of fire from electrical systems and appliances is incurred by improper installation, lack of maintenance, improper use, and carelessness, such as failure to turn off a device when no longer needed. The manufacture, use, and maintenance of electrical installations are governed in the United States by the *National Electrical Code* and other NFPA standards. These standards cover a wide variety of systems, locations, equipment, and procedures, ranging from building wiring, design, and protection to signaling and communications systems. Adherence to the requirements of these standards ensures that electrical systems and appliances are designed, installed, and maintained properly, thus reducing the risk of fire.

SECTION 9

Processes and Facilities

Amy Beasley Spencer

9.1 Woodworking Facilities and Processes
9.2 Spray Finishing and Powder Coating
9.3 Dipping and Coating Processes
9.4 Plastics Industry and Related Process Hazards
9.5 Metalworking Processes
9.6 Welding, Cutting, and Other Hot Work
9.7 Storage and Handling of Grain Mill Products
9.8 Protection of Records
9.9 Semiconductor Manufacturing
9.10 Oilseed Solvent Extraction Plants
9.11 Protection of Wastewater Treatment Plants
9.12 Fire Protection of Laboratories Using Chemicals
9.13 Fire Protection of Telecommunications Facilities
9.14 Electric Generating Plants
9.15 Nuclear Facilities
9.16 Mining and Mineral Processing
9.17 Oxygen-Enriched Atmospheres

Section 9 gathers chapters dealing with fire protection of various processes and highly specialized facilities that in earlier editions of the *Fire Protection Handbook*® were located in the very large section entitled "Fire Prevention." The relocation of chapters to the smaller "Processes and Facilities" section groups similar information for more convenient access. The first nine chapters primarily cover processes, whereas the last eight chapters address specialized facilities.

Chapter 1, "Woodworking Facilities and Processes," addresses the fire protection problems that are unique to wooden product manufacturing facilities and processes.

Spray application of coatings is a process basic to the manufacture of a broad variety of fabricated products. Chapter 2, "Spray Finishing and Powder Coating," explains types of coatings, the equipment and components associated with both spray finishing and powder coating, and hazard control for both fluid spray and powder coating processes. The treatment of coating processes continues in Chapter 3, "Dipping and Coating Processes." That chapter discusses dipping and coating processes, equipment that uses flammable and combustible liquids, the inherent hazards and means of hazard reduction, and fire protection for dipping and coating processes.

The goal of Chapter 4, "Plastics Industry and Related Process Hazards," is to provide an overview of the plastics industry, what constitutes a plastic, the terminology used in the industry, the types of processing techniques used to produce a product, the hazards that exist when producing that product, and the steps that the industry and government have taken to provide a safe working environment for the personnel working within the facility and those people living nearby.

Chapter 5, "Metalworking Processes," explains the metalworking process, considers alternative means of machining, and identifies hazards (such as cutting fluid, lubricating oil, and metal dust) and safeguards.

NFPA 51B, *Standard for Fire Prevention During Welding, Cutting, and Other Hot Work,* defines hot work as "work involving burning, welding, or a similar operation that is capable of initiating fires or explosions." Chapter 6, "Welding, Cutting, and Other Hot Work," discusses prevention guidelines and safety precautions, contract operations, processes using electricity or oxyfuel gas, thermal spraying, and special situations.

Chapter 7, "Storage and Handling of Grain Mill Products," deals with grain mill products and explains grain elevator design before discussing dust control, relevant fire and explosion hazards, and safeguards.

Chapter 8, "Protection of Records," outlines storage options, including bulk storage, mobile shelving, and open shelf storage, and discusses extinguishment, including damageability and salvage of records.

Amy Beasley Spencer is a senior chemical engineer in the Fire Protection Applications and Chemical Engineering Division at NFPA.

Chapter 9, "Semiconductor Manufacturing," considers both preproduction and production processes, as well as fire hazards, health hazards, and hazard control.

The second half of Section 9 concentrates on specialized facilities, beginning with Chapter 10, "Oilseed Solvent Extraction Plants," which discusses plants that house devices such as desolventizer-toaster (D-T) units, rotary coolers, and rotary steam tube dryers.

Wastewater treatment plants are covered in Chapter 11, "Protection of Wastewater Treatment Plants." The chapter covers operations and equipment, general and process hazards, fire and explosion mitigation, and fire protection measures for wastewater treatment plants.

Strategies for protection of laboratories using chemicals are explored in Chapter 12, "Fire Protection of Laboratories Using Chemicals." This chapter describes passive and active fire protection strategies for laboratories, as well as safe storage and handling of chemicals, chemical waste, and compressed and liquefied gases.

Chapter 13, "Fire Protection of Telecommunications Facilities," discusses protection against fire in the public and private telecommunications networks in the United States and Canada. This chapter describes many industry changes, their potential impact on fire risk, and methods to assess fire risk and determine appropriate fire protection programs.

The next two chapters deal with power facilities. The purpose of Chapter 14, "Electric Generating Plants," is to help the reader achieve a well-developed fire safety program tailored to the needs of an electric generating plant. This chapter offers guidance on how to develop a program that addresses life safety, continuity of operations, and property protection for individuals who are responsible for the design, construction, operation, and protection of electric generating plants that are fueled by fossil fuels, alternative fuels, and hydroelectric plants. Chapter 15, "Nuclear Facilities," discusses nuclear reactors, radiation machines, radioactive materials, and radiation exposure, in addition to fire protection concerns.

Chapter 16, "Mining and Mineral Processing," discusses typical surface and underground mining methods, the excavation and distribution equipment used in mining, and the various and typical mineral concentration or coal preparation processes used to convert mined materials into intermediate or final consumer products. Fire and explosion hazards presented by the mining and processing of coal and metal and nonmetal ores as well as structural and construction materials are the focus.

The section closes with Chapter 17, "Oxygen-Enriched Atmospheres." Such atmospheres are commonly used in medical applications, industrial processes, underwater tunneling and caisson work, deep-sea exploration, space flight operations, and commercial and military aviation. This chapter discusses the fire hazards that may be associated with oxygen-enriched atmospheres and presents methods that can reduce and protect against fire hazards.

Fire Protection

Key Terms

deflagration, design brief, dust collection system, explosion, fire prevention, flammable liquid, flammable solvent, forest products, heat transfer fluid, process hazard, wood products, wood waste, woodworking

After millennia of civilization and technological progress, wood—humanity's first structural material—remains the favorite material for the construction of both our homes and the furnishings we choose to live with. The demand for wooden products has not diminished with the introduction of plastics as some had predicted; it has increased. For example, timber product consumption (in industrial round wood consumption) increased 70 percent from 1960 to 1997.[1] With the ever-increasing demand for wooden products, there has been a continued growth in the forest products industry.

The tens of thousands of timber-based manufacturing facilities average 20 to 30 paid employees apiece.[2] Some forest products firms are housed in old timber-frame structures, whereas others are in new fire-resistive structures—ultramodern facilities with automated processes controlled by computers. Some woodworking facilities are one-person shops whereas others employ as many as 2000 people. Some woodworking shops produce custom-designed high quality furnishing, whereas others produce dimension lumber, paneling, engineered wood products, rifle stocks, knobs, millwork, picture frames, cutting boards, or musical instruments. It is the wide size, age, business volume, and product range, coupled with the inherently combustible nature of wood, that makes fire protection for any woodworking facility a challenge.

This chapter addresses the fire protection problems that are unique to wooden product manufacturing facilities and processes. It will not discuss wood as a material, which is covered in Section 6, Chapter 4, "Wood and Wood-Based Products." Nor will it discuss the fire protection concerns over wooden construction and timber-frame construction under fire exposure. These topics are covered elsewhere. This chapter is devoted to the woodworking facility and the production processes commonly employed in those facilities.

For the purposes of this chapter, a *deflagration* is the propagation of a flame-front through a fuel/oxidizing gas mixture at a velocity that is sufficient to cause an increase in pressure but is slower than the speed of sound in the gas. In the case of most woodworking and wood-processing facilities, the fuel is wood dust, and the oxidizing gas is air. Where the wood particles are relatively large, the flame-front propagates slowly enough that an observer would describe it as a rapidly expanding fireball or flash-fire. However, where the particles are finer, the flame front propagates too fast to discern, and it appears to be an instantaneous burst of flame. When a deflagration occurs within a building, room, or other enclosure, the expansion of the hot combustion product gases produces so much pressure that the enclosure ruptures. For the purposes of this chapter the rupture of an enclosure due to the development of excessive pressure within from a deflagration is called an *explosion.*

For related topics, see Section 6, Chapter 1, "Fire Hazards of Materials"; Section 6, Chapter 4, "Wood and Wood-Based Products"; Section 6, Chapter 8, "Dusts"; Section 8, Chapter 7, "Heat Transfer Systems and Fluids"; and Section 21, Chapter 4, "Vehicle Fueling Using Gaseous Fuels."

John M. Cholin, P.E., FSFPE, is an independent fire protection consultant and engineer with J. M. Cholin Consultants, Inc., in Oakland, New Jersey. He chaired NFPA's Technical Committee on Wood, Paper, and Cellulosic Materials from 1992 through 2002 and continues to serve on the committee.

FOREST PRODUCTS INDUSTRY

The forest products industry is often categorized based on the type of product produced. Forest products are commonly divided into four general categories:

1. Primary forest products
2. Secondary forest products
3. Tertiary forest products
4. Pulp and paper

Primary forest products, including structural timbers, dimensioned lumber, shingles, and veneers, are produced from a wide variety of tree species. Only cutting and drying are required to derive these products from the raw log. Primary forest products are usually produced in facilities that are dedicated to a specific product and situated close to the forest source. The primary product is then shipped as a commodity to various producers of either secondary or tertiary forest products. There are exceptions to this general scheme of things. Some *secondary forest products,* such as plywood, particle board, flake board, oriented strand board, and fiberboard, are produced in large centralized facilities that consume logs in their raw form as well as chips and wood waste shipped in from other locations.

Other secondary forest products, including millwork, knobs, spindles, paneling, glue-laminated beams, composite wood joists, and dowels, are made from the primary dimension stock in separate facilities or portions of larger entities that produce the tertiary product. Each of these forms of wood has specific structural characteristics that make them the material of choice for specific applications. These products are referred to as "secondary" because processes subsequent to cutting and drying are necessary to create the product, yet the product is still not in a form that is normally consumed at the retail level.

The majority of the primary and secondary forest products are consumed as raw material for *tertiary forest products,* forest products that are consumed at the retail level. The most obvious examples of tertiary forest products are houses and furniture. Lumber, a primary forest product, is cut and shaped into wooden components that are then assembled with other components to ultimately become a finished piece of furniture.

The final category is *pulp and paper.* Paper production is generally a wet process, where wood particulate is suspended in a water-based slurry. The fire hazards associated with paper production are unique to pulp processing and paper manufacture and are not addressed in this chapter.

PROCESS HAZARDS MANAGEMENT

Process Hazards Analysis (PHA)

In general, woodworking and wood-processing facilities represent both a fire and explosion hazard. In order to manage that hazard down to an acceptable level of risk, the entire process and facility should be analyzed in an orderly process where the hazards associated with each stage in the process are identified and documented. Once all of the hazards are documented, the relevant metrics required for the management of the hazard should be identified and quantified. Then a hazard management method can be selected to manage the fire or explosion hazard down to an acceptable level. This stepwise analytical process is generally referred to as a *process hazards analysis* (PHA). A prudent facility operator should perform a process hazards analysis on her or his facility to identify those areas where there is a demonstrable fire or explosion hazard.

Hazard Management Strategy

Once the analysis has been performed and reduced to a document, a hazard management strategy can be developed. The hazard management strategy is derived from the quantity and physical nature of the fuel, the type of ignition sources present, and the expected nature and extent of the resulting fire. These factors will dictate whether the ignition can be reliably prevented. If it cannot, what fire suppression or extinguishing methods will be necessary and sufficient to prevent the extension of the fire? This thought process leads to a hazard management strategy, usually documented in the form of a *design brief.*

Implementation and Maintenance

With a strategy in place the next step is implementation. Ignition prevention features are added where appropriate. Fire suppression and extinguishing systems are designed and installed where they are needed. Where the process hazards analysis identified a potential for a deflagration, the means to manage the explosion hazard are selected and installed. Finally a maintenance program is adopted to maintain the performance of the hazard management assets.

Ignition Process

In a woodworking or wood-processing facility, the process hazards analysis will almost invariably identify both fire and deflagration hazards. The fuel, wood, is ubiquitous. Virtually all woodworking processes involve reducing the size of a piece of wood through mechanical means. Whenever mechanical work is done on matter, heat is liberated. This is a principle of physics called the work/heat equivalence. Consequently, one must anticipate the liberation of heat whenever wood is processed. If this heat is allowed to accumulate in a sufficiently small mass of wood, the temperature will increase until it reaches the point where exothermic pyrolysis begins. Once exothermic pyrolysis begins, usually approximately 536°F (280°C), the reaction liberates more heat than it consumes, and it will continue without additional energy input.[3] Ignition has been achieved, and the wood will char. Such temperatures can easily be achieved from frictional heating through the use of powered cutting and shaping tools. Figure 9.1.1, for example, shows a milling cutter that was turned blue, indicating a temperature in excess of 600ºF (316ºC), during a routing operation that led to the ignition of a fire in the dust collection system. If conditions conducive to sustained combustion are maintained, wood brought to this temperature will ultimately break into open flame. Consequently, every mechanized woodworking process represents a very real ignition hazard.

Machinery that performs cutting, sanding, milling, sawing, or grinding operations on wood will occasionally ignite

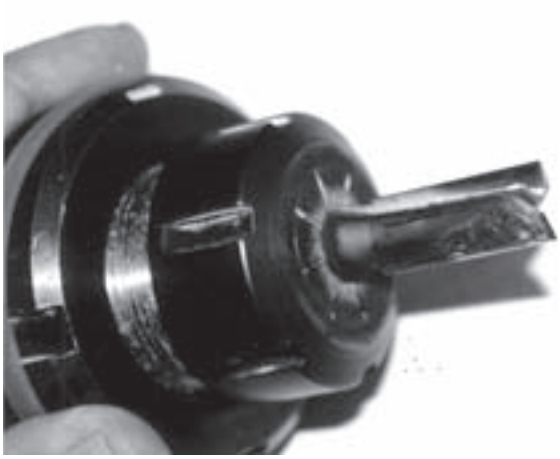

FIGURE 9.1.1 Milling Cutter Turned Blue from High Temperature During a Routing Operation (Source: J. M. Cholin Consultants, Inc.)

the particulate being generated. The heat liberated by the friction attendant to the cutting operation is the ignition source. The probability of spark generation is related to both the wood species and the woodworking process. In general, species that exhibit wide variations in density are prone to produce more sparks. The feed rate of a saw or milling machine is generally adjusted for the average density of the species. When the cutter encounters an abnormally hard portion of a board, excessive heat is generated. The other important species-dependent factor is the average hardness of the wood. The harder the wood, the more likely it is to generate sparks when maximum recommended feed rates are exceeded.

Some generalities can be made regarding the relative tendency of various species to present a spark generation problem, but only in the context of the process. The hardwoods maple, hickory, cherry, and white oak are commonly viewed as representing a high probability of spark generation in the context of milling and cutting. Other hardwoods, including beech, red oak, birch, yellow poplar, and ash, have represented less of a problem.

The softwoods tend to be less prone to spark generation in sawing and milling. The theory is that the resin in the softwood chips can evaporate with a cooling effect, whereas hardwoods lack these resins, and consequently, ignite. However, in sanding operations, the resinous softwoods tend to load the abrasive grit much more aggressively than do the nonresinous hardwoods. This results in a tendency of resinous softwoods to generate sparks several orders of magnitude higher than that of hardwoods in the sanding operation.

Management of Wood Waste

Since most woodworking processes produce waste wood as a by-product of the size reduction to the desired size and shape, wood-waste management is a major design and operational concern. Wood waste exists over a wide range of particle sizes, from board-size pieces to fine powdery dust. Management of wood waste is a ubiquitous problem throughout the forest products industries. Fine wood particulate is very easily ignited. When suspended in air, it burns very aggressively, producing a deflagration.

When wood particulate exists in a mass or pile, such as an accumulation on a floor, it can smolder for extended periods of time (days), producing a charring mass. As soon as sufficient air, at sufficient velocity, is provided to suspend the particulate in the air a deflagration can result. The accumulation of wood dust and wood-waste particulate is a serious problem that plagues almost every forest products facility.

WOODWORKING PROCESSES

There are many distinct types of woodworking equipment. Each has specific operating characteristics that make it both an ignition source and a generator of wood particles that are relatively easy to ignite. Despite this fact, it is important to note that, collectively, only about one-fourth of reported fires in woodworking facilities, based on 1994–1998 structural fire data, had any type of processing equipment involved in ignition. One-third of fires involved no equipment at all. A significant share of the reported fires were caused by cutting and welding operations, heating equipment, and electrical distribution equipment. It is important not to overlook common hazards while addressing special hazards.

The combustibility of wood-waste dusts is the basis for the concern with the generation of sparks by woodworking machinery. NFPA 664, *Standard for the Prevention of Fires and Explosions in Wood Processing and Woodworking Facilities,* addresses both the fire and explosion prevention and protection features for each principal type of woodworking process. In many cases, particular types of woodworking processes present unique fire protection problems. The reader is urged to consult this standard before undertaking a design of a wood-processing facility.

Raw Material Storage

The storage of wood products represents a fire protection challenge, as large quantities of inherently combustible material are commonly stored in a single location. The storage material can consist of logs, chips, stuck lumber (wood stacked for drying), dense packed lumber, or panels. Regardless, once ignited, the fire has a tremendous fuel load available to it and, if proper precautions are not observed, the fire can rapidly become impossible to extinguish.

Fire protection criteria for bulk wood storage are found in NFPA 1, *Uniform Fire Code*™. This standard addresses indoor storage of lumber at retail and wholesale locations, as well as outdoor storage of timbers, logs, and chips. It states that large undivided piles, congested storage conditions, delayed fire detection, inadequate fire protection, and ineffective fire-fighting tactics are the principal factors that allow fires to escalate to large losses.

Fire Prevention Program. NFPA 1 also states that the fire hazard potential inherent in forest products storage operations,

with their large quantities of combustible materials, can best be controlled by a positive fire prevention program under the direct supervision of top management and should include the following:

1. Selection, design, and arrangement of storage yards or areas and materials-handling equipment based on sound fire prevention and protection principles
2. Systems for early fire detection, transmission of alarm, and fire extinguishment (see *NFPA 72®*, *National Fire Alarm Code®*)
3. Fire lanes to separate large piles and to provide access for effective fire-fighting operations
4. Separation of yard storage from mill operations and other exposing properties
5. An effective fire prevention maintenance program, including regular yard inspections by trained personnel

Danger of Deflagration and Explosion. NFPA 1 provides specific recommendations for pile size, separation between piles, and water supply for each type of storage. Where dry wood particulates are stored in silos, bunkers, and bins, there is also an explosion hazard. Loading operations usually produce suspensions of fine wood particles (dust) in the ullage space above the top of the fuel. Unloading operations often are accompanied by cavitation deep within the fuel mass. When such cavities collapse a dust suspension is created. If there is any burning material present when either of these two dust-suspending circumstances exists, that material can serve as the ignition source for a dust deflagration.

Consequently, it is advisable to monitor the material being conveyed into such storage vessels for burning material (sparks or embers). This is usually done with a spark detection system that is coupled with an intermittent water spray extinguishing system mounted on the in-feed conveyor or conveyors. In some cases the spark detection system is used to activate diverter valves to divert the flow to a safe location known as a *fire dump,* rather than rely on extinguishment of the ember(s) in the particulate flow stream.

Storage of Lumber. Where lumber and panels are stored indoors, they should be oriented horizontally, not vertically. Furthermore, indoor lumber and panel storage should be kept separate from other combustibles, neat and free of clutter or extraneous material. Lumber should be kept in dense-packed units until used, as this practice minimizes the exposed surface area and hence the heat release rate in the event of an ignition.

Dimension Cutting

Dimension cutting usually occurs at a specialized facility called a sawmill. Raw logs are first debarked and then cut to one of several standard working lengths. The bark is collected beneath the debarker and usually transported to a collection silo by a belt conveyor. The log is then squared on at least two sides. The slabs taken from the log to square it are waste and are either diverted to a pile for residential firewood or introduced into a wood-waste system via a hog. (A hog is a high-power mill that reduces large pieces of wood to chips, splinters, or flakes.) The squared-up log is then run through the saw and converted into rough green dimension stock.

When raw logs are reduced to green dimension stock, the moisture content in the wood is usually in excess of 25 percent. This moisture content is generally considered sufficiently high to make ignition of the stock being cut unlikely. However, the sawdust that accumulates beneath and around the saw will rapidly air dry to a moisture content of approximately 10 percent. At this moisture content wood is readily ignitable. The inherently ignitable state of the sawdust in the vicinity of the saw constitutes the most serious fire hazard associated with the sawing operation.

Rough sawing does introduce ignition sources from "inclusions" in the log. These inclusions run the gamut from arrowheads, bullets, nails, and sugar-taps to stones and knots. Although larger mills may have either radio frequency or ultrasonic metal detectors monitoring the logs being fed to the saw, inclusions can still occasionally be hit by the saw. This generally produces large quantities of heat, resulting in the ejection of sparks, embers, or broken saw teeth into the sawdust that has accumulated in the vicinity of the saw. The removal of wood waste, including sawdust, is an important means of managing the fire hazard in the sawmill. Usually the hazard is managed with the installation of a wood-waste removal system to prevent accumulations of wood dust in the sawmill.

Drying

Most tree species yield green wood with a moisture content between 30 and 50 percent water, by weight. As green wood dries, it shrinks. Consequently, green wood is generally deemed unusable as a structural material and must be dried before it can be used. Most wood intended to be used as *dimension stock* is kiln dried to a moisture content of between 5 and 7 percent. Wood chips, flakes, and strands intended for use in particle board, oriented strand board, flake board and similar engineered wood products are often brought to lower moisture contents to aid in the adhesion efficiency of the glues used to form these products.

In the lumberyard, boards are individually inspected and built into hacks for drying and handling. A *hack* is a stack of green boards in layers with a narrow gap between adjacent boards, created by thin sticks called *kiln sticks* or *stickers.* The stickers provide for the flow of air between layers of boards.

Lumber hacks are usually approximately 14 ft (4.3 m) long, 6 to 8 ft (1.8 to 2.4 m) wide, and from 4 to 6 ft (1.2 to 1.8 m) in height. Hacks are stacked by forklift trucks, back to back and as high as 16 ft (4.9 m). The honeycomb construction and the resulting easy access to combustion air make it almost impossible to extinguish a fire in a lumber hack once it is underway. Consequently, aisle widths in both the staging and storage area, as well as the kiln should be sufficiently wide to allow fire-fighting equipment to maneuver effectively.

Dry Kilns. The kiln (Figure 9.1.2) removes the moisture from the lumber in a manner that minimizes the differences in rate of shrinkage throughout the board. The hacks are placed into the kiln. Once fully loaded the kiln temperature is raised, often as high as 300°F (149°C), and the humidity is maintained at

FIGURE 9.1.2 Typical Wood Kiln Used for Drying Dimension Stock (Source: J. M. Cholin Consultants, Inc.)

100 percent. Once the entire stack of lumber has attained the kiln temperature, the humidity is allowed to decrease slowly, while the temperature is maintained. This drives the moisture from the wood without causing cracks (called *checks*), warping, twisting, or other defects in the dried planks. The hacks of kiln-dried (KD) lumber emerge from the kiln (Figure 9.1.3) after a period of usually several weeks having a uniform moisture content throughout the board. For most wood species a moisture content of approximately 7 percent is considered ideal for use in construction, furniture, and other tertiary forest products.

Veneer driers are a special subset of kiln. They are designed to dry the thin plies of wood used in the manufacture of plywood and decorative paneling. The plies usually range in thickness from ⅛ in. (3.2 mm) down to 1/32 in. (0.8 mm). The thinness of the ply aids in rapid drying. The plies are loaded onto racks which move through the kiln.

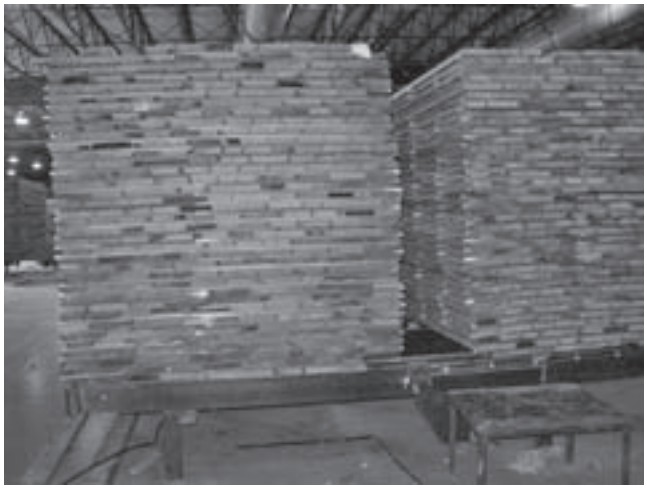

FIGURE 9.1.3 Two Hacks from a Dry Kiln (Source: J. M. Cholin Consultants, Inc.)

