*Column Nos. 70 to 75 tested at UL. Test No. 70 of the group was stopped at 8 hours 40 minutes; others at failure or at 8 hours, and all loaded to failure at end of fire exposure (NBS Tech. Paper 184). All other columns tested at NBS Laboratory at Pittsburgh, PA. The fire endurance test of Col. No. 7 stopped at 5 hours, all others of series stopped at 4 hours. Figures in parentheses are estimates of fire resistance if tests had continued to failure (NBS Tech. Paper 272).

For SI units: 1 in. = 25.4 mm; 1 in.² = 645 mm²; 1 lb = 0.45 kg.

TABLE 19.2.5 Concrete Protection for Steel Beams (All re-entrant portions filled)

Fire Resistance Rating		Thickness of Concrete Protection (in.)							
		Grade 1 Size of Member (Flange Width)				Grade 2 Size of Member (Flange Width)

1	—	1½	1	1	1	1¾	1¼	1	1

Note: Protective concrete having thickness one-fourth of flange width or less must have steel wire reinforcement spaced nor more than four times the thickness of the concrete covering the flange.
For SI units: 1 in. = 25.4 mm.

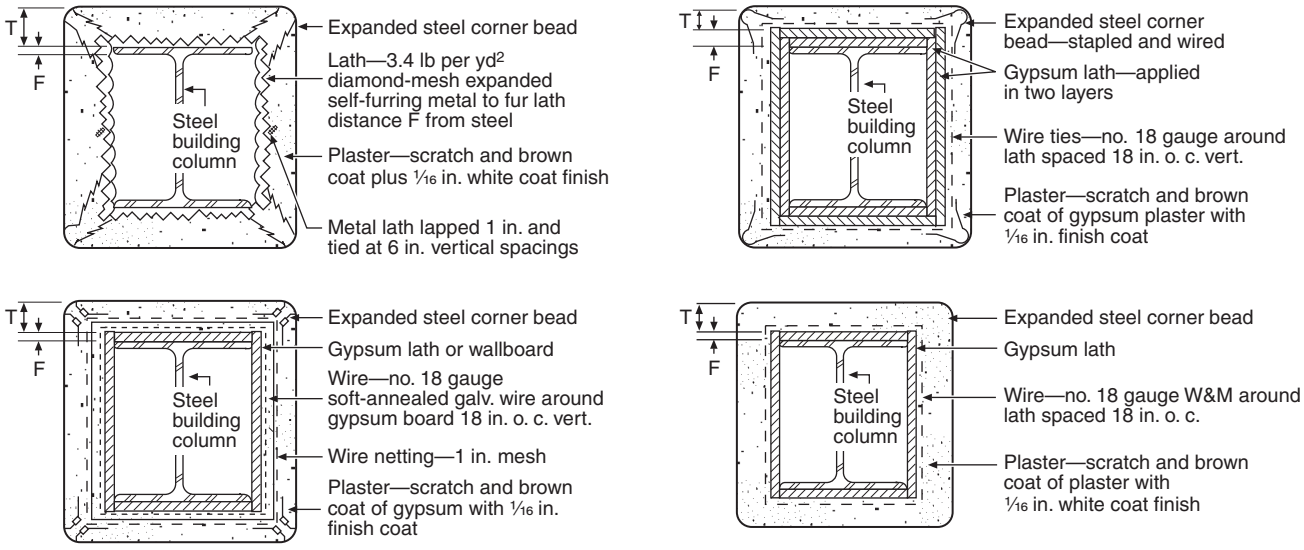

FIGURE 19.2.4 Typical Steel Column Protection of Lath and Plaster Assemblies. For SI units: 1 in. = 25.4 mm; 1 lb = 0.454 kg.

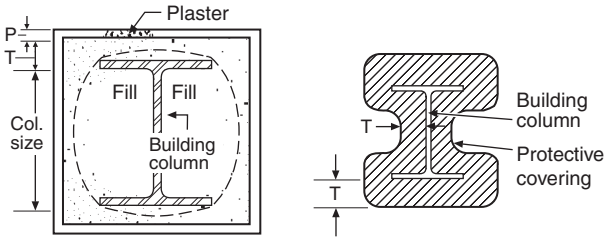

FIGURE 19.2.5 Typical Steel Column Protection of Concrete, Masonry, or Sprayed Fibers

Floor/Ceiling Assemblies

Fire resistance for floor/ceiling assemblies of reinforced concrete, structural steel, and wood can be achieved in several ways. For example, Figure 19.2.7 illustrates the influence of floor thickness and aggregate type on the fire resistance of reinforced-concrete slabs, whereas Table 19.2.8 shows the fire resistance for several types of concrete floor constructions. Table 19.2.9 shows the test results for structural steel joist floor and roof constructions, and Table 19.2.10 provides some data on the fire resistance of steel-formed concrete floor systems.

[a]Concrete mix—1 part cement to 6 parts total aggregate including sand and coarse aggregate.
[b]Gypsum concrete—7 parts gypsum stucco to 1 part wood shavings, by weight.
[c]Mineral fibers, with bonding agent as required, sprayed on to all surfaces of column shaft to thicknesses indicated. (Thickness different on account of characteristics of fiber and binder.)
[d]Concrete-filled columns require vent holes to prevent explosion in the event of fire.
[e]Approximate depth, flange width per Table 19.2.5.
[f]Inside diameter.
For SI units: 1 in. = 25.4 mm; 1 $in.^2$ = 645 mm^2; 1 ft = 0.305 m; 1 lb = 0.454 kg.

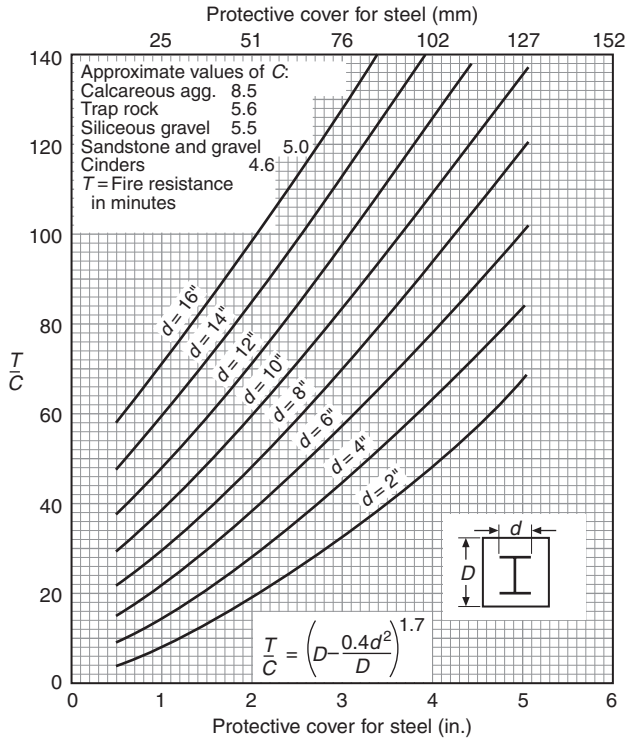

FIGURE 19.2.6 Encasing Requirements of Steel Columns and Other Free-Standing Steel Members. For SI units: 1 in. = 25.4 mm.

FIGURE 19.2.7 Fire Resistance Ratings of Reinforced-Concrete Floors of Varying Thicknesses. The dotted line represents concrete floors made with regular aggregates, and the solid line represents lightweight concretes.

Walls and Partitions

Walls and partitions are commonly constructed of masonry, wood, or metal studs faced with fire-resistant materials. Table 19.2.11 gives the fire resistance of load-bearing brick or clay tile walls. Figure 19.2.8 shows a graph that allows the fire resistance of burned clay brick walls to be estimated. Tables 19.2.12 and 19.2.13 provide fire resistance ratings for wood stud walls, whereas Figure 19.2.9 gives the fire resistance of stud walls

TABLE 19.2.8 Concrete Floor Constructions

Materials	Fire Resistance Rating *hr*	*min*
Reinforced Concrete (free or partly restrained, 1500–2500 psi)

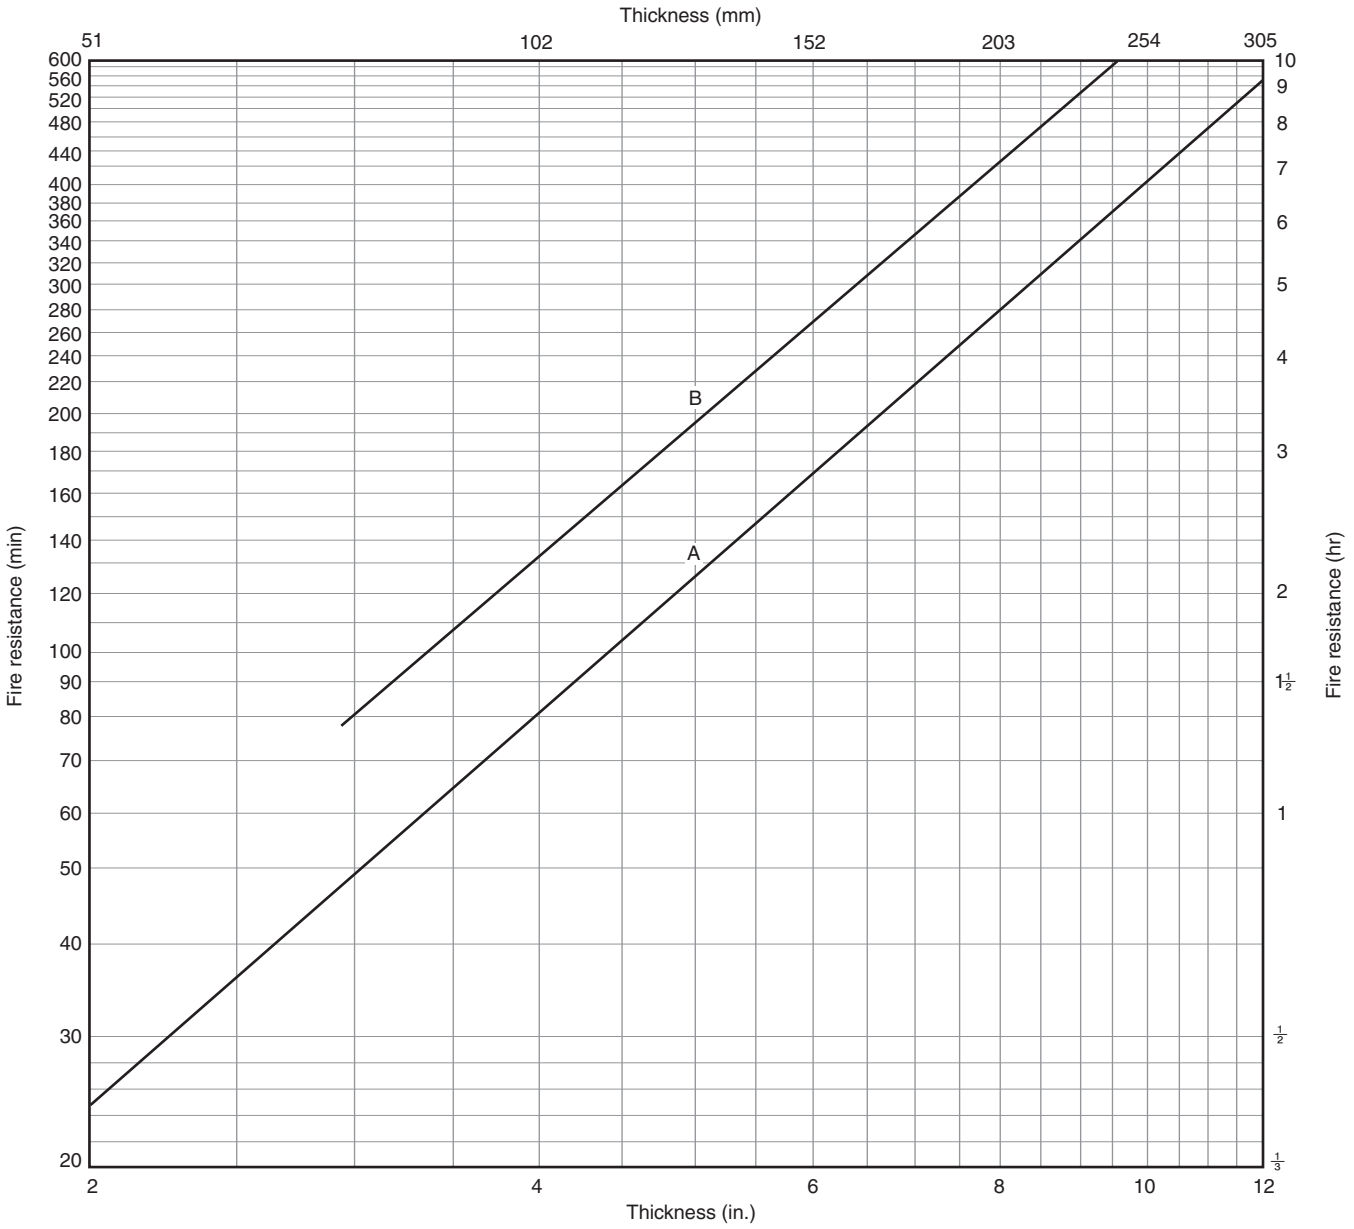

FIGURE 19.2.8 Fire Resistance of Burned Clay Brick Walls: (A) Unplastered; (B) Plastered Both Sides

faced with common construction materials and can be used to estimate quickly and conveniently. Table 19.2.14 and Figure 19.2.10 are very useful descriptions of the fire resistance of solid, non-load-bearing partition materials.

CALCULATING FIRE ENDURANCE

As previously noted, the traditional approach to structural fire protection is by specification of fire resistance ratings through building and safety regulations. Structural members and assemblies are evaluated to the standard fire test (NFPA 251) to establish fire resistance ratings.

Over the past five decades, a substantial amount of research has been conducted on behavior of structural elements in fires. One development is the use of computer models to approximate compartment fire behavior, heat transfer, and structural performance at elevated temperatures. These models utilize scientific research on mechanical and thermal properties of materials at elevated temperatures with some having undergone a degree of validation. This research and computer model application resulted in a broader range of predictions of structural behavior in fires than has been possible with only the traditional code and standard fire test procedures.

A fairly recent development occurred in 1999 when the American Society of Civil Engineers (ASCE) and the Society of Fire Protection Engineers (SFPE) published a jointly developed standard intended for the calculation of fire resistance of structural elements. ASCE/SFPE 29, *Standard Calculation Methods for Structural Fire Protection,* provides the methods of

calculating the fire resistance ratings that are equivalent to the results obtained from the standard fire test method (NFPA 251, ASTM E119). The calculation methods in ASCE/SFPE 29 are used as an alternative to the laboratory test results. These calculation methods are applicable only to structural steel, plain and reinforced concrete, timber and wood, concrete masonry, and clay masonry. Limitations of applicability are also identified.

Calculation methods offer advantages in economy and better predictability over the traditional test approach. The calculation methods may be grouped into two categories: (1) calculation of the fire endurance that would have been obtained in the standard fire test and (2) calculation of structural or thermal performance in an actual building fire compartment. Careful consideration must be given when using the latter category. If

a wall is calculated for a certain duration using a less severe fire (thermal) load and the occupancy changes (increased fire loading), the expected fire resistance of the wall with the new occupancy must be recalculated.

Building code requirements specify fire resistance ratings as reflected by the standard fire test. Consequently, it has been beneficial to develop methods to calculate the fire resistance that would have been obtained in the standard fire test. Illustrative equations and graphs for this type of evaluation are given later. A brief description of procedures to calculate performance in actual building fires is given at the end of this chapter.

Equivalent Fire Endurance of Structural Steel

As noted previously, fire testing has been ongoing for many years, yielding a large amount of data and experience. The procedures described here reflect the type of methods that will enable equivalent fire resistance to be calculated. It should be noted that many of these calculation methods are obtained from test data. Consequently, one should be critical when applying these methods to materials that have not been used in the tests that were the basis for the calculation procedures. For example, the data for structural steel has been based on testing of A7 or A36 structural steel. High-strength steels have become popular. The mechanical properties of high-strength steels at both normal and elevated temperatures are different from those of A7 and A36 steel. Consequently, for fire resistance calculations, when the term *structural steel* is used in this section, A7 and A36 steels are intended.

The fire resistance of structural steel beams and columns can be improved by insulating the members. Equation 1 calculates the fire resistance of steel columns protected by light insulation.[4,5] The members may be protected by boxing the slope or by a contour protection. The equation is:

$$R = \left(C_1 \frac{M}{D} + C_2\right) l \qquad (1)$$

where

R = Fire endurance (min)

M = Mass of the member (lb/ft)

D = Heated perimeter (in.)

l = Thickness of protection (in.)

C_1, C_2 = Constants that are empirically derived for the insulating units

In SI units:

$$R = \left(0.672C_1\frac{M}{D} + 0.039C_2\right)l \qquad (1m)$$

where

R = Fire endurance (min)

M = Mass of the member (kg/m)

D = Heated perimeter (mm)

l = Thickness of protection (mm)

C_1, C_2 = Empirical constants, the same as used for U.S. customary units

The heated perimeter, D, varies depending on whether the structural member is a column or beam. It also varies depending on the shape of the member and whether the coating is directly applied to the contour of the member, or in a box fashion.