While the drying of lumber and veneers does not involve reducing the size of the lumber, it does involve heating a cellulosic combustible material to a temperature close to 392°F (200°C), a temperature usually taken to be sufficient for the onset of endothermic pyrolysis.[2] Furthermore, the productivity of the kiln is measured by the number of board feet of lumber that exit the kiln per unit of time and per quantity of heating fuel consumed. This creates a financial incentive to run the kiln as hot as possible.

Rotary Drum Driers. The drying process for wood particulates used in engineered wood products such as particle board, medium density fiberboard (MDF), flake board, and oriented strand board (OSB) is radically different. Particles are usually dried in rotary drum driers. Figure 9.1.4 is a photograph of a rotary drum drier. Figure 9.1.5 is a schematic diagram of the

FIGURE 9.1.4 Rotary Drum Drier (Source: Energy Unlimited, Inc.)

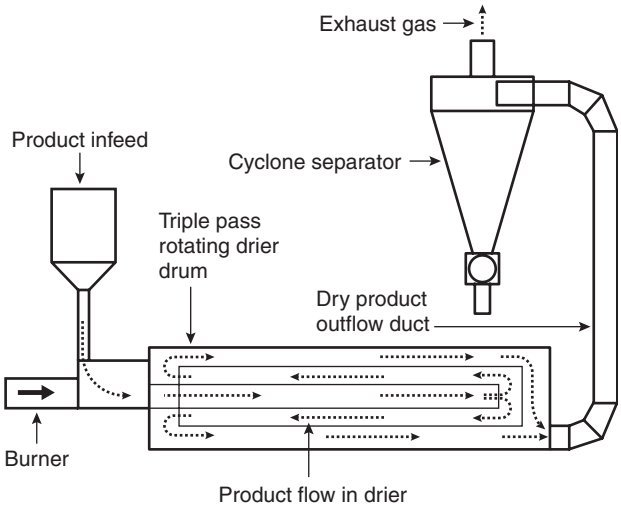

FIGURE 9.1.5 Schematic Diagram of a Rotary Drum Drier (Source: J. M. Cholin Consultants, Inc.)

rotary drum drier with flue gas and particulate flow. Most rotary drum driers are *direct-fired,* meaning that the drying fluid is flue gas taken directly from a burner, often fueled with wood waste. The flow of the flue gas is used to pneumatically convey the wood particulates through the dryer, driving the moisture out of the particulates as the flue gas flows past the particles. The flue gas and water vapor are usually separated from the wood particulates in a cyclone separator.

The operation of a rotary drum drier must be carefully controlled. Usually the flue gas enters the drier at a temperature close to, if not above, the ignition temperature of the wood. By closely controlling the flue gas temperature and flow rate compared to the particulate flow rate and rotational speed of the drier, the operator can dry the particulate down to the target moisture content without igniting any of the particulate. However, imbalances in the operating parameters can lead to ignition of the wood particulates by the drying process. This fact makes it very important to have a well-thought-out fire detection and extinguishing strategy for the conveying and storage equipment downstream from this type of drier. Usually spark/ember detection and intermittent water spray extinguishing systems are used to manage the frequency of sparks entering the production space and deflagration hazard management measures are used to manage the explosion hazard associated with downstream conveyors and storage vessels.

Wood-Waste Particulate. Driers, regardless of type, often use heat generated from the combustion of wood waste. Wood-waste particulate is usually collected from a number of sources, including sawdust, planer chips, and the discharge from a wood hog. The wood waste is conveyed to a storage silo. As boiler fuel is needed, the wood particulate is then conveyed to the boiler via a pneumatic conveyance system or screw conveyor.

Wherever wood is handled as a particulate solid, the potential for fire and deflagration exists. This will be covered in detail later under wood-waste management. NFPA 664 includes detailed fire protection requirements for the various types of wood-drying equipment in common use. These criteria focus on the fire hazard in drying operations handling lumber and veneers. NFPA 664 also addresses explosion prevention in drying operations handling fine particulates.

Veneer Cutting

The object of veneering is to obtain more square feet of visually appealing or usable wood from a log. In general, there is less waste generated in veneering than in the dimension sawmill. However, there is still waste in the form of sawdust, veneer flakes, veneer strands, bark, flattening slabs, and cutoffs. This waste represents a fire hazard similar to that in the sawmill. Management of the fire risk depends on the wood-waste removal system to minimize the accumulation of wood waste in the site. This will be covered in detail later under wood-waste management.

Veneer mills are unique in that the size reduction is performed with knives rather than saws. Veneer logs are often air dried for an extended time period prior to processing. They are then cut to length prior to slicing with knives. Veneer is cut either by a rotary machine or a rift machine. The rotary machine turns the log and slices a thin layer from the circumference as it rotates. Rift cut veneer is produced by slicing along the length of a log that has been sawn down its middle. As the veneer comes off the log, it is transported via conveyor to a dryer where it is rapidly brought to the nominal 7 percent moisture content. Most commercial hardwood veneer is a nominal 1/32 in. to 1/24 in. (0.8 to 1.1 mm) thick, whereas softwood veneers and plies vary from 1/24 in. (1.1 mm) for face ply to 1/8 in. (3.2 mm) for core plies. As a consequence of thinness, drying of veneer occurs quite rapidly. The dried veneer is either stacked flat and baled for shipping or transported via conveyor belt to a paneling facility, where it is laminated into multi-ply material or onto a composite wood core.

Veneer-cutting operations require very large mechanical forces. These forces are generated by large electrical motors or hydraulic systems that introduce additional ignition mechanisms and attendant fire hazards.

Panel Manufacture

The need to obtain greater quantities of useable product from each tree has created an environment in which tremendous strides have been made in the manufacture of panels from wood particulate. Whether particle board, oriented strand board (OSB), flake board, medium-density fiberboard (MDF), or plywood, manufactured panels continue to comprise a significant portion of the wood used in the United States and abroad. Panels employ a mixture of wood particulate or, in the case of plywood, thin plies of wood and petroleum-based adhesive resin to produce a product that provides many of the structural advantages of wood at a reduced cost.

In the production of traditional dimensioned lumber, almost 25 percent of the wood in the tree ends up as waste. By the time traditional dimensioned stock is turned into a finished product, another 25 percent is lost as waste. The use of manufactured panels reduces the waste overhead considerably by reducing the entire log to particulate and reassembling the log into a flat panel that is more conducive to efficient use.

Reduction of Log to Particulate. The first step in the panel manufacturing process is the reduction of the log to "small" particles. In the case of plywood manufacture, the small pieces are thin plies of wood. In the case of flake board, OSB, MDF, and other products, the log is chipped and, in some cases, hogged to produce a particulate of a predetermined target average particle size. In many cases, wood particulate is purchased from third-party producers and trucked in from diverse sources. In this case, there is the potential for the importation of burning material into the facility from a third-party supplier. This potentiality must be considered in the fire protection strategy for the particle board facility.

Particulate Storage and Drying. The wood particulate for particleboard is usually stored in large piles outdoors until needed. The particulate is first screened to remove stones, grit, tramp metal, and particles that are both too large and too small. The particulate is then dried to an acceptable moisture content, usu-

ally below the 7 percent usually preferred for dimension lumber. In the case of plywood production, the drying is carried out in veneer dryers. In the case of the other types of panels, such as particle board, the drying is carried out in dryers specifically designed for the type of particle being processed, such as rotary drum dryers, mentioned previously. Each type of dryer presents its own fire hazard as heat is used to drive off the water in the wood. Particular attention should be paid to the source of heat for the dryers. Occasionally, dryers employ either heat transfer fluid (HTF) or steam as a source of heat. (See Section 8, Chapter 7, "Heat Transfer Systems and Fluids.") However, many dryers are direct-fired. Dryer heat sources can represent a serious source of ignition. Once the wood particulate is dried, it is often classified by particle size and stored as dry particulate in intermediate storage silos or bunkers.

Panel Assembly. The dry wood particulate is conveyed from intermediate storage to a blender, where it is mixed with a thermoset adhesive resin. One or more flat layers are then extruded down onto a wide stainless steel belt. The layers of wood particulate are called the *mat.* The mat is conveyed to the press and compressed at high pressure and heat to form the finished board.

In particle board manufacture both gang and continuous presses are used. In the gang press a large number of layers of the wood particulate mat are sequentially stacked, separated by a stainless steel divider sheet, into the press. The press then closes and both heats and compresses the layers of wood particulate mat, causing the thermoset resin to react and glue the particles together into a single panel. After the requisite press time the press opens, and the panels are removed and conveyed to a panel cooler.

Continuous presses use a set of long continuous stainless steel bands between which the wood particulate mat is extruded. These two bands, one beneath and one above the mat, slide into the press where the heat and pressure are applied as the bands slide through the press. As the bands leave the press, a long, continuous panel results. As the panel exits the press it is cut to length and conveyed to the panel cooler.

Since the press uses both heat and pressure, there are concerns over the presence of the heat transfer fluid (HTF), usually called thermal oil in the forest products industries, and hydraulic fluids used by the press. As a general rule, continuous presses are larger, much more costly, and use far more HTF at higher pressures than the sequential gang presses they replace. All of these factors make fire protection much more demanding.

Plywood. The process for making plywood is similar to that for particle board. A ply is laid down, sprayed with adhesive, and covered with the next ply, the process continuing until the intended number of layers are in place. The press then closes, and heat and pressure are applied to cause the adhesive to react, producing a panel.

As for the particle board presses, the heat source for the press is usually HTF. HTF represents a serious fire hazard whenever it is used. Usually it is used at temperatures above its flashpoint and is pumped from the heating plant to the utilization equipment at both high pressure and high volumetric flow rate. In the event of a leak this can result in the release of a combustible liquid above its flashpoint as an atomized spray or rapidly expanding pool over large portions of the facility. This is an obvious and serious fire hazard.

Each of the operations in producing a panel product involves specific fire protection problems, usually associated with the type of equipment used. The fire protection engineer or specialist must study the specific process and its equipment in detail to identify the fire hazards and the most cost-effective means of managing the fire risk.

Milling

Rough-sawn dimension stock serves as a raw material for the production of lumber. Most dimension stock is milled to standard nominal dimensions, such as 2 in. (5 cm) by 4 in. (10 cm) or 1 in. (2.6 cm) by 6 in. (15.4 cm). Milling involves passing the stock through edgers, jointers, and planers, all of which have hardened steel cutters rotating at high speed that cut away enough wood to assure a smooth, straight, and flat surface on all four faces. Often short sections of plank are joined end-on to form a long plank. This process involves the use of finger joiners. Finger joiners produce interlocking fingers on the ends of boards allowing them to be joined end-to-end with glue to make longer pieces.

Other secondary milling operations further reduce the lumber to pieces with specific cross-sections for door stiles, door frames, window frames, window sills, moldings, tongue and groove flooring and paneling, and other special uses. These specific cross-sections are produced by mills with cutters that have been precisely ground to produce the desired shape.

Milling produces large quantities of wood chips and dust. The high speeds of the cutters and the high feed rates make the generation of sparks and embers the rule rather than the exception. This reality complicates the problems in the wood-waste management for the site. The wood waste must be removed from the milling machine to prevent an accumulation of chips, yet the wood-waste stream is likely to contain embers.

NFPA 664 includes detailed fire protection and explosion prevention requirements for wood-waste handling systems (dust collection systems). Although the chips from milling operations are generally too large to support a deflagration, there is usually a sufficiently high concentration of fine dust mixed with the chips that these portions of the dust collection system should be evaluated for explosion hazard.

Cutting

As lumber is used as a raw material in tertiary forest products facilities, one of the most common processes is cutting to component dimension. Cutting across the grain of the board is called cross-cutting, and cutting parallel to the grain is called ripping or resawing. The by-products of cutting are sawdust, block scraps from cross-cutting, and kerf scraps from resawing.

The cutting creates a severe fire ignition exposure, as dry stock is processed by a machine that can transfer large quantities of energy into the fine wood waste created by the machine. The sawdust is produced at elevated temperatures and is easily

ignited. This is especially true of facilities that process woods with large variations in density in a single board or billet. When the wood density increases, the feed rate must be reduced to keep operating temperatures below the auto-ignition temperature of the sawdust. In mechanized facilities, the feedback from the saw to the feeding unit may not be sufficiently responsive to assure adequate control over cutting temperature in the workpiece. The result is sparks and embers in the sawdust stream from the unit when knots, crotches, burls, and butts are encountered in the cut. This is especially common in resawing.

High saw speeds and high feed rates make the generation of sparks and embers in the cutting operations a common occurrence. As in milling, this complicates the problems of wood-waste management for the site. The wood waste must be removed from the saw to prevent an accumulation of chips, but this waste stream is likely to contain embers. As stated previously, NFPA 664 includes detailed fire protection and explosion prevention requirements for wood-waste handling systems. Although the sawdust from cutting operations is generally too large to support a deflagration, like milling operations, there is usually a sufficiently high concentration of fine dust mixed with the chips that such dust collection systems should be evaluated for explosion hazard.

Turning

Turning has historically represented somewhat less of a fire risk than other shaping methods. However, when billets of wood with wide variations in density or glue-ups are used, there is an ignition potential. Part of the difficulty with turning is that the roughing, final shaping, and sanding are often done at the same location, without removing the workpiece from the lathe. This introduces a very wide range of dust particulate into the waste removal system, increasing the likelihood of a dust collector fire. Previous comments regarding the potential for explosion in wood-waste handling systems apply here as well. See NFPA 664 for applicable requirements.

Laminating

Laminating covers a very wide range of processes. There is an incredible range of surfaces, substrates, and adhesives in use today. Some lamination surfaces are themselves engineered materials consisting of multiple layers of different materials, all integrated into a single layer with advanced adhesives. Amendments to the Clean Air Act have placed pressure on laminators to reduce volatile organic compound (VOC) emissions (see Section 21, Chapter 4, "Vehicle Fueling Using Gaseous Fuels," for a discussion of volatile organic compound emissions). Consequently, many toluene- and xylene-based glues have been replaced with casein, acrylic, and urethane adhesive systems. These adhesive systems are typically heat activated and are applied at a very high solids content.

Application of the adhesive is usually performed at a spray station. Adhesive application does not involve the complexities of spray finishing. Overspray is easily controlled and electrostatic spraying is rarely employed, due to the poor electrical conductivity of wood-based substrates. Once the adhesive is applied, the laminate facing is applied, and the adhesive is activated by applying both heat and pressure, either by passing the laminate through heated rollers or placing the laminate in a heated press. The heat source for the heated rollers or press is usually either steam or heat transfer fluid. Combustible heat transfer fluids have been known to provide an ignition source when lines have ruptured while at elevated temperature and pressure.

Sanding

Each component that is to become an exposed part of a finished assembly must be smooth and free of sharp edges. This is achieved by sanding. The sanding operation is particularly hazardous because of the fineness of the dust created. The final form and surface quality of virtually all wooden products are achieved by sanding. A wide variety of sanding machines are used in the tertiary forest products industries, from hand-held random orbital sanders for finish sanding to wide-belt abrasive planers capable of taking over ⅛ in. (3.2 mm) in a single pass. The sanding machine shown in Figure 9.1.6 is being used to smooth the surface of furniture legs and represents the small end of the size range in sanding machines.

Dust Collection. Sanding operations probably represent the greatest hazard to the modern forest products plant. Sanders can produce large quantities of dust at the same time they generate high temperatures from the sanding operation. Usually pneumatic conveying systems are used to pull the sander dust from the sander toward a dust collector. Generally, the dust collection system is designed to operate at dust concentrations well below the minimum explosible limit for the wood dust generated by the sander. However, when an extremely large reduction in panel thickness must be achieved, the dust concentration in the duct can exceed the minimum explosible concentration (MEC). This renders the atmosphere within the duct deflagrable and the dust collection system an explosion hazard.

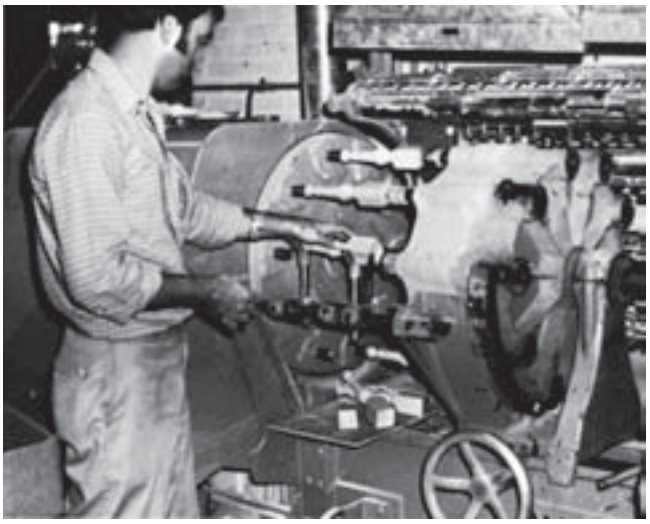

FIGURE 9.1.6 Sanding Machine Smoothing the Surface of Furniture Legs

Deflagration Prevention Systems. Under these circumstances explosion prevention strategies must be provided for the dust collection ducts and the dust collector. Dust collection systems serving sanders should always be designed to operate well below the MEC at the worst-case operating condition, removal of the maximum depth of cut at the maximum feed rate. While this design strategy introduces additional cost into the dust collection system by requiring large air flows in large diameter ducts, it eliminates the need for explosion prevention systems on the ducts. See NFPA 664 for additional information.

The larger sanding machines also are capable of producing substantial quantities of heat, which vaporizes resins and extractives in the wood; these vapors then condense on the interiors of the dust collection system ducts, coating the interior surface over time. The grit on the sanding belt can become "loaded" with compressed wood dust, forming a composite material that can achieve red-hot temperatures as it is rubbed across the stock.

Sander dust, vaporized resins, and red-hot bits of wood/resin composite are all picked up by the dust collection system. The pneumatic wood-waste ducts running from the sanders to the dust collector are frequent sources of fire. The four-head abrasive planer shown in Figure 9.1.7 represents the large end of the size range of sanding machines. Note the number of dust removal ducts rising from the top of this machine.

Glue-Up/Assembly

The glue-up and assembly of tertiary forest products is the least hazardous portion of the production facility. Although glues have traditionally been dissolved in mineral spirits, toluene, or other volatile organic compounds, the new polyurethane and acrylic adhesives are not.

Finishing

Years ago, finishing operations represented a more serious concern than they usually do today. The concern over VOC emissions has made finishes using nitrocellulose, toluene, xylene, and methylethyl ketone (MEK) vehicles far less common than they once were. New acrylic, urethane, and water-based finishes are replacing the older finishes in most large-volume facilities.

FIGURE 9.1.7 Four-Head Abrasive Planer (Source: J. M. Cholin Consultants, Inc.)

Many of the larger, more modern woodworking plants employ as many as 20 spray booths in a conveyorized finishing operation, using about 20,000 to 40,000 ft^2 (1900 to 3700 m^2) of floor space. Ovens for curing the finished pieces operate at approximately 250°F (121°C). Due to the competitive pressure to produce a flawlessly finished product, multicoat finishes are customary, necessitating curing ovens operating at high temperatures and air flows and overnight storage between coats to ensure finish quality.

The lower-volume, smaller facilities are often found to still be using older finishing procedures based on volatile vehicles. Wherever volatile flammable liquids are used, there is the possibility of a fire. The principal flammable solvents used in wood finishing are listed in Table 9.1.1 with their approximate flashpoints.

All of the materials listed in Table 9.1.1 are prone to electrostatic ignition under certain circumstances. Furthermore, fires can be caused when flammable vapors come in contact with lighting fixtures, heaters, sparking motors, electrical switches and other well-known sources of ignition.

Finished Products Storage

The storage of finished forest products naturally varies with the type of product. However, the storage areas should be protected in a manner consistent with the combustible loading that can be achieved in a storage area used for the storage of furnishings or other cellulosic combustibles.

Wood-Waste Management

Most forest products production processes generate wood waste. By the time parts have progressed through rough milling and finish machining, approximately 50 percent of the original log has been reduced to waste.

Large chips, chunks, board ends, resaw kerfs, and lumber scraps account for approximately 35 percent of the wood waste. The larger pieces are usually conveyed by belt conveyor, front-end loader or wheelbarrow to a hog. The wood hog reduces large pieces of wood waste to chips, splinters, or flakes, which can be conveyed pneumatically. Larger facilities operate hogs that can consume entire wood pallets and tree trunks, reducing them to a shower of chips. The outlet of the hog is usually connected via a high-power fan to a pneumatic conveying duct, which transports the chips to a silo for storage.

TABLE 9.1.1 Flashpoints of Flammable Solvents

Solvent	*Flashpoint °F*	*Flashpoint °C*
Acetone	–4	–20
Methylethylketone	16	–9
Naphtha VM&P	50	10
Xylene	81	27
Toluene	40	4

Dust Collection. All the previously described wood shaping and cutting processes also generate wood chips, shavings, and dusts, which are gathered by the dust collection system. This particulate material is usually removed from the machine producing it via the dust collection system. The dust collection system consists of ducts extending to each of the woodcutting machines, a large fan to provide the motive force, and a dust collector. The chips and dust are sucked up by the dust collection system and are conveyed while suspended in air to a dust collector where the wood chips and dusts are separated from the conveyance air.

There are two general designs of dust collection systems common in the forest products industries. The first is the single-stage system, shown in Figure 9.1.8. This system consists of a single dust collector either in the form of a cyclone separator or a combination cyclone/bag filter unit. The second is a two-stage system, shown in Figure 9.1.9. This system usually consists of a cyclone separator followed by a bag type filter house, usually referred to as a "baghouse."

Cyclone separators remove the larger particulate matter from the air stream. However, they cannot remove fine dusts efficiently enough to be practical where conveying air is being returned to the workplace. If conveying air is returned to the workplace, a design decision that is usually selected to save on the cost of heating or cooling the facility, a filter must be used to remove the fine, dusty particulates. The filter usually consists of an array of cloth bags in a steel enclosure, the baghouse. The baghouse removes wood dust having particle sizes larger than the weave of the cloth.

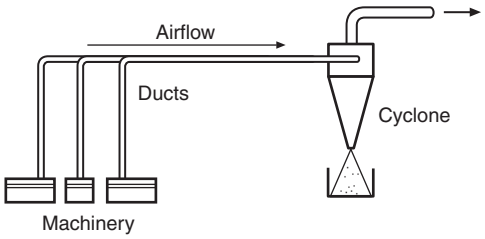

FIGURE 9.1.8 Single-Stage Collection System Consisting of a Cyclone Separator

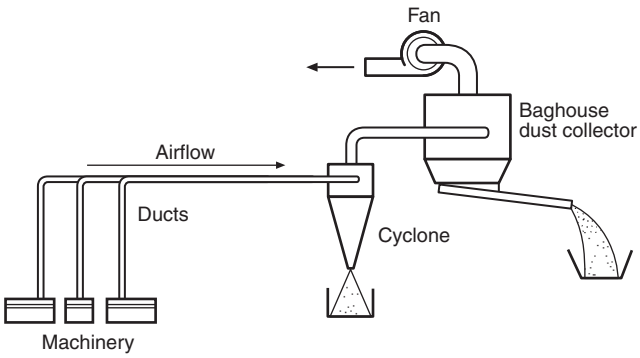

FIGURE 9.1.9 Two-Stage Collection System Consisting of a Cyclone Separator and a Baghouse

Most facilities have two-stage systems. Historically, they began as single-stage systems, using only a cyclone to separate the larger, usable wood waste from the air stream and exhausting the conveying air to the outside. Subsequently, a baghouse was added, allowing the return of the heated conveying air back to the facility. Newer facilities are now often designed with a single-stage cyclone/baghouse combined unit, where the bottom of the unit acts as the cyclone separator and the upper portion contains the bag-type filters (Figures 9.1.10. and 9.1.11).

In many installations, about 80 percent of the air used by the dust collection system is returned to the plant. Return of this air into the plant atmosphere can cut down on the air make-up requirement and reduce plant heating needs. However, it introduces serious fire protection concerns that must be addressed.

Fire and Explosion Hazard Management. Dust collection systems and the dust collectors at the ends of these systems represent a serious fire and explosion hazard because wood dust suspended in air can deflagrate on ignition. In the context of U.S. standards, a *deflagration* is the rapid propagation of a flame front through a fuel/air mixture at a rate that is sufficient to cause a pressure front but slower than the speed of sound in the unreacted medium. An *explosion* is the rupture of a containment enclosure due to the excessive pressure produced by a deflagration. The deflagration is the process and the explosion is the result. European standards apply a different definition to the terms *explosion* and *deflagration* than U.S standards.

Requisite Conditions for Deflagration. To produce a deflagration four basic conditions must exist concurrently as shown in Figure 9.1.12. First there must be present a combustible particulate solid of sufficiently small particle size. The rate of combustion is controlled by surface area, and the smaller the

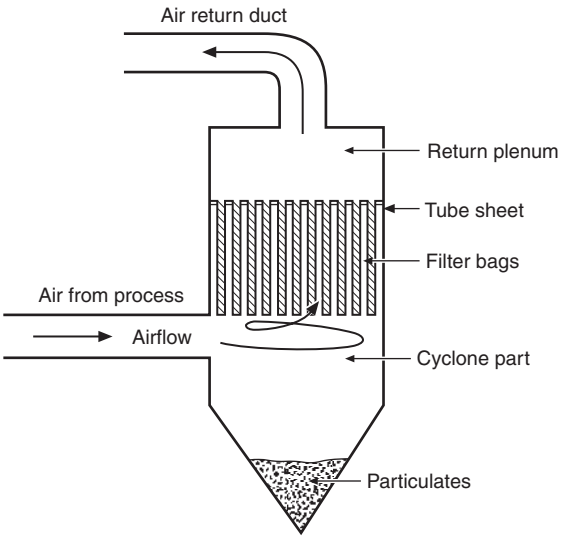

FIGURE 9.1.10 Single-Stage Dust Collector with Combination Cyclone Separator and Baghouse (Source: J. M. Cholin Consultants, Inc.)

FIGURE 9.1.11 Single-Stage Dust Collector Installation (Source: J. M. Cholin Consultants, Inc.)

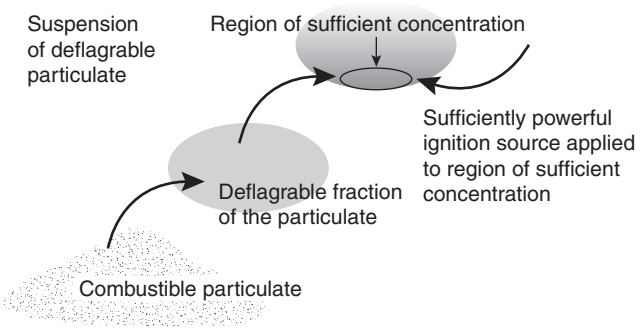

FIGURE 9.1.12 Basic Conditions Required for Deflagration (Source: J. M. Cholin Consultants, Inc.)

particle size the greater the surface area to mass ratio. In general, particles must have an equivalent diameter of less than 420 microns to be capable of supporting a deflagration. Second, the particulate must be suspended in the air. This state exposes the maximum particle surface area to the atmosphere and the oxygen needed to carry out the combustion reaction. Third, the suspension of combustible particulates must have a concentration of particles, measured in units of mass per unit volume, sufficient to propagate a flame front. Each particulate has its own MEC. In this day and age, MEC is usually expressed in terms of grams per cubic meter (g/m^3), but older references might express it in terms of ounces per cubic foot. Finally, there must be a competent igniter. The source of ignition must be capable of introducing sufficient energy per unit of time and unit of volume to bring the dust/air mixture to its auto-ignition temperature. Thus the ignition source must be quantified in terms of a power density measured in watts per unit volume. This value is usually derived experimentally. Consequently, where the energy investment and concentration are both sufficient, a deflagration will propagate through a suspension of wood dust in air.

Deflagrable Fractions. Particulates with equivalent diameters greater than 420 microns will not produce a deflagration. These particulates will still burn, but the rate of combustion will be too slow to result in the generation of potentially dangerous pressure. Where a broad range of particle sizes exists, only the sub-420 micron fraction is generally deemed capable of deflagration. The remainder will burn but can actually serve as a flame-quenching fraction, reducing the probability of a propagating deflagration if the concentration of the nondeflagrable fraction is large compared to the deflagrable fraction. The extent of the quenching phenomenon can only be quantified, at this time, by testing.

For the deflagrable fraction, the general rule is that as particle size decreases, the maximum deflagration pressure, P_{max}, increases. Likewise, the maximum rate of pressure increase, dP/dt_{max}, increases. The volume-normalized rate of pressure increase, K_{St}, often called the *dust constant,* also increases. These are all artifacts of the higher rate of combustion for finer particulates due to the larger surface area per unit of mass.

Particulate Size. The finer the particulate the more easily ignited it is. Ignition behavior is usually quantified by determining the minimum ignition energy (MIE). Consequently, one can see that the finer the particulate the more hazardous it is. This observation is valid until the particle sizes decrease below approximately 20 microns. Decreases in particle size below 20 microns generally do not increase the hazard associated with a particulate.

Particle size is usually determined by using standard sieves. If the particulate passes through the sieve it is ascribed a nominal diameter equivalent to the opening in the sieve. This method works well for particulates that are essentially spherical or cubic in particle shape. Unfortunately, wood particulates are rarely round or cubic in shape. Consequently, when working with wood particulates the designer must use equivalent particle diameter rather than actual diameter. The equivalent particle diameter is the diameter of a round particle that has the same surface area to volume ratio as the particulate under consideration. Highly elongated and fibrous particles will behave as if they were much smaller because of the larger average particle surface area to average volume ratio they have. The net result is that simple sieve analyses can lead to dangerous underestimation of the hazard posed by wood particulates. Figure 9.1.13 shows a photomicrograph of wood dust from a particle board plant showing fibrous particle shapes that are typical of wood dusts.

Particulate Concentration. Wherever there exists a sub-420 micron fraction of wood particulate that can attain suspension in

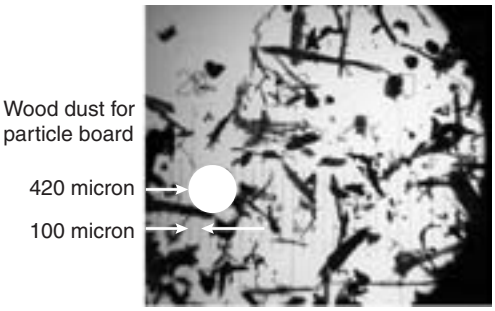

FIGURE 9.1.13 Photomicrograph of Wood Dust (Source: J. M. Cholin Consultants, Inc.)

the air at concentrations above the MEC, a deflagration hazard exists and must be managed. Since both cyclones and baghouses separate wood waste from the conveying air, there is a continuous concentration gradient within these units as a normal part of their operation. The concentration gradient effectively guarantees that some portion of the interior volume of the cyclone or baghouse used as a dust collector has an environment capable of supporting a deflagration. Most cyclones are not designed to separate the fine "deflagrable" dust from the conveying air under normal operating conditions, but they will produce an environment capable of deflagration during startup and shutdown. The baghouse is designed to collect fine particulate and conditions conducive to a deflagration exist during startup, normal operations, and shutdown.

Dust collectors that employ filter media (i.e., baghouses) also must have some means of removing accumulated dust from the media while operating. Otherwise, the media becomes clogged with dust and the flow of air through the media lessens, decreasing the ability of the entire system to efficiently transport wood waste from the point of generation to the collector. To address this problem, dust collectors are usually equipped with bag shakers or reverse pulse cleaners to periodically remove the accumulated dust from the surface of the filter bags and maintain filtration efficiency. A concentrated dust cloud is produced inside the operating dust collector during the bag cleaning cycle. If burning material exists within the dust collector when the bag cleaning cycle occurs, it is likely that a deflagration will result. Figure 9.1.14 shows the bag cleaning cycle in a baghouse that produces a dust suspension at regular intervals, which can lead to a deflagration.

Returned Dust. Dust collectors are *not* 100 percent effective in removing dust from the air. To varying degrees, all dust collection systems remove only the larger, less-combustible wood particles, allowing the finest particles to pass through the filter medium and back into the production facility. This results in an accumulation of ultrafine wood dust on many of the undisturbed, upward facing, horizontal surfaces in production shops (Figure 9.1.15). As the efficiency of the dust collection system is improved in an effort to keep the facility cleaner, the combustibility of the dust in the collector increases, making it more likely that it will be the site of an explosion. The combustibility of the residual dust that passes through the filter, returning to the occupied space, also increases. In short, the better the dust

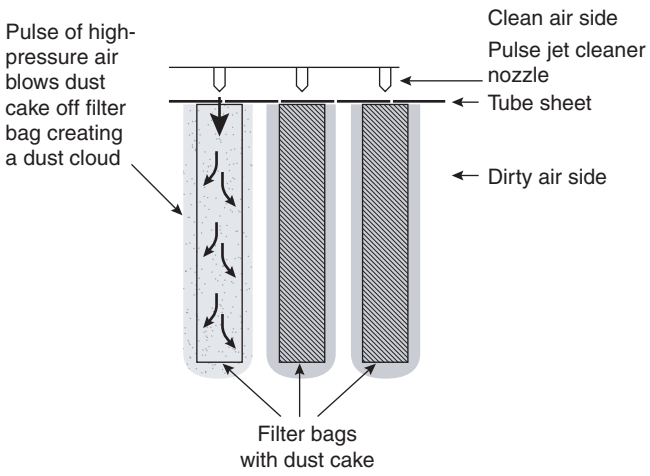

FIGURE 9.1.14 Bag Cleaning Cycle (Source: J. M. Cholin Consultants, Inc.)

FIGURE 9.1.15 A Dangerous Accumulation of Very Fine Dust on the Upward-Facing Surfaces of the Ducts Can Be Seen Here (Source: J. M. Cholin Consultants, Inc.)

collection system, the finer the dust returned to the facility and the greater the fire hazard.

The fire hazard does not go away if there is no dust collection system. If the wood chips and dusts are not collected, the employees are exposed to the health risks associated with inhaling the dust. The dust is simply free to migrate throughout the workplace. In this circumstance, whenever someone drops a plank or otherwise causes the dust to billow up, there is the possibility that the dust cloud will ignite. The choice is between an explosion and fire hazard distributed throughout the facility or an explosion and fire hazard concentrated in a specific spot. The explosion and fire hazards are always there.

Process Heat Production

One of the major fire hazards in the modern wood-processing facility is the process heat production equipment. Often, the heat used to fabricate particle board, plywood, laminates, and

other engineered wood products is transferred from the point of generation to the point of utilization by means of HTF, sometimes referred to as "thermal oil." These systems are operated at temperatures that usually exceed the flashpoint of the fluid. Any release of the fluid poses an immediate threat of fire. Furthermore, these systems usually contain large quantities of HTF and pumps designed to circulate it through transfer piping at high flow rates.

NFPA 664 includes detailed fire protection criteria for heat transfer or thermal oil systems. It provides for a performance-based design or a prescriptive design. In performance-based designs, NFPA 664 requires that the hazard be assessed on the basis of the "largest credible spill," taking into account the total quantity of oil available, maximum flow rate through the utilization piping, system instrumentation for detecting a loss of fluid from the system, automatic shutdown controls and interlocks, the presence of trained personnel that can reliably isolate portions of the system, and the spatial organization of the facility. The assessment should determine the worst-case spill area, considering the ability to limit flow as well as the ability of the structure to contain a spill. This assessment will lead to a quantification of the spill area and hence the fire suppression capacity needed to control the fire resulting from an ignition. Once the extent of the hazard has been assessed, the consequences of the fire should be evaluated based on the life safety threat, probable property loss, and interrupted operations loss. A design is then developed to limit the loss to a level acceptable to the authorities having jurisdiction, who represent the public, and all involved stakeholders.

In the prescriptive design approach, NFPA 664 includes extensive detailed criteria for the design of systems that have been developed over many years of experience. These design criteria generally achieve the performance expectations of most operators. Regardless of the design method selected, these HTF systems must be designed and maintained properly.

FIRE PREVENTION

Design

The fire safety of a new facility can be improved substantially by addressing fire prevention concerns during the layout of the production area. Significant fire safety improvements can be made in most existing facilities by reorganizing the layout. Where the process hazards analysis determines that a fire or explosion hazard exists, the facility design should be modified to eliminate, if possible, or minimize those hazards.

Separation of Processes. Processes that are likely to cause ignition should be moved away from processes or areas where there is significant fuel loading or fuels of elevated combustibility. Whenever possible, fire-resistive separations equipped with listed fire doors at each penetration should be installed between the wood shaping/cutting, finishing, assembly, and storage areas.

Since most of the commonly used wood finishes have a solvent of flammable liquid, there is an increased fire hazard wherever finishes are stored or applied. The facility, regardless of size, should be organized to keep flammable vapors out of confined spaces and away from ignition sources. All flammable materials should be stored and used in compliance with NFPA 30, *Flammable and Combustible Liquids Code.*

Space Heaters. The use of fixed or portable space heaters to supplement building heat introduces ignition sources throughout the facility. The heating plant should be designed to eliminate any need for space heaters. Appliances that produce controlled heat, such as glue pots and bending irons, should be restricted to specific dedicated areas that are dust free and physically separated from cutting, shaping, and sanding machines, as well as from inventory storage and finishing areas.

Electrical Hazards. Properly grounded electrical outlets, suitable for the electrical classification of the area, should be installed where electric power is needed. Extension cords, three-wire to two-wire adapters ("cheater plugs"), cube taps, and outlet extenders should be replaced with permanent electrical service in compliance with NFPA 70, *National Electric Code®*.

Tramp Metal. Provisions should be made to prevent the introduction of foreign material, such as stones and tramp metal, into dust collection systems. These tramp materials can become heated as they collide with the steel walls of the pneumatic conveying system duct and cause ignition where they come to rest in the hopper section of either a cyclone or dust collector. Where floor sweep pick-ups are connected to the dust collection system, they should be equipped with magnets or other equivalent means of preventing the introduction of ferrous material into the dust collection system.

Fans and Blowers. Fans and blowers represent a potential ignition source in the dust collection system. The surface of large blocks of wood and knots can reach ignition temperature when they strike the impeller of a fan. NFPA 664 establishes criteria regarding when wood particulate is permitted to pass through a fan. Green material, material with a moisture content of 25 percent or greater, is permitted to flow through fans. Dry material is not permitted to flow through a fan without providing fire detection and extinguishment downstream from the fan. When dry, deflagrable wood particulate passes through a fan, both fire and explosion protection should be installed on downstream dust collectors.

Dust Collectors. NFPA 664 also establishes a number of requirements on the design of the facility, especially as it relates to the dust collection system and pneumatic conveying systems used to transport particulate material. One of the requirements is that dust collectors be of noncombustible construction and situated outside the structure. Furthermore, if cleaned conveying air is to be returned to the facility interior, a listed spark detection system activating an abort gate is required (see NFPA 664). Figure 9.1.16 shows an abort gate diverting an airstream to the outside, preventing passage of flames and combustion gases into the facility via the clean air return duct.

Reducing the Risk of Dust Collection System Fires. Several other design methods can reduce the likelihood of a dust collection system fire. They do not eliminate the possibility of a fire but do reduce the probability. They are derived from the fundamentals of spark physics. A small wood particle (such as

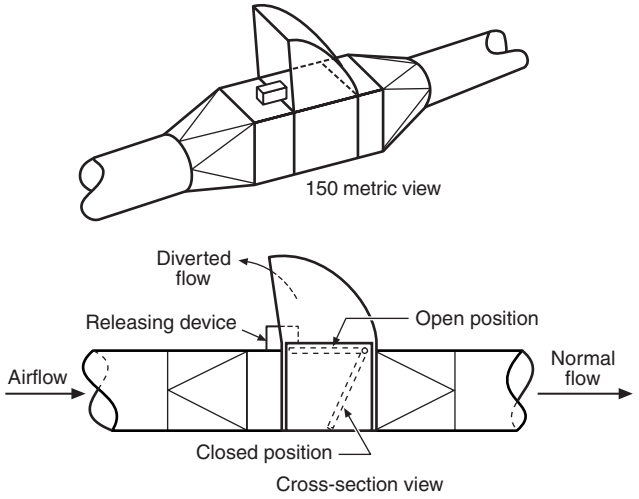

FIGURE 9.1.16 Abort Gate Diverting Airstream to the Outside (Source: J. M. Cholin Consultants, Inc.)

sander dust) is easily ignited, but it burns out very quickly, since the individual particle consists of very little fuel. Large wood particles (such as router chips) are harder to ignite, but will burn for a longer period of time, sometimes long enough to survive until they reach the dust collector (baghouse). For this reason, there is added fire risk when fine sander dust and larger chips from routers, planers, and saws are conveyed together in the same duct. That risk can be reduced by conveying fine dust and large chips in separate ducts until they reach the collector.

The same strategy holds true for separating the lines that come from the sanding of finished surfaces or resinous woods and the sanding of unfinished surfaces or nonresinous woods. The resins in the finishing materials tend to load up grit on the belts. When the resin/wood composite reaches ignition temperature, it can ignite the nonresinous dust in the line. Finally, longer ducts provide more opportunity for the ember or spark to burn out before it reaches the dust collector, where the continuous concentration gradient exists that is conducive to the development of a deflagration leading to an explosion. These steps will only reduce the probability of a dust collector fire; they will not eliminate the possibility.

Equipment Maintenance

There are ignition hazards associated with electrically powered woodworking machines, both stationary and portable. Switches can wear out and start "arcing." Power cords can become worn and frayed. Bearings can fail and overheat. All of these are possible electrically generated ignition sources. Lighting can also be the cause of excessive heat or catastrophic electrical ignition. Frayed power cords, arcing switches, clogged ventilation ports, worn bearings, worn belts, misaligned pulleys, and misaligned guards and fairings around moving parts have all been identified as sources of ignition. Corrective action should be taken as soon as these conditions become evident.

Cutting tools should be maintained as sharp as practical. This improves both productivity and the fire safety of a facility. Sharper tools cut more cleanly, producing less dust and chips with smoother surfaces, both factors that reduce the fire risk. Furthermore, a sharp tool produces less heat during the cutting process, making it less likely that the cutting process will raise particles to their auto-ignition point. Cutters should be kept sharp and there should be a specific quantitative method (such as motor current demand or cut roughness) of determining when sharpening is needed.

Finally, abrasive cutters, such as sanding belts and discs, should be kept clean, in good repair, and free of "loading" of compressed wood dust. A specific quantitative method for determining when abrasive belts should be replaced should be developed and enforced. Overall grit thickness can be used to infer the degree of grit wear and breakdown. When a belt becomes loaded, it can generate tremendous frictional heating that will readily ignite the dust produced by the sanding operation. Excessive abrasive belt temperatures can cause the cloth backing of the belt to fray, resulting in catastrophic failure of the belt. When a belt fails, shards of sanding belt material are often ejected into the dust collection system ducts, where they can strike sparks as they pass down the duct.

Heating Systems

Furnaces and other sources of space heat should use a source of combustion air that is isolated from the air in the woodworking facility. Most furnaces use ambient interior air as their source of combustion air. The furnace burns fuel to produce hot flue gas, which passes through a heat exchanger on its way up the chimney. Interior cool air is passed across the heat exchanger, absorbing heat in the process and is then forced into the interior space (Figure 9.1.17).

If wood dust is allowed to mix with the combustion air, it will ignite, potentially upsetting the inflow of air into the combustion chamber and sending flames into the production area. This is especially true of gas-fired space heating units, commonly found in industrial spaces. This concern can be addressed by installing a fresh combustion air inlet duct, running from the outside to the furnace air inlet, as shown in Figure 9.1.18. This will prevent wood dust from invading the combustion airstream of the furnace.

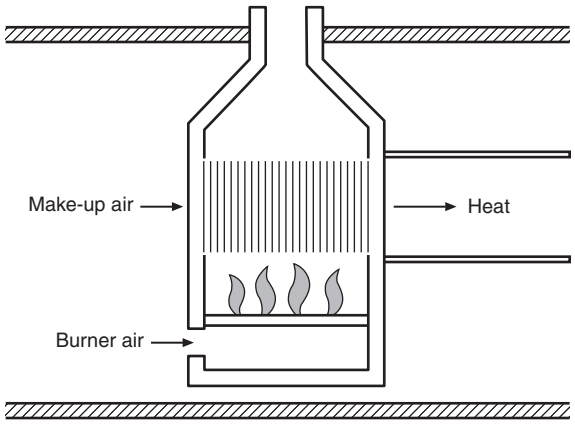

FIGURE 9.1.17 Simplified Hot Air Furnace (Source: J. M. Cholin Consultants, Inc.)

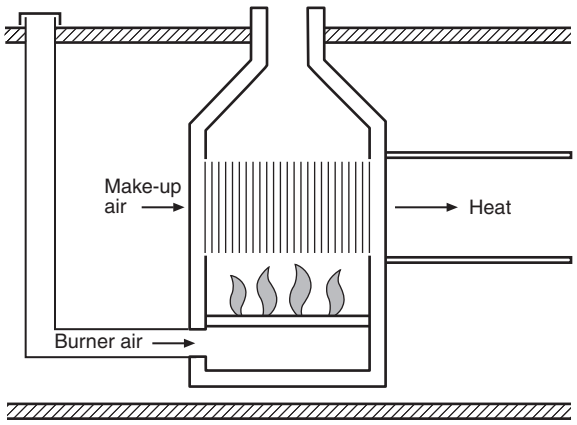

FIGURE 9.1.18 Modified Furnace/Heater (Source: J. M. Cholin Consultants, Inc.)

Regular inspection of the heating system is advisable. Furthermore, routine facility inspections during the winter months should be conducted to prevent the use of small portable space heaters, as these units present a much higher hazard of fire than engineered central heating. Production employees often try to solve local discomfort problems with portable space heaters. A facility auditor who understands fire hazards can remove the space heaters while encouraging work on a more systematic solution, through adjustments to the central heating.

Personnel/Procedures

Safe operating procedures should be established and reviewed on a regular basis. Out-feed from all cutting and sanding machines should be monitored on a regular basis to identify any machines that are cutting too hot. The need for adjustments to feed rates and cutting implement maintenance are often first noticed by scorching and burning of the wood as it is cut. The staff should be properly trained in the correct method of installing and achieving proper alignment of abrasive belts.

There are procedural ways to manage the ignition risk represented by electrically driven machinery. The single least-reliable, most failure-prone component in the entire electrical system are the switches. Since the on/off electrical switches of equipment are operated often, they represent a potential source of electrical failure. To avoid having a switch fail in the "On" position, the facility should be equipped with a dedicated set of circuit breakers for the machinery, enabling those responsible for the facility to turn off the source of electrical energy before leaving for the night. An alternative, where small machinery operating at 110 V ac is used, is an "unplug when you're done" policy. If such a policy is in place it should be monitored by management to ensure that all equipment is disconnected when not in use.

A specific location should be reserved for lunch break. This limits the probability that small appliances such as coffee makers are placed in uncontrolled locations. Furthermore, small cooking devices such as coffee pots, microwave ovens, and hot plates should be powered through switched outlets that are de-energized when the lights are turned off. Smoking should not be allowed in a woodworking facility. Improper disposal of smoking materials still represents a pressing threat to any woodworking facility.

Welding and Hot Work. Welding should be performed in accordance with NFPA 51B, *Standard for Fire Prevention During Welding, Cutting, and Other Hot Work.* Welding should be controlled and carefully monitored. When welding is performed, small pellets of molten metal fly off from the material being welded. If these land on combustible material, a fire can result. It often takes several hours for the fire to develop. Every year, buildings burn down due to latent sparks from welding. Welding should not be performed unless and until the area is thoroughly cleaned of all wood and wood waste and the appropriate fire-extinguishing equipment is in place. A fire watch, maintained for at least two hours after the welding has ended, should be required whenever welding is performed, regardless of how small the needed repair is.

Housekeeping. The wood dust that is an inescapable part of a woodworking facility is a combustible material that represents a serious and extensively distributed fire and explosion hazard. Every effort must be made to minimize the accumulation of wood dust on upward-facing horizontal surfaces and to routinely remove all dust that evades preventative measures.

An efficient, properly constructed dust collection system is the first step in keeping dust levels under control. However, no system is 100 percent effective. Routine vacuum cleaning of the entire facility is of paramount importance. Under no circumstance should high-pressure air be used to "blow down" a work area as a routine part of the production process while production equipment and other sources of ignition are energized. This merely stirs up the dust and will cause the finest, most combustible fraction of the dust to be deposited in the highest, most difficult to clean spaces. Blow-down is permitted during production shutdowns, when all equipment is de-energized. Often this is the only practical way to dislodge the dust from high spaces. As a general rule, the finest, most hazardous dust will accumulate on upward-facing surfaces near the ceiling. This dust cannot be allowed to accumulate, as it is the fuel for the secondary deflagrations that cause the most injuries and fatalities when explosions occur.

The heat exchanger in the furnace/heaters should be kept clean. The surface of the heat exchanger will get hot enough to ignite surface dust or dust in the air. This is especially true in the autumn when the furnace/heaters are turned on for that first cold morning of the year.

FIRE PROTECTION

Sprinkler Coverage

In general, woodworking facilities are highly combustible environments, filled with wood and/or fabric-covered finished and semifinished goods, as well as other raw materials. Automatic sprinkler coverage is considered the most appropriate general area protection for woodworking facilities. However, in some older buildings, it may be difficult to achieve full protection. In 1994–1998, 54 percent of reported structure fires in wood,

paper, and related product manufacturing facilities were in buildings with sprinklers, a percentage that is typical of manufacturing in general.

NFPA 13, *Standard for the Installation of Sprinkler Systems,* requires design of sprinkler systems to be based on Ordinary Hazard-Group 3 design rules for the woodworking machinery spaces. Other areas, such as finishing rooms and upholstery rooms, should be designed for these special occupancies. They often require designs based on a higher density, involving larger pipe sizes and closer spacing of sprinkler heads. Whenever possible, these processes should be located in separate buildings or separated from each other by fire-rated construction with openings protected by automatic fire doors.