Most commonly, insulating materials will have densities less than 20 lb/ft^3. For the cementitious material in UL Design Nos. X701, X704, X722 and X723, $C_1 = 69$ and $C_2 = 31$. For the mineral fiber material in UL Design Nos. X801, X807, X818, X821 and X822, $C_1 = 63$ and $C_2 = 42$.

Empirical coefficients that should be used for other coatings can be found in the AISC Steel Design Guide 19.[6] It should be noted that the version of the above formula used in that document calculates the fire resistance in hours instead of minutes (as done in the original derivation), so the values of the coefficients have been adjusted accordingly. The formula for determining the heated perimeter (D, in.) for beams and columns in contour or box profiles, can also be found in that document.

For insulating materials, such as mineral fibers, vermiculite, and perlite, having densities r in the range of 20 to 50 lb per ft^3 (32 to 80 kg/m^3), the factors C_1 and C_2 are:

$$C_1 = \frac{1200}{r}, \text{ and } C_2 = 30$$

For insulating materials of the same range of densities but incorporating cement pastes or gypsum, the factors C_1 and C_2 are:

$$C_1 = \frac{1200}{r}, \text{ and } C_2 = 72$$

To calculate the fire resistance of columns boxed with gypsum wallboard, the total weight of the column plus wallboard must first be calculated using the following formula:

$$W' = W + \frac{50\,(hD)}{144}$$

where

W' = Total weight of the column plus wallboard

W = Weight of steel shape (lb/ft)

h = Thickness of gypsum wallboard (in.)

D = Heated perimeter of column (in.)

Using W' (instead of W), the column fire resistance, R, is then calculated as follows:

$$R = 130\left[\frac{h(W'/D)}{2}\right]^{0.75}$$

Most columns normally used only offer a few minutes of fire resistance when unprotected. Very heavy, unprotected steel columns are capable of exhibiting some significant fire resistance. Equations 2, 3, 2m, and 3m can be used to predict the fire resistance of unprotected steel columns.[4]

$$R = 10.3\left(\frac{M}{D}\right)^{0.7} \quad \text{for} \quad \frac{M}{D} < 10 \qquad (2)$$

$$R = 8.3\left(\frac{M}{D}\right)^{0.8} \quad \text{for} \quad \frac{M}{D} > 10 \qquad (3)$$

where

R = Fire endurance (min)

M = Mass of the member (lb/ft)

D = Heated perimeter (in.)

In SI units:

$$R = 75.1\left(\frac{M}{D}\right)^{0.7} \quad \text{for} \quad \frac{M}{D} < 171 \qquad (2m)$$

$$R = 60.5\left(\frac{M}{D}\right)^{0.7} \quad \text{for} \quad \frac{M}{D} > 171 \qquad (3m)$$

where

R = Fire endurance (min)

M = Mass of the member (kg/m)

D = Heated perimeter (mm)

Beams with a larger W/D ratio can always be substituted for the structural member listed with a specific fire-resistive covering without changing the thickness of the covering.

Beams with different shapes than those listed in a fire-resistive assembly may be substituted for the listed shape as long as the coating thickness is adjusted as a function of the W/D ratio according to the following equation:

$$h_1 = \left(\frac{W_2/D_2 + 0.6}{W_1/D_1 + 0.6}\right)h_2$$

where

h = Thickness of the spray-applied fire protection (in.)

W = Weight of steel beam (lb/ft)

D = Heated perimeter of the steel beam (in.)

Subscript 1 refers to the substitute beam and required protection thickness

Subscript 2 refers to the listed beam and protection thickness

The following are the limitations of this formula:

1. W/D values must be 0.37 or greater.
2. h must be ⅜ in. (9.5 mm) or greater.
3. The unrestrained beam rating and restrained beam rating must both be at least 1 hour.
4. For restrained beams, the beam must be a "compact" section per AISC Steel Construction Manual.[7]

Equivalent Fire Endurance of Reinforced Concrete

Thermal and mechanical properties vary for all materials with the temperature of the material. Because the heat transmission through concrete is quite slow, the variability of properties throughout the member is quite nonuniform. As a result, the behavior of reinforced concrete in fire is very complex. Nevertheless, equations have been developed to predict the fire resistance of reinforced concrete columns. The resistance depends on the weight and aggregate of the concrete, the minimum dimension of the column, the area of vertical reinforcement in the column, and the effective length of the column.

The effective length of the column is equal to the length of the column multiplied by a factor. The factor can range from 0.65 to 2.1, depending on how the column is secured in the top and the bottom. If the exact method of securement is unknown, a factor of 1 can be used. When the column is constructed of normal-weight siliceous aggregate and columns 1 and 3 are used in Table 19.2.15, use Equation 4. When the column is constructed of normal-weight carbonate aggregate and columns 1 and 3 are used in Table 19.2.15, use Equation 5. When the column is constructed of normal-weight carbonate or siliceous aggregate and column 2 is used in Table 19.2.15, use Equation 6. When the column is constructed of lightweight aggregate and any column is used in Table 19.2.15, use Equation 7.

TABLE 19.2.15 Values for f

	f		
		Effective length, kL 12 ft < kL < 24 ft	
Overdesign Factor	Effective Length, kL (kL_{max} = 12 ft)	$\rho \le 0.03$ $t \le 12$ in.	All Other Cases
Column	*1*	*2*	*3*
1.00	1.0	1.2	1.0
1.25	0.9	1.1	0.9
1.50	0.8	1.0	0.8

For SI units: 1 in. = 25.4 mm; 1 ft = 0.305 m.
L = column length (feet).
k = effective length factor (dimensionless); if unknown, assume k = 1.

$$R = \frac{t}{3.2f} - 1 \quad (4)$$

$$R = \frac{t}{3.2f} - 0.75 \quad (5)$$

$$R = \frac{t}{4f} - 1 \quad (6)$$

$$R = \frac{t}{3f} - 1 \quad (7)$$

where

R = Fire resistance (hr)

t = Minimum dimension of the column (in.)

f = A factor that considers overdesign (Table 19.2.15 provides values for f)

In SI units:

$$R = \frac{t}{81.3f} - 1 \quad (4m)$$

$$R = \frac{t}{81.3f} - 0.75 \quad (5m)$$

$$R = \frac{t}{101.6f} - 1 \quad (6m)$$

$$R = \frac{t}{76.2f} - 1 \quad (7m)$$

where

R = Fire endurance (hr)

t = Minimum dimension of the column (mm)

f = A factor that considers overdesign (Table 19.2.15 provides values for f)

Equation 8 gives calculated fire endurance for normal-weight concrete slabs,[8,9]

$$R = 0.031\rho^{1.2}L^{1.85} \quad (8)$$

where

R = Fire resistance (hr)

ρ = Concrete density (lb/ft^3)

L = Slab thickness (ft)

In SI units:

$$R = 0.031\rho^{1.2}L^{1.85} \quad (8m)$$

where

R = Fire resistance (min)

ρ = Concrete density (kg/m^3)

L = Slab thickness (m)

Equivalent Fire Endurance of Timber

When timber members are tested, they burn. As burning continues, a char layer is formed on the exposed surfaces. This char layer reduces the usable strength of the timber members. The time duration that elapses before the member reaches its critical failure load is the fire endurance. The fire endurance for wood beams is calculated by determining the breaking strength of the uncharred residual cross section. The time to reach a critical depth may be calculated using the applicable equations in ASCE/SFPE 29. The critical residual depth, *d,* can be obtained from Figures 19.2.11 and 19.2.12.[10]

STRUCTURAL MATERIALS AT ELEVATED TEMPERATURES

All structural materials used in building construction are adversely affected by the elevated temperatures caused by fire. The degree and significance of this adverse behavior depend primarily on the function of the elements and on the degree of protection afforded. The mechanical properties of strength and stiffness decrease as the temperature rises. Other adverse behavior, such as excessive expansion and accelerated creep, also develops with increasing temperatures. In general, however, the design parameters that are of concern at normal temperatures are the same parameters that are of concern at elevated temperatures.

Structural Steel

Property of Structural Steel. Steel is the backbone of modern building design. Whether it acts as the reinforcement for concrete or the skeleton framework for buildings, it constitutes the major load-carrying material in modern building construction. From the designer's viewpoint, steel possesses many qualities, such as high strength and good ductility, that make it an ideal structural material. However, steel, like all other materials, is adversely affected by fire.

Steel is noncombustible and does not contribute fuel to a fire. In the past, these properties have sometimes provided a false sense of security with regard to its durability in a fire because they overshadow the fact that steel loses strength when subjected to temperatures easily attained in a fire. The relative seriousness of the problem depends on several factors, such as the function of the steel element, its level of stress, the support conditions, its surface area and thickness, and the temperature within the steel itself. This temperature can be quite different from the ambient temperature in the compartment.

From a structural viewpoint, the yield stress of steel is the significant parameter in establishing load-carrying capacity. The tensile stress strain diagram for A36 steel at various temperatures is shown in Figure 19.2.13.[11] It can be seen that both the yield strength and the modulus of elasticity decrease

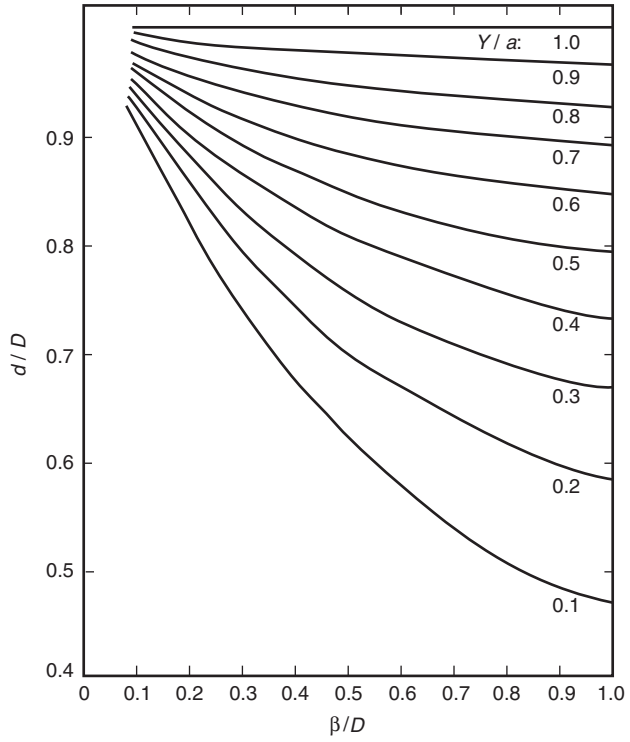

FIGURE 19.2.11 Critical Depth of Solid Timber Beams of Rectangular Cross Section Exposed on Three Sides to Fire

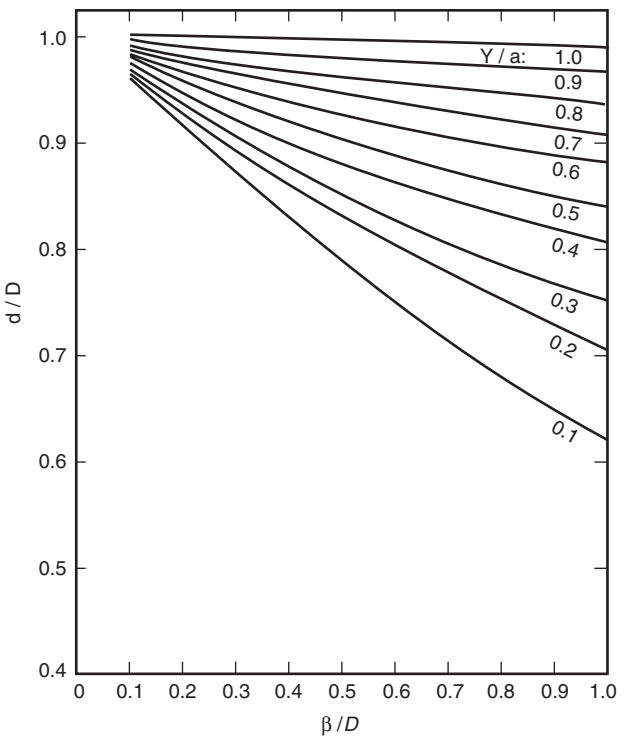

FIGURE 19.2.12 Critical Depth of Solid Timber Beams of Rectangular Cross Section Exposed on Four Sides to Fire

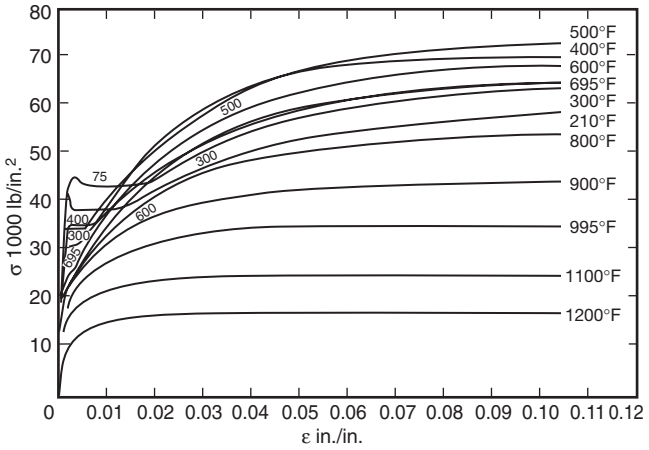

FIGURE 19.2.13 Stress-Strain Curves for an ASTM A36 Steel

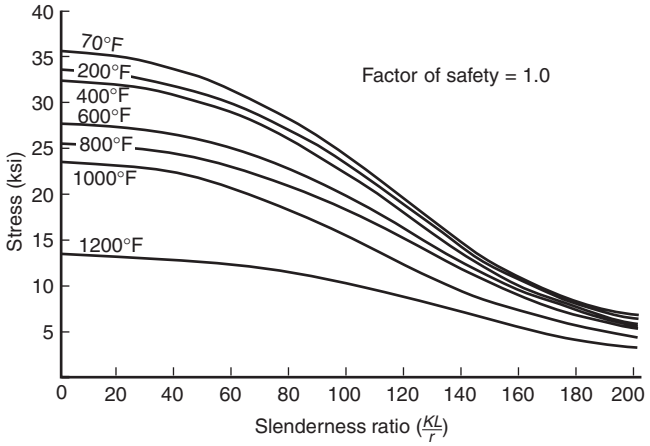

FIGURE 19.2.15 Critical Stress as a Function of the Slenderness Ratio for Various Temperatures—A36 Steel

with increasing temperatures. Figure 19.2.14 shows the ratios of modulus of elasticity and yield stress for A36 steel at various temperatures.[12] As can be seen, both values decrease with an increase in temperature.

This reduction in strength, combined with the reduction in the modulus of elasticity, causes compression members to be more sensitive to higher temperatures than tensile or flexural members. Figure 19.2.15 shows the influence of temperature on the critical stress of compression members of A36 steel.[12]

It should be recognized that the temperature considered for stress limitations is the temperature within the steel and not the ambient temperature. Because steel has a high thermal conductivity, it can transfer heat away from a localized heat source rather quickly. This property, in conjunction with its thermal capacity, enables steel to act as a heat sink. When the steel has an opportunity to transfer heat to cooler regions, it can take a relatively long time for a member to reach its critical value. On the other hand, an extensive fire that distributes heat simultaneously over a greater area reduces this time considerably.

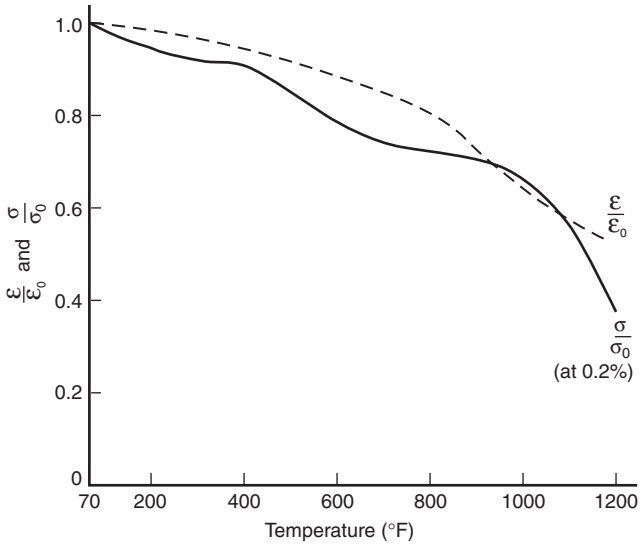

FIGURE 19.2.14 Ratio of Modulus and Yield Strength with Temperature—A36 Steel

Related to this thermal activity is the effect of mass and surface area of structural steel members. Heavy, thick sections have a far greater resistance to the effects of building fires than do lighter ones. Unprotected lightweight sections, such as those found in trusses and open-web joists, can collapse after 5 or 10 minutes of exposure.

Another property of steel that has an effect on its performance at elevated temperatures is its coefficient of expansion. The linear coefficient of expansion of steel at temperatures up to 1100°F (600°C) is given as:

$$\alpha = 0.0000061 = 0.0000022\Delta t$$

where

α = The coefficient of expansion

Δt = Temperature change in degrees Fahrenheit

In SI units:

α = The coefficient of expansion

Δt = Temperature change in degrees Celsius

$$\alpha = 6.1 \times 10^{-6} + 3.96 \times 10^{-9}\Delta t$$

This high coefficient affects the structure in two ways. If the ends of a structural member are axially restrained, the attempted expansion due to the heat causes thermal stresses to be induced in the member. These stresses combine with those of the normal loading, causing more rapid collapse. If the structural member is not axially restrained, the increased stresses described do not occur; instead, movement takes place. This movement causes the ends of steel columns to be moved laterally, producing an eccentrically loaded column. In other cases, walls can be moved to the point of collapse by expansion of beams. This creates an

extremely hazardous condition both for the building itself and for fire fighters.

In October 2006, NIST issued their final report on the September 11, 2001, collapse of the World Trade Center Towers.[13,14] In this report they note very limited test data that indicates that, all else being equal, as the length of a horizontal structural member increases, the fire endurance may be reduced. Insufficient data currently exists to either substantiate or quantify this relationship. The limited testing also leaves questions regarding benefits of restrained versus unrestrained conditions on fire endurance of protected steel structural members. The discussion of potential research studies began in 2006 to evaluate current fire endurance test methods to see if changes in test procedures, or adjustments to the thickness of a tested fire-resistive coating (to reflect an increase in length over the tested span), are needed.

To illustrate the magnitude of movement, consider a 50 ft (15.24 m) long steel beam that is heated uniformly over its length from 72 to 972°F (22.2 to 522°C). The average value for alpha is 0.0000073, and the increase in length, delta, becomes approximately

$$\delta = \alpha L\, \Delta t = (7.3 \times 10^{-6})(50 \times 12)(900)$$

Thus, $\delta = 3.9$ in.

In NFPA 251, alternate tests may be used to evaluate protection of steel beams and columns. These alternate tests evaluate the thermal protection of the insulating materials by measuring the temperature in the steel for the standard time-temperature exposure. In these alternate tests, failure occurs when the average temperature reaches 1000 to 1100°F (538 to 593°C).

If critical temperature for structural steel is intended to describe the steel temperature at which collapse is impending, temperatures in the range of 1000 to 1100°F (538 to 593°C) can be viewed as a reasonable failure criteria. The actual temperatures at which collapse will occur will likely differ from the 1000 to 1100°F range, depending on the load and support conditions, dimensions, and geometry of the structural member. The actual temperature at which collapse is likely to occur is the temperature at which the yield stress is reduced to the point where it is approximately equal to the stress the member was designed to have applied to it, at or near its full design load.[15] The yield stress is the force per unit area at which permanent deformation occurs. In other words, that temperature range is where the safety factor utilized in the structural design has been reduced to unity due to the reduction in strength.

The modulus of elasticity (E), or ratio of stress to strain, is also reduced at elevated temperatures. Since the deflection of a horizontal structural member is inversely proportional to E, all else being equal, deflection will increase with increased temperatures.

Rather than focus exclusively on temperature, it is more appropriate to focus on the load-carrying capacity of a member at different temperatures. For example, one may question, what is the load-carrying capacity of the structural member when the temperature reaches x°F? The related question may then be asked: What is the likelihood that the steel temperature will reach this value in a room fire? Modern calculation methods enable both of these questions to be addressed with a reasonable degree of confidence, although not yet as a simple, routine evaluation.

Fire Protection of Structural Steel. Because unprotected structural steel loses its strength at high temperatures, it must be protected from exposure to the heat produced by building fires. This protection, often referred to as "fireproofing," insulates the steel from the heat. The more common methods of insulating steel are encasement of the member and application of a surface treatment. Installation of a suspended ceiling as part of a floor-ceiling assembly has been used to increase the fire resistance of the assembly. Additional methods, such as sheet steel membrane shields around members and box columns filled with liquid, have been introduced.

Over the years, encasement of the structural steel member has been a very common and a very satisfactory method of insulating steel to increase its fire resistance. In floor systems of reinforced-concrete slabs supported by structural steel beams, the encasement can be placed monolithically with the floor. Figure 19.2.16 illustrates an older technique of encasement. The major disadvantage of this procedure is the cost, which is related both to the added formwork and concrete and to the increased weight of the supporting members due to the added dead load. To reduce the cost of encasement, systems utilizing lath and plaster or gypsumboard, or spray-on mineral fiber or cementitious coatings, have been developed, as shown in Figures 19.2.17[16] and 19.2.18.

Because of labor costs and the weight increases of encasement, surface treatments applied directly to the member have become quite popular. Low density (13 pcf) sprayed-on

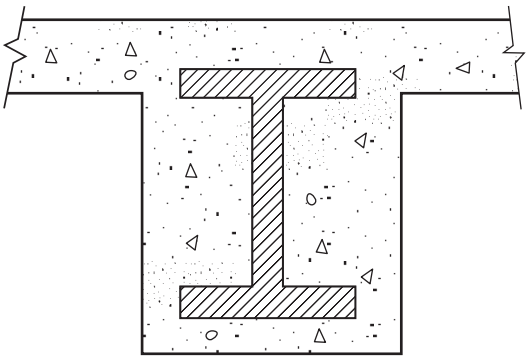

FIGURE 19.2.16 Encasement of a Steel Beam by Monolithic Casting of Concrete Around the Beam

FIGURE 19.2.17 Spray-On Fireproofing

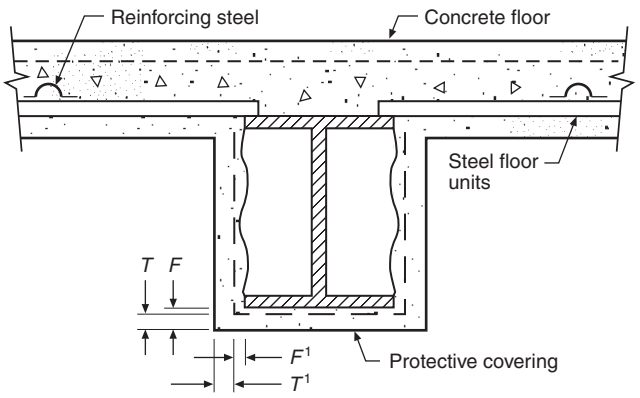

FIGURE 19.2.18 Furred Steel Beams with Noncombustible Protective Coverings

cementitious and mineral fiber coatings are widely used for protecting structural steel. While the protection is excellent if applied correctly, it can easily be scraped off the member during construction or renovations. Consequently, sprayed-on coatings are suspect in their effectiveness over long-term use.

Sprayed-on coverings can spall, and adhesion problems also have been experienced. Thus, effective application, complete coverage, and long-term maintenance are attributes that must be evaluated in considering sprayed-on applications. The application of sprayed-on material must be monitored. The material being applied has specific guidelines that must be met. Conditions that are too humid or too cold may cause the material to fail earlier than it normally would.

The proper surface condition of structural steel is important to assure adequate adhesion of sprayed fire-resistive materials (SFRM) to the steel. The steel surface must be free of dirt, grease, oil, and loose mill scale. Blast cleaning of the surface is generally not required. Also, for common SFRM, such as cementitious or mineral fiber type, the use of primer paint is generally not required or recommended. In most cases, the use of a primer paint will result in a considerable reduction in adhesive strength of the coating to the steel and, if a primer paint is to be used, it is imperative that it be approved for use with the specific SFRM that is to be used. Whether or not a primer is used, conducting field tests to assure adequate thickness, density, adhesion and cohesion is achieved in the actual installation is recommended. Guidance can be found in ASTM E 605 and E 736. The NIST WTC report[14] confirmed existing concerns regarding how surface preparation for structural steel affects the adhesion of spray-applied fire-resistive material. Prior to selecting a coating, lab test information should be reviewed to assure that the coating is appropriate for the conditions of service. Guidance on these tests can be found in ASTM E759, E760, E761, E859 and E937.

Intumescent coatings have been utilized to increase the fire endurance of structural steel. These coatings intumese, or swell, when heated, thus forming an insulation around the steel. Prolonged exposure to flame can destroy the char coating.

Suspended ceilings consisting of lath and plaster, gypsum panels, or acoustical tile supported on a grid system as part of a floor-ceiling assembly are a popular method of fireproofing. The grid system can be suspended from wire hangers or it can be attached directly to the bottom chord of joists or to the bottom flange of beams. Sometimes ceiling tiles are either mechanically fastened or fitted into splines to prevent the pressures that occur in building fires from lifting them out of place.

The overall effectiveness of this type of barrier protection, often called membrane protection, is questionable. This is due to experiences where a lack of control during construction resulted in improper installation procedures, such as inattention to expansion control in the suspension system. In addition, maintenance of ductwork and fixtures in the plenum area may be done by personnel who are not aware of the importance of the integrity of the ceiling to the fire protection system. Removed tiles are not replaced in a manner that will ensure their integrity during a building fire. Consequently, the unprotected steel in the plenum area is exposed to fire and hot gases, which significantly reduce its strength.

Structural steel members also can be protected by sheet steel membrane shields. The sheet steel holds inexpensive insulation materials in place, thus providing a greater fire resistance. In addition, polished sheet steel has been used in tests to protect spandrel girders. The shield reflects radiated heat and protects the load-carrying spandrel.

Reinforced Concrete

Concrete is often used as a protective covering for other materials, as well as a primary load-bearing structural material. Consequently, reinforced-concrete buildings give a sense of fire security. However, concrete as a material also is adversely affected by heat from a fire. Although collapse of reinforced-concrete structures is comparatively rare, there is some experience with collapse of such structures in a fire. Loss in strength, spalling, and other deleterious effects do occur. The collapse of several multistory reinforced concrete buildings during fire exposure is discussed in the report, NIST GRC 02-843.[17]

When the temperature of a reinforced-concrete member is raised, the member loses strength. The amount of strength reduction is influenced by a number of factors. Among the most significant from a structural viewpoint are the type of aggregate, moisture content, type of loading, and level of stress during the fire exposure.

One of the more significant factors in determining the change in strength and the thermal characteristics of concrete is the type of aggregate. Aggregate types can vary widely from region to region. Consequently, numerical values of strength properties are related to a percentage of the original strength, rather than a specific stress value. The qualitative behavior of concrete is generally accurate, however.

Lightweight concrete performs better at elevated temperatures than does normal-weight concrete. Not only does it retain more of its strength during heat buildup, but it also has a lower coefficient of thermal conductivity. Concrete using aggregates of vermiculite of perlite is particularly good at protecting structural steel from a heated environment.

Figures 19.2.19 and 19.2.20 illustrate the effect of aggregates on the fire resistance of reinforced-concrete slabs.[3] The lightweight aggregates, such as expanded shale and expanded slag, have considerably more fire resistance than do normal-weight concretes made from carbonate and siliceous aggregates.

The moisture content of concrete has a significant influence on its thermal performance. A considerable quantity of the heat energy of a fire is expended in vaporizing the absorbed and capillary moisture in concrete. In the case of horizontal members, the water vapor is driven upward and maintains a temperature at the top of the member of 212°F (100°C) until the water has been driven off. This increases the fire resistance, as it keeps the temperature on the unexposed side below that defined as the failure temperature. However, the voids caused by the evaporation of water contribute to shrinkage and a decrease in concrete strength.

The mechanical properties of concrete are significantly reduced at elevated temperatures. Figure 19.2.21 shows the effect on the compressive strength and modulus of elasticity by increasing the temperature.[3] There is some question about whether concrete completely regains its strength after exposure to high temperatures.

Concrete structures generally have less stringent requirements regarding expansion joints for normal thermal expansion.

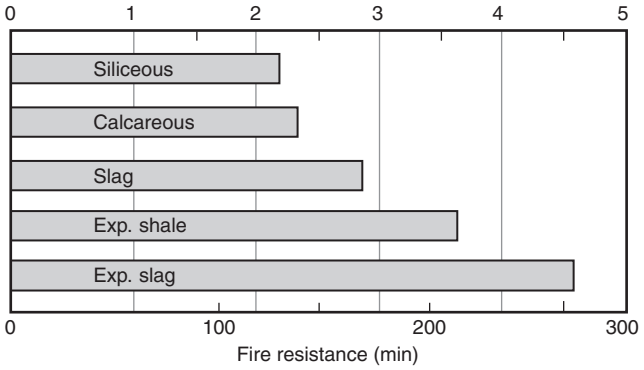

FIGURE 19.2.19 Effect of Various Types of Aggregate on the Fire Endurance of 4¾ in. (121 mm) Slabs

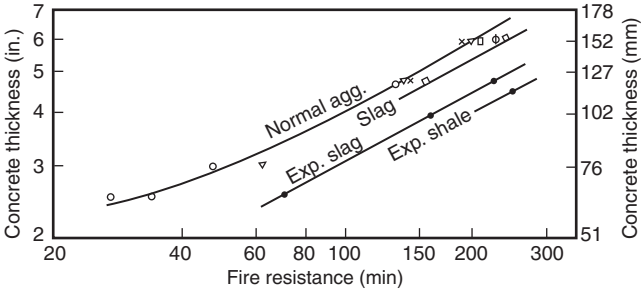

FIGURE 19.2.20 Relationship of Slab Thickness and Type of Aggregate to Fire Endurance

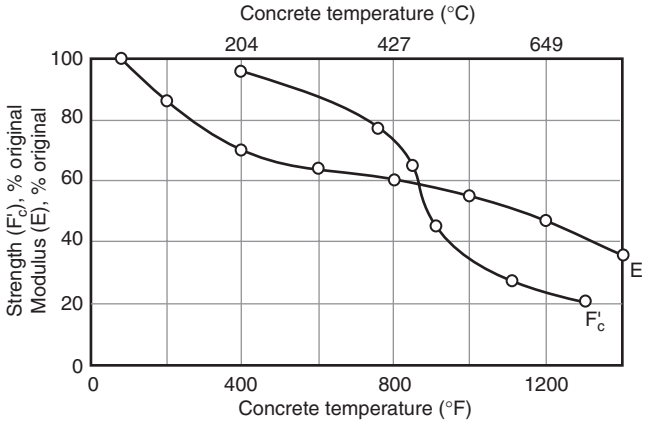

FIGURE 19.2.21 Effect of Temperature on Modulus of Elasticity and Compressive Strength. The curves are taken from two differing specimens.

Consequently, a large concrete structure exposed to an uncontrolled fire can experience large horizontal forces due to the expansion of beams, which can cause structural damage at the junction of beams and columns. In 1973, an uncontrolled fire occurred in a military personnel records storage center in Overland, Missouri. The building was 730 ft (222 m) long, but had no expansion joints. Floors, beams, and columns (20 in. × 20 in. [508 mm × 508 mm]) were made of reinforced concrete. An estimated 28 in. (700 mm) of horizontal expansion occurred during the fire, causing severe structural damage at the junction of the beams and columns, resulting in partial collapse.[18]

Prestressed Concrete

The factors that are significant in the behavior of prestressed concrete are similar to those that affect reinforced concrete. In addition to the influences of moisture content and aggregate, the higher strength concrete and the function and type of steel used for prestressing are important considerations. The concrete used for prestressed concrete is of a higher strength than that used in ordinary reinforced-concrete construction. The overall fire resistance of this concrete is somewhat better than the lower-strength concrete. The heat transmission is about the same for the two systems. However, there is a somewhat greater tendency for prestressed concrete to spall, thus exposing the prestressing steel.

The greatest problem of prestressed concrete subjected to elevated temperatures involves the prestressing steel. The fact that the steel is put under high initial stress, coupled with the fact that the reinforcing wires are high-carbon, cold-drawn, rather than low-carbon, hot-rolled steel, is the root of the problem. Normal prestressing losses due to deformation and creep are considered in prestressed concrete design. At elevated temperatures these losses are accelerated. Creep in the steel increases, and the modulus of elasticity of the prestressing wires is reduced by about 20 percent when the temperature reaches 600°F (316°C). These losses reduce the carrying capacity of the member.

Another problem of prestressed concrete relates to thermal expansion. Because of the prestress in the design procedures, the compressive stresses near the top of a beam are less than those for reinforced concrete design. The thermal expansion of the concrete at the bottom of a beam can induce an upward movement, resulting in an initial failure opposite in direction to that normally assumed in collapses.

The type of steel used for prestressing is more sensitive to elevated temperatures than the steel used in reinforced-concrete construction. Not only is its strength reduced at temperatures somewhat less than those for hot-rolled steel, but also that strength is not regained after cooling. Prestressing wires are permanently weakened when they reach a temperature of about 800°F (427°C).

Wood

Depending on its form, wood may or may not provide reasonable structural integrity in a fire. The important factors that influence fire resistance are the physical size and the moisture content of the members. Fire-retardant treatments may be used to delay ignition and retard combustion. This provides time for extinguishing procedures. However, all wood will burn.

The burning of wood produces a charcoal on the surface at an average rate of about 1/40 in. per minute (0.6 mm/min). This charcoal provides a protective coating that insulates the unburned wood and isolates it from the flame, thus retarding pyrolysis. Therefore, thick members provide much more structural integrity over the period of fire exposure than do thin ones.

Heavy timber construction has proved to be an excellent form of construction. It maintains its integrity during a fire for a relatively long time, providing an opportunity for extinguishment. When the fire is extinguished relatively soon, much of the original strength of the members is retained and reconstruction is possible.

Glued laminated frames, arches, and beams have become increasingly popular. These members also provide reserve strength during a fire, and, if the layer is not deep, the char may be removed by sandblasting to restore the aesthetic appearance.