The degree of protection needed can vary from facility to facility, but a basic recommendation is that a yard system of mains and hydrants capable of supplying at least 1000 gpm (3.78 m^3/min), enough to sustain four 2½ in. (64 mm) hose streams simultaneously, should be installed in accordance with NFPA 24, *Standard for the Installation of Private Fire Service Mains and Their Appurtenances,* as appropriate. If conditions warrant, expanded supplies and larger fire stream appliances might be needed for effective fire control. Unobstructed fire lanes are needed in the yards, so that fire equipment can approach the lumber piles. NFPA 1 provides requirements for the protection of stored lumber, logs, and chips.

In facilities where heat transfer fluid is used for hot presses, such as in panel manufacturing, sprinkler protection is required. NFPA 664 provides explicit criteria for the safe design of these systems and the fire protection for them. The presence of a heat transfer fluid system in a wood-processing facility increases the fire hazard considerably because of the added fuel and the speed with which the fire can extend beyond the point of origin due to the horizontal flow of burning oil across floors and equipment. It is important to keep in mind that woodworking and wood-processing facilities represent not only a fire hazard, but an explosion hazard as well.

Protection Strategies

Fire protection is used to manage the fire hazard. Explosion prevention is used to manage the explosion hazard. As a general rule, the installation of fire protection does *not* make a major contribution to the management of the explosion hazard. Similarly, the installation of explosion prevention equipment does *not* generally contribute to the management of the fire hazard. The prudent facility operator will employ both protection strategies. NFPA 664 provides detailed fire protection and explosion prevention criteria for each general type of process equipment found in the modern forest products production facility. These include particle size reduction equipment (mills, grinders, and hogs), veneer and fiberboard dryers, rotary dryers, flash-tube dryers, kilns, finish dryers, pollution control equipment, silos and storage bins, and various types of hot presses.

Portable Fire Extinguishers

Portable fire extinguishers should be installed in accordance with the requirements of NFPA 10, *Standard for Portable Fire Extinguishers,* and any local codes. There is a wide diversity in the types of fires that are apt to occur in a woodworking plant. Fires that require the use of Class A, Class B, and Class C extinguishers are abundant.

There should be water or aqueous film-forming foam (AFFF) extinguishers for the wood storage and general production areas. Dry chemical agent extinguishers should be used for the finishing areas and wherever combustible or flammable liquids are stored or used. Dry chemical extinguishers would also be preferable for use on electrical equipment. Gaseous extinguishers, including both clean agent and carbon dioxide (CO_2) units should *not* be used in a woodworking shop. When these units are discharged, the jet of extinguishing agent gas can cause a great deal of turbulence in the surrounding air. This turbulence can lift any wood dust in the vicinity of the discharge into suspension, resulting in a dust cloud. This is an extremely dangerous situation. If the suspended wood dust contacts the flame, a deflagration will probably result.

ABC dry chemical is often called a "universal dry chemical." However, a given extinguisher's effectiveness varies greatly with the fuel. Although a given extinguisher could easily extinguish a 10-ft-diameter (3.1-m) combustible liquid fire, it would not be able to extinguish a fire in a stack of wood pallets the same size. Nevertheless, ABC dry chemical is electrically nonconductive and effective on two-dimensional wood, paper, and combustible liquid fires. It is an excellent choice as a general-purpose fire extinguisher for most of the areas in the woodworking environment. In the finishing areas, there is a concentration of combustible liquids, and it is appropriate to use a fire extinguisher that is optimized for that fuel. Type BC sodium bicarbonate dry chemical extinguishers are generally recommended for this type of service. The ABC unit will extinguish flammable liquid fires, but might not be as effective as the BC-type units. Sodium bicarbonate units are not very effective on wood and paper fires. Consequently, they should only be used on fires involving flammable and combustible liquids and gases.

AFFF is excellent on wood and paper and on combustible or flammable liquids. However, foams are not as effective on three-dimensional fires—fire where the fuel is stacked vertically. AFFF is also electrically conductive. These factors often limit its applicability. However, AFFF is generally considered a good choice for stockrooms and veneer, lumber, and corrugated cardboard storage areas.

The diversity of combustible materials does introduce some risks associated with fire extinguishers. Their placement and signage should be designed to minimize the likelihood that the wrong type of unit will be used.

Finishing

A principal hazard in the spray application of finishes involves flammable and combustible liquids, their vapors or mist, and combustible residues in spray booths. Spray booths that are properly constructed in accordance with NFPA 33, *Standard for Spray Application Using Flammable or Combustible Materials,* and with adequate mechanical ventilation, are the ideal way to discharge vapor to a safe location. Minimizing all sources of ignition in the spraying area and constantly supervising the overall finishing process are essential to a safely conducted operation.

NFPA 33 provides the minimum compliance design criteria and operating procedures for spray application of flammable coatings. This standard should be applied to all finishing areas.

Mechanical ventilation of the spraying area should remove solvent vapors and control overspray. The ventilation system should maintain a sufficient average velocity over the entire open face of the booth to entrain and confine overspray to the booth interior. In some larger facilities, the spray booths exhaust over 25,000 cfm (708 m^3/min). This necessitates careful management of the make-up air demand.

Curing ovens associated with finishing processes are generally classified in accordance with NFPA 86, *Standard for Ovens and Furnaces,* as continuous Class A ovens. These are enclosures that operate at nominal atmospheric pressure and in which there is an explosion or fire hazard due to the presence of flammable volatiles and combustible residues. The oven exhaust system is usually vented to a solvent recovery system prior to discharge to the outside.

Explosion Hazard Management

Wherever there is wood dust, there is an explosion hazard. Furthermore, the single deflagration leading to the rupture of a single compartment or enclosure is the exception rather than the rule. In most woodworking facilities, a fire that does not involve a cloud of wood dust suspended in air can be adequately controlled with a properly designed sprinkler system. However, in woodworking and wood-processing facilities, the fire protection specialist must also have systems in place to deal with the contingency of a deflagration involving suspended wood dust.

Typical Progression of a Dust Explosion. Most explosion events involve multiple deflagrations, occurring in rapid succession, each more powerful and damaging than its predecessor. It is critical that the fire protection strategy be designed to interrupt this progressive development. The progressive nature of explosions in woodworking facilities relies on the presence of a source of additional fuel in the form of accumulated fugitive dust in the facility interior. Usually, fugitive dust accumulates over the years within the facility building. The finest dust is found highest in the interior space, on upward-facing surfaces of beams, pipes, electrical conduit, and wall ledges. Even the pores of cement block used to construct walls harbor fine dust. This combustible material fulfills the critical precondition of ample available fuel. Where this precondition is met, the stage is set for a propagating chain of deflagrations that can lead to the destruction of the facility.

Primary Deflagration. Most explosion events begin as a single deflagration within a piece of equipment. It could be a mill, hog, sander, dust collector, dust bin, chip silo, or other such enclosed equipment. Figure 9.1.19 shows the beginning of an explosion event as an unmanaged deflagration within enclosed equipment.

When this initial deflagration occurs it produces an acoustic wave that radiates from the locus of the initial deflagration at the speed of sound through the structure (Figure 9.1.20). The speed of sound in air is usually taken to be 1100 ft/sec (330 m/sec), whereas the speed of sound through steel and concrete is closer to 15,000 ft/sec (4560 m/sec).

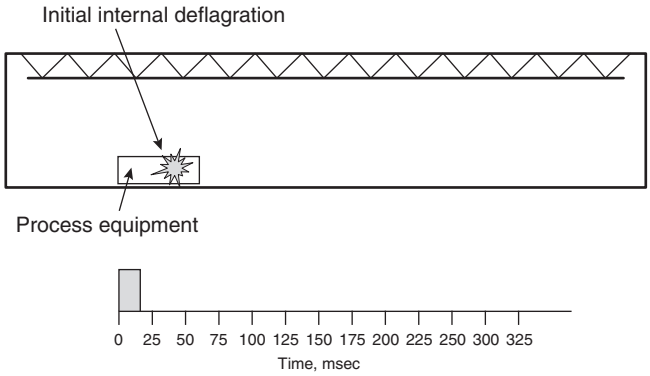

FIGURE 9.1.19 Beginning of an Explosion Event Within Enclosed Equipment (Source: J. M. Cholin Consultants, Inc.)

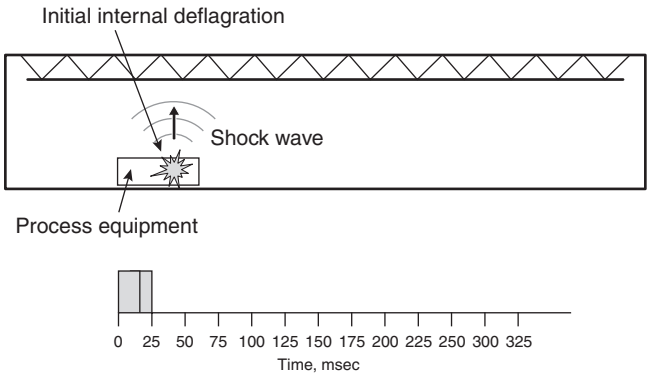

FIGURE 9.1.20 Acoustic Impulses Traveling Through a Building (Source: J. M. Cholin Consultants, Inc.)

Every component of the structure is to some degree elastic. The floor slab flexes, walls vibrate, and the roof deflects as the acoustic wave from the initial deflagration propagates through the building (Figure 9.1.21). This movement propels accumulated fugitive dust from its resting place into the interior airspace. In Figure 9.1.22, the rebound of the building compartment or enclosure suspends accumulated fugitive dust into dust clouds. This process occurs in a fraction of a second, producing dust clouds throughout the facility. Since the acoustic wave through the building travels many times faster than the wave through the air, dust dispersions occur throughout the facility. When the enclosure containing the initial deflagration ruptures and its flame front exits the enclosure, it extends into the building interior where there are already-established dust dispersions. For example, Figure 9.1.23 shows that when a deflagration within the enclosure produces more pressure than the enclosure can withstand, it ruptures, releasing the flame to the building interior.

Secondary Deflagration. When the flame from the initial deflagration, moving at a velocity substantially lower than the

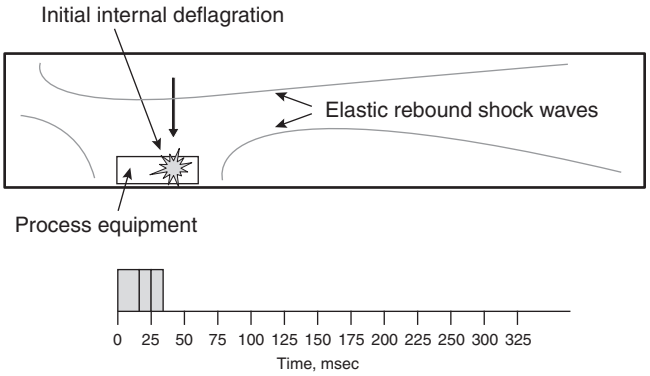

FIGURE 9.1.21 Elastic Rebound of the Building (Source: J. M. Cholin Consultants, Inc.)

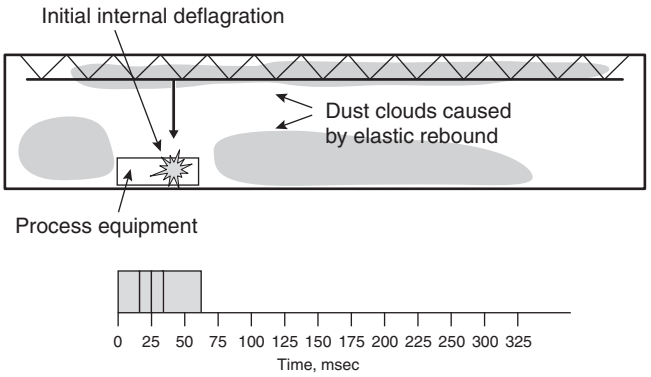

FIGURE 9.1.22 Suspension of Accumulated Fugitive Dust into Dust Clouds (Source: J. M. Cholin Consultants, Inc.)

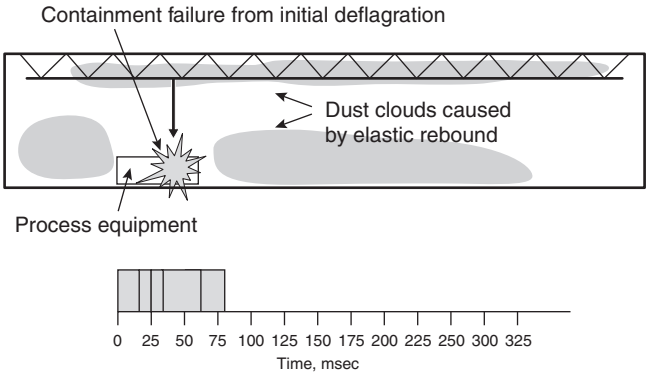

FIGURE 9.1.23 Rupture of Enclosure Caused by Deflagration (Source: J. M. Cholin Consultants, Inc.)

acoustic wave, impinges on any portion of any of the dust clouds produced by the acoustic wave, a secondary deflagration is usually ignited. This secondary deflagration usually occurs within a building compartment where there might be occupants. For example, Figure 9.1.24 shows a situation in which the flame

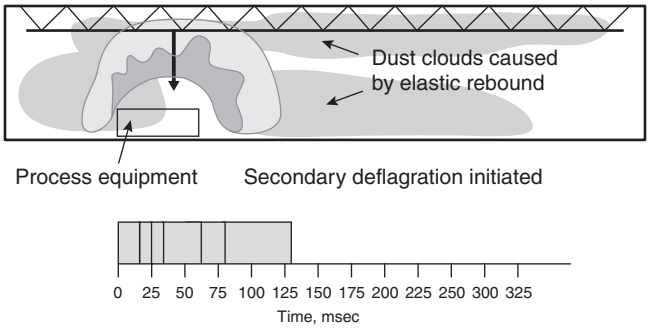

FIGURE 9.1.24 Flame Front from Initial Deflagration Ignites a Secondary Deflagration (Source: J. M. Cholin Consultants, Inc.)

front from the initial deflagration ignites a secondary deflagration within the building compartment.

The deflagration within the building compartment propagates through the dust/air mixture of the dust dispersions. The combustion of the wood dust liberates huge quantities of heat, causing the air within the building to rapidly expand. The rapid expansion of the air within the building increases the pressure and causes the building envelop to rupture. Since the weakest part of the building envelope is usually the wall-to-roof joint, this joint is often the first to fail. Figure 9.1.25 diagrams a situation in which the deflagration within the building pressurizes the building until it ruptures at a wall-to-roof seam. As the pressure within the building continues to build, the roof might even lift from its points of attachment to the walls. The failure of the walls and roof allow the combustion product gases to vent to the outside (Figure 9.1.26).

Eventually the dispersed fuel in the air within the building is consumed and the combustion product gases cannot support the roof any longer and it falls back down onto the building slab (Figure 9.1.27). Even if the building does not collapse, numerous residual fires have been ignited and often the fire suppression sprinkler system has been damaged to such an extent that it is no longer capable of controlling these fires. This process can pro-

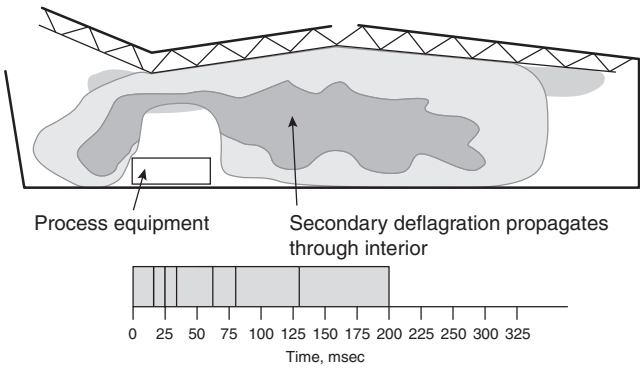

FIGURE 9.1.25 Deflagration Ruptures Wall-to-Roof Seam (Source: J. M. Cholin Consultants, Inc.)

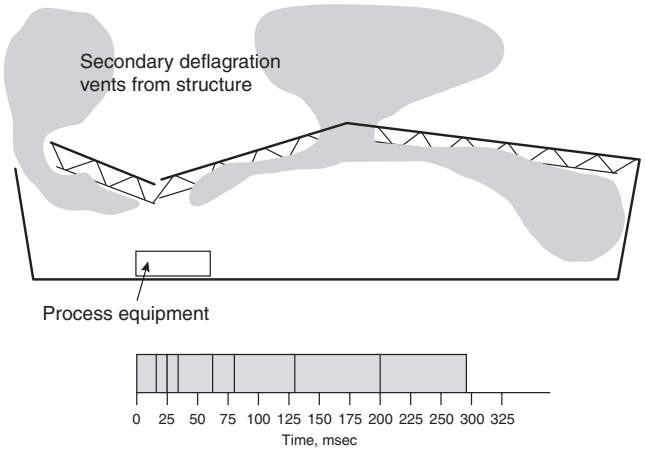

FIGURE 9.1.26 Deflagration Gases Vent to the Outside (Source: J. M. Cholin Consultants, Inc.)

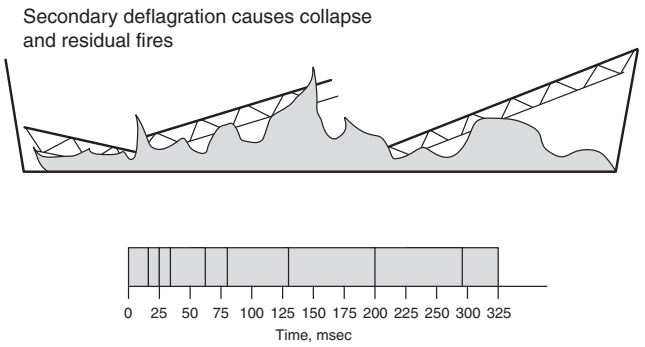

FIGURE 9.1.27 Building Collapse on Escape of Deflagration Gases (Source: J. M. Cholin Consultants, Inc.)

duce multiple deflagrations of increasing severity, even resulting in the catastrophic failure of the building structure. Furthermore, the secondary deflagrations often occur in occupied portions of the building, resulting in severe burn injuries to those occupants.

Hazard Management. Critical in this process is the dust accumulation within the facility. If the dust accumulations are held below that which is sufficient to fuel a deflagration, the process does not go forward. Consequently, in NFPA 664, the hazard analysis hinges on determining where a deflagration hazard exists. A deflagration hazard is deemed to exist wherever there are accumulations of dust of sufficient depth to render the compartment deflagrable or where dust dispersions exist due to normal operations. As part of the process hazards analysis, each compartment in the facility and each point in the process and dust collection system should be evaluated for the presence of a deflagration hazard. Where the deflagration hazard exists, protective features should be employed to mitigate that hazard.

Managing Combustible Concentration. Since the source of ignition is inherent in wood-processing equipment, there is no alternative to proactively managing the deflagration and explosion hazard. Process-generated ignitions are usually introduced into the dust collection system along with the wood particulate being produced by the process equipment. Consequently, one management tool is to design the dust collection systems so that they operate at wood dust concentrations well below the MEC. For most wood particulates, the MEC is approximately 30 to 60 g/m^3 (0.03 to 0.06 oz/ft^3). If the pneumatic system is designed to operate with dust concentrations well below this level of fuel loading, a deflagration cannot propagate through the duct, and spark detection and extinguishment systems can be used to prevent sparks from reaching the dust collector where deflagrable conditions exist. Where the dust loading is at or above the MEC, there is no alternative to considering it to be a deflagrable environment and measures to manage the effects of deflagrations in the duct must be employed.

The fact that many dust collectors have been operating for decades without a fire does not justify a lack of protection for both the employees and the facility from a dust collector fire or explosion. In the context of the dust collection system, the "fire" is an ember or "spark," sometimes as small as a BB (approximately 0.177 in. [4 mm] in diameter) produced by the wood working machinery that has been picked up by the dust collection system.

In some cases, the machinery in the modern forest products facility can generate an endless succession of sparks. As many as dozens of sparks per hour have been detected in some facilities. Even though the conveying velocity might be several thousand feet per minute, under normal circumstances most of the sparks burn out. They are quenched as they collide with the walls of the duct, with large wood chips, or with resinous material in the duct. Most sparks do not survive enough long to reach a location where they can ignite a dust cloud. Perhaps only one in a million sparks generated will survive the journey from its source to the dust collector.

Dust Collector Fires. There are some management options that can reduce the probability of a spark reaching the collector. However, the laws of probability predict that a fire will occur in every dust collector handling wood particulates sooner or later. Once the burning material, the spark, enters the dust collector, it encounters one of four possible fates. First is that it impinges on the filter media and initiates a fire on the surface of the media. In this scenario, as soon as the next automatic bag cleaning cycle occurs, a dust cloud will be produced adjacent to the surface fire on the filter media. This usually leads to a deflagration within the dust collector interior.

The second possibility is that the burning material falls to the bottom of the collector. As it falls, it passes through the continuous dust concentration gradient between the airspace and the accumulated dust in the hopper section of the dust collector. If the spark is sufficiently large, it can ignite the dust suspension in the hopper section, resulting in a deflagration within the dust collector interior.

The third potentiality is that the spark ignites the filter media and the resulting fire burns through the filter media before the bag cleaning cycle begins. As the fire burns through the filter media it will cause a pressure drop across the filter

media. With the loss of pressure, there is no longer a force holding the dust to the surface of the media, and the dust begins to fall to the bottom of the collector. As the dust falls, it creates a dust suspension that could encounter the flames of the fire and ignite. However, it is possible that it might not necessarily lead to a deflagration. The last possibility is that the burning material burns out without igniting a sustained fire.

It is important to keep in mind that a deflagration will not result every time a spark is introduced into a dust collector. It is rare that a single spark has sufficient energy and can deliver sufficient power to ignite a deflagration. It is more likely that it will initiate a fire within the dust collector. With the air movement providing plenty of atmospheric oxygen, a fire that develops on the filter media can rapidly involve the entire collector interior. In this case, the heat release is very rapid and if the dust collector is equipped with a fire suppression sprinkler system, the release of heat from the combustion of the filter media could actuate a sprinkler head. Unfortunately, if the sprinkler system is a dry pipe system there is a remote possibility that the exhausting of air from the dry pipe system could force dust into suspension and yield a deflagration. However, this last concern has not yet been validated by postincident investigations.

If the dust collector is located outside the facility and is deemed expendable, then there is no compelling need to protect it. The only need is to prevent the deflagration flame front from entering the building via the dust collection system ductwork. When the inlet duct interior is nondeflagrable, this need is usually fulfilled by installing backflash dampers on the inlet ducts from the facility to the dust collector. To prevent the flow of flame back into the facility via the return air ducts, abort gates are installed on the return air ducts to divert flame and burning material to a safe outside location. When the inlet duct interior is deflagrable, provisions must be made to prevent the propagation of a deflagration in the duct upstream from the dust collector to the factory interior. Deflagration flame front velocities are generally at least an order of magnitude greater than conveying air velocities, so the airflow makes little, if any, contribution to preventing deflagration propagation from a dust collector into the factory interior.

Since most woodworking facilities rely on the operability of the dust collector, the expendable dust collector is the exception rather than the rule. Furthermore, since there is no guarantee that an ignition will result only in a fire, there is no alternative to designing the dust collector with provisions to deal with a deflagration.

Dust Collector Deflagration Management. There are three practical means of dealing with the deflagration in the collector. The first is deflagration venting designed in accordance with NFPA 68, *Standard on Explosion Protection by Deflagration Venting.* The second is venting the deflagration through a listed dust retention/quenching vent assembly designed, installed, and maintained in accordance with NFPA 69, *Standard on Explosion Prevention Systems.* The third is deflagration suppression designed, installed, and maintained in accordance with NFPA 69.

These solutions deal only with the potentiality of deflagration—not fire. Prudent design practice dictates that dust collectors be protected from both fire and deflagration; both a fire protection system and a deflagration management system will be needed. Usually the fire protection is implemented with either a sprinkler system or a water deluge system.

Protecting the Facility and Occupants from the Dust Collector. NFPA 664 provides requirements for the protection of dust collection systems based on whether the dust collection system represents a fire hazard or an explosion hazard. In many cases, a single dust collection system will represent both and must be protected for both hazards.

Life safety objectives are addressed with protective features that address both the potential for deflagration and fire. Where pneumatic conveying air is to be recycled back into the facility, a means must be provided to prevent flame and combustion product gases from being conveyed into the facility in the event of a fire. This is important for two reasons. First, if smoke and combustion gases are conveyed into the facility, the occupants are immediately placed at risk. Secondly, the flow of the hot combustion gases into the facility can produce a hot layer of smoke and gas at the ceiling plane, especially if the return air discharge is located at or near the ceiling (usually the case). Under these circumstances the flame from the dust collector fire is conveyed back into the facility where the most easily ignited, most hazardous dust is located, at the ceiling plane. Even if this does not ignite a deflagration at the ceiling plane, it has the potential to cause numerous sprinkler heads (if present) to operate. But sprinkler systems are designed to supply a finite number of heads, based on the presumption that a fire in a given location is producing a plume that forms a ceiling jet. When flame and gas from the dust collector fire move across the ceiling, all of the heads might operate, exceeding the capacity of the system riser. This sets the stage for potential failure of the system to control the fire.