Wood-frame construction utilizes structural members considerably smaller than mill construction. The exposed area is greater, relative to mass, and the fire resistance considerably reduced. When this type of construction is exposed to a fire, it offers relatively little structural integrity. Therefore, protective surfaces, such as gypsum wallboard or plaster, are important to provide fire resistance. Lightweight wood trusses, due to their connection design, usually offer very limited integrity during fire exposure. Several related articles are referenced in Section 19, Chapter 1, "Types of Building Construction."

FIRE BEHAVIOR OF OTHER BUILDING MATERIALS

Many materials other than steel, concrete, and wood are commonly used in modern building construction. They frequently make up a large volume and/or surface area of the structure. Nonbearing partitions, insulation, building services, and finish materials are all important parts of building construction. Some of the nonstructural, thermally inert materials are used as fireproofing. Others may contribute significant fuel to a potential fire.

Glass

Glass is utilized in three common ways in building construction. The most obvious is glazing for windows and doors. In this capacity the glass has little resistance to fire. It quickly cracks because of the temperature difference between the surfaces. Double glazing does not provide much improvement. Wire-reinforced glass is an improvement, as it provides somewhat greater integrity in a fire if it is properly installed. However, no glazing should be relied on to remain intact in a fire. Ordinary annealed glass has minimal resistance to fire and will break at heat fluxes near or below that required for piloted ignition of ordinary combustibles like wood. Fully tempered glass can resist higher heat fluxes but will break if engulfed in flames.

Glass block and ceramic glass also provide some duration (45 minutes or more) of endurance against fire, although the reduction of heat transmission is limited. The test standard for such assemblies is NFPA 257, *Standard on Fire Test for Window and Glass Block Assemblies.* Only certain types of glass significantly limit heat transmission, such as a special double or triple layer glass with a clear gel between layers of glass. When exposed to fire, the gel becomes opaque, reducing radiant heat transfer in addition to conductive heat transfer. Such insulating glass has been tested in NFPA 251.

A second common use of glass in buildings is in fiberglass insulation. The fiberglass does not burn and is an excellent insulator. Glass fiber is often coated with a combustible resin binder. When used as an insulation, the amount of resin binder and resultant fuel load is such that the insulation is considered limited-combustible (see NFPA 220, *Standard on Types of Building Construction,* and NFPA 259, *Standard Test Method for Potential Heat of Building Materials*). Facings used as vapor barriers over glass fiber insulation, such as asphalt-coated kraft paper and some plastics, generally present more potential for fire spread than the insulation itself.

A third form in which glass is found in buildings is as reinforcement for fiberglass-reinforced plastic building products. The products include translucent window panels, siding, and prefabricated bathroom units. They have distinct advantages of economy and aesthetic appeal. The fiberglass acts as reinforcement for a thermosetting resin, usually a polyester. The resin, combustible even with fire retardants incorporated in the composition, frequently comprises 50 percent or more of the material. Although the fiberglass itself is noncombustible, the products are quite combustible.

Gypsum

Gypsum products, such as plaster and plasterboard, are excellent fire protection materials. The gypsum has a high proportion of chemically combined water. Evaporation of this water requires a great deal of heat energy, making gypsum an excellent, inexpensive, fire-retardant building material. A detailed description of numerous fire-rated assemblies using gypsum can be found in the "Fire Resistance Design Manual" by the Gypsum Association.

Lightweight Concrete

Lightweight concrete, made with noncombustible aggregates, resists high temperatures extremely well without degradation. Vermiculite and perlite are the most common types of light concrete used for this purpose. Vermiculite is an inert aggregate made from weathered mica. The mica is crushed and roasted, which causes it to expand to form pellet-like aggregates. Perlite is a volcanic rock that is crushed and heat treated. The heat treatment causes the rock to expand in volume. During the process, water vapor is absorbed by the rock particles, and the perlite takes the form of glasslike, cellular-structured particles.

Asbestos

Asbestos is a mineral fiber that historically had been used in several forms in building construction. It was used with a cementitious binder and sprayed onto structural members to form an excellent fireproofing agent. Asbestos was combined with portland cement to make asbestos cement products. Although these products are noncombustible, they often shattered during the temperature buildup of a fire, thus reducing their effectiveness. Asbestos was also combined with materials other than portland cement to form products such as asbestos insulation board and asbestos wood. These products behaved quite well in fires, providing a great deal of fire resistance and protection. However, because of health hazards during application, construction, occupancy, and demolition, asbestos products are now banned. Nevertheless, it is still found in older buildings undergoing renovation.

Masonry

Brick, tile, and concrete masonry products behave well when subjected to the elevated temperatures of a fire. Hollow concrete blocks may crack from the heat, but they generally retain their integrity. Brick can withstand high temperatures without severe damage. The fire resistance of masonry can be determined based on the type of aggregate used and the equivalent thickness of material.[19]

Plastics

There is a wide range of plastic products used by the building industry. They provide numerous aesthetic, physical, and economic advantages in building applications. Their major disadvantage is that all plastics are combustible. Although there are certain treatments that increase ignition temperatures or inhibit flame spread, there is no known additive that will make them noncombustible.

CONTEMPORARY TRENDS IN STRUCTURAL FIRE PROTECTION

There is an increased interest internationally in the development of more rational methods of structural fire design. These methods attempt to establish a theoretical base for the design of structural members and assemblies that will predict their actual fire performance more accurately than present methods. This section briefly addresses some of these modern trends. A more detailed discussion is provided in Section 19, Chapter 5, "Approaches to Calculating Structural Fire Resistance."

Usual Structural Design Procedures for Fire Conditions

The standard fire resistance test, combined with building code requirements that specify fire resistance ratings for structural frames and barrier assemblies, is the usual basis for structural fire design. The building code identifies building construction classifications based on materials and fire resistance requirements for barriers and structural framing members. The code relates these construction classifications with use groups, the building height and area, and adjustments for fire protection features. These code requirements for fire resistance are the subjective judgments of the code-writing groups.

The numbers and assemblies are laboratory tested in accordance with a standard fire test. This test is the equivalent to NFPA 251 or ASTM E119 for the jurisdiction served by the code. An acceptable design occurs when the test results exceed the code requirements. Although this procedure is common, its validity is subject to increasing doubts. The fire test itself is being severely criticized. In addition to the concerns identified earlier in this chapter, considerable variation can occur for the same assembly when it is tested in different laboratories. The relationship between test results and field performance is subject to debate. The code requirements have a weak technical base. The procedure, however, is relatively easy to administer from a regulatory viewpoint, and many other code requirements can be related to the form of construction anticipated by the fire resistance ratings.

Analytical Methods of Design

Research has been conducted along two different but related aspects of structural fire design.[20] Both attempt to provide rational analytical procedures for predicting structural fire behavior. One procedure is to develop analytical methods by which the fire resistance of a member or assembly may be calculated. The American Society of Civil Engineers (ASCE) and the Society of Fire Protection Engineers (SFPE) jointly developed ASCE/SFPE 29, *Standard Calculation Methods for Structural Fire Protection.* ASCE/SFPE 29 can be used for the calculation of fire resistance of structural elements. The calculation method computes the fire resistance that one would expect from the standard fire test. This method uses structural characteristics of the members, thermal properties of the materials, heat transfer characteristics of the assembly, mechanical properties of structural materials and compartment, and design service loads. This method enables the important considerations of structural restraint to be taken into account more easily than the standard fire test. This procedure is identical to the traditional design procedure, except that calculated fire resistance ratings are substituted for fire test ratings.

The provisions of the American Concrete Institute and the Masonry Society standard ACI 216.1/ TMS 0216.1 can be used to calculate the fire resistance of concrete and masonry elements

or assemblies. The two above references are acceptable to use for calculated fire resistance per the *NFPA 5000* building code.

Another approach to which considerable research effort has been devoted is an analytical design based on real fire-exposure characteristics. There are basically two methods in this approach. The first relates the time-temperature characteristics of real fires to the structural behavior at elevated temperatures. In connection with this approach, NFPA and SFPE have recently initiated two independent projects to establish fire loads for engineering design of structural fire resistance in buildings. The second method relates the properties of real fire development to an equivalent standard time-temperature curve. This method relates a theoretically equivalent time to experimental fire test results. It is important to understand that exposure fires estimated for the proposed occupancy will change with future occupancy changes.

Design Procedure

The Swedish Institute of Steel Construction publishes a design manual, entitled "Fire Engineering Design of Steel Structures."[21] A building designer has the option of designing the structural system in accordance with the traditional code or by the procedures described in the manual.

The manual describes a rational fire-engineering design process for steel structures on the basis of performance requirements. The manual consists of four parts. The first part is a relatively detailed description of fire energy impacts and structural behavior at elevated temperatures. This part provides the foundation for the design procedures. The second part presents the detailed design procedure. Design charts and curves which provide the numerical base are provided. Worked examples comprise the third part, and an alternate design method based on the concept of equivalent fire duration is given in the fourth.

The American Iron and Steel Institute (AISI) published *Firesafe Structural Steel, A Design Guide,*[22] for exterior structural members. Exterior members, of course, cannot be tested in the standard laboratory test. The guide provides a design procedure by which interior members can be designed for fire conditions. The design guide presents step-by-step procedures to arrive at a design. The basis for this design guide is *Design Guide for Fire Safety of Bare Exterior Structural Steel.*[23] Part One of the AISI guide presents the theory and validation of the method, while Part Two reviews the state of the art of relevant research programs conducted during the past 20 years.

The Prestressed Concrete Institute has published a procedure to analytically determine the fire resistance of prestressed concrete structures. This method is described in *PCI Design for Fire Resistance of Precast Prestressed Concrete.*[24] The method calculates fire resistance by obtaining temperatures at various locations for the various standard fire test times, using tables and diagrams based on test results. This information is then used to compute a fire resistance value.

SUMMARY

Two important considerations in designing for structural integrity of a building during a fire are the ability of the structure to avoid collapse and the ability of barriers to prevent the fire from spreading to adjacent spaces. Three approaches to structural frame and barrier design for fire resistance include (1) standard fire resistance testing and building code requirements; (2) analytical calculations to determine fire resistance; and (3) analytical structural methods based on real fire exposure characteristics. Currently, the first two approaches are accepted in building codes. Testing of structural assemblies determines the fire resistance rating, as well as the behavior of structural materials at elevated temperatures. Several methods are under development that would establish a more scientific base for the design of structural members and assemblies that will predict their fire performance under a broader range of conditions than the standard fire tests.

Chapter 3

Structural Fire Safety in One- and Two-Family Dwellings

Revised by
Kuma Sumathipala

Chapter Contents

Modern Construction
Construction Considerations for Fire Safety

Key Terms

construction (Type III), construction (Type V), dwelling, manufactured home, structural integrity

According to the 2003 American Housing Survey data, 76.4 percent of occupied housing units were in single-family attached or detached dwellings, including manufactured homes.[1] Another 8.0 percent were in buildings having two to four housing units. Therefore, one- and two-family dwellings can be estimated to represent approximately 80 percent of all occupied U.S. housing units in 2003. This chapter addresses the structural elements of one- and two-family dwellings as they affect the fire safety of the structure. Manufactured homes are also included in the discussion of one- and two-family dwellings.

This chapter does not cover the influence of interior finish or energy conservation measures, the hazards of building facilities (heating and electrical installations), or the role of detection, extinguishing, or egress systems as fire and life safety features. Those subjects are included in other chapters of this handbook. See Section 1, Chapter 2, "Fundamentals of Structurally Safe Building Design"; Section 8, Chapter 13, "Electrical Systems and Appliances"; Section 10, Chapter 2, "Heating Systems and Appliances"; Section 14, Chapter 6, "Household Fire Warning Equipment"; Section 18, Chapter 2, "Interior Finish"; Section 20, Chapter 6, "One- and Two-Family Dwellings"; Section 20, Chapter 7, "Manufactured Housing"; and Section 21, Chapter 6, "Recreational Vehicles."

MODERN CONSTRUCTION

Various types of construction are used in the design and building of one- and two-family dwellings. Specific requirements are dictated by state and local building codes and, in the case of manufactured homes, by federal regulation, via the Manufactured Housing Consensus Committee administered by the National Fire Protection Association. In general, most one- and two-family residential buildings are built of Type V (frame) or Type III (ordinary) construction, as defined by building codes such as *NFPA 5000®, Building Construction and Safety Code®,* the International Residential Code, and NFPA 220, *Standard on Types of Building Construction.* There are, of course, exceptions: some dwellings are erected of Type I (fire resistive), Type II (noncombustible), or possibly Type IV (heavy timber) construction.

Type V (Frame) Construction

The principal categories of Type V construction are (1) platform or western, (2) balloon, (3) braced, (4) plank and beam, and (5) veneer (a combination of one of the previous four with a facing wythe of brick, concrete masonry units, or stone on the exterior walls). The buildings may be constructed on foundations that consist of slab on grade or which incorporate basements, cellars, or crawl spaces. Geographical peculiarities or the needs of the owner generally dictate which foundation type is used. Where basements, cellars, or crawl spaces are provided, they play a distinct role insofar as residential fire safety is concerned, since heating, air-conditioning, and water heating equipment

Kuma Sumathipala, Ph.D., P.E., is the senior manager of fire technology of the American Forest & Paper Association, Washington, DC.

are often installed in these spaces, and this equipment can be an ignition source. These spaces are also often used for storage of combustible materials by building occupants. Roof framing can be either of rafter or trusses. Where trusses are used, interior bearing partitions might not be required.

Platform or Western, Balloon, and Braced Framing. This construction type is often referred to as stick-built. The basic difference among platform or western, balloon, and braced framing is the manner in which the floor, roof, and bearing walls are supported and/or erected.

In platform or western framing (Figure 19.3.1), which is by far the most common type of framing, walls made of studs nailed to top and bottom plates are set on top of the floor sheathing and joists, with the joists bearing on sills at the foundation level and on beams or partitions at intermediate locations. Platform construction combines safety for framers working on a building with inherent firestopping qualities once the walls are sheathed. In both balloon and braced framing, the stud-bearing walls are set on sills at the foundation level.

In balloon framing (Figure 19.3.2), the studs in exterior-bearing walls extend for two stories, with the joists supported by 1 in. by 6 in. (25.4 mm by 152.4 mm) ledger strips or ribbon boards at the intermediate level.* Early house construction was balloon framed. Unless firestopping is added, fire within the wall can easily spread vertically, since there are no top plates in the wall cavity. Fire originating in the floor/ceiling assembly can spread horizontally and eventually vertically through the walls.

In braced framing, the bearing wall extends for only one story, with joists at the second level of bearing walls bearing on 4 in. × 6 in. (101.6 mm × 152.4 mm) girths. In both framing types, the interior bearing partitions are erected in one-story heights.

Plank and Beam Framing. In plank and beam framing, a few larger structural members replace the more closely spaced smaller wood members used in typical wood framing. In other words, larger dimensional beams (4 in. × 10 in. or 5 in. × 12 in.) are spaced 4 ft or 6 ft on center. This arrangement is used rather than the standard floor and/or roof framing in which smaller dimensioned members such as 2 in. × 8 in. or 2 in. × 10 in. joists or rafters are spaced on 16 in. centers. The decking for floors and roofs is planking in nominal thicknesses of 2 in. or more, as opposed to ½ in., ⅝ in., or ¾ in. plywood sheeting. Instead of 2 in. × 4 in. bearing partitions supporting the floor or roof joist or rafter systems, the beams are supported by posts. Wood foundation walls are used for some homes, and crawl spaces can be utilized as return air plenums.

Veneer. The exterior wall finish of buildings of frame construction, except for masonry veneer, generally consists of stucco, wood, plastic siding, metal, or concrete siding over wood, foam plastic, or gypsum sheathing. Masonry veneer exteriors utilize one of the wood framing systems, with the addition of a wythe of masonry secured by metal ties to the wood frame exterior walls. Usually an insulating board of some type is provided between the studs and the masonry veneer. Although the exterior exposed surfaces can be of masonry, veneer construction is generally considered a combustible frame construction because the load-bearing members are usually wood.

*Nominal dimensions are used throughout this chapter. For comparison, 1 in. = 25.4 mm, 1 ft = 0.305 m, and 1 ft^2 = 0.0929 m^2.

FIGURE 19.3.1 Platform Construction

Steel Framing. Steel framing for residential building is becoming more widely used. Steel framing has many similarities to conventional wood framing classified as either Type III or Type V construction. Steel framing methods are available for stick-built (balloon or platform), panelized, and pre-engineered building types. Steel, like the exterior masonry walls of Type III construction, is noncombustible. However, unprotected steel loses its structural capacity under severe exposure to heat. Extensive testing has been conducted on steel-framed assemblies. The Steel Framing Alliance has compiled a summary of fire resistance testing of floor-ceiling, roof-ceiling, and wall assemblies utilizing combinations of metal studs and other building products, such as concrete, plywood, and gypsum wallboard. This compilation is available at http://www.steelframing.org.

Type III (Ordinary) Construction

The significant difference between Type III (ordinary) and Type V (frame) construction lies mostly with the construction of the exterior walls. Whereas in Type V (frame) construction

FIGURE 19.3.2 Balloon Framing

the load-bearing components of the walls are usually of wood, in ordinary construction the exterior walls are masonry or other noncombustible materials. The interior partitions, floor, and roof framing systems are of wood and, in general, utilize either the platform or braced framing methods previously described.

Manufactured Home Construction

The structural system of the manufactured home comprises four major components or subassemblies: (1) chassis, (2) floor system, (3) wall system, and (4) roof system. Manufactured homes are designed specifically to meet the requirements of an efficient assembly-line production.

The chassis, the structural base of the manufactured home, receives all vertical loads from the walls and floor and transfers them to a substructure of either the wheel assembly (when the home is in transit) or to a foundation (when the home is installed at a permanent site). The chassis generally consists of two longitudinal steel beams, braced by steel cross members. Steel outriggers cantilevered from the outsides of the main beams bring the width of the chassis to the approximate overall width of the superstructure. The running gear used when the unit is in transit is also considered part of the chassis.

The floor system consists of its framing members, generally conventional 2 in. × 6 in. or 2 in. × 8 in. (50.8 mm × 152.4 mm or 50.8 mm × 203.2 mm) wood joists, with wood structural panels glued and nailed to the joists, glass fiber insulation blankets installed between the joists, and an asphalt-impregnated insulation board sealing the bottom of the floor system. Ductwork and piping are installed longitudinally within the floor system, often requiring the cutting of the joists. The floor finish is generally carpeting or resilient flooring, such as linoleum or tile.

The wall system sometimes utilizes the stressed-skin principle and consists of an interior skin of wood structural panels glued and nailed to wood studs and an exterior skin of aluminum siding. The actual sizing of members is dictated by the structural loads. Often, however, conventional 2 in. × 4 in. (50.8 mm × 101.6 mm) exterior bearing walls are used.

The roof system consists of either a rafter and ceiling joist system or a wood truss system. Roof decking is generally a rigid insulation board attached to the top of the roof rafters or trusses. Finished roofing is galvanized steel, aluminum decking, or asphalt shingles. The ceiling is either acoustical planks or gypsum wallboard attached directly to the bottom of the ceiling joists or the bottom chords of the trusses. Insulation blankets provide the roof insulation. Steel tie plates reinforce connections between wall and floor systems; diagonal steel strapping binds the floors, walls, and roof into a complete unit.

CONSTRUCTION CONSIDERATIONS FOR FIRE SAFETY

One- and Two-Family Dwellings

A dwelling unit is defined as a one or more rooms arranged for complete and independent housekeeping purposes, with space for eating, living, and sleeping; facilities for cooking; and provisions for sanitation. A one-family dwelling unit is generally defined as a building that consists solely of one dwelling unit with independent cooking and bathroom facilities. A two-family

dwelling unit is a building that consists solely of two dwelling units with independent cooking and bathroom facilities.

In terms of size and occupant density, one- and two-family dwellings present lower overall occupant loads when compared to other building types. However, fire in single-family homes results in a significant portion of the overall life loss and injury statistics when compared to other building types.

Means of Escape. Some building regulation requirements concerning fire safety for one- and two-family dwellings differ substantially from those for other types of buildings. For example, depending upon certain conditions, single-family dwellings are required to have a primary means of escape that leads directly to the outside of the building. Single-family dwellings are also required, depending on certain conditions, to have a secondary means of escape. The secondary means is most often at least one escape window or outside door from basements with habitable spaces and from every sleeping room. Unlike office buildings, which require a certain number of means of egress, single-family homes require means of escape, which is a different egress concept.

Automatic Sprinklers. Building codes such as *NFPA 5000* limit the height of Type V unprotected one- and two-family dwellings that are not equipped with automatic sprinkler systems to two stories. The structural members in Type V unprotected construction do not possess any fire resistance rating.

Fire-Rated Separation. Within dwelling units, fire-rated separation between spaces is not generally required. However, attached garages are typically required to be separated from other parts of the dwelling by ½ in. (12.7 mm) gypsum wallboard on the garage side. In addition, doors to attached garages must be solid wood, steel, or 20 minute fire-rated doors. No door is permitted to connect garages and bedrooms. Within dwelling units, unrated gypsum wallboard, which is the most commonly used wall and ceiling material in the housing industry, affords a certain degree of passive fire protection.

Flame Spread Testing. The 2006 edition of *NFPA 5000* and the 2006 edition of NFPA *101®, Life Safety Code®,* no longer exempt materials less than 1/28 in. thick from flame spread testing. Wall and ceiling finishes must have a flame spread classification of not greater than 200. Wall and ceiling finishes must have a smoke developed index of not greater than 450. Testing must be done in accordance with NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials. NFPA 5000* prohibits the use of foam plastic materials unless they are tested in a full-scale fire test or fire test that simulates conditions of actual use. There is an exemption in *NFPA 5000* for the limited use of cellular or foamed plastic.

Building Codes and Regulations. Building codes require that, with the exception of windows, doors, and moldings, wall and ceiling finishes have a flame spread classification of not greater than 200. As stated above, as of the 2006 editions, *NFPA 5000* and NFPA *101* no longer exempt materials less than 1/28 in. (0.91 mm) thick from flame spread testing. Wall and ceiling finishes must have a smoke developed index of not greater than 450. Testing must generally be done in accordance with NFPA 255 or ASTM E84, *Standard Test Method for Surface Burning Characteristics of Building Materials.* Building regulations also place limitations on foam plastic insulation, such as requiring it have a flame spread classification of not greater than 75 and be covered with ½ in. (12.7 mm) gypsum board or other thermal barrier to retard ignition and flame spread.

The majority of one- and two-family dwellings are built of frame or ordinary construction. The physical nature of these construction types necessitates the addition of certain features that will inhibit the spread of fire. The combustible materials in the structural framework of these construction types, in conjunction with the presence of voids and concealed spaces, create conditions that can contribute to the propagation and migration of fire throughout the concealed spaces of the structure. These conditions are addressed in building regulations by the requirement for the installation of draft stops, fire blocking, and firestopping materials.

Fire Blocking and Draft Stopping. In wood frame construction, fire blocking is generally required in walls at ceiling and floor levels; at 10 ft (3.05 m) intervals, both vertically and horizontally; at interconnections between concealed vertical and horizontal spaces such as occur at soffits, drop ceilings, and cove ceilings; at concealed spaces between stair stringers at the top and bottom of the stairs; at openings around vents, pipes, and ducts at ceiling and floor levels; at chimneys and fireplaces; and at cornices of a two-family dwelling at the line of dwelling unit separation.

Draft stopping is generally required within all open-web floor and ceiling systems and between a suspended ceiling and the floor or ceiling above it, to reduce the size of the concealed spaces to not more than 1000 ft^2 (92.9 m^2). The spaces must also be divided into nearly equal areas.

Construction Contributing to Flame Spread. A 1977 study of fires in multifamily residential buildings of frame or ordinary construction revealed a number of built-in contributing factors to the spread of fire that may also be relevant to some one- and two-family dwellings:[2]

1. *The use of nonrated soffit materials, both combustible and noncombustible, and the use of soffit or eave vents.* These practices can allow fires that break through an exterior wall opening to spread into the attic or roof space by the flue action of the attic or roof ventilation system (Figure 19.3.3).

2. *Mansard roofs extending below the top-story windows with the windows recessed.* The soffit extending from the face of the window to the edge of the roof is typical of nonrated materials. In addition, the wall construction is not extended in back of the plane of the mansard roof, thus providing an interconnected void. A fire breaking through the window impinges on this soffit, burning through in a relatively short time and involving the attic and roof spaces.

3. *Unfirestopped penetrations of the gypsum wallboard partitions by plumbing, mechanical, and electrical work.*

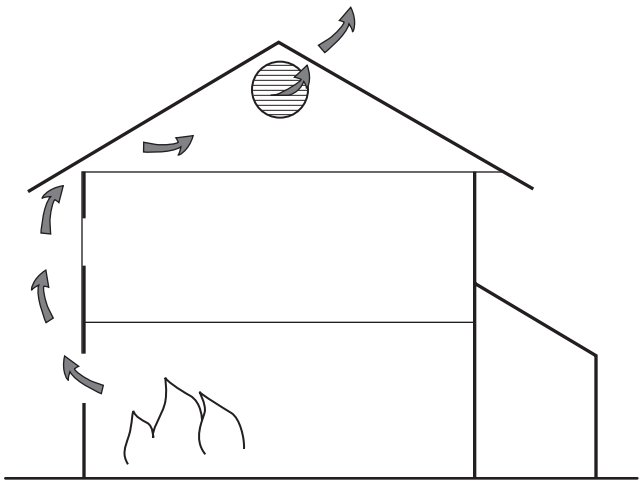

FIGURE 19.3.3 Attic Vents Under Eaves Presenting Serious Potential for Outside Extension of Fire into Attic Space

FIGURE 19.3.4 Soffits (arrow) over Kitchen Cabinets Connecting Wall Voids to Ceiling Voids, Permitting Fire Extension Both Vertically and Horizontally in Concealed Spaces

4. *The widespread use of wood-trussed roof and floor framing.* Such use precludes the need for the interior bearing partitions normally required where solid sawn joists and rafters are provided. Regulations typically required joists to be doubled under interior bearing partitions running parallel to joists and bridging to be installed under partitions running perpendicular to joists. This results in a minimum amount of firestopping of joist spaces. Current building codes compensate for this by requiring draft stopping of the trussed floor systems to reduce the spread of fire.

5. *Installing cabinets and other fixtures directly to stud framing, without an intervening protective diaphragm.* Such installation presents a situation where the only firestopping between a room fire and the concealed stud spaces are the materials that constitute the bottoms and backs of the cabinets or fixtures (Figure 19.3.4). This same practice exists in the installation of bathtubs or shower stalls.

Manufactured Housing

In 1999, manufactured homes constituted 6.6 percent of U.S. occupied housing units.[1] This share has generally been growing, as households sought more affordable housing in a rapidly increasing real estate market.

Over the years, the growth in popularity of manufactured housing was viewed with some concern within the fire service and the fire protection community, because manufactured homes were considered to pose a greater life safety risk than stick-built homes. In response to this concern, in 1976 the U.S. Department of Housing and Urban Development (HUD) promulgated "Mobile Home Construction and Safety Standards," later termed "Manufactured Home Construction and Safety Standards," which was then based on NFPA 501B, *Standard for Mobile Homes.* NFPA 501B has since been withdrawn and replaced by NFPA 501, *Standard for Fire Safety Criteria for Manufactured Home Installatinos, Sites, and Communities.* These standards have been amended several times to strengthen requirements for interior finish and firestopping and to identify acceptance criteria limiting the use of materials that generate smoke and gases more toxic than those produced by untreated wood.[3] Today HUD regulations depend heavily on the requirements in NFPA 501 and the recently published NFPA 225, *Model Manufactured Home Installation Standard.* In December 2000, the Manufactured Housing Improvement Act of 2000 (MHIM-2000) was passed by Congress. MHIM-2000 established a 21-person Federal Advisory Committee. This committee operates utilizing many of the principles for consensus standards development as outlined by the American National Standards Institute (ANSI). This Federal Advisory Committee has made numerous recommendations to the Secretary of the Department of Housing and Urban Development to improve both the quality and safety of manufactured homes. See Section 20, Chapter 7, "Manufactured Housing," for more discussion on fire and life safety of manufactured housing units.

SUMMARY

The structural elements of one- and two-family dwellings, including manufactured homes, affect the fire safety of those structures. Most one- and two-family residential buildings are of Type V (frame) or Type III (ordinary) construction, as defined in NFPA 220. Manufactured homes have four major components: chassis, floor system, wall system, and roof system. Building and life safety regulations concerning fire safety for one- and two- family dwellings differ from those for other types of buildings. Several factors may contribute to the impact of fires in one- and two-family dwellings, including attic vents, mansard roofs, unfirestopped penetration of gypsum wallboard partitions, wood-trussed roof and floor framing, and cabinets affixed directly to stud framing. Manufactured homes pose their own set of problems in relation to fire safety. However, standards established by HUD and NFPA continue to be updated to address these concerns.

Chapter 4

Analyzing Structural Fire Damage

Revised by
Stephen Pessiki

Chapter Contents

Building Types
Structural Systems
Evaluating Fire-Damaged Structures
Evaluating Damage to Specific Materials
Fire During Construction

Key Terms

building code, building collapse, construction (type of), fire resistant, lateral load, prestressed concrete, structural steel, vertical load, World Trade Center

This chapter addresses several factors that should be considered in evaluating the integrity of structures for safe use and occupancy after exposure to fire. Initially, the focus will be on evaluating structural systems and identifying the structural damage that may affect overall and local structural stability. Subsequently, special attention is directed to the techniques for evaluating the postfire strengths and weaknesses of basic building materials—that is, steel, concrete, masonry, and wood—in structural assemblies; the use of plastic materials is also discussed. Finally, unique problems of fires at construction sites are considered.

All structural materials, whether classified as combustible or noncombustible, inherently possess a degree of fire resistance. However, they are adversely affected when exposed to elevated temperatures during a fire. The degree of damage varies with the different materials and building configurations. Where there is no visible cosmetic damage to the building after a fire, such as glass breakage, concrete spalling, or steel distortion, there is little chance of serious damage, although this is no guarantee. Thorough inspection is necessary to verify that no further damage has occurred due to the effects of excessive expansion, contraction upon cooling, and hidden deterioration. A building that is deemed safe for occupancy requires that the structural system and all its individual elements and their connections are able to safely support the structure's weight, contents, and environmental loads.

Other chapters in this handbook address structural fire protection and provide necessary background information. For topics related specifically to this chapter, see the following chapters: Section 11, Chapter 4, "Fire Hazards of Construction, Alteration, and Demolition of Buildings"; Section 18, Chapter 1, "Confinement of Fire in Buildings"; Section 19, Chapter 1, "Types of Building Construction"; Section 19, Chapter 2, "Structural Integrity During Fire"; and Section 19, Chapter 5, "Approaches to Calculating Structural Fire Resistance."

BUILDING TYPES

As discussed in Section 19, Chapter 1, building codes classify buildings by types (I, II, III, etc.) according to fire resistance. In general, the fire resistance of the construction varies from the most fire resistant for Type I to the least fire resistant for Type V. Though this classification system is useful in codifying levels of fire resistance, other more descriptive nomenclature could better differentiate a structure's performance during and after a fire. One would be better served by a more comprehensive system for identifying structures subjected to fire.

The text *Building Construction for the Fire Service*[1] discusses various aspects of the following construction and building arrangements:

1. Wood
2. Ordinary
3. Garden apartments

Stephen Pessiki, Ph.D., is professor of structural engineering and chairman of the Department of Civil and Environmental Engineering at Lehigh University in Bethlehem, Pennsylvania.

4. Steel
5. Concrete
6. High Rise

Each has unique characteristics relative to its susceptibility to fire damage and to the challenges that it presents to fire fighting. Here one can begin to appreciate that the fire performance of two structures built of the same construction type can differ—for example, a convention center versus a high-rise building, both of Type I construction. Differences in various building construction types are addressed in this book.

Dunn's book, *Collapse of Burning Buildings,*[2] addresses the collapse hazards of the five standard types of constructions when exposed to fire, but the work also expands to cover the following:

- Masonry wall and parapet collapse
- Wood floor collapse
- Wood roof collapse, including peaked, flat, and timber truss types
- Lightweight steel roof collapse
- Ceiling collapse
- Stairway and fire escape collapse
- Wood frame building collapse

This text is another comprehensive guide for building performance during and after a fire. The collapse types that Dunn covers are those that have caused the majority of fire fighter casualties in the recent past.

ATC-20, *Post Earthquake Safety Evaluation of Buildings,* and its companion Field Manual, ATC-20-1,[3] present a state-of-the-art guide for evaluating structures after devastating earthquakes. ATC-20 provides detailed guidance for evaluating various combinations of materials in structural types as indicated in Table 19.4.1 and addresses unique structural damage patterns. These structure types were originally presented in ATC-21, *Rapid Visual Screening of Buildings for Potential Seismic Hazards,*[4] and are referenced in NFPA 1670, *Standard on Operations and Training for Technical Search and Rescue Incidents,* Annex C.

It should be understood that some buildings may have structures that have elements of more than one category, such as wood buildings that are braced with shear walls and steel frames, or steel frame buildings with moment frames and diagonally braced frames. Also, the category URM usually indicates structures with exterior masonry walls and wood framed floors (ordinary construction).

The ATC-20-1 Field Manual has been especially helpful in enabling engineers to provide more consistent postearthquake evaluations since its introduction in 1989 (just prior to the Loma Prieta earthquake). Much can be learned from its systematic approach in providing guidelines that help differentiate between "significant" and "acceptable" degradation of structural systems when subjected to severe environmental loading. ATC has also published *Field Manual for Post Flood and Windstorm Safety Evaluation of Postal Buildings;* but, unfortunately, no similar publication is available to aid in postfire building evaluation. The authors strongly recommend that those involved in evaluating buildings after any type of event that could cause degradation should become familiar with the ATC-20 methodology.

TABLE 19.4.1 Combinations of Materials in Structural Types

Structural Type Identifier	*General Description*
W	Wood buildings of all types
S1	Steel moment-resisting frames
S2	Braced steel frames
S3	Light metal buildings
S4	Steel frames with cast-in-place concrete shearwalls
C1	Concrete moment-resisting frames
C2	Concrete shearwall buildings
C3/C5	Concrete or steel frame buildings with unreinforced masonry in-fill walls
TU	Tilt-up buildings
PC2	Precast concrete frame buildings
RM	Reinforced masonry
URM	Unreinforced masonry

STRUCTURAL SYSTEMS

Every building has some sort of a vertical and lateral load resisting system. Even though these systems may be poorly organized and difficult to determine, the essential first step in evaluating any structure is to define and assess the competency of these systems.