Abort Gates. The recycling of flame into the facility by way of the return air duct is usually prevented with an abort gate situated at the dust collector exhaust. Usually, spark detection is used to actuate the abort gate. The spark detection is usually installed on the dust collection system ducts at one of two locations relative to the dust collector. One location is on the inlet to the dust collector. Figure 9.1.28 shows a minimum code-compliant implementation of spark detection for return air abort, with spark detectors located on the inlet to the dust collector. The detector actuates the abort gate whenever a spark enters the dust collector.

While this approach is the safest, it is not always practical. Where the spark detectors are located a long way from the dust collector, excessive downtime due to nuisance activations must be considered. A second location is in the exhaust duct, as shown in Figure 9.1.29. This location relies on the fact that when a fire is ignited in the filter media bits of burning wood dust and filter material from a dust collector fire begin to flow back toward the facility via the return air duct. These bits of burning material are easily detected with spark detectors. The specifics relating to how spark detection systems are designed and installed are addressed in *NFPA 72®, National Fire Alarm Code®.* Activation of an abort gate is a remedial action necessary to secure the life safety and property of the site. Consequently, a listed protected premises

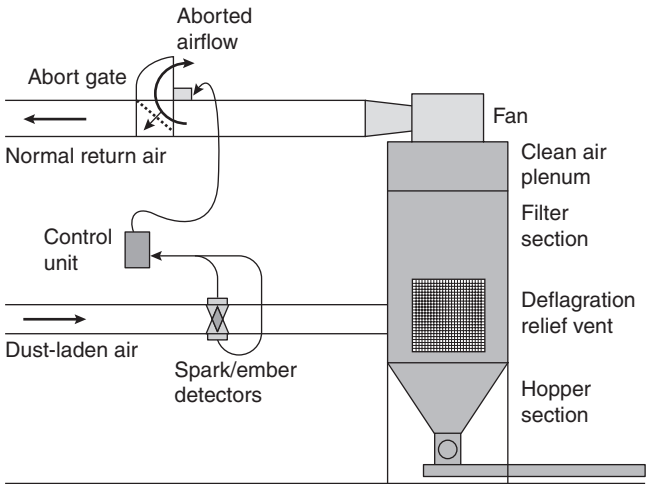

FIGURE 9.1.28 One Minimum Code-Compliant Implementation of Spark Detection for Return Air Abort (Source: J. M. Cholin Consultants, Inc.)

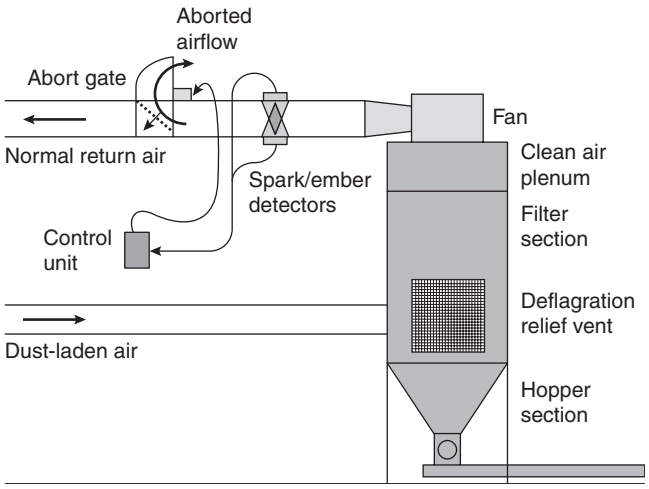

FIGURE 9.1.29 An Alternative Minimum Code-Compliant Implementation of Spark Detection for Return Air Abort (Source: J. M. Cholin Consultants, Inc.)

fire protective signaling system control panel, listed as a releasing device, is required for the activation of the abort gate.

This system does nothing to protect the dust collector itself. Once the abort gate has operated, the occupants of the building and the building itself are considered adequately protected, and the dust collector is allowed to burn. Since the dust collector is of noncombustible construction, it represents, in theory, a limited fire threat. The air moving through the dust collector serves as a heat transfer medium. As the filter media (bags) are consumed, the probability of a dust deflagration becomes increasingly remote. Prudent design dictates that whenever a return air abort gate is tripped, the automatic bag cleaning feature of the dust collector be shut down also. This reduces the probability that a fire in the dust collector will transition to a deflagration because of a dust/air suspension caused by the operation of the bag cleaning feature.

Dust Collector Rupture. In the context of a dust collector deflagration, the life safety objectives require the prevention of the catastrophic rupture of the dust collector and the prevention of flame extension into the facility interior by way of the inlet ducts and the return air ducts. Prevention of the dust collector rupture is usually achieved by either venting the dust collector to a safe outside location, following the guidelines in NFPA 68, or with deflagration suppression systems designed, installed, and maintained in accordance with NFPA 69. These deflagration control measures reduce the pressure in the dust collection system and should be adequate to limit flame extension via the ductwork.

Spark Detection and Extinguishment Equipment. This represents the minimum code compliant protection for the woodworking facility dust collector. This does not represent the commonly accepted best design practice. In most cases additional spark detection and extinguishment equipment is installed to minimize downtime and preserve the capital investment in the dust collection system. Spark detection is usually used in conjunction with an automatic intermittent water spray extinguishing system to quench sparks before they enter the dust collector.

The typical spark detection and extinguishing system consists of three basic components, shown in Figure 9.1.30, each listed by a nationally recognized testing laboratory as a system:

1. Set of spark/ember detectors mounted on the duct
2. Water spray extinguishing unit mounted downstream from the detectors
3. Control panel to provide power to and receive signals from the detectors and to provide power to actuate the extinguishing unit

Spark detection and extinguishing systems rely on the extreme sensitivity and speed of response of spark detectors to detect sparks as they travel down the pneumatic conveyor duct, often at speeds as high as 6000 ft/min (30 m/sec). When the detector detects the radiant emissions from the spark, it signals the control unit. The control unit energizes the solenoid of a water spray extinguishing unit. The extinguishing unit establishes a water discharge pattern within the duct to quench the spark as it arrives at the extinguishing unit location (Figure 9.1.31).

The distance between the detector and the extinguishing unit must be carefully computed, based on the duct diameter, conveying air velocity, and the response time parameters of the spark detectors, extinguishing unit, and control panel. Likewise, there is usually a minimum distance between the dust collector and the extinguishing unit. This distance is determined by the conveying air velocity, duct diameter, and water pressure. Failure to properly compute these factors renders the system of limited value, as it then becomes possible for the spark to pass the extinguishing unit before the water discharge has established an effective extinguishing concentration in the duct.

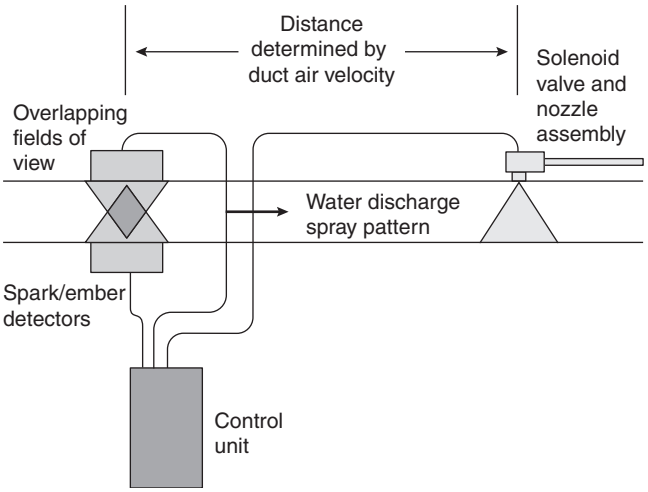

FIGURE 9.1.30 Basic Spark Detection and Extinguishment System Design (Source: J. M. Cholin Consultants, Inc.)

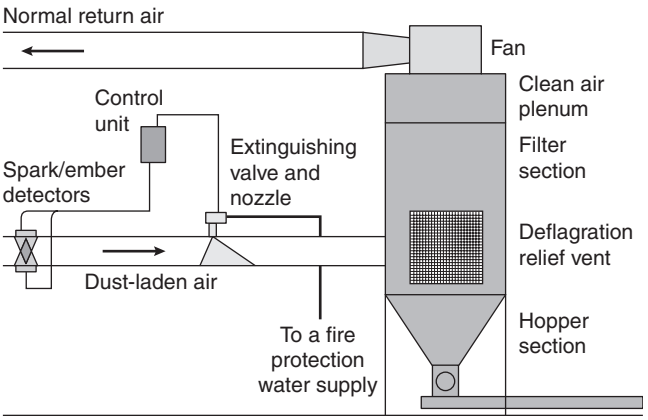

FIGURE 9.1.31 Spark Detection and Extinguishing System Protecting the Inlet to a Dust Collector (Source: J. M. Cholin Consultants, Inc.)

Limitations to Spark Detection Systems. Spark detection and extinguishing systems are listed as integrated systems to be installed on the inlet pipes that convey dust to the collector. Each duct entering the dust collector must be monitored. The principal concern is the protection of the collector from sparks entrained in the airflow. Each time a spark is detected, the extinguishing unit is energized and a spray of water is established in the duct. The control panel is equipped with a timer, which controls the duration of the water discharge usually to a period between 3 and 15 seconds. After this brief spray, the extinguishing unit is de-energized and the system waits for the next spark. The air movement is not shut down. The whole dust collection system continues to operate. The water discharge is normally limited to less than approximately 6.6 gal (25 L), a quantity that readily evaporates in the dust collection system airflow.

Spark detection and extinguishing systems are applicable only when the concentration of combustible dust within the pneumatic conveyor duct is below the MEC. Where ducts are operating above the MEC, the dust/air mixture is capable of propagating a deflagration. There is the potential that a spark could ignite a deflagration in the duct. If this occurs the spark detection system would be of little value for several reasons. First, deflagration flame fronts move at speeds substantially greater than the normal conveying velocity of the dust collection system. Since the distance between the spark detectors and the extinguishing unit is based on normal conveying velocity, this greater speed would mean that the flame front would pass the extinguishing unit before a water spray pattern had been established. Secondly, the quantity of water delivered by extinguishing units has not been evaluated for capability of quenching a deflagration flame front. There is no basis to conclude that the intermittent water spray unit listed for spark quenching provides sufficient extinguishing water density to quench a deflagration flame front. Finally, deflagration flame fronts in ducts tend to accelerate until they exceed the speed of sound, turning into a detonation. Consequently, ducts in which a deflagration can occur must be protected with either deflagration venting or deflagration suppression systems.

Spark detection and extinguishing systems are one tool available to the facility designer to manage the fire hazard inherent in the modern woodworking and wood-processing facility. They are usually used as part of an overall fire protection strategy. A spark detection and extinguishing system located on the inlet lines detects and quenches the sparks in the wood particulate stream, preventing burning material from entering the collector. A second set of spark detectors is used to actuate the abort gate to prevent smoke, flame, and burning material from re-entering the facility from the collector and to shut off the automatic bag cleaning facility on the dust collector. This design concept is shown in Figure 9.1.32. In some cases, the second set of spark detectors is employed to actuate a water deluge system in the dust collector.

In general, it is not recommended that a single set of spark detectors on the inlet side of the collector be used to actuate the

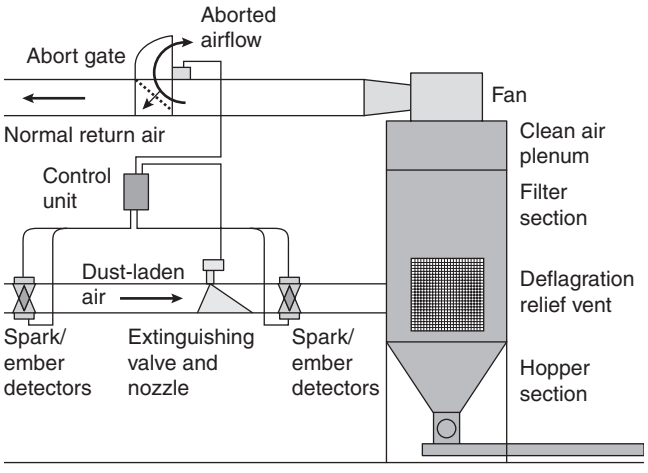

FIGURE 9.1.32 Typical Spark Detection and Extinguishing System for Managing the Hazards Associated with a Dust Collector (Source: J. M. Cholin Consultants, Inc.)

abort damper on the outlet side. In many woodworking operations, sparks are a regular occurrence, and a properly operating spark detection system will detect several sparks per day under normal conditions. Once the abort damper has operated, the air movement must be shut down to enable the manual reset of the damper. This is a serious inconvenience if it happens too frequently. Furthermore, the interruption of the air movement through the dust collector allows all the dust that has adhered to the filter bags to fall down into the bottom of the collector. If there is any burning material within the collector, the air shutdown could cause a fire to transition to a deflagration.

Spark detection and extinguishing systems can make very significant reductions in the hazard associated with pneumatic wood particulate conveying systems, subject to one important caveat. Spark detection and extinguishing systems cannot be used where deflagration conditions exist in the ducts. When deflagration conditions exist in the ducts, explosion prevention systems that meet the requirements of NFPA 69 or deflagration venting designed in accordance with NFPA 68 must be employed. Spark detection and extinguishing systems should be thought of as fire-extinguishing systems that reduce the probability that burning material will enter the dust collector.

In general, a spark detection system does not "completely protect" a dust collection system, the dust collector, or the facility it serves. The spark detection and extinguishing system covering the inlet lines and the detection activating an abort gate on the air return lines address a substantial part of the fire risk. However, a properly protected dust collection system will include either deflagration vents installed in accordance with NFPA 68 or explosion prevention and protection systems installed in accordance with NFPA 69 to address the contingency of a deflagration in the collector producing a flame front that travels too fast to be diverted by the abort gate. Furthermore, a sprinkler system in the dust collector installed in accordance with NFPA 13 should be considered, as it will probably limit the structural damage to the dust collector in the event of a fire and hence facilitate the return to operation.

Other Design Approaches. Some fire protective design concepts should be carefully scrutinized before using them to protect dust collectors for combustible particulate solids. The use of heat detectors to actuate a gaseous extinguishing system can increase the hazard rather than reduce it. In a 50,000 cfm (1400 m^3/min) dust collection system, at standard temperature and pressure, it takes a fire of about 15.3 Btu/sec (16 kW) to produce a 1°F (0.556°C) increase in the temperature of the air flowing through the collector. Fixed temperature heat detectors generally require temperature increases on the order of 50°F (27.8°C) before operating. Differential temperature detection systems are rarely stable when the threshold differential is less than 10°F (5.5°C). Using the 10°F (5.5°C) temperature differential, such a system could be expected to initiate response when the fire had achieved a heat output of 153 Btu/sec (approximately 160 kW). This is equivalent to a pool of burning gasoline of approximately 1.0 ft^2 (0.1 m^2). If the air movement through the collector is disrupted (by the discharge of an extinguishing agent and the shutdown of the air movement necessitated to attain and maintain extinguishing concentration) while a fire of this magnitude exists within the collector, a deflagration is likely. A similar set of concerns should be addressed in the event that water deluge actuated by heat detection is contemplated.

SUMMARY

The nature of wood as a raw material and the methods employed to convert that raw material into a finished product contribute to a substantial level of fire hazard in woodworking facilities. In addition, the production methods produce large quantities of wood particulate that are easily ignited and in many cases can deflagrate. These factors demand an aggressive loss prevention posture in woodworking facilities.

The fire risk inherent in a forest products processing facility can be very effectively managed through conscious facility design, operations, and fire-protective systems. Woodworking facilities can be designed to minimize the opportunities for ignition by organizing the production process to keep combustibles away from ignition sources, compartmentation of the facility, properly designed wood-waste management systems, and utilization of automatic sprinklers. Operational policies can contribute to the reduction of fire risk, especially through a strictly enforced housekeeping program. Finally, the proactive protection of the wood-waste/dust collection system can reduce the probability of an explosion to acceptable levels.

Spray application of coatings is a process basic to the manufacture of a broad variety of fabricated products. Factories frequently operate at least one paint spray booth. Regardless of the purpose for which the coating is applied, flammable or combustible materials are commonly used in the process. Fires in paint operation areas develop very quickly, have high heat release rates, and produce large volumes of toxic smoke. The risk of fire can be kept to an acceptable level through a combination of efforts directed at the control of sources of ignition, the control of ignitable atmospheres (vapor- or powder-air mixtures), limitation of available fuel, isolation of the process, explosion prevention, and provision of an adequate means for extinguishing a fire. Simply stated, the person who manages his or her process safely must do those things that will tend to prevent a fire from starting and those things that will limit the size of any fire that does occur to a scale that can be quickly extinguished with immediately available resources. If these things are done, the process can be operated with minimal risk to life and property.

For related topics see Section 9, Chapter 3, "Dipping and Coating Processes"; and Section 9, Chapter 4, "Plastics Industry and Related Process Hazards."

TYPES OF COATINGS

Fluid Coatings

Flammable and combustible fluid coatings have been in industrial use for many years. Their use involves familiar fire risks, discussed here at some length.

Waterborne coatings, which are enjoying expanded use, present somewhat of an enigma; namely, many formulations that exhibit a flashpoint do not have a fire point and will, therefore, not sustain a flame. Although these materials do not present fire hazards typical of flammable liquids, their dried residues are combustible and must be managed as such. ASTM D4206, *Standard Test Method for Sustained Burning of Liquid Mixtures by the Seta Flash Apparatus (Open Cup),*[1] sets forth a procedure useful to determine whether a given material, as a liquid, will support flame. If it does, it should be treated as a flammable liquid.

The most familiar atomizing device for fluid coatings is the air spray gun, which uses jets of high-pressure air to break up fluid into a fine mist. The high-volume, low-pressure (HVLP) spray gun is an adaptation of the air spray gun that produces a somewhat coarser spray, thereby reducing the fine mist. Another device commonly seen in high-volume production processing is the airless atomizer, which generates a spray of fluid by hydraulic means without using compressed air. Fluid pressures used with this type of atomizer range from 300 psi (2068 kPa) to approximately 7000 psi (48,265 kPa).

Air and airless atomizers are also used in electrostatic spray operations. For this process, the appropriate atomizer is built into a spray gun that has a high-voltage electrical input. Voltages applied to the charging electrode range from approximately 35,000 V to somewhat over 100,000 V.

Don R. Scarbrough is the former safety staff consultant for the Nordson Corporation, Westlake, Ohio, and is now a consultant. He serves on NFPA's Technical Committee on Finishing Processes and Technical Committee on Static Electricity.

There is less overspray with the electrostatic method than with the air or airless spray methods because the charged atomized particles are attracted to the grounded workpiece.

A third type of atomizer depends on electrostatic forces for its operation. In its most common configuration, a sharp-edged disc with a diameter of 6 to 12 in. (150 to 300 mm) is mounted with its axis oriented vertically and is then charged electrically to about 100 kV. The disc is spun about its axis while the coating fluid is poured slowly onto the surface. Centrifugal force spreads the fluid into a thin film and carries it to the sharp edge of the disc, where the film is disrupted by electrostatic forces and sprayed in a 360 degree pattern. Workpieces are carried to the process zone by a conveyor and collect coating as they pass through. A form of this device that has gained popularity has the disc developed into the form of a cup or bell 2 or 3 in. (50 or 76 mm) in diameter that rotates at a high speed—sometimes approaching 60,000 rpm. Bell atomizers are frequently seen mounted in banks of 6 to 12 units at a single spray station.

Powder Coatings

A coating process that has gained broad acceptance is the application of organic coatings in the form of dry powder. In this process, the powder is first suspended in air and then charged electrostatically from a dc power supply operating between 60 and 120 kV. The powder is then directed toward the grounded workpiece and held in place by electrostatic forces. The powder is formed into a continuous coating as it melts during passage through a process oven. The powder coating process differs substantially from the fluid coating processes because no organic solvents are used and no readily ignitable residues are produced.

Electrostatic application of powder is most commonly accomplished with spray guns. These spray guns are simple devices to which a mixture of powder and air is fed through a single tube. A separate cable connected to the gun provides the high voltage necessary for operation of "corona-type" guns, whereas those that operate by frictional charging (referred to as "tribocharging" guns) require no external source of high voltage.

Workpieces having dimensions less than approximately 4 in. (102 mm) or that are configured as long ribbons or cables can be powder coated with a device known as an electrostatic fluidized bed. In this process, powder is held in a container having an open top and a porous bottom through which an upward flow of air causes the powder mass to levitate or "fluidize." Charging electrodes near the surface or beneath the fluidizing plate impart an electrical charge to the powder. Electrically grounded workpieces pass over the surface of the bed and collect a coating of powder. The coating is then cured in a baking oven.

Although they are not widely used, there are techniques for applying dry powder coatings without the use of electrostatics. These processes typically involve preheating the workpiece to a temperature substantially above the melting point of the powder and then applying the powder, either by dipping the workpiece into a fluidized bed or by spraying air-suspended powder directly onto the hot surface of the workpiece. The powder melts immediately on contact and flows to form a film, which is subsequently cured in a bake oven.

SPRAY PROCESS EQUIPMENT AND COMPONENTS

Fluid Supply

Air spray guns draw their coating fluid from either small cups mounted on the guns or through hoses connected to larger pressurized containers called paint tanks or pressure pots that have capacities varying from ½ to 60 gal (2 to 227 L). In very high production arrangements, the coating can be fed by a pump from a bulk tank. Fluid pressures between 3 and 75 psig (21 and 517 kPa) are customary.

To ensure satisfactory results, industrial coating mixtures are usually modified shortly before spraying by the addition of solvents to adjust viscosity. A safety tank or container is used to reduce the possibility of a flammable liquid spill while handling or transporting this blended material.

Spray Guns and Devices

Among the various forms of industrial air spray guns, the two most commonly used are the pistol grip hand spray gun and the machine-mounted automatic air spray gun. Air is supplied to the hand spray gun through one hose, while fluid is either hose fed or drawn from a gun-mounted container (Figure 9.2.1).

Electrical grounding of airless spray guns to drain off static electricity generated during spraying is provided through a wire or conductive layer built into the fluid hose. A manual safety lock is usually provided on hand units to secure the trigger and prevent accidental actuation.

Handheld and automatic electrostatic spray guns have electrically nonconducting extensions at the front end to insulate the

FIGURE 9.2.1 Hand Air Spray Gun with Fluid Supplied from 2 qt (1.9 L) Pressure Pot (Source: DeVilbiss)

energized components from the grounded parts. In addition to being connected to coating fluid and air supplies, these guns are also connected to high-voltage power supplies. Voltage at the atomizer is in the 30 to 75 kV range for handheld units and in the 30 to 120 kV range for automatic units. In hand spray guns of this type, the cable carrying the high-voltage power to the gun also supplies an electrical ground for the pistol grip and trigger. To prevent electrical sparking from accidental contact of the charged elements of the gun with a grounded object, the cable is usually terminated at the gun in an electrical resistance on the order of 75 to 250 MΩ (megohm). In a more recent development, the high-voltage power supply has been integrated into the gun, thereby eliminating the high-voltage cable. Some automatic electrostatic spray guns are not equipped with a high-impedance termination but rely on the process control approach of maintaining separation between gun and workpiece to prevent electrical sparking.

Figure 9.2.2 shows an electrostatic disc surrounded by chairs hanging from a conveyor loop. Immediately above the disc is its motor drive. Partially obscured, at the top of the illustration, is a device that moves the disc up and down, enabling it to coat workpieces over the entire height of the carriers. Separate electrical and fluid inputs are remotely controlled. Discs are commonly equipped with variable voltage power supplies that can be adjusted over a range of approximately 50 to 120 kV. Because considerable electrical energy is stored on the disc, adequate distance must be maintained between it and the workpiece to prevent sparking.

Spray Booths

A spray booth is a power-ventilated structure used to enclose a spraying operation. Although in most cases the booth structure physically surrounds the spray operation, some configurations leave the spray operation unenclosed and surround the operation with a controlled stream of air drawn into the booth.

The most popular type of spray booth is the "open face" or "open front" arrangement. It is a boxlike structure that has one open side. The ventilation system associated with the booth may provide an airflow horizontal to the floor (cross draft) or vertical to the floor (downdraft) as demanded by process requirements.

For some operations, such as production finishing of automotive bodies, a tunnel spray booth is used (Figure 9.2.3). This structure is virtually always arranged with vertical downdraft ventilation and a horizontal floor-mounted conveyor running the length of the tunnel. Makeup air is introduced through special ductwork and air diffusers in the ceiling.

Limited Finishing Workstations

A type of spray enclosure, referred to in NFPA 33, *Standard for Spray Application Using Flammable or Combustible Materials*, as a "limited finishing workstation," is gaining acceptance for use in automotive repair shops and similar uses. Originally developed to control dust from surface preparation operations, such as sanding and grinding, these limited finishing workstations are allowed to enclose limited spray application, if certain requirements of NFPA 33 are met.