Vertical Load Resisting Systems

Vertical load resisting may be described using a plumbing analogy. Building loads derived from component weights, contents, occupants, and so on are collected by the smallest members in the horizontal planes, then collected by beams, and finally delivered by columns to the foundation. The connections of all components are required to competently transfer the loads. The failure of any member or its connection can cause a collapse.

Vertical load resisting systems may be framed systems consisting of a coherent system of beams and columns. They may also be unframed systems that have some beams and columns, but with bearing walls that provide most of the vertical support. The size of the collapse will be determined by the importance of the member or members that are compromised. In general, a framed system has a greater potential for a larger collapse. These easily understood concepts sometimes become lost in the chaos of a disaster situation.

Lateral Load Resisting Systems

Lateral load resisting systems (LLRS) may not be as apparent upon examination of a structure. They can be described using a "pushover" analogy. The structure must have elements and interconnections that will transfer lateral loadings, acting in any horizontal direction, into the foundation system. Without a competent system, the structure will rack; that is, rectangular spaces will become parallelograms, and possibly collapse to the

ground. LLRS can be categorized as one of the following three types, or a combination of types:

1. Box buildings
2. Moment resistant frames
3. Diagonally braced frames

Box Buildings. The majority of buildings are box-type structures. They maintain their stability by having horizontal (roof and floor) planes that need to be strong, relatively rigid, and well interconnected. Plywood or solid wood diagonal sheathing on roof/floors usually performs this function in modern wood structures. Less desirable materials, such as parallel wood sheathing or decking, may be found in older and/or more poorly braced buildings. The floor sheathing provides lateral stability to joist and beams as well as transferring lateral forces to the walls. Wall sheathing, if adequately connected to the floors and wall structure, will keep the structure from racking as it transfers the forces to the foundation. The term *shear wall* is used to describe a wall that has this ability to prevent racking, which may also serve as a bearing wall. Again, plywood and diagonal wood sheathing are the most desirable sheathing types; but wallboard, plaster, and parallel sheathing may be the only type found on walls in marginally braced buildings. Box buildings may also be constructed with concrete or masonry shear walls/bearing walls. Also, floors of concrete or concrete-filled corrugated steel decking are normally strong enough to act as "floor diaphragms."

Moment Resistant Frame Structures. Moment resistant frame (MRF) structures are usually constructed using steel or reinforced concrete. The frames provide both vertical and lateral resistance. MRF structures require a competent floor plane (diaphragm) for lateral stability and load transfer. As previously stated, this is easily provided by a concrete or concrete-filled steel floor system. The interconnection of beam and column is the most critical feature of the MRF, since, in order to resist the repeated loading during high winds or earthquakes, the joints must exhibit great toughness and ductility. Prior to the 1970s, few concrete structures were capable of the required ductile performance. The 1994 Northridge earthquake demonstrated that the then standard welded joints did not possess the required ductility to reliably transfer severe earthquake stresses.[5] One needs to be aware of these difficulties when evaluating MRF structures after a severe fire. It is possible that connection damage caused by expansion or contraction forces could be hidden by fireproofing.

Diagonally Braced Frame Structures. Diagonally braced frame structures are similar to MRF, except that diagonal steel braces are strategically placed between columns to prevent racking by acting similarly to shear walls. In most occupied buildings, where rigidity is important, the diagonals are proportioned to resist both tension and compression forces. The toughness and rigidity of the diagonals and their connections are very important. Again, these members may be subjected to expansion or contraction damage during a prolonged fire.

In light industrial buildings, thin rods or small angles capable of only tension resistance are used as diagonal braces. They need to be configured as "X" bracing and need competent connections to function properly.

EVALUATING FIRE-DAMAGED STRUCTURES

Evaluation of structural damage to buildings following exposure to fire needs to be undertaken at any one or at all three time periods in the fire episode. The first would take place while the fire is still in progress, the second immediately after the fire, and the third somewhat later when the structure has been stabilized. The urgency and focus of an evaluation would be different in each of these conditions. Fire fighter safety is paramount in the first instance; public safety, including the protection of adjacent structures and their occupants, is the focus in the second; and safety issues involving long-term occupancy is the main consideration of the final, more detailed evaluation.

When considering damage incurred from fires, one must take into account deterioration of structural elements that accompanies normal aging. Wood is subjected to shrinkage/drying effects, rotting due to wetting/drying cycles, animal and insect infestations, corrosion of fasteners, and the effects of poor repair and maintenance practices. Steel may have deteriorated because of inadequate corrosion protection or thermal insulation.

Evaluation During a Fire

The primary purpose of evaluation during a fire is to ascertain whether it is safe for fire fighters to conduct control operations in or near the fire-involved building. Fire unit commanders need to quickly assess the risk of entry versus the likelihood of saving lives and property. Obviously there needs to be a different calculation for each. In some instances, such an early and preliminary evaluation can also be helpful in determining the necessary strategy for fighting the fire. As with all stages of structure evaluation, identification of building type along with vertical and lateral load resisting systems should be done immediately. Assessment should then be made based on a systematic approach to the problem. In some cases the choices may be very limited, as was the case in the 1991 fire at One Meridian Plaza in Philadelphia. There, based on inadequacy of available water supply, the decision was made to withdraw fire forces, with the result that the fire burned through ten floors prior to being controlled at an upper floor by sprinklers.

In noncombustible and significantly fire-protected structures, the decision to enter may be made with greater confidence than is the case in other buildings. Structure collapse is usually not an immediate problem. However, in the case of steel frame structures, thermal expansion may cause very high stresses in floor beams that are restrained by shear walls or diagonal braces. In addition, expansion in unrestrained floor systems can cause the enclosing walls to become dangerously out of plumb. Thermal expansion and material degradation may also cause damage to both cast-in-place as well as precast concrete structures.

At the opposite end of the spectrum, wood buildings, especially those with small member roof framing and trusses, provide the conditions that can lead to a collapse in minutes. Since these structures are relatively small and common, their performance

should be well understood by most fire-fighting units. An NFPA review examined 69 incidents from 1985 through 1997 involving fire fighter deaths or injuries as a result of roof or floor collapses in wood frame buildings. Although the data being used were anecdotal rather than statistically representative or comprehensive, the report illustrates failure modes that have been reported. A number of the cited cases involved fires in attic spaces, where the structural elements can be directly exposed to fire.[6] It should be noted that most sloped, roofed wood structures with flat ceilings are framed with some sort of wood truss. These trusses may have been constructed in place in older structures or prefabricated using metal plate connectors in more modern ones, but all present a difficult problem for fire fighting.

Structures with Timber Trusses. Timber trusses have been constructed in the United States for more than one hundred years. They are a very efficient way of spanning large spaces. Most roof trusses have some sort of a sloped, top compression member (upper chord), a level, bottom tension member (lower chord), and a series of interconnected diagonal tension or compression members (webs). Flat roof and floor trusses usually have parallel upper and lower chords connected by the webs, and some sloped roof trusses (scissors trusses) have sloped bottom and top chords. Prior to the advent of the glued laminated beam in the early 1950s, large timber trusses were used in industrial and commercial structures to span up to 100 ft (30.5 m) and more, spaced 16 to 24 ft (4.9 to 7.3 m) apart, with wood joist infilling members. These trusses were configured in a bowstring shape, or had partly sloped and partly near flat upper chords that were interconnected with steel plates and bolts (strap and pin) or diagonal steel rods and vertical wood posts (rod and block). The lower chords in these trusses are most critical since they are highly stressed in tension and interconnected by bolts. Due to normal defects in sawn timber, these bolted connections may deteriorate with time, especially in hot attic spaces. They may be a disaster waiting to happen when exposed to fire, and they should be approached with extreme caution when fire-fighting tactics are considered. A single lower chord failure could result in a large collapse. Fortunately, these trusses are limited to older buildings. The informed observer should be able to easily recognize structures with these trusses.

Structures with Light Timber Trusses. Light timber trusses, spaced from 2 to 4 ft (0.6 to 1.2 m) on center have also been constructed for more than one hundred years. Since the 1960s, with the advent of the metal plate connection, they have been engineered using very small wood members for maximum economy. As roof trusses, they are often configured with a sloped top and a flat bottom (A trusses) or may be made as scissors trusses. When intended for floors or flat roofs, parallel chord trusses are used. Some parallel floor and roof trusses may use a combination of wood chords and tubular metal webs.

Unfortunately, the attributes that make light timber trusses economical and efficient construction elements can lead to sudden, catastrophic collapse during a fire. This type of construction has the undesirable properties of highly stressed, small, easily consumed wood members that are placed in concealed spaces where fire may grow and spread between members. Collapse can and has occurred within minutes. NFPA: Alert Bulletin #97-1 of the NFPA Fire Investigations Department states that 30 fire fighters were killed in 16 incidents involving wood trusses from 1977 to 1995. Before planning interior operations in wood structures, one must identify the type of roof and floor structures. It is most difficult to determine the presence of floor trusses, but it should be assumed that any building with a sloped roof and flat ceiling is framed with trusses until determined otherwise.

Heavy-Wall Buildings. Heavy wall buildings can present some difficult and dangerous problems for fire fighters, during and immediately following a fire. These buildings are characterized as structures that are surrounded by masonry or concrete walls and are framed with wood roof/floors, and include ordinary, URM, tilt-up, and various other classifications. Since the walls usually act to confine the fire, the roof and floors can rapidly lose strength and collapse. Older buildings have the potential of containing deteriorated wood members, and newer, long span structures have the potential for a large area collapse. Both conditions can lead to a sudden entrapment of fire fighters. The 1999 Worcester, Massachusetts, cold storage building fire is a tragic example of the catastrophic performance of this type of structure.

In some cases, masonry walls, even with "fire cut" ends (i.e., ends cut at an angle to allow the floor beam to collapse without levering the masonry wall over) on wood members, have been pulled in by the collapsing floors with lethal results. The potential for this type of collapse is even greater in the western United States earthquake regions, by the practice of mechanically tying masonry and concrete walls to the roof and floor structures to limit wall collapse during seismic events. Also, walls can be forced outward by the ladder-type forces generated when an interior collapse results in large floor or roof sections being angled up against the wall. As discussed earlier, structures of this type, built prior to the 1950s, may have large, long span roof trusses, with their associated risk of sudden collapse. For more information on assessing the potential for building collapse during a fire, see *Structural Fire Fighting*.[7]

Initial Postfire Evaluation

Depending on the severity of the fire, the number of victims, the type of collapse, and so on, the authority having jurisdiction (AHJ), fire chief, or building official may require that a recovery and stabilization operation be conducted. This is the essential first postfire requirement. In cases where building departments normally have jurisdiction over certification of whether a building is safe for occupancy, there will be instances in which the necessary technical competence and experience to conduct a postfire investigation is not available within such agencies. In such cases appropriate expert consultation must be engaged.

In cases where roof and/or floor burnout have occurred, the remaining unsupported structures may require stabilization. The public way and adjacent, occupied structures must be protected, since heavy, freestanding exterior walls can collapse due to high wind forces. If major supporting elements have been weakened or if parts of the structure have become misaligned,

the building must be stabilized. The vertical and lateral load resisting systems need to be identified, and significant degradation needs to be addressed. A careful, well-documented, step-by-step evaluation should be performed. The investigator needs to identify and assess all structural systems and provide an adequate load path of resistance for all probable environmental loadings, including wind, water, and snow. To accomplish this, shoring may need to be constructed and/or safety evaluation and monitoring may be required. If the fire has produced trapped victims, recovery operations must be allowed to proceed safely and carefully. In addition, fire investigators also need time to do their essential work in a reasonably safe environment. All these operations may need to be performed prior to allowing the owner's engineer and insurance investigator access. This may appear to impede their investigations, and may cause complaints to be filed. However, safety should not be compromised at this time. If local fire and building officials do not have the necessary technical competence and experience to conduct the recovery operations or the postfire investigation within their agencies, it is imperative that expert help and consultation be engaged. This help may be available from federal, state, or local sources. The Federal Emergency Management Agency (FEMA) Urban Search and Rescue (US&R) system has developed coherent emergency shoring systems that are being taught to US&R teams throughout the United States. The U.S. Army Corps of Engineers, through its Readiness Support Center in San Francisco, California, has published *Structure Specialist Field Operations Guide,* which includes information and step-by-step procedures for constructing this emergency shoring. It also includes other information useful during rescue situations. The FEMA US&R system can also provide assistance. This system is composed of 28 locally based task forces made up of individuals with special search, rescue, engineering, communication, and medical skills (Figure 19.4.1).

CASE STUDY: Oakland, California. Following the 1992 firestorm in Oakland and at the request of the California Office of Emergency Services, a structural evaluation performed just prior to final search and recovery operations at a multibuilding apartment project. The original three-story wood apartment buildings, built over one-story concrete parking garages, had burned down to a deep pile of debris on top of the concrete structure. The parking structure was partly subterranean, and it was observed that large cracks had developed in the longitudinal, spaced shear/bearing walls of the 150 ft (46 m) long structures. The 10 in. (250 mm) thick slab was still warm to the touch a week after the fire. It was most probable that thermal expansion had caused the cracking in the restraining walls, but that the damage was not severe enough to preclude the recovery operation. Since the search could be completed within 4 hours, the risk of a major earthquake that could further compromise the walls was judged to be minimal. There was no possibility of live recovery, but there was little risk to search dogs and handlers, especially after formulating a good escape plan.

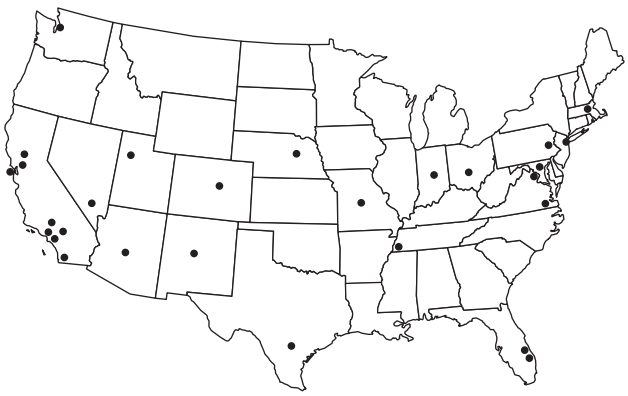

FIGURE 19.4.1 Location of the 28 FEMA US&R Task Forces

CASE STUDY: Worcester, Massachusetts. Immediately after the 1999 Worcester cold storage building fire, search and engineering elements from the FEMA Massachusetts US&R Task Force I (MA-TF-1) were dispatched to aid the Worcester Fire Department with the recovery operations involving six missing fire fighters. The search element included teams of canines with handlers that were experienced in forensic and cadaver search work. They were instrumental in locating all six victims.

The engineers deployed by MA-TF-1, known in the US&R system as structure specialists, provided initial analysis of the six-story high, unreinforced masonry walls. They then developed a safety strategy for the weeklong recovery operation that included 24 hour monitoring of the walls and the wind speed. Recommendations for safe deconstruction of the structure to aid recovery efforts were also provided by rigging experts from the task force.

CASE STUDY: Sacramento, California. In early 2001, structure specialists from the Sacramento US&R Task Force 7 provided initial evaluation of the fire hazard when a large truck rammed the state capitol building while the legislature was in session. Fortunately, in this case, there was only one casualty, the truck's driver.

Postfire Building Evaluation and Reoccupancy

Most often, inspection and evaluation of fire damage would be undertaken immediately after the fire department has extinguished the fire and declared the building stable and able to safely support an engineering investigation. There is a tendency for owners to quickly remove fire debris from the scene and thereby disturb evidence of interest in damage assessment. For this reason it is necessary that cleanup and repair operations be carefully monitored and controlled while the investigation of fire damage is underway. Some aspects of the fire damage evaluation process require that certain transient conditions regarding fire deterioration of materials and the loss of strength be allowed

to take place prior to the initiation of detailed study. This is particularly true in the case of estimating residual strength of concrete materials, which may undergo cracking, calcination, layering, and discoloration in the weeks following exposure to fire temperatures.

It should also be noted that the work and reports of engineers engaged in the assessment of fire damage will often be of interest in litigation following severe and high-loss fires. For this reason, the methodology for conducting inspections, testing, and the manner of reporting should, as a minimum, follow the evaluation procedures outlined in ATC-20, and a report should be written that documents all observations made by the investigator and any physical tests that are performed. Owners or their insurance companies will normally pay for the reports and choose the engineer. However, tenants or their legal representatives, and even the local building official, may also be involved in the selection process.

A detailed engineering study will be necessary to determine the parameters for repair and/or partial replacement of the building. Damage to vertical and lateral load resistant systems as a whole, as well as to individual members, will need to be assessed and carefully tabulated. The determination of significant degradation versus cosmetic damage requires well-informed engineering judgment. A qualified professional engineer specializing in structures should conduct the evaluation, since the influence of distortion and residual stresses may have a significant negative effect on parts of the structure. Prudence and legal liability concerns may cause engineers to err on the conservative side. Insurance interests and the owner's needs for reoccupancy may argue for a greater acceptance of partly damaged structural elements. This natural conflict should be anticipated, and it may need to be emphasized that, since the building is being renewed at least in part, it needs to be at least as safe as in its prefire condition or satisfy current code requirements.