Limited finishing workstations differ from spray booths structurally in that the enclosing walls are usually not walls at all but movable curtains. In addition, the units might or might not exhaust to the building exterior and some are mounted on wheels to facilitate movement around the shop. NFPA 33 limits the total amount of material that can be sprayed in any 8 hour period to 1 gal (3.8 L). Refer to NFPA 33 for the requirements that must be met for these units to be used for spray application.

Special-Purpose Enclosures

Continuous Coaters. Continuous coater enclosures are individually engineered for a specific coating process. Within the

FIGURE 9.2.2 Electrostatic Disc (Source: ITW Ransburg)

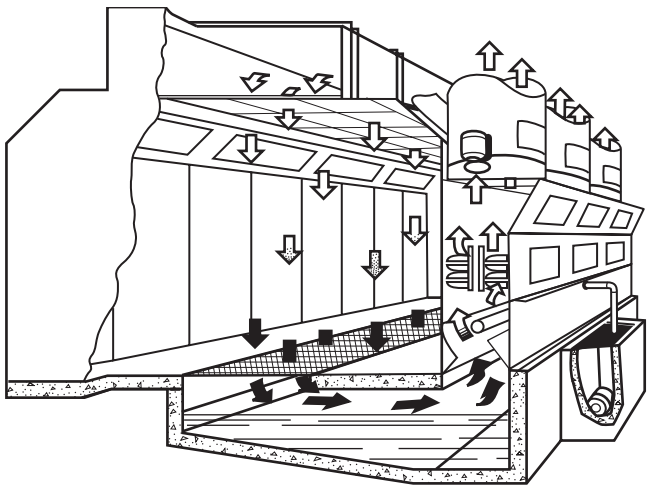

FIGURE 9.2.3 Tunnel Booth Configured for Downdraft Ventilation

coater enclosure is an array of spray guns that apply coatings to workpieces that pass through the coater at conveyor speeds between 100 and 600 ft/min (30 and 183 m/min). The interior of the coater is not exhausted, but the entry and exit vestibules are equipped with exhaust shrouds to capture any vapors or minor amounts of overspray that drift out from the main enclosure. Most of the overspray is collected in a sump and drawn off through a pumping system, which recycles the coating into the coating process.

Decorating Machines. These machines are used in conjunction with masking devices to paint stripes or other patterns on workpieces, such as automobile grilles and side moldings. The mask is mounted in the opening beneath a row of cylinders at the front of the machine, and the workpiece is placed face down on the mask. When the operating cycle is started, air-driven pistons in the row of cylinders clamp the work to the machine. Spray guns inside the cabinet automatically tilt in one direction and travel the length of the workpiece. At the end of the workpiece, the spray guns tilt in the opposite direction and travel back to the starting point. The air-driven clamps automatically release the work at the end of the operation.

An exhaust system draws fresh air in through the grille at the front of the machine, and internal filters remove overspray from the air-vapor stream before it is exhausted. Because the process is totally enclosed, the risk of escaping vapors or overspray and subsequent ignition is significantly diminished.

Spray Rooms

The size, shape, and weight of some workpieces might make the use of spray booths impractical. When this case occurs, an entire room dedicated to the spray process is a legitimate alternative. Such rooms, called spray rooms, are classified as hazardous areas. Power ventilation removes the combustible vapors that are released during the process, but velocities are not high enough to capture particulate matter. Therefore, overspray is permitted to settle to the floor where it accumulates as a combustible residue until it is removed by a mechanical cleaning process. Vapor removal systems are most effective when the exhaust intake is located along one wall within 1 ft (300 mm) of the floor and the makeup air is introduced along the opposite wall.

Open-Floor Spraying

A spray operation conducted without a spray booth and in an area not separated from general factory operations by a partition is called open-floor spraying. Depending on the quantity of volatiles to be released in the operation and existing ventilation within the building, forced ventilation might or might not be provided. Whether forced or not, adequate ventilation must be provided to prevent accumulation of flammable concentrations of vapor. Particulate overspray materials are allowed to settle to the floor and their residues are removed by mechanical means. Ignition sources incidental to other factory operations are a great concern whenever open-floor spray techniques are used, and it is common to establish a buffer zone surrounding the spray area for about a 20 ft (6 m) radius to separate processes.

Overspray Collectors

Vapor and overspray removal systems associated with spray booths or enclosures typically include a fan to create an airflow and a collection system that separates and collects particulate matter from the airstream, then exhausts vapors to the exterior of the building. Overspray collectors can generally be placed into one of four categories, as follows.

Baffle Maze. The baffle maze consists of a series of flat panels arranged in a staggered pattern through which the airstream is directed. A substantial portion of its particulate burden is removed by direct impaction and collection on the surface of the dry baffle panels where it remains until removed by mechanical cleaning. Such systems are of limited efficiency and permit appreciable amounts of fine particulates to pass through.

Dry Filter. Collectors using paper or fiberglass filter elements are called dry filters and are popular for low- to intermediate-volume spray operations. The typical filter used in this type of collector is a replaceable element approximately 20 in. (508 mm) square and perhaps 2 in. (51 mm) thick. Secondary cloth filters might be found mounted in the plenum behind the primary filters to provide more efficient capture of fine particles. Particulate residues are permitted to accumulate on the filter until a significant obstruction of the airflow through the filter is noted. Then the fouled filters are discarded and replaced.

Waterfall and Cascade Scrubbers. Where high-volume spray coating operations are conducted for several hours a day, waterfall or cascade scrubbers are commonly used. The exhaust airstream either is scrubbed directly by sprays of water coming from nozzles or follows a path that takes it through several stages of waterfall. Figure 9.2.4 is an example of one variation of this type of scrubber. Particulate matter is accumulated in a water tank from which it is removed either manually or automatically by a sludge removal device.

Chemical compounds must be added to the water to prevent paint residues from adhering to the walls or clogging nozzles, thereby creating open channels through the water curtain. Air passing through these open channels will not be adequately cleansed and will carry particulate matter into the exhaust system; the particulate matter can then be deposited on the lining of the exhaust stack, on exhaust fan blades, or on the roof of the building.

Venturi Scrubbers. Perhaps the most efficient overspray collector is the venturi scrubber. This device directs the exhaust airflow through a narrow throat (venturi) through which a high-velocity spray of water is also directed. Virtually all particulate matter is extracted from the airstream and trapped in the water. The water is processed through a tank where residues are removed by settling and skimming. The same chemical compounds mentioned in the discussion of the waterfall-type scrubber must be added to the water used in this system to prevent plugging and blocking of nozzles. Figure 9.2.5 is a schematic of a venturi scrubber.

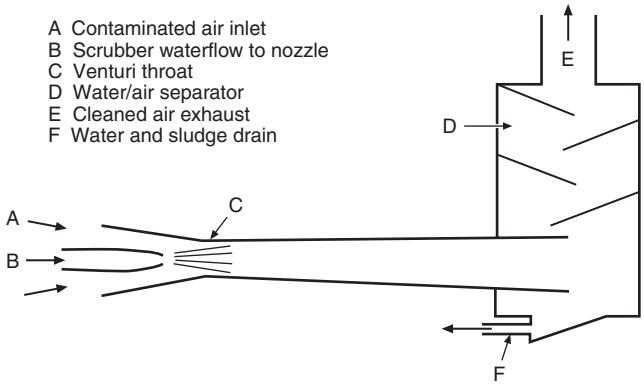

FIGURE 9.2.5 Venturi Scrubber

POWDER COATING PROCESS EQUIPMENT AND COMPONENTS

Spray Process

The powder coating spray process utilizes a device called a feeder that mixes powder with air and supplies the mixture to the spray guns. The powder is contained in a fluidized bed or in a hopper having a cone-shaped bottom. Feeders might supply a single gun or several guns with a separate ejector for each gun.

The most common coating powder is epoxy powder, but others include acrylic, polyester, vinyl, nylon, butyrate, polyolefin, and alkyd. These powders are shipped from the manufacturer to the user in containers of 25 to 1000 lb (11.34 to 453.6 kg). They may be classified as ordinary combustibles and, as such, may be stored without requirements for extra hazard protection.

FIGURE 9.2.6 Automatic Powder Gun (Source: Nordson Corp.)

Spray guns used for the electrostatic application of dry powders do not differ greatly in appearance from guns used for the electrostatic application of fluids (Figure 9.2.6). Because no atomization is required, the functions of the spray gun are simply to control the shape of the spray pattern and to impress a high-voltage charge on the powder cloud. Powder and electrostatic power input connections can be made at the rear of the barrel or from below to the base of the grip and the forward portion of the barrel. Connections to automatic guns typically are made at the rear. Guns having integrated power supplies have no high-voltage cable but are commonly powered through a lightweight cable carrying about 12 V.

Electrostatic power supplies rectify stepped-up common ac line voltage inputs, either 115 or 230 V, to produce dc output ranging from 30 to 100 kV. Several automatic guns may be connected to a single power supply. For handgun applications, however, a separate power supply is provided for each gun, and each supply has a control circuit that prevents the voltage from being energized unless the trigger is actuated.

The interconnection between power supply and spray gun is usually made through a high-voltage coaxial cable. At the termination of the cable within the spray gun, the charging circuit is connected to the gun electrode through a 75 to 250 MΩ resistor. In operation, a faint blue glow, called a corona, is developed around the end of the electrode that is projected through the front of the gun. Individual powder particles are charged as they pass through the corona.

In a class of equipment commonly referred to as tribocharging guns, no external power supply or cable is used (Figure 9.2.7). These devices generate static charge directly on the surface of the powder granules through frictional contact between the high-velocity airborne granules and internal surfaces of the apparatus.

FIGURE 9.2.7 Automatic Tribo Gun (Source: Nordson Corp.)

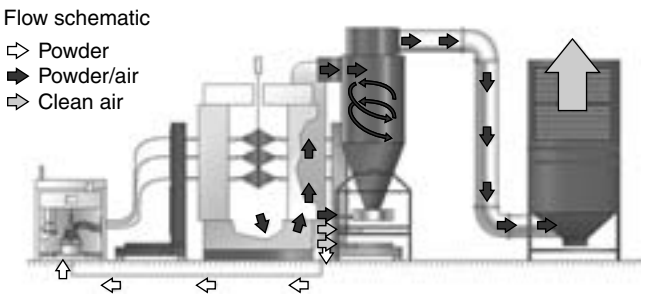

FIGURE 9.2.8 Automatic Recycle of a Single-Color Powder-Coating System Showing Booth, Collector, Fan, and Filter

A common facility in which electrostatic powder spray operations are conducted is a spray booth with a hopper bottom through which exhaust air is drawn into a ductwork that leads to a powder collector. A cloth or fabric filter within the collector separates the powder from the airstream. Powder separated within the collector falls to the bottom of the hopper from which it is extracted and is subsequently reintroduced to the feeder for the spray guns. A basic outline of this arrangement is shown in Figure 9.2.8.

In some installations, a cyclone is placed in the airstream between the booth and the filter collector. This device uses centrifugal force to separate larger particles from the airstream prior to filtration.

A more recent development is the integration of the spray booth and powder recovery system into a single structure (Figure 9.2.9). In this equipment, cartridge-type filters and the exhaust fan are built into the structure of the spray booth. The ductwork, which conventionally would separate the booth from

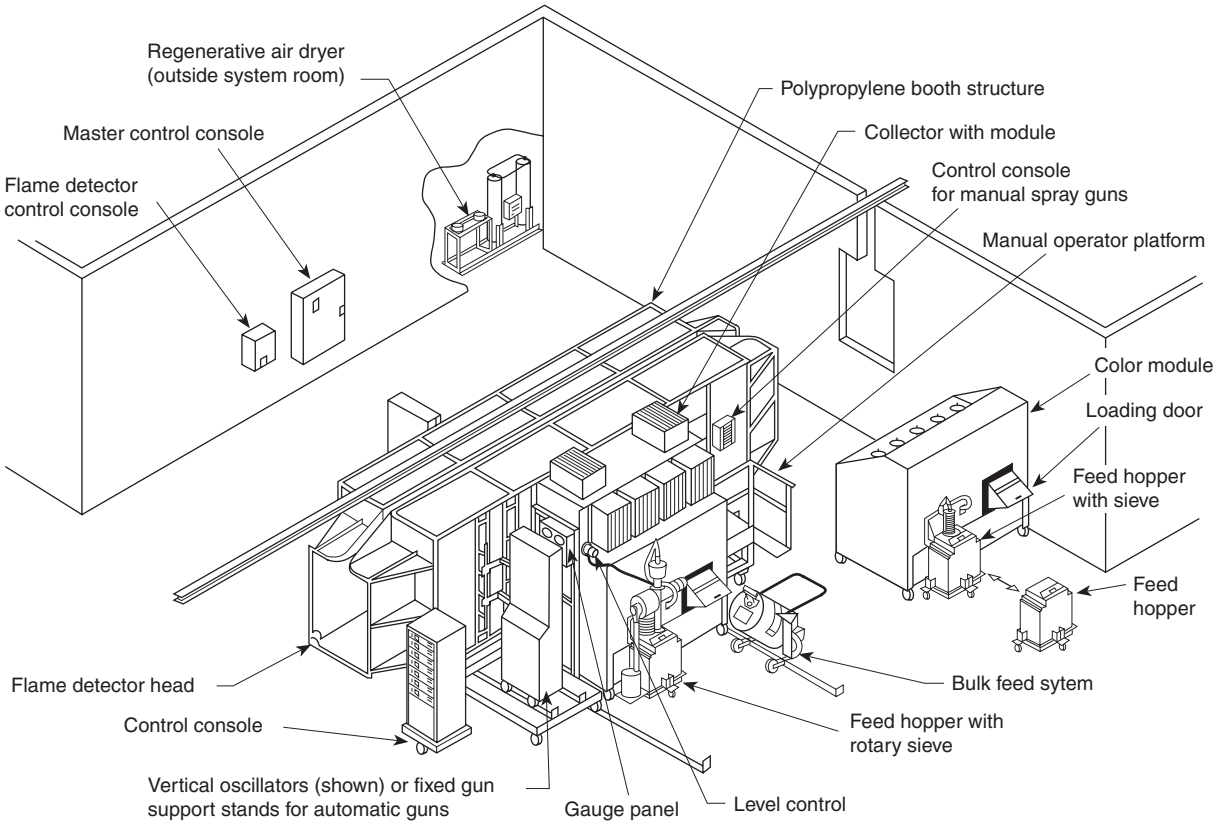

FIGURE 9.2.9 Integrated Powder Spray Booth/Recovery System

the powder collector, is eliminated. Collected powder is pneumatically pumped from the hoppers immediately beneath the recovery filters directly back to the spray gun feeders. Within the last three decades this arrangement has gained dominance in new installations. A further development that has gained broad acceptance is the use of flame-retardant plastics for the spray enclosure. Many of the powder booths currently manufactured have plastic walls and roof panels.

Electrostatic powder coating can also be conducted within an enclosure commonly referred to as a pipe coater. The device consists of a steel enclosure, a ring of automatic electrostatic powder spray guns, and a conveyor. The workpiece, typically a pipe or structural steel form, enters at one end, passes through a cloud of coating powder, and leaves the coater at the opposite end. The workpiece is preheated to a temperature above the melting point of the powder, so the powder will fuse on contact. The coater is provided with an exhaust system and powder recovery filter system similar to that used with the booth arrangement described in connection with Figure 9.2.9.

Fluidized Bed

Fluidized beds are constructed in a wide variety of sizes. They have vertical walls (typically steel) and a porous floor (textile or plastic). Air flows upward through the floor and through the powder. When the airstream is adjusted properly, the powder will behave as a liquid, flowing readily around and contacting all surfaces of any object that is dipped into it. It will immediately fuse to a workpiece that has been preheated above the melting point of the powder. After the workpiece has been removed from the bed, it is placed in an oven to complete the curing of the coating.

An electrostatic fluidized bed has a series of high-voltage electrodes near the surface of the fluidized powder mass or, alternatively, below the fluidizing plate. Grounded workpieces, which might or might not be preheated, pass above the surface of the fluidized bed and are coated electrostatically, then cured in a bake oven. (Dipping is not required.)

Both regular and electrostatic fluidized bed arrangements usually are provided with peripheral air exhaust systems that collect any powder grains escaping the bed and prevent their distribution into the general factory area (Figure 9.2.10).

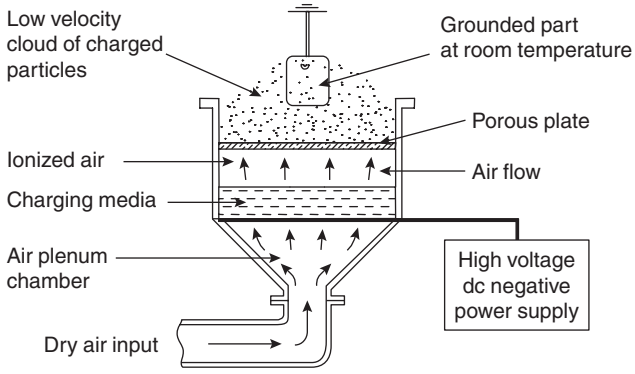

FIGURE 9.2.10 Fluidized Bed Feed Hopper (Source: Nordson Corp.)

FLUID SPRAY PROCESS HAZARDS AND CONTROL

Materials and supplies used in organic spray finishing processes are usually flammable or combustible, are often toxic, and, in some cases, might be highly reactive or unstable. For these reasons, spray finishing operations are considered hazardous, and suitable preventive and protective measures should be taken to minimize the hazards.

Fire Prevention

Hazard Identification. Materials' hazards should be identified as soon as they arrive in the facility, and personnel should be trained on these hazards. A detailed method of identification is contained in NFPA 704, *Standard System for the Identification of the Hazards of Materials for Emergency Response.* The NFPA 704 system provides for the identification of five degrees of health, flammability, and reactivity hazards, including special hazards for consideration during emergency response, such as water reactivity or oxidizer status.

Storage and Handling. Bulk supplies of flammable liquids should be stored outdoors away from buildings or in special indoor storage facilities. Smaller quantities are then brought indoors to a mixing room where they are prepared for use. The mixing room should be located adjacent to an outside wall provided with explosion-relief vents and should be isolated from the rest of the building by fire-resistant construction. The room should have sufficient mechanical ventilation to prevent the development of flammable vapor concentrations in the explosive range. To prevent rupture of the container due to fire exposure, all flammable liquid containers of greater than 5 gal (19 L) capacity that are kept indoors should be equipped with a special plug that incorporates a pressure relief valve, a vacuum-relief valve, and a flame arrester. See NFPA 33 for additional requirements.

Prepared coating materials are transported from the mix room to the spray area in containers or through piping. Containers should be equipped with tightly clamped lids that will retain vapors and liquids in the event the container is upset. Piping should be identified as process pipe containing flammable materials, and a shutoff valve should be installed at each point where a hose is connected to the system. Emergency stop controls and fire alarm interlocks are very important to keep runaway pumps from continuing to feed a fire after hoses have been burned off. All piping, pumps, and supply and receiving vessels must be electrically grounded and bonded to prevent accumulation of dangerous static electrical charges during transfer of fluids.

Quantities of flammable or combustible liquids kept in or near process areas should be limited to the amount needed for one working shift at a time. The materials should be put in closed containers equipped with appropriate pressure relief devices and flame arresters at all openings. These materials are best kept outside the spray booth and separated from it by several feet (1 or 2 meters) to prevent them from becoming involved in a spray booth fire.

Flammable or combustible liquids should never be transferred from one container to another by the application of air pressure to the original shipping container. Pressurizing such containers might cause them to rupture, creating a serious flammable liquid spill. Any pressure vessels used should be designed specifically for such use or should be manufactured in conformance with the American Society of Mechanical Engineers' (ASME) *Code for Unfired Pressure Vessels.*[2]

Fluid hoses connected to some electrostatic equipment must have a special structure to resist both fluid and high-voltage electrical stresses that result from use of electrically conductive paint. If ordinary hose or tube is substituted for this use, electrical failure of the hose wall will lead to pinhole failures and ignition of fires.

Control of Vapors and Overspray. Limitation of vapors and overspray to the smallest practicable area is accomplished through the combination of process enclosures and power ventilation systems. Ventilation systems should be checked frequently to ensure they are operating properly and that specified flow rates are being maintained.

Ignition Sources. All sources of ignition should be barred from, or controlled in, areas defined as Division 1 or Division 2 in NFPA 70, *National Electrical Code®*. The careless use of smoking materials and improperly supervised welding or flame cutting operations pose significant threats to a fluid-coating applications system. A hot work permit system and prohibition of smoking should be in practice. See NFPA 51B, *Standard for Fire Prevention During Welding, Cutting, and Other Hot Work.*

To minimize chances of ignition, open flames, spark-producing equipment, and any exposed surfaces exceeding ignition temperature of the material being sprayed should be prohibited in either Division 1 or Division 2 areas. No equipment or process capable of producing sparks or hot particles should be located above or adjacent to those areas classified as hazardous unless partitions or other means of separation are provided.

All electric wiring and equipment, unless specially designed and manufactured for use in hazardous areas, can be regarded as potential ignition sources. Only those devices and wiring types listed for this use should be installed or used in areas classified as hazardous. To accommodate failure, electric lighting fixtures located above a classified area should be totally enclosed or provided with a guard that will prevent hot particles from dropping into the hazardous area. Exhaust fans should be nonsparking and conform to Air Movement and Control Association (AMCA) Class C requirements.

Static electricity remains a common source of flammable vapor ignition in electrostatic spray finishing operations. Energized electrodes send generous amounts of electrical charge into the air, and they then collect on surrounding surfaces. Accumulation of this charge can raise a surface to a high voltage. Electrostatic spray systems should be equipped with electrical interlocks to de-energize the electrostatic power supply any time the spray guns are not actually spraying. Most modern electrostatic spray guns that are listed for use with flammables include a charging circuit that limits the energy of a discharge arc to a value below that which is sufficient to cause ignition.

Electrostatic ignition can be prevented by electrically bonding together all the elements of a fluid transfer or spray system along with the workpiece and all other electrically conductive objects located within 10 ft (3 m) of the charged elements and then grounding the bond. Additional information on bonding and grounding can be found in NFPA 77, *Recommended Practice on Static Electricity.*

Human beings are also conductors of electricity; thus, the spray operator cannot be overlooked in the grounding process. Gripping the grounded spray gun with the bare hand or wearing shoes with electrically conductive soles, provided the floor is grounded, are two workable methods for grounding the operator. Even in the absence of electrostatic equipment, dangerous static electrical charges can be generated by the simple act of walking across a spray area floor that is covered with sticky paint residue. The charging mechanism is identical to that seen in the more familiar act of walking across a wool or nylon carpet on a dry day: a spark and shock result when a doorknob or switchplate is touched. That spark is quite capable of igniting flammable vapors.

Static electrical charge is also generated by the operation of nonelectrostatic air and airless spray equipment, resulting in discharge sparks from either the spray apparatus or the object being sprayed. To prevent ignition of fires from such discharges, electrical bonding and grounding of apparatus and the sprayed object is necessary.

Housekeeping. Residues of spray materials are a solid form of readily ignitable fuel. A routine maintenance program should provide for the periodic removal of overspray residue from walls, floor, and ceiling of the spray booth, room, or area, as well as from conveyors and the interior of ventilation ducts. Residue buildup on conveyors may become particularly hazardous by acting as electrical insulation, which interferes with workpiece grounding. Contaminated spray booth filters should be either removed from the building as soon as they have been replaced or kept immersed in water until disposal, as they present a serious spontaneous heating hazard. Only a few hours of "fermenting" is required for a waste container holding paint-fouled filters or rags to become so hot that it bursts into flame. Alternately, the spontaneous heating hazard can be eliminated by curing the paint in fouled filters or rags by processing them through a paint bake oven before disposal.

Operator Training. Operating personnel should be thoroughly trained when they begin the job and should be given periodic additional training to maintain their appreciation of the hazards involved, to teach them hazard control procedures, and to educate them in new processes. They should be aware of the inherent hazards of the spray materials being used, particularly if the materials are toxic, chemically unstable, or reactive. They should also be familiar with the system of hazard identification that is employed. Operators should be drilled in proper operating, bonding and grounding, emergency, and maintenance procedures.

Fire Protection

Areas in which fluid spray processes are conducted and areas where coatings and solvents are mixed or stored should be separated from other plant operations by appropriate distance or partitions. Automatic sprinklers inside spray booths, inside ventilation ducts, and at the ceiling contribute considerably to the control of fire. In open areas, draft curtains extending down from the ceiling around spraying operations, along with smoke and heat vents, will slow the "mushrooming" of hot combustion gases along the ceiling and, thus, limit the number of sprinklers that will activate. This scenario will concentrate sprinkler discharge into the area where it is most needed and will minimize smoke and heat interference with fire-fighting efforts.