If a significant percentage of the structure needs to be rebuilt, the entire building may be required to meet current building codes. Some building codes, such as *NFPA 5000®*, *Building Construction and Safety Code,* specifically address building rehabilitation and include provisions for damaged and unsafe buildings. More specifically, Chapter 15 of *NFPA 5000®* indicates that where the structure of a building is damaged, an evaluation is to be conducted to determine whether such damage is substantial as defined by the code, and whether the building was structurally unsafe prior to the damage. *NFPA 5000®* determines that a building has substantial damage when either:

(a) The total strength of a structural element or group of elements, supporting more than 30 percent of the structure's vertical loads has been reduced by more than 25 percent from the pre-damaged condition, and the remaining capacity with respect to all dead and live loads is less than 75 percent of that required by this Code, or
(b) The combined lateral strength of resisting structural elements in any story has been reduced by more than 20 percent from the predamaged condition.

Depending on the degree of damage and the determination as to when the damage occurred, the building structure is to be restored to either conditions prior to the damage or into compliance with the Code. As indicated by the description of unsafe buildings in *NFPA 5000®*, the damage or unsafe structural condition can result from a number of events, including fire, explosion, wood-destroying pests, winds, earthquake, vehicular impact, or ground subsidence.

Some building codes might have requirements for "abatement of dangerous buildings" that are less restrictive than *NFPA 5000®*. Buildings that are significantly damaged by fire are considered dangerous. It should be noted that local building officials have considerable discretion in applying abatement requirements. Changed zoning requirements and economic considerations may also influence reconstruction. In some codes, buildings may be reconstructed according to prior regulations, providing the cost for renovation does not exceed a given percentage of the original cost.

Historic buildings may be treated somewhat differently. Many historic buildings do not meet current codes, and if significantly damaged by fire, they may not be able to be economically upgraded to current code requirements. Chapter 15 of *NFPA 5000®* has specific provisions that address historic buildings and structures. As a result of what preservationists considered unnecessary demolition following earthquakes, a guidebook, *Temporary Shoring and Stabilization of Earthquake Damaged Historic Buildings,*[8] was developed in 1998. It discusses the difficult issues facing local building, emergency, and other governmental officials regarding the saving of damaged historic buildings.

Finally, cooperation with the fire department is essential to establish the path and progress of fire, including the method of extinguishment. It may be possible to establish maximum temperatures reached during the fire by examining debris from melted material and by inspecting structural members for spalling, cracking, discoloration, deflection, and so on. The influence of temperature on the mechanical properties of structural materials raises the question of the usability of the material after it has cooled down to ambient temperature. The evaluation of the structural behavior of steel, concrete, masonry, and wood is described in general in the following section. A more detailed evaluation procedure and a case study of renovations is given in Chapters 12 and 13 of *A Complete Guide to Fire and Buildings.*[9]

EVALUATING DAMAGE TO SPECIFIC MATERIALS

Design of Structures Against Fire[10] contains useful information on the behavior of common building materials, including structural steel, reinforced concrete, and wood, when exposed to high temperatures. Of interest in this same publication is information on repair of fire-damaged structures that includes an assessment procedure for fire-damaged structures and a visual damage classification system for reinforced concrete elements. Also of interest to the fire investigator is the ASCE publication, *Guidelines for Failure Investigation.*[11] Here, the organization and details of postfire examinations are outlined in enough detail to better suit the rigors of forensic inquiries. NFPA 921, *Guide for Fire*

and Explosion Investigations, is also a useful resource in this regard.

Structural Steel

Thermal and mechanical properties of steel are given in ASCE's manual of practice, entitled *Structural Fire Protection.*[12] This publication presents information on the modulus of elasticity at elevated temperatures, stress-strain curves for structural steel at various temperatures, and deformation properties. Most important for evaluating load-carrying capacity following exposure to fire is the loss of strength suffered as temperatures rise from about 212 to 1292°F (100 to 700°C). Steel loses significant stiffness above 600°F (316°C) and loses significant strength above 1000°F (538°C). A second factor that influences the behavior of steel during fire incidents is the coefficient of thermal expansion, which increases with increasing temperatures and reaches a value of approximately 0.008 in./in. at a temperature of 1112°F (600°C).

The use of several grades of steel in buildings and bridges is accepted in modern building codes and design standards. Although different grades of steel have a wide range of strengths, tensile and yield strengths of all steel grades are similarly affected by the temperatures that may be expected in building fires.

The behavior of beams or other members subject to bending stresses under fire conditions is complex (Figure 19.4.2). In a building fire, the steel temperature may vary considerably over a single cross section, as well as along the length of a structural member. Information relating to the strength properties of steel at elevated temperatures has been derived from the results of tests on small specimens heated so that the entire specimen was at or close to the measured temperature. Conclusions relating to strength characteristics from such small-scale tests may not be applicable to steel structural members. Moreover, plastic action results in the redistribution of stresses in steel members that are loaded close to the design limit. This characteristic permits steel members to sustain loads greater than those calculated to be safe on the base of yield strength alone; therefore, the strength of a given steel member cannot be determined only from isolated temperature data.

FIGURE 19.4.2 Unprotected Steel Damage on Floor of Office High Rise with Minimal Fire Load but Extensive Loss

In a building fire, parts of the structure may have been exposed to heating followed by abrupt cooling by water from hose streams. This temperature change is usually less severe than what accepted practice allows in heat-treating of steel during manufacture. Tests performed on structural steel specimens taken from buildings that experienced fire during and after construction have indicated that yield strengths did not drop below the specified minimums. However, when a postfire test is compared with the original mill tests, one can find that the original yield strength, usually at least 10 percent above minimum, has dropped to the minimum value. This can be explained as a loss in the nominal gain in strength that occurs during the rolling process. The members that exhibited scorched paint will most often suffer this loss. It then becomes the responsibility of the investigating engineer to determine if the loss is significant. Steel members that show some distortion due to heat, but that can be straightened, should have their physical properties thoroughly evaluated. Connections between members should also be examined for cracks around fastener holes and welds.

Occasionally, steel exposed to a fire will have a somewhat roughened appearance due to excessive scaling and grain coarsening. The coarsening is caused by exposure of steel to temperatures around 1600°F (870°C) or higher. The steel will usually have a dark gray color, although other colors may be present if certain chemicals have been involved in the fire. Steel so modified is commonly called "burnt" steel. Members that have become burnt will usually be severely corroded as well, and their suitability for further use is a matter for individual judgment. The FEMA Report 403, "World Trade Center Performance Study,"[13] Appendix A, presents a detailed discussion on the effects of fire on steel structures. The NIST report on the collapses of the World Trade Center towers also includes an analysis of the structural fire response of steel.

Protective Coating on Structural Steel. Excluding other factors that affect fire growth, such as extinguishing systems, low fire loads, compartmentalization, and so on, damage to structural steel members may be minimized by application of protective coatings that provide a period of fire resistance. Generally, a mineral fiber or cementitious mixture is applied by spray application; however, the adherence and durability of such coatings, even under normal circumstances, has been the subject of some concern. Too often, questionable application resulted in unreliable fire resistance and subsequently, considerable structural damage. The absence of protective coatings over even relatively small areas of the flange or web of steel beams and columns can have a dramatic impact on the structural fire behavior of these elements.[14,15] The local heating of the structural steel at the exposed location can reduce the resistance of the beam or column. In contrast, even a small remnant thickness of protective coating can significantly improve the behavior of the structural element as compared to bare steel (Figure 19.4.3).

A large fire in a 50 story office building known as One New York Plaza occurred in 1970 in New York City and resulted in three fatalities. Much of the $10 million in physical damage

FIGURE 19.4.3 Large Unprotected Steel Girders Damaged Beyond Repair, Illustrating Vulnerability of Steel in a Fire

arose from failure of sprayed-on thermal insulation. This incident was instrumental in the passage of New York City's Local Law Number 5, which is a comprehensive approach to improving life safety in high-rise office buildings.

Sprayed-on protective coverings can be expected to be easily dislodged during fire-fighting and overhaul operations. Usually problems of this kind are easily detected, but a complete examination of the structure must be made to determine the extent of damage. Also, before occupancy is permitted, it is imperative to determine that fire damage to a specific section of a building does not impair the integrity of zones of safety, means of egress, and smoke towers, or the operation of fire doors, fire dampers, or other protective devices or systems in areas not damaged by fire.

Fire Tests. The principal fire test used to establish fire resistance for structural elements is NFPA 251, *Standard Methods of Tests of Fire Resistance of Building Construction and Materials,* or its ASTM equivalent, ASTM E119, *Standard Test Methods for Fire Tests of Building Construction and Materials.* In using test results, however, it is essential that architects and design engineers look closely at differences between standard test conditions and potential fire conditions the structure may be exposed to. Only with such a review can accurate and safe conclusions be drawn about the performance of a building design. At best it is a destructive comparative test with little relation to actual fire conditions.

For fire-resistive purposes, many floor/ceiling and roof/ceiling assemblies are considered as a single fire-resistive element. The ceiling by itself does not provide a specific fire resistance rating. It should be noted that many floor or roof and ceiling tests provide an assembly rating, as well as a beam rating. The beam rating should not be interpreted as a measure of protection afforded by the ceiling. Unfortunately, if the ceiling membrane does not provide fire resistance, structural components above the ceiling are subject to damage in a fire.

Cast Iron. The use of cast iron as structural material has all but ceased. If found, these buildings are undoubtedly archaic historical preservations. A number of such buildings may still be found in New York City and elsewhere. In some instances, only the facades are of cast iron; in other cases, both the structural elements and facades are of this material. The behavior of cast iron when exposed to fire temperatures is substantially different from that of steel. Cast iron exposed to temperatures of 800°F (427°C) will deteriorate and fracture if struck with water from a fire hose.

Concrete

In a fire lasting 1 to 2 hours, concrete will generally suffer only moderate damage, so routine cutting and patching procedures will usually be adequate for repairs. In intense and long-lasting fires, such as those that may occur in large, heavily stocked warehouses and department stores, severe damage to concrete may occur. Restoration may entail the removal of severely damaged areas and patching in areas less severely damaged. Experienced engineering judgment is required for evaluating the residual strength of those areas that are somewhere between moderately and severely damaged. An example of one approach to the problem of evaluating the residual strength of apparently marginally damaged concrete structural units can be found in the article "Prestressed Concrete Resists Fire" by Zollman and Garavaglin.[16]

Damage Analysis. Over the past two decades much progress has been made in the improvement of methods for analysis of properties and behavior of concrete exposed to elevated temperatures. Better understanding of the fire behavior of concrete is a result of full-scale test results, model studies, and analytical methodologies directed to long-standing issues, including influence of restraints on reinforced concrete columns, deformation behavior, and thermal damage. These developments offer valuable tools for estimating the extent of fire damage and residual strength following fire exposure of structural elements and systems. *Fire Safety Design & Concrete,*[17] discusses structural response of concrete elements to fire. This work presents basic engineering concepts for considering flexural elements, compression elements, and complex structures and frames.

The use of admixtures to produce various desired characteristics in concrete has increased over the years. There are now on the market dozens of products for strength enhancement, set acceleration and retardation, shrink reduction and flowability, early strength, reduced permeability, and other qualities. Long-term effects of some of these additives on strength and durability are not well researched, and the same is true for behavior of these concretes during and following exposure to fire conditions.

With the increasing use of high-performance concrete (HPC) with compressive strengths exceeding 16,000 psi (110,000 KPa), the matter of spalling at high temperatures has become of interest. Research in the United Kingdom and elsewhere indicates that *explosive spalling* greatly reduces the fire resistance of concrete and that increasing the strength of concrete can be expected under certain conditions to reduce fire performance.[18,19] The identification and control of unfavorable factors, such as curing and drying conditions, aggregate size

and type, and concrete permeability, remain under investigation. Research indicates that the addition of polypropylene fibers to the concrete mixture will reduce spalling and improve the fire load behavior of high strength concrete columns.[20] Work on the characterization of high-performance concrete is underway at the National Institute of Standards and Technology (NIST), using quantitative image analysis to determine the macro- and microstructures of HPC in relation to the response to fire.

A waiting period of perhaps several weeks should elapse after the fire has been extinguished before careful study of structural damage is initiated. This delay will allow any damage to the concrete, such as cracking, layering, calcination, and discoloration change from the natural gray color to pink or brown, which is indicative of heating to temperatures in excess of 450°F (232°C), to become more discernible. The thickness of fire-damaged concrete in structural members can be determined by chipping with a pick or geologist's hammer. Unsound concrete may be colored and will be more or less soft and friable, whereas sound concrete will give a distinctive ring when struck with a pick or hammer. Cored concrete samples for compressive strength tests and reinforcing steel for tensile strength determinations will enable a closer evaluation of the residual strength of damaged members. Load tests may be applied but should only be conducted under the supervision of a registered structural engineer. ACI Committee Report 437R-03, "Strength Evaluation of Existing Buildings," provides guidance on the planning, conduct, and interpretation of load tests.[21]

A variety of nondestructive evaluation (NDE) test methods may be deployed to help evaluate the postfire condition of a concrete structure. A detailed explanation of these methods is beyond the scope of this chapter. Two ACI Committee Reports provide the state of the art on NDE methods for concrete. ACI Committee Report 228.1R, "In-Place Methods to Estimate Concrete Strength,"[22] describes procedures to estimate the in-place strength of concrete in existing construction, including methods that may be applicable to a postfire evaluation, such as rebound number penetration resistance and ultrasonic pulse velocity. The principle, inherent limitations, and repeatability of each method are reviewed, and procedures are presented for developing the relationship needed to estimate compressive strength from in-place results. A second report, ACI Committee Report 228.2R-98, "Nondestructive Test Methods for Evaluation of Concrete in Structures,"[23] reviews nondestructive test methods for evaluating the condition of concrete and steel reinforcement in structures. The methods discussed include visual inspection, stress-wave methods, nuclear methods, penetrability methods, magnetic and electrical methods, infrared thermography and ground-penetrating radar. The principle of each method is discussed and the typical instrumentation is described. In addition, the testing procedures are summarized and the data analysis methods are explained. Finally, the advantages and limitations of each of the methods are summarized. Severe exposure of heavy concrete sections to fire may cause layering, that is, partial separation of the outer 1 to 2 in. (25 to 51 mm) of concrete of a building member from the interior mass. Such layering can complicate the application of the NDE methods described in the ACI Committee 228 reports. Successful application of the methods described in the reports requires an experienced operator.

A complete report dealing with a survey of fire damage to a multistory reinforced-concrete building and the subsequent repair procedure can be found in the paper "Fire Damage to General Mills Building."[24]

CASE STUDY. A severe fire occurred in 1951 in an unsprinklered paper warehouse. This fire lasted for more than 44 hours, and it is estimated that heat intensities of more than 1600°F (870°C) existed for 3 hours or longer. Even after severe fire, the structure was still standing and the concrete floors prevented the spread of fire and major water damage. An inspection of the structure after the fire showed that the concrete roof and columns appeared to have suffered little damage, except that the roof showed deflection up to a maximum of approximately 2½ in. (64 mm) in a 20 ft (6.1 m) span. When holes were cut through the roof, it was found that the concrete was calcined and had a light brown color in varying depths. This damaged concrete had almost no strength and began to disintegrate after a period of several weeks. As a result, the portions of the roof slab that showed appreciable amounts of calcined concrete were replaced. Many of the columns required removal of the concrete down to the reinforcing steel spiral, and, in some cases, calcining appeared inside the spiral. In these cases, the entire column was replaced. The column caps were replaced completely if more than one-half of the column showed evidence of calcining. Reinforcing rods showed some reduction in tensile strength, but most were salvaged and reused and downgraded to about three-quarters of their original strength.

If a decision is made to repair the damage, the usual procedure is to shore up the structure, if necessary, and to remove the fire-damaged concrete, using a hammer, chisel, or a lightweight mechanical hammer. (Use of heavy hammers is discouraged, since they might aggravate the damage by inadvertently chipping good concrete.) The steel reinforcements are then cleaned and, if necessary, additional reinforcements are added and, finally, the concrete is built up with air-blown grout. Durable concrete repairs have been made with epoxy resins also (unfortunately, epoxy is subject to significant strength loss at temperatures above 150°F [66°C]).

The significant difference between conventional reinforced concrete and prestressed concrete in fires is the performance of the high-strength steel wire, strands, or rods used for prestressing. Under fire conditions, the prestressed steel concrete units are susceptible to rapid loss of strength at temperatures in excess of 752°F (400°C). A load test is recommended in postinspection for significant pronounced sag or an indication of excessive temperature in a range where stress loss may have been sufficient to seriously affect the strength.

Tilt-up construction is a popular, simple, and effective type of concrete construction. As the name implies, slabs are site precast adjacent to their final location and lifted into place. In older structures, dating from the 1950s and 1960s, the reinforcing steel projecting from adjoining wall panels was encased in cast-in-place concrete columns. These systems provided relatively reliable fire resistance. In more recent construction, the

wall panels are connected by exposed steel weldments, which are vulnerable to fire damage. The joints in this type of newer "value engineered" construction are filled with flexible, combustible mastic instead of concrete.