Fire in the paint spray pattern radiates heat at an extremely high rate.[3] Temperature of surfaces 3 ft (900 mm) from the spray gun have been shown to rise more than 150°F (66°C) per second. Residues exposed to such radiant heating ignite within a few seconds.[3] Fast-acting optical flame detectors have been shown capable of interrupting spray within a small fraction of a second, thereby preventing ignition of surrounding residue. NFPA 33 requires such detectors for automatic electrostatic installations.

Any fluid transfer or supply system for flammables, whether driven by pump or by pressure vessel, should be arranged with emergency shutdown provisions and an interlock with the fire alarm and flame detector to interrupt flow in the event of fire or accidental spill, thereby limiting available fuel. "Panic button" actuators should be located at the operator control station and at the exit door.

Hoses should be constructed of material that has a nominal resistance to fire. For example, polyethylene tubing will melt immediately when exposed to fire, whereas rubber hoses will be more resistant. Polytetrafluoroethylene (PTFE) hoses are even more fire resistant.

Portable fire extinguishers and standpipe hoses are useful against fires involving small spray operations. The rate of fire development across residue accumulations can be very high, however. It must be recognized that in only a few seconds a fire can grow to a size that will be beyond portable extinguisher control, particularly in spray booths of the baffle- or the dry-filter type or in operations where paint residues are permitted to accumulate on the floor. For enclosed or semi-enclosed coating processes, such as in continuous coaters or automatic decorating machines, automatic fire-extinguishing systems can be used to flood the interior of the machines.

A spray booth and its exhaust ductwork should maintain structural integrity (i.e., not collapse) during a fire of nominal proportions so that the major portion of flame, heat, and fire gases produced will vent from the building through the exhaust ductwork. This venting diminishes the chances of fire spread in the building that will interfere with egress and access to the seat of the fire by members of the fire service. Exhaust fans and air makeup units should remain in operation during fire conditions to maximize smoke removal. Spray booths and their exhaust ductwork are required by various codes and standards to be constructed of steel, masonry, or other material of equivalent fire resistance. Survivability of booth structure is considerably enhanced by the cooling effect of water from sprinklers inside the stack and booth. The probability that heat from a fire within a booth and stack will ignite nearby combustible materials can be reduced to an acceptable level by reasonable clearances between any combustible structure or stored materials and the surfaces of the booth or stack. (For recommended clearances, see NFPA 33.) Spray rooms are usually required to be separated from other occupancies within the same building by walls, floors, and ceiling structures with a minimum 2 hour fire resistance rating.

POWDER COATING PROCESS HAZARDS AND CONTROL

Powder coating operations using combustible organic powders are classified as hazardous processes because the powders can burn vigorously when suspended as airborne dusts and can explode when confined. There are no flammable vapors in the powder coating process. The energy required to ignite a cloud of air-suspended coating powder is from 100 to 1000 times higher than that required to ignite flammable vapors. Powder deposited onto workpieces or booth walls or lying on the floor is not readily ignitable.

Fire Prevention

Storage and Handling. Coating powders that are kept in shipping containers are not customarily classified as hazardous materials and are commonly stored under conditions appropriate for ordinary combustible materials. Reasonable care is required in the handling and movement of the powder containers because a fire hazard could be created should the containers be broken and the powder distributed as an air-suspended cloud of dust.

Waste powder is commonly packaged into fiber drums or cardboard cartons lined with plastic bags and shipped to a landfill for disposal in accordance with Environmental Protection Agency (EPA) regulations. If the waste container has been processed through a baking cycle, the waste powder will have fused into a solid block of plastic that is no longer vulnerable to scattering or dispersion in air if the container is broken.

Spilled powder pickup and routine cleanup are usually accomplished with an industrial vacuum approved for use with combustible dust. Explosions have occurred when unapproved vacuums (with open-frame universal motors and sparking commutators) were used.

Coating Operations. Virtually all spray powder coating processes are conducted in spray booths that are more tightly enclosed and permit considerably less overspray to escape than those booths used for fluid coating processes. All connections in the hoses and piping associated with pneumatic transfer equipment should be routinely checked to confirm that they are secure and that ground connections are in place. Breakage of any such connection during operation could create a substantial hazard by blowing powder into the workspace air outside the process enclosure.

To prevent the escape of powder, the spray booth must have adequate ventilation that provides effective capture velocity at

all its openings. Minimum average velocities are considered to be in the vicinity of 60 ft/min (18 m/min). Interlocks should be installed to permit operation of the powder application equipment only while the ventilation equipment is in operation and, similarly, to permit operation of the electrostatic power supply only during the time the powder is actually being applied.

Ignition Sources. The control methods for ignition sources for powder coating are similar to those for spray finishing. Electrical apparatus in the Division 1 area should be listed for use in Class II, Division 1 locations; in the Division 2 area, wiring and apparatus should be dust tight and not have hot surfaces. Explosionproof wiring and apparatus (i.e., equipment listed for Class I areas only) are not appropriate.

Static accumulations on electrically isolated conductive objects are a major potential cause of fires in electrostatic powder coating installations. Metal workpieces suspended from conveyor hangers that do not provide an effective electrical circuit between the workpiece and ground pass through the coating process zone while discharging hot electrical sparks. Ungrounded metal blowpipes, or "wands," used for booth cleaning may become highly charged by tribo effect during use, and discharges from the pipe can ignite the powder being blown from the floor of the booth. Propagating brush discharges within thin-wall nonconductive transfer hoses and within grounded metal ductwork of dust collector systems, where thermoplastic powder has impact fused to form a nonconductive coating at a duct elbow or wye, have ignited the powder cloud within the hose and the duct. This sparking can ignite the powder cloud and flames will be sustained by the continuing flow of powder and air. Some application equipment will discharge incendiary sparks when approached too closely by a grounded object. Proper use of this type of equipment requires safeguards to prevent any grounded object from approaching the electrically charged high-voltage elements closer than twice the sparking distance. Discharge sparks that do occur during use of this type of equipment may be traceable to improper racking of parts on a conveyor or swinging of the conveyor racks. To reduce the probability of a small fallen part being drawn into a duct and producing mechanical sparking, grillwork at the intake of any exhaust duct is highly recommended, and magnetic devices can be added to catch tramp metal. A hot work permit system and prohibition of smoking should be in practice.

Fire Protection

Protective measures for powder coating installations are (1) keep the powder collector from becoming involved in a fire that has originated in the spray operation, (2) equip the collector with pressure relief vents and ductwork in order to prevent its rupture in an explosion, (3) protect the building from heat and pressure effects that would be generated by an explosion, and (4) provide sprinklers or other approved fire suppression systems to control a persistent fire.

To prevent a fire in a powder spray booth from spreading through connecting ductwork, the ventilation system is usually arranged to keep powder concentrations in the ductwork below one-half the minimum explosible concentration (MEC). In those cases in which fire has persisted in the spray booth for periods ranging beyond approximately 15 seconds, however, the powder collector is threatened by glowing embers that have formed in the spray fire. These glowing embers are independent of powder concentration and are capable of igniting the powder collector.

Powder collectors can be protected by a fast-acting flame detector within the spray booth, interlocks to shut down equipment, and a fast-acting damper to interrupt airflow in the duct between the spray booth and the powder collector. In operation, this apparatus will recognize any flame that has ignited in the spray booth and respond quickly (within ½ second) to the flame by shutting down all process equipment energy supplies (including electricity and compressed air) and by closing the ductwork damper. This same equipment can be arranged to extend the response sequence by discharging an inerting gas into the dust collector.

Use of multispectral "smart" flame detectors from one manufacturer has been monitored for several years (millions of hours of operation) in industrial service. Although fires ignited many times, not a single case of damage resulted when the detector system was properly installed and maintained. Use of optical flame detectors was initiated in 1974–1975. Prior to that time, fires and explosions resulting in damage were common. Since then, incidents (about a dozen total) involving damage have all been found to have either:

1. No detectors or detectors bypassed
2. Inoperable (not maintained) detectors
3. Detectors installed with line of sight to the guns obstructed

For those application systems that require operation with combustible concentrations of powder in the ductwork between the application area and the powder collector, the potential exists for almost instantaneous explosion of the collector whenever a fire occurs in the application area. Such systems should either be equipped with appropriately engineered suppression systems or designed in such a manner that the powder application and collection equipment will be fire and explosion resistant.

Airborne clouds of powder in a confined space will burn at far higher rates than in an unconfined space. Because the interior of a conventional dust collector is a confined space, steps must be taken to accommodate the sudden pressurization and volumes of smoke and fire gases that will evolve in the event of ignition. The usual protective technique used is to install automatic pressure relief vents in the collector housing. These vents will open should ignition occur and allow the combustion products to escape, thereby limiting pressure development. When the collector is located within a building, ductwork is usually required to direct the vented combustion products to the exterior of the building or to a safe location. Vent ductwork must be kept short. Lengths in excess of 10 ft (3 m) are of questionable value.

When a collector explosion occurs, fire, clouds of unburned powder, and molten globules of partially burned powder are projected from pressure relief openings and from spray booth openings. If vented into a building, a major secondary explosion may occur, resulting in catastrophic damage.

If powder escapes from the collector into the building during normal operation, it can collect on horizontal surfaces and create a potential for a secondary explosion. The primary explosion may disperse powder into the air in suspension where it could be ignited by flames or embers that persist from the initial combustion. If a substantial quantity of powder is thrown into suspension by the primary explosion, the secondary explosion could be considerably more serious than the primary. Protection is achieved primarily through (1) maintenance of process equipment, (2) procedures, and (3) scrupulous housekeeping to collect any powder that does escape.

The dust explosion hazard is virtually eliminated (through elimination of the confined space necessary to form an explosion) in an integrated spray booth/collector of the type shown in Figure 9.2.9 and in other apparatus incorporating the same design principles. This class of equipment, because it operates without explosion risk, needs no explosion vent or ductwork. However, flame detectors are still needed—when automatic spray guns are used—to quickly interrupt powder feed in the event of fire and thereby limit heat damage and formation of toxic smoke.

After ignition of a spray gun powder cloud or a fluidized bed, the flame can usually be extinguished almost instantly by simply turning off the spray gun feeder or the air supply to the fluidized bed. The normal velocity of the feed systems exceeds typical flame-front propagation velocities and flame; therefore, it does not backstream in hoses from guns to feeders, even though powder concentrations in hoses may exceed MEC.

Automatic sprinkler systems are commonly required in factory areas where powder coating operations take place, as well as within the booth and collector. Because sprinklers have rather long operating delays relative to the duration of a powder fire (in a system equipped with automatic flame detectors), it is common for powder fires to be extinguished by shutting down the equipment before sprinklers can activate.

In those cases in which small fires have persisted in spray booth residues, portable water fire extinguishers or sprinklers arranged to protect the filter cartridges or bags have been found to be adequate.[3] *Adequate* means damage did not extend beyond the collector when water was used to suppress the fire. The unpublished research includes privately conducted experimental fires (hundreds), and immediate (within one day) fireground investigations of accidental industrial fires (several dozen) in powder systems. No formal consolidation of these results has been written.

Fire Experience

Investigations of explosions and fires in powder coating operations that resulted in damage have shown, in virtually every incident known to the author, that flame detectors were absent, were disconnected, or were mounted so that they could not see the spray gun fire. Dirty lenses or deliberately covered lenses were frequently seen. In addition to flame detector deficiencies, powder collector explosions resulted from powder concentrations in the ductwork that were above the MEC because of (1) increases in the application rate to more than double the original design rate and (2) decreases in airflow through the system due to improper filter maintenance and replacement practices. Replacement of wear components with other than parts supplied or authorized by the original equipment manufacturer (such as hoses, ejector throats, filters, or electrostatic gun parts) has, in several cases, led to ignition.

SUMMARY

A broad variety of fabricated products undergo a process in which flammable or combustible fluid or powder coatings are spray applied. Air spray guns draw their coating fluid from small cups mounted on the guns or through hoses connected to pressurized containers. In the powder coating spray process, a feeder mixes powder with air and supplies the mixture to the spray guns. The spray booth is a power-ventilated structure in which the spraying operation takes place; the spray enclosure can be individually engineered for a specific coating process. Vapor and overspray removal systems typically include a fan and a collection system that exhausts vapors to the exterior of the building. In a fairly recent development in powder coating, the spray booth and powder recovery system are integrated into a single structure. Because materials and supplies used in organic spray finishing processes are usually flammable or combustible and in some cases highly reactive or unstable, spray finishing operations are considered hazardous and require suitable preventive and protective measures.

Chapter 3

Dipping and Coating Processes

John Katunar III

Chapter Contents

The Processes
Process Hazards
Hazard Reduction
Fire Protection

Key Terms

combustible liquid, curtain coating, dip tank, electrostatic detearing, exhaust system, flammable liquid, flow coating, process tank, roll coating, tank

The flammable and combustible liquids used in dipping and coating operations have tremendous heat energy and heat release capabilities, which, if not properly protected, can cause rapid property destruction when involved in a fire. The heat of combustion of flammable liquids is approximately two and one-half times that of an equivalent weight of wood.[1] In addition, heavy concentrations of smoke and products of combustion can develop. These factors make fire fighting extremely difficult. This chapter discusses dipping and coating processes, equipment that uses flammable and combustible liquids, the inherent hazards and means of hazard reduction, and fire protection for dipping and coating processes. It does not, however, discuss toxicity or industrial hygiene.

See also Section 6, Chapter 12, "Flammable and Combustible Liquids"; and Section 9, Chapter 2, "Spray Finishing and Powder Coating."

THE PROCESSES

Applications

Dipping and coating processes include, but are not limited to, finishing, impregnating, priming, cleaning, and other similar operations by which materials are immersed in, passed through, or coated by flammable or combustible liquids. Processes vary widely and range from the cleaning of small parts in small quantities of liquid to an automated coating process that uses a very large tank containing a flammable or combustible liquid. As is the case with any potentially hazardous operation, a complete evaluation of the process and an understanding of the properties of the liquid(s) in use are essential.

Equipment

The equipment associated with basic dipping and coating processes (such as dip tanks, flow coaters, curtain coaters, roll coaters, solvent cleaners, electrostatic detearing, and vapor degreasers) have similar hazards. Process equipment that is utilized in dipping and coating operations include conveyors, pumps and piping systems, flammable or combustible liquid storage tanks, ovens, liquid heaters or heat exchangers, agitators, detearing equipment, and ventilation and exhaust systems. Exhaust systems can include energy recovery devices and environmental protection devices. Auxiliary equipment should be selected and installed with full consideration of the inherent process hazards.

Dip Tanks. Dipping processes are used to apply coating material, or to accomplish other specific applications, through the immersion of the workpiece in a tank, vat, or container of flammable or combustible liquids. Dip tanks are liquid containers of various sizes and shapes designed for the specific process. Tank sizes vary from a small exposed surface area to a very large exposed surface area. Dip tanks, their drainboards, and their covers should be constructed of noncombustible material, such as heavy gauge steel, reinforced concrete, or masonry. They should be designed for the process and liquid involved, with consideration given to the static head of the liquid contained, corrosion, mechanical damage, and ease of maintenance and repair. Spill or exposure fires could weaken tank supports, possibly causing tank collapse. Therefore, supports for large tanks should

John Katunar III is a technical specialist at Swiss Re, Global Asset Protection Services, Rolla, Missouri, and a member of the NFPA Technical Committee on Finishing Processes.

be reinforced concrete or protected steel with a fire resistance rating of at least 1 hour.

Figure 9.3.1 is an example of a typical dip tank process system. The salvage tank is shown below grade and outside of the building, as allowed by NFPA 30, *Flammable and Combustible Liquids Code*. However, below-grade salvage tanks are strongly discouraged due to environmental regulations, confined space rules, clean out difficulties, and the need for some form of periodic inspection and supervision. Also, salvage tanks should not be located in below-grade areas within a building if flammable liquids are handled or used in the process.

Flow Coaters. Flow coaters apply the coating material from nozzles or slots in an unatomized state onto the material being coated. This typically involves an enclosure or tunnel arrangement. Figure 9.3.2 is an example of a flow coating process, which is protected by a typical total flooding carbon dioxide system. The excess coating material is collected in a trough or sump below the workpiece, returned to the reservoir, and recirculated to the nozzles by a pump. The nozzles can be fixed or oscillating. The more nozzles used, the larger the reservoir and pump capacities required, and the greater the solvent loss. The workpiece usually enters and leaves through conveyor openings, and a drip tunnel is used in place of the drainboards that are used with dip tanks. The tunnel is enclosed on all sides, except for the conveyor opening, and is sloped toward the trough or sump. Airborne solvent concentration in the tunnel is sometimes used to keep the coating from drying before it gets to the oven.

Curtain Coaters. Curtain coaters apply a coating material to flat or slightly curved workpieces. Figure 9.3.3 is an example of a curtain coating process. Coating material is pumped from a reservoir to a coating head, which has a small reservoir with a dam or weir forming one side. Coating material that is pumped to the head overflows the dam and forms a continuous vertical stream, which drops down onto the workpiece. The excess coating material drops into a trough and returns to the reservoir, then it is recirculated.

Roll Coaters. Roll coaters apply a coating material by bringing the workpiece into contact with one or more liquid-coated rollers. Figure 9.3.4 is an example of a roll coating process. The

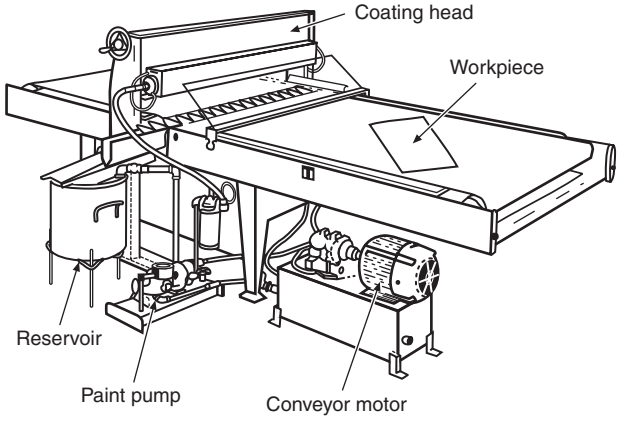

FIGURE 9.3.3 Curtain Coater

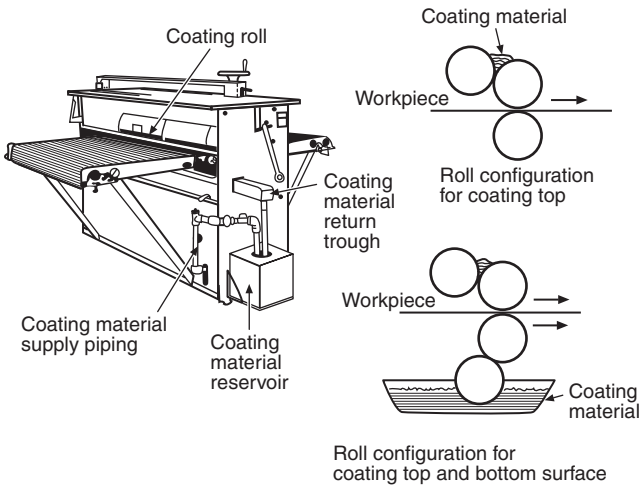

FIGURE 9.3.4 Roll Coater

coating material comes from an open pan or from a nip formed by two rollers. Coating material is supplied from a reservoir by a pump and piping system.

Solvent Cleaning and Distillation Units. Solvent removes material from an object using processes such as immersing, soaking, spraying, agitating, or ultrasonics.

Electrostatic Detearing. This is process whereby excess wet coating material is removed from the bottom edge of a dipped or coated object by passing it through an electrostatic field.

Peripheral Vapor Containment. This is a process that cools the perimeter of a vapor degreaser tank near the top for the purpose of condensing a saturated vapor blanket from boiling flammable solvent. Figure 9.3.5 is an example of a degreasing process.

Secondary Enclosure. This is an enclosure or guard constructed around but separate from a dipping and coating process whose purpose is other than fire protection, confinement of a possible fire, or confinement of vapor or mists.

PROCESS HAZARDS

Dipping and coating of articles or materials by passing them through flammable and combustible liquids involves the inherent danger of fire and explosion. Generally, the severity of the hazard increases with use of lower flashpoint liquids, increased depth or quantity of liquid, increased surface area of liquid, increased rate of vapor generation, and increased accumulation of combustible residues in and around process equipment. (Characteristics of flammable and combustible liquids are discussed in detail in Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids.")

The severity of the hazard is determined by (1) ease of ignition and (2) rate of flammable vapor generation from the liquid surface and from surfaces of freshly coated articles, floors, drain or drip boards, and ancillary equipment. Two factors for consideration in further evaluation of hazards are (1) the intensity and burning characteristics of the flammable vapor evolved and (2) the probability of fire spread from radiated heat or from the flow of burning liquids because of a container rupture, boilover, or overflow.

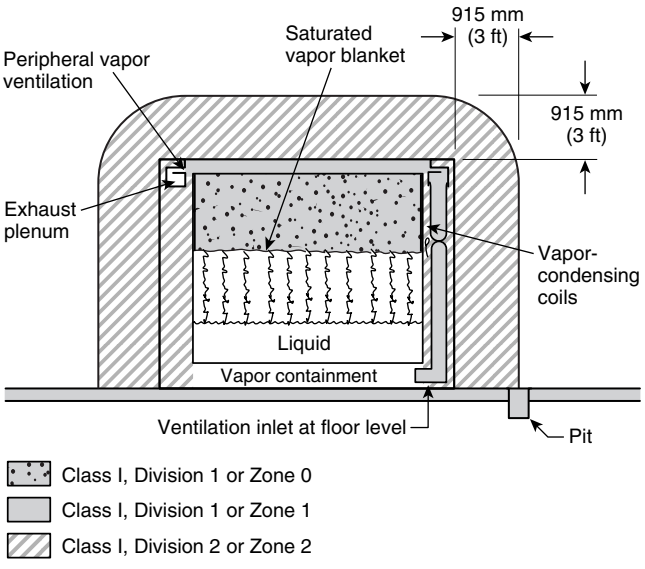
Flammable liquid vapors are usually denser than air and, therefore, flow to low points. They can travel great distances before reaching an ignition source that can cause flashback to the process area.

Flammable liquids are often less dense than and immiscible in water. During fire-fighting operations, water applied to such liquids can cause overflow and float the burning liquid away from the process to other areas.

Flammable and combustible liquids can be transported by closed containers, approved portable tanks and intermediate bulk containers, approved safety cans, or a piping system. All pumps, meters, pipe, fittings, and so on should be approved for handling of the liquids used in the dipping and coating process. If the dip tank is filled from the top, the discharge opening of the fill pipe should be within 6 in. (150 mm) of the bottom of the tank. If a pump is used to fill the tank, the pump should be arranged with a relief valve to prevent overpressurizing the system. Process tanks should have a limit device to prevent overfilling of the tank.

According to NFPA 34, *Standard for Dipping and Coating Processing Using Flammable or Combustible Liquids,* the volume of Class I, Class II, or Class IIIA liquids stored in a listed storage cabinet or cabinets is limited to (1) one storage cabinet with total volume of 120 gal (454 L) in a process area, (2) a total aggregate volume of 360 gal (1350 L) in storage cabinets in a single fire area, (3) a total aggregate volume of 360 gal (1365 L) in each group of cabinets in the same fire area for an industrial occupancy if a minimum separation of 100 ft (30 m) is maintained between each group, and (4) a total aggregate volume of 720 gal (2700 L) in storage cabinets stored in a single group for an industrial occupancy if the building is protected by an approved automatic sprinkler system.

According to NFPA 34, Class I and Class II liquids should only be transferred between their original shipping containers and process equipment within a building by (1) containers with a capacity of 5 gal (19 L) or less, (2) approved safety containers, (3) a closed piping system, (4) an approved pump located on top of a portable tank or container, or (5) gravity through a listed, self-closing valve or self-closing faucet.



Definitions

Freeboard: The distance from the maximum solvent or coating material level to the top of the tank.

Freeboard ratio: The freeboard height divided by the smaller of the interior length or interior width of the tank.

FIGURE 9.3.5 Electrical Area Classification for Open Dipping and Coating Process with Peripheral Vapor Containment and Ventilation—Vapors Confined to Process Equipment

HAZARD REDUCTION

Hazards inherent in dipping and coating operations can be reduced by properly locating the processes, installing ventilation

and exhaust systems, eliminating ignition sources, and providing proper maintenance and periodic inspections. Special equipment design, employee training, proper fire protection systems, and effective fire prevention procedures will also help to reduce process hazards.

Process Location

The principle of segregating hazards to confine fires and limit damage is fundamental in the selection of locations for dipping and coating operations. The personal safety of workers and other building occupants as well as the potential exposure of large values must also be considered.

Dipping and coating processes should be separated from other operations, materials, or occupancies by location, fire walls, or fire partitions. A preferred location for dipping and coating operations is a detached or cutoff one-story sprinklered building of fire-resistive construction. When operations are located on upper stories, floors should be made liquid-tight and equipped with drains to a safe location. Dipping and coating operations should not be located below grade, directly over basements, or near pits or trenches, because liquid drainage and vapor removal will be difficult to achieve. Curbs and trapped drains should be provided to control liquid flow where necessary.

When, due to its nature, the process cannot be cut off, it should be located in an area that is clear of combustible storage and separated from other important processes. Combustible floors, ceilings, and surrounding walls should be protected to minimize fire exposure. Noncombustible curtain boards should be installed around the perimeter of the process area and extended downward from the roof level as far as is practical. Also, curbs should be installed on the floor to minimize the potential flow of liquids to other areas. This arrangement should offer a minimum level of process separation from adjacent areas.

Because flammable and combustible liquid fires generally develop rapidly and release large amounts of heat, automatic roof vents are desirable. Roof vents allow heat and smoke to escape, improving the chances of fire control by automatic sprinklers or the fire department.

When processes are located in confined areas and highly flammable or unstable liquids are used, deflagration relief venting might be necessary to lessen potential losses. Venting can be in the form of lightweight walls and roofs or explosion-relieving wall panels, roof latches, and windows. For more detail, see NFPA 68, *Standard on Explosion Protection by Deflagration Venting.*

Careful evaluation of the process is necessary in selecting the proper location for dipping and coating operations. Small dipping and coating operations should be considered in the same light as the larger operations, because it is often the small operation that produces a major fire loss. Figures 9.3.6 and 9.3.7 show common location features of dipping and coating operations. In Figure 9.3.6, the tank is located near an outside wall and is cut off from the main plant areas by fire-resistive construction. In Figure 9.3.7, the tank is located in the main plant area and is cut off by draft curtains and curbing. The heat and smoke vents should limit opened sprinklers to those near the fire and therefore reduce smoke damage.

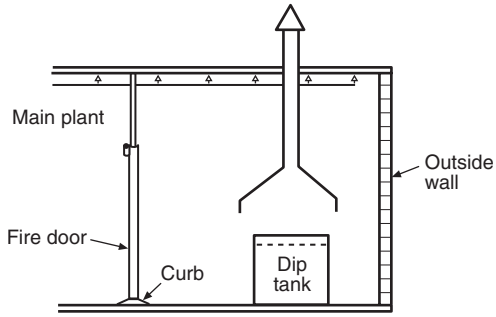


FIGURE 9.3.6 Most Satisfactory Arrangement for Location of Dipping and Coating Processes

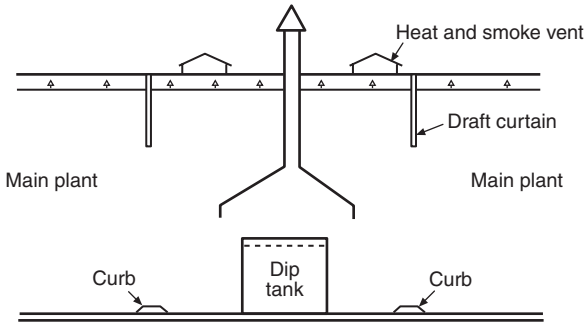

FIGURE 9.3.7 Satisfactory Arrangement for Location of Dipping and Coating Processes

Figure 9.3.8 shows unsatisfactory location features for this process, in which the tank is not cut off from the main plant area. In this situation, water from hose streams will leak down through the floor and damage the finished product.

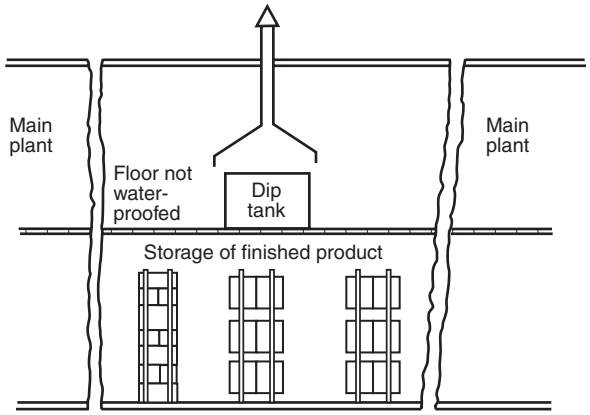

FIGURE 9.3.8 Unsatisfactory Arrangement for Location of Dipping and Coating Processes

Ventilation and Exhaust Systems

Ventilation is defined as movement of air that is provided for the prevention of fire and explosion and is sufficient to prevent accumulation of vapor-air mixtures in concentrations over 25 percent of the lower flammable limit.

When processes involve liquids that emit flammable or combustible vapors, ventilation is necessary to limit the vapor source to the smallest practical space possible. The vapor source created by dipping and coating processes is defined as the liquid exposed in the process and on the drainboard. Also, any dipped or coated object from which it is possible to measure vapor concentrations exceeding 25 percent of the lower flammable limit at a distance of 1 ft (305 mm) in any direction from the object.

The vapor area is defined as any area in the vicinity of: (1) a dipping or coating process and its drainboards, (2) associated drying or conveying equipment, (3) the interior of any exhaust plenum or any exhaust duct leading from the process, or (4) other associated equipment that could contain a flammable vapor concentration exceeding 25 percent of the lower flammable limit during operation or shut-down periods. The extent of the vapor area of a process depends on the properties of the liquid, such as vapor pressure, flashpoint, boiling point, and evaporation rate, along with the characteristics of the process, the liquid surface area, and the wetted surface area of the object being coated as well as the process equipment. Figure 9.3.9 shows the difference in exposed wetted surface area between two dip tank operations using the same quantity of liquid. With all else being the same, the process shown in the upper part of the figure would generate a greater volume of vapor and have a higher rate of heat release than that in the lower part. In this comparative example, the dip tank with the smaller liquid surface area would offer a greater fire hazard.

Vapor areas for each process should be kept as small as is practical but should not extend more than 5 ft (1.5 m) from the vapor source. The extent of a vapor area can be determined with a combustible gas analyzer. The concentration of vapors in the exhaust air stream should not exceed 25 percent of the lower flammable limit. A properly designed enclosure, including ventilation system capable of confining all vapors to the enclosure, may be necessary. A theoretical ventilation rate can be determined when the liquid usage rate is known. Because vapor concentrations vary widely from one process to another, a standardized exhaust ventilation system cannot be designed for all operations. The prime objective is to limit the vapor area to the smallest space possible and to prevent dead air spaces or pockets where vapors can accumulate. Freshly dipped or coated objects should be dried only in spaces or enclosures that are adequately ventilated.

Because flammable vapors are typically denser than air, low-point peripheral ventilation systems are usually more desirable than overhead hood arrangements. Two types of design are shown in Figure 9.3.10. The least efficient system is the overhead, or canopy, hood that allows migration of vapors to other areas.

When exhaust systems are considered, the ratio of air to vapor is important. However, the effectiveness of exhaust air in picking up and diluting the vapor is often lost in design. Entrain-

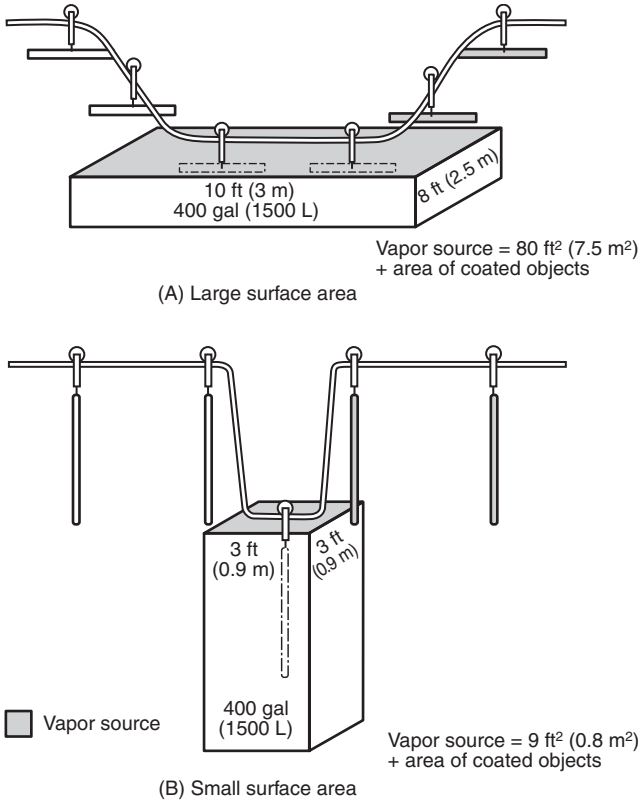

FIGURE 9.3.9 Difference in Vapor Source Area Between Two Dip Tanks with Same Coating Volume

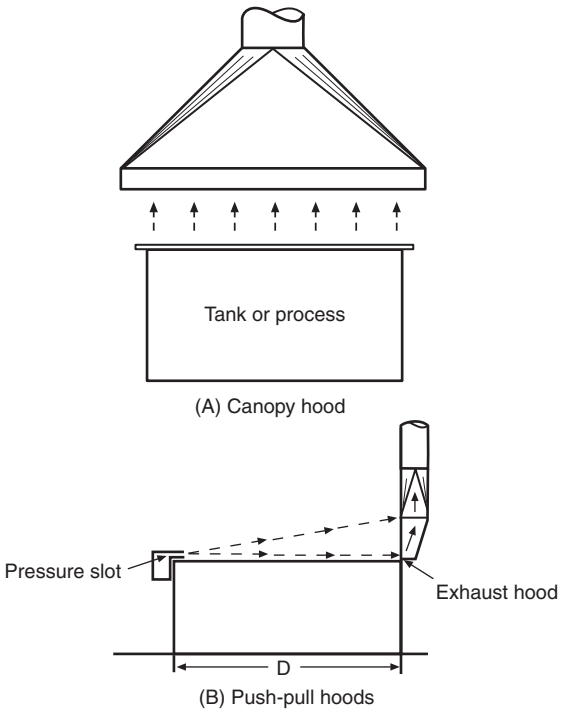

FIGURE 9.3.10 Ventilation Systems Used for Open Process Tanks

ment velocity with mixing action becomes the key to efficient use of exhaust air. Exhaust rates per square foot or square meter typically range from 50 to 200 ft^3/min (15 to 60 m^3/min) based on wetted surface area. Effective entrainment of vapor often requires slot velocities of 1000 to 2000 ft^3/min (28 to 56 m^3/min).[2]

Several of the important considerations when designing or evaluating ventilation systems for dipping and coating processes follow:

1. Ventilation should be kept in operation at all times while dipping or coating processes are conducted and for a sufficient time thereafter to allow vapors to be exhausted until the vapor area no longer constitutes a vapor source.

2. Automatic processes should be interlocked to shut down the operation in the event of a ventilation system failure.

3. The supply of makeup air should be sufficient to allow efficient operation of the exhaust fans and to minimize dead air spaces.

4. Ideally, each exhaust system should discharge directly outdoors. When exhaust streams must be treated to satisfy environmental protection requirements or when energy conservation measures are used, individual and/or direct discharge of each system might not be practical. Manifold systems increase the hazard. Therefore, manifold exhaust systems should be specifically evaluated including development and enforcement of strict preventive maintenance procedures. Reactive materials and coatings should not be used when ducts are connected to a manifold.

5. Exhaust air should not be recirculated as makeup air in occupied spaces. It could be recirculated to unoccupied areas, but only if solid particulates have been removed, concentration of vapors in exhaust stream are less than 25 percent of the lower flammable limit and monitored by approved detector, and the process stops automatically if vapor concentration exceeds 25 percent of the lower flammable limit.

6. Exhaust ducts should not discharge near air intakes, nor should they discharge less than 6 ft (1.8 m) from any exterior wall or roof. Exhaust ducts should not discharge within 25 ft (7.6 m) of combustible construction. Also, exhaust ducts should not discharge in the direction of an unprotected opening in any noncombustible or limited-combustible construction that is within 25 ft (7.6 m) of the discharge point.

7. Exhaust ducts should be equipped with enough access doors to facilitate inspection, maintenance cleaning, and access to fire protection devices.

8. Ducts and fasteners should be of noncombustible or limited-combustible construction, such as steel or masonry. Other materials of construction could be used in cases where the conveyed materials are not compatible with steel. These ducts should be substantially supported to prevent collapse under fire conditions. They should be installed with adequate clearance from combustibles. Dampers should not restrict exhaust ventilation to below minimum safe levels.

Ignition Sources

The key to minimizing the hazard of fire or explosion from vapor-air mixtures in dipping and coating processes is maintaining vapor concentrations less than 25 percent of the lower flammable limit using properly designed ventilation systems. Without vapor (fuel) and air (oxygen) properly mixed, ignition cannot take place even though sources of ignition are available. Since it is almost impossible to keep processes free of flammable vapor-air mixtures in the explosive range, sources of ignition should be eliminated or equipment should be designed for use in hazardous areas containing ignitable atmospheres or combustible residue.

Electrical Equipment. Where Class I liquids are used, or where Class II or III liquids are used at or above their flashpoint temperatures, electrical equipment should conform to the requirements for hazardous locations as outlined in NFPA 70, *National Electrical Code*® (*NEC*®). The *NEC* classifies areas in which special types of electrical equipment must be used. In the case of dipping and coating processes, the classified areas are measured from the vapor source, which may be the liquid surface (open tank) or wetted surfaces (freshly coated workpieces, drainboards, floors). The space containing hazardous vapor concentrations normally extends laterally and upward a short distance from the vapor source, and then downward to the floor, because the vapors are usually denser than air.

For open processes, classified areas are shown in Figures 9.3.11, 9.3.12, and 9.3.13. Class I, Division 1 (Zone 1) electrical equipment is required within a radial distance of 5 ft (1.5 m) from the vapor source and within a horizontal distance of 25 ft (7.6 m) from the vapor source when the equipment is in pits. If a pit is not vapor-stopped at a point 25 ft (7.6 m) from the vapor source, the entire pit is considered a classified area. Class I, Division 2 (Zone 2) electrical equipment is required 3 ft (0.9 m) beyond Division 1 (Zone 1) in all areas down to 3 ft (0.9 m) above the floor. In the space between the floor and 3 ft (0.9 m) above the floor, the Division 2 area extends 20 ft (6.1 m) beyond the Division 1 (Zone 1) area. An exception to these electrical requirements is tanks containing 5 gal (19 L) or less and having 5 ft^2 (0.5 m^2) or less of exposed surface area. Vapor concentrations during operating and shutdown periods cannot exceed 25 percent of the lower flammable limit. These small installations generally present less of a hazard and ordinary electrical equipment is permitted, if it is located more than 8 ft (2.4 m) from the vapor source.

For enclosed processes, classified areas are shown in Figure 9.3.14. Class I, Division 1 (Zone 1) electrical equipment is required within the enclosure. Class I, Division 2 (Zone 2) electrical equipment is required within 3 ft (0.9 m) in all directions from any opening in the enclosure and extending to the floor.

For open containers, locate supply containers, waste containers, and solvent distillation units that contain Class I liquids in a ventilated area. Hazardous classified areas are shown in Figure 9.3.15. Class I, Division 1 (Zone 1) electrical equipment is required within 3 ft (0.9 m) in all directions from the container and extending to the floor. Class I, Division 1 (Zone 0) electrical equipment is required inside any tank or container that contains Class I liquids. Class I, Division 2 (Zone 2) electrical equipment is required for 2 ft (0.6 m) beyond the Division 1 (Zone 1) area and extends 10 ft (3.1 m) horizontally beyond the Division 1 (Zone 1) area up to a height of 18 in. (458 mm) above the floor.

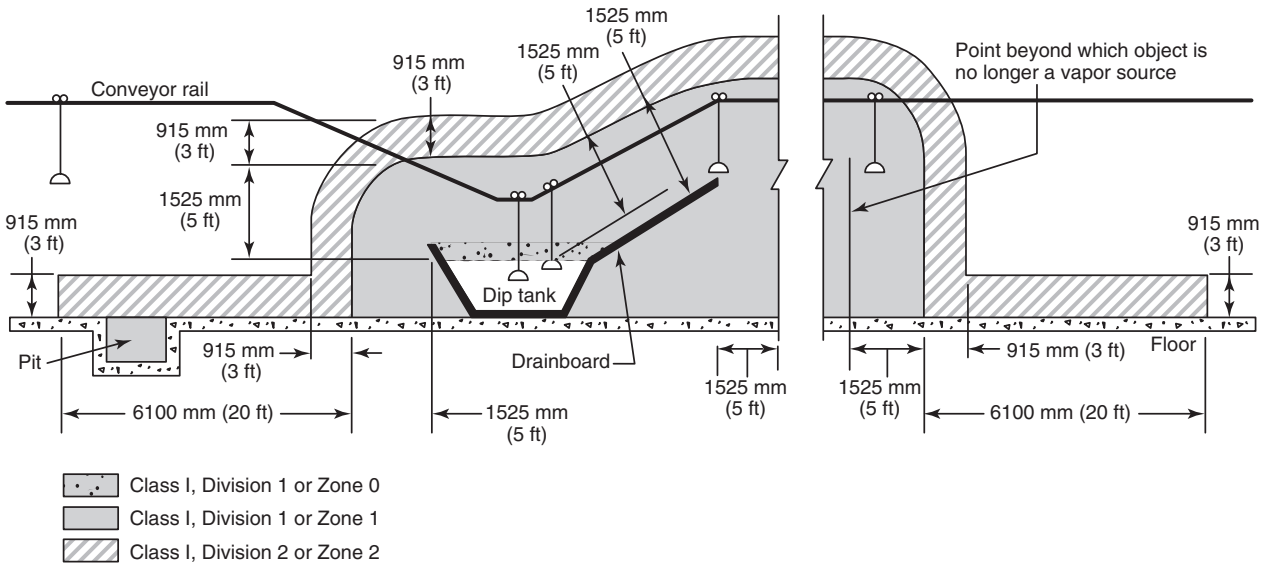

FIGURE 9.3.11 Class I, Divisions 1 and 2, Hazardous Locations for a Dipping Operation

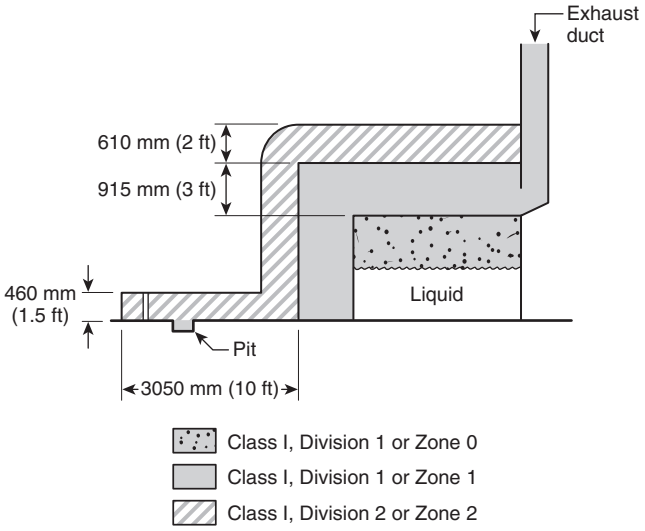

FIGURE 9.3.12 Electrical Area Classification for Open Dipping and Coating Process with Partial Peripheral Vapor Containment and Ventilation—Vapor NOT Confined to Process Equipment

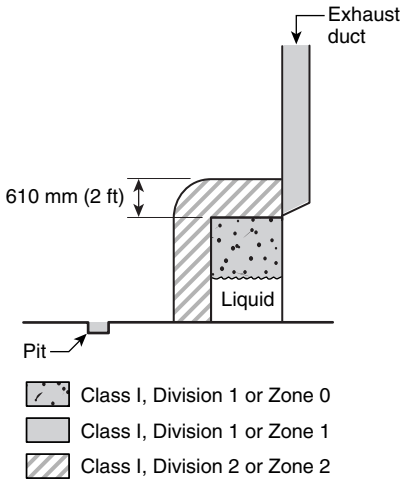

FIGURE 9.3.13 Electrical Area Classification for Open Dipping and Coating Process with Partial Peripheral Vapor Containment and Ventilation—Vapors Confined to Process Equipment

It is usually undesirable to install electrical equipment in the vicinity of dipping and coating operations. In such locations, the equipment would be subject to deposits of combustible residue, which would complicate maintenance and cleaning procedures. However, if electrical equipment must be installed in such locations, it should be a type that can be exposed safely to flammable vapors and combustible residues as explained above. Wiring in rigid conduit or in threaded boxes or fittings containing no taps, splices, or terminal connections is permitted in both residue and vapor areas.

Fixed lighting fixtures located outside of, but above, classified areas should be protected against physical damage. These fixtures should be arranged, so that they do not become sources of ignition for flammable vapors.

In areas where the electric service is supplied from overhead wires and lightning is a fairly common occurrence, protection against lightning-induced surge voltages should be provided. In the absence of lightning protection, high surge voltages could enter vapor areas and create high-energy ignition sources. Suitable protection includes lightning arresters, interconnection of all grounds, and surge protection capacitors.

Under abnormal conditions, overheating and arcing can occur in electrical circuits and equipment. Therefore, it is important that electrical circuits and equipment servicing dipping and coating processes have the proper overcurrent

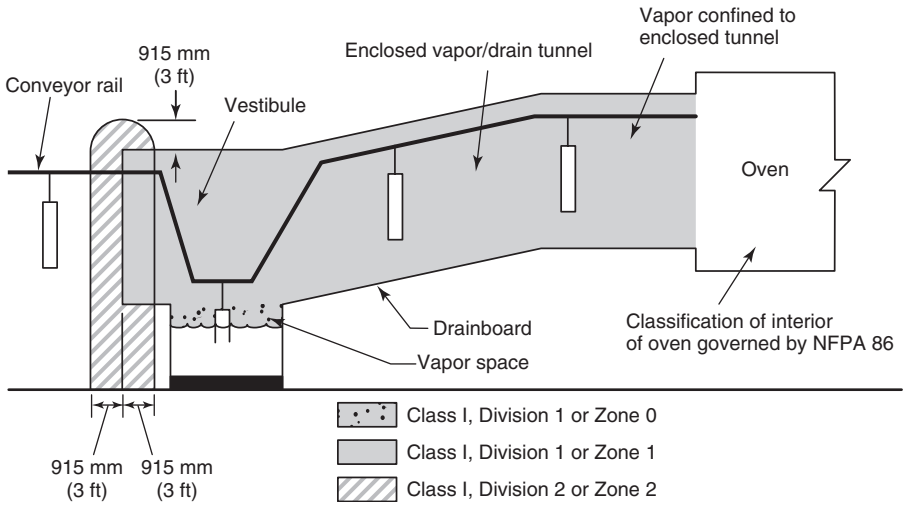

FIGURE 9.3.14 Electrical Area Classification Around Enclosed Processes

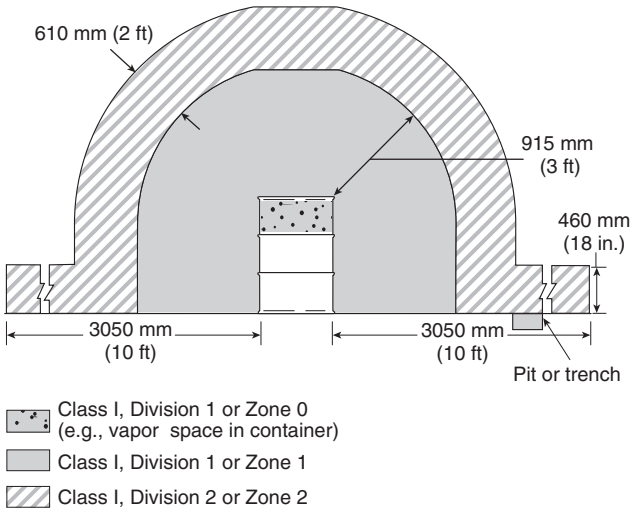

FIGURE 9.3.15 Electrical Area Classification Around an Open Container

protection, are grounded, and receive regular preventative maintenance.

Dipping and coating processes are frequently changed when new coating materials are introduced, production demand is increased, and new equipment is installed. Quite often, unsafe electrical installations and poor maintenance habits creep into the production process. It is common to find extensions connected to additional fans and lighting that are not suitable for use in classified hazardous areas.

Other Ignition Sources. Open flames, spark-producing processes, and equipment whose exposed surfaces exceed the autoignition temperature of the dipping or coating liquid should not be located in the dipping and coating process area or in surrounding areas. Ovens located directly above or adjacent to dipping and coating operations have been the ignition source for many reported fires. This equipment should be located as far as practical from dipping and coating operations, with noncombustible partitions provided when reasonable distances cannot be maintained. Exhaust systems of ovens and dryers located directly above or adjacent to dipping and coating processes should be interlocked, so that heating and process equipment cannot function unless all ventilation equipment is in operation. Indirect heating systems, which do not normally present ignition sources, are usually preferred in drying operations. (For more information on heating systems, see Section 8, Chapter 8, "Industrial and Commercial Heat Utilization Equipment.")

Dipping and coating processes often involve the use of conveyors, rollers, collectors, festoon dryers, and other devices that move the workpiece or liquid through the process. Flowing liquids and materials moving through a process can generate static electricity. A static electric charge can accumulate on process equipment and develop a difference in electrical potential sufficient to cause a spark containing enough energy to ignite flammable vapor-air concentrations. Static elimination by bonding and grounding of the process equipment, or by humidification or ionization of the local atmosphere, is essential in reducing the hazard of fire or explosion. (See NFPA 77, *Recommended Practice on Static Electricity*.)