Tilt-up construction does not normally allow the walls to be as well connected to the foundations as in normal cast-in-place construction. This can result in an even more potentially dangerous condition when the roof has been burned away. The then unsupported walls are quite vulnerable to tip-over in windy conditions. Some building codes require that this and similar "heavy wall" buildings be designed for "burn-out " conditions, and mandates more competent wall foundations. One should be especially aware of this inherent weakness, during and immediately after a fire.

Several fires on the West Coast have displayed these inherent weaknesses (Figure 19.4.4). Complete collapse and highly damaged panels precluded any effort of cost-effective repair.

Brick

During production, clay bricks are exposed to temperatures in excess of 2000°F (1093°C); hence their strength is retained in actual fires. Reinforcing steel embedded in the center of a clay brick wall would normally be protected by a minimum of 3 to 4 in. (76 to 102 mm) of brick and not be affected. Spalling should be expected, especially if hot bricks are drenched with water from a fire hose. In most cases, temporary repairs can be made with epoxy cement or air-blown grout. Permanent repairs are more appropriately made by replacement, in kind, of the defaced brick.

Wood

Wood is one of the oldest and most widely used building materials. Its behavior in fire conditions varies considerably, depending on the species of wood and the design configuration, that is, solid sawn lumber, glue laminates, plywood, wood chipboard, and so on. The effect of fire on glue laminates may be considered the same as that on solid sawn lumber (heavy timber), assuming that the adhesives used were not affected by heat and that metal plates joining members and their attachment are not damaged. Generally, the phenol-resorcinal and melamine adhesives are not affected by heat. Plywood and chipboard are also dependent on proper adhesives, the difference potentially being slow burning versus a hazardous flash fire caused by delamination.

FIGURE 19.4.4 Fire Damage to Building of Tilt-Up Construction (Source: Oakland, CA, Fire Department)

There are two primary aspects of the behavior of wood materials exposed to fire and other sources of ambient heat. The first involves loss of strength as a result of burning away of material. The second is its contribution to the energy released in a fire through its combustion. Time rates of loss of material and strength can be estimated in terms of char depth and direction of fire spread can be estimated by developing char depth contours. This was the procedure used to trace the extension of fire in the Happy Land Social Club that took 87 lives in New York City in 1991. Ignition temperatures and contributions to heat release in a specific fire depends on a number of factors, including species, density, and moisture content. Long-term exposure of wood to elevated ambient temperatures reduces strength and lowers ignition temperature. Both of these effects can be important in the overall investigation and evaluation of structural damage from fire.

ASCE's "Guide and Commentary for the Evaluation, Maintenance and Upgrading of Wood Structures"[25] provides detailed information on serviceability factors, inspection, evaluation of load-carrying capability of timber structures and methods of repair.

Redwood, found on the West Coast of the United States, withstands high fire exposures. It is reported that the high resistance is due to the lack of the usual volatile resins and oils found in other woods. Redwood forests have resisted fire for centuries.

When wood structural members are subjected to fire, the ability to withstand the imposed loads is dependent to a degree on the remaining undamaged cross-sectional area. The average rate of penetration of char when flame is impinged upon an exposed wood member is approximately 1½ in. (38 mm) per hour. Beyond the char area to a distance not more than ¼ in. (6 mm), the structural properties of wood may be affected by its exposure to high temperatures. The degree of strength loss in this small zone adjacent to the char is not exactly known but is presumed to be insignificant.

Fire tests made on two solid sawn wood joists, 4 × 14 in. (102 × 356 mm), nominal size, at the Southwest Research Institute showed that, after 13 minutes of fire exposure, 80 percent of the original wood section remained undamaged and available to carry the load. In another test of two 7 × 21 in. (178 × 533 mm) glued laminated beams, after a 30 minute fire exposure, 75 percent of the original wood section remained and continued to support the design load.[26]

The previous tests, as well as actual fire experience, substantiate the fact that large-dimension wood members will remain in place under fire conditions and continue to support design loads. It is usually in the larger or heavy timber members that char can be scraped clear and an evaluation made by a qualified engineer or architect to determine the remaining load-supporting capacity of the wood member. As previously discussed, trussed wood roof structures constructed with 2 × 4 and 2 × 6 members have a history of lethal, sudden collapse when exposed to fire.

The practice in older, wood frame buildings was to diagonally cut the tops of wood beams within the bearing wall pocket so that in the event of failure due to fire, the weight of the member would not tear out the wall masonry and/or cause collapse. Further, on reuse of older wood beams it was the practice to invert the beam, which then placed the cut in the pocket, resulting in a reduced bearing area and ability to take shear load. The notching of wood structural members can play an important role in determining the time for failure and the estimation of residual strength of structural timber constructions in fires. The inverting of these members on reuse can also contribute to early failure and collapse. Because of the large number of wood framed buildings in existence, the condition of floor and roof beams at bearing walls should be carefully examined following exposure to fire.

Unanticipated problems often arise following building conversions and other structural and spatial renovations, which may either conceal spaces that were originally open or expose spaces and structural members that were originally concealed and protected from fire. The latter can be particularly hazardous in unsprinklered buildings.

A good example of the complexity of restoration work following a fire is described in the paper "Saving the Exeter Street Theater."[27] This landmark building in Boston, Massachusetts, was constructed in 1885 and ravaged by fire in 1985. One of four 80 ft (24.4 m) long, 18 ft (5.5 m) deep wood trusses and the roof were severely damaged. Besides preserving the original character of the building, engineers were obliged to meet structural requirements of the modern building code. Among other conditions, designers were faced with serious truss decay at the bearing locations and distortion and shrinkage defects of the top and bottom chords. Restoration efforts plus changes in the useable spaces in the building required use of a full range of structural technology. The paper illustrates the importance of careful evaluation of all aspects of wear and aging in addition to fire damage that must be addressed when older buildings are to be repaired.

The special case of evaluating and predicting possibilities for collapse while a fire is still in progress is of interest to fire forces engaged in rescue and fire control operations. Here there is need for the evaluator to recognize early signs of impending failure of both structural and nonstructural elements and systems. Failure resulting in collapse of ceilings, sheathing, glass, and other elements of construction that do not directly affect structural integrity can endanger fire fighters and can contribute to the growth and extension of fire.

Plastics

Plastic construction has been limited to small structures, such as cabins and radomes. However, the use of plastics in building contents and as building materials has steadily increased,[28] as has the resultant fire load. The products of combustion of plastic can be very corrosive and can severely damage structural elements in buildings during a fire. The Munich Reinsurance Company reported extensive losses due to corrosion from gaseous decomposition of burning plastic. Twelve buildings were listed as having extensive corrosion-damaged structural steel members. In several cases, it was necessary to destroy the buildings. Steel members moderately damaged by corrosion may be sandblasted, but it is suggested that a stress analysis be conducted before repairs are started. Damage to reinforcement concrete is more complex, since corrosion, in time, is apt to penetrate to the reinforcing material. Preliminary analysis is necessary before power hammers are used to inspect the extent of damage to reinforcing steel.

FIRE DURING CONSTRUCTION

A dangerous practice is often found during the course of construction of steel-frame buildings; it is common during the application of fireproofing to structural steel members that the coating on the lower first and second stories is postponed until the final stages of construction. The application of fireproofing to these lower floors is often delayed due to the potential physical damage to the coating in these high-traffic areas. These heavy-working areas usually also contain storage of construction materials and equipment, much of which is highly combustible (Figure 19.4.5). The amount of combustible material can provide a fire load capable of destroying the building.

Buildings of reinforced concrete may depend on wood shoring supports and form work to support the fresh concrete pour and to retain their shape until the concrete gains sufficient strength to support its own weight and possibly portions of the floors above that are under construction (Figure 19.4.6). At this stage of construction the building is also highly vulnerable to fire damage. A fire before the concrete curing process is complete could result in a total loss.

Awareness of this problem was demonstrated at the reconstruction of St. Mary Cathedral in San Francisco, California. Built at a cost of $10 million to replace a former church destroyed by fire, its cupola walls extended some 150 ft (46 m) above the ground floor. The supporting scaffolding filled the interior with 1½ million board feet (3500 m^3) of lumber at a cost of $100,000. The chief building superintendent, aware of the fire loss potential, directed that a temporary sprinkler system be installed.

FIGURE 19.4.6 Timber Used as Shoring and Support of Reinforced-Concrete Construction, Essentially a Forest of Wood

SUMMARY

Several factors must be considered in the evaluation of the integrity of a structure after a fire. First, structural damage that may affect overall or local stability must be identified. Then the postfire strengths and weaknesses of the basic materials of the structural assembly must be assessed. Structural steel, concrete, brick, wood, and plastics exhibit different behaviors both during and after exposure to fire. The age and deterioration (e.g., from corrosion, animal infestation, or poor maintenance practices) of the individual materials must also be taken into account. Finally, thorough engineering studies are necessary to determine the parameters for repair and/or replacement of the building's structural elements, as well as to document insurance and litigation claims.

aluminum, composite steel, concrete, design fire, fire resistance, fire test, heat transfer, postflashover fire, section factor, single element analysis, spalling, structural integrity, structural performance, structural steel, time-temperature curve, wood

This chapter provides an overview of structural fire resistance calculation techniques, developed over many years, to address the critical parameters that can affect structural performance in actual building fires. It concentrates on the international body of work on the subject. As discussed in the first few sections, determination of structural fire resistance is typically associated with standardized laboratory fire resistance testing, which finds its roots in the 19th century. However, over several decades, researchers have investigated structural response of building elements to real-world fire loads and postulated various theories for use in the design domain.

It is a misnomer to conclude that any standard fire resistance test can demonstrate or approximate the full-scale complex structural fire performance of building elements. Instead, standard test methods serve well as a comparative assessment method, providing valuable data on the relative performance of materials and small-scale assemblies for a specified fire load.

Concern with the limitations of these standardized tests in providing a comprehensive assessment of full-scale structural fire resistance and the use of these test results as the primary basis for fire-resistant design in building structures has led to the development of alternative assessment and calculation methods over the years. The primary concern is the reliance on the assumption that a structural system tested at a relatively short span, in a laboratory furnace, can robustly translate into a basis for design at the scale required in real buildings. Concerns also exist regarding the lack of assessment of the performance of structural connections as well as the universal application of a standardized fire load during the test.

Initially researchers concentrated on the concept of a standardized fire load (time-temperature curve) and whether it adequately represented the broad range of fire conditions that could be experienced in actual building fires. As such, initial efforts attempted to gain a better understanding of the heating regime that can occur in a compartment (enclosure containing a fire). These investigations concentrated on determining whether a common set of parameters affected overall fire loading such as duration of the fire, the peak temperatures and heat release rates attained in the enclosure, the rate of heating in the compartment once flashover had occurred, and so on. The section "Alternative Approaches to Fire Resistance" describes some of the techniques that address the fire resistance rating appropriate to specific compartment geometry and its contents.

Further clarification on the critical parameters to consider when specifying the fire load that forms the basis of a structural fire design are outlined in the section "Determining a Design Fire for a Structural Analysis" and result in temperature-time relationships that form the basis for calculating structural fire resistance that is not based on standardized tests.

Over time, it became apparent that not only was a better understanding of fire parameters required to understand real fire resistance, but also the performance of structural elements in these fires. As such, individual structural element response to the elevated temperatures that occur in fires was investigated. Analytical methods to capture these very specific responses to fire are presented in the section "Single Structural Element Analysis."

This growing understanding of basic structural response was further developed over the years in part by more critical observations during fires, as well as formal full-scale testing. The data produced

Barbara Lane, Ph.D., is the technical leader of Arup Fire in the firm's London office. She specializes in structural fire engineering design and implementation, with an international portfolio of completed projects.

have resulted in the creation of more advanced structural analysis techniques specifically targeted for fire conditions. The increasing work in this domain is resulting in a substantially greater understanding of true building structural performance in response to fire and is prompting the view that structural detailing and specific structural design for fire is the next and much needed step in optimizing building safety. Methodologies that exist to carry out such assessments are presented in the section "Use of Advanced Analysis in Global Structural Response to Fire."

It is increasingly clear that this important topic requires the attention of fire protection engineers and structural engineers, and that only through successful integration of the expertise in both professions can the result be a robust and commercially beneficial approach to improving the effectiveness of structural design for fire safety.

For related topics, see Section 19, Chapter 2, "Structural Integrity During Fire"; and Section 19, Chapter 4, "Analyzing Structural Fire Damage."

UNDERSTANDING STRUCTURAL RESPONSE TO FIRE

Standardized Fire Resistance Test and Refinements to Fireproofing Thickness

The standard fire resistance test (NFPA 251, *Standard Methods of Tests of Fire Resistance of Building Construction and Materials;* ASTM E119; ISO 834; BS 476; etc.) has formed the basis of fire resistance ratings in building codes worldwide for more than a century, resulting in structural fire resistance being treated separately from the concerns typically addressed by structural design. The implementation of the standardized fire resistance tests called for establishing adequate protection to the structural material with respect to limiting its temperature rise in fire. Time was the sole emphasis—providing fire resistance time to meet code requirements for building structure elements. See Section 19, Chapter 2, "Structural Integrity During Fire," for more discussion on the implementation of the standardized fire resistance test.

Typical building code requirements call for ratings appropriate to specific structural elements as a function of the building use, height, and area, and remain an established "best practice" approach to designing structures for fire resistance worldwide.

In brief, therefore, steel structures require varying amounts of applied fireproofing as a function of building height and use; concrete structures require varying amounts of cover for reinforcement; and timber structures require varying section sizes to allow for the loss of material in elevated temperatures. These measures, in the case of steel, were simply to limit the temperature rise beyond the material's estimated failure temperature of 550°C. For concrete, requirements sought to prevent the reinforcement bars from similarly exceeding these temperatures, whereas for timber, to ensure that the remaining timber portion could still carry its design loads once the charred portion of timber was no longer considered.

Small changes were made over the years, mainly coming from continuing strides to bring efficiency to fire protection costs. In the United Kingdom particularly, the ability of structural elements to sustain the load path in fire was increasingly studied to reduce the amount of fireproofing materials required. Refinements to the formulized fireproofing thicknesses were made, based on individual structural element failure temperatures rather than on the assumption of the generic 550°C concept. The refinements were also made based on the postulated theory that structural elements carry less of a load in the fire (fire limit state) relative to the "normal temperature" conditions (BS 5950-8: 2003). In addition, the sensitivity of section size to heat was incorporated via the heated perimeter to cross-sectional area concept.

Studies After Broadgate Building Fire

This refined single element approach served the design community well, albeit in the specialist domain only. More change was to come, however, after a real fire at the Broadgate building in London, where the steel structure was in essence unprotected and yet managed to survive the severe fire that occurred there. The steel industry in the UK and also in Australia started to question just how much real understanding of structural performance in fire existed and established a major program of full-scale fire tests on real-scale structures.[1–4] The findings caused a fundamental change in the understanding of steel structural performance in fire. It is worth noting that the concept of specific fire-related structural mechanisms is also being investigated and applied to other types of structural materials.

The studies after the Broadgate fire made it clear that the traditional emphasis on limiting temperature rise in materials to prevent degradation of strength was just one important parameter in the fire condition. Similarly, it became clear that refinements to fireproofing thickness based on generic reduced loading conditions for fire, and taking account of the specific strength of an individual structural element and therefore its unique failure temperature, were only touching the surface of what in fact was an incredibly complex problem. The effect of the expansion of structural materials in fire was shown to be of dominant concern, even at very low temperatures. Work such as the British Steel data from the Cardington fire tests,[5,6] the Cardington Fires Main Report from Edinburgh University,[7] and Usmani et al.[8] provide detailed background information on the test observations and structural mechanics in fire.

Although it is true that strength of steel structural materials decreases with increasing temperature, the geometry of the structural component itself also changes over the time of the fire due to the expansion of structural materials. This expansion effect is not just a function of very high temperatures experienced during a fully developed fire, but also a function of the span of the structural elements, their arrangement, and strength losses. These structural responses during fire were observed at temperatures as low as 100°C.

The results of the test program at both Cardington and William Street indicated that, for some structural arrangements, less fireproofing than expected was needed to provide structural stability as well as to maintain compartmentation (i.e., fire separation) requirements for the duration of a severe fire, including the cooling regime as the fire died out.[2]

To clarify this point, fire resistance is classified in two ways: (1) rating for the structural elements to maintain the structural

stability of the building in fire and (2) rating for walls, floors, shaft walls, and so on, whose aim is to limit fire spread from one fire compartment to the next. For example, one story in a building may be one compartment, or, for a different use, one story may in fact contain several fire compartments. The work at Cardington looked at the effect of removing fireproofing from specific—namely, secondary—beams and observing whether (1) structural integrity was maintained (i.e., there was no overall building collapse) and (2) compartmentation was maintained. In other words, if the floor, for example, was deforming in the fire, it might not interfere with the overall stability of the building, but it could cause a breach in a compartment wall (as the result of the deforming floor pulling on the wall) and therefore could create a gap that allowed the fire to spread to another fire compartment.

Robust Response Analysis

Thus, there is a growing trend to apply this increasing understanding to real buildings, as well as carry on with investigations of full-scale structural response mechanisms in fire. Prior to the collapse of the World Trade Center, particularly in the United Kingdom and Europe, the emphasis for such detailed analysis of structures in fire and its practical implementation was very much on bringing efficiency to mostly steel design arrangements. However, since the collapse of the World Trade Center, robustness of response has formed the theme of this analysis, particularly for tall building structures. This means understanding the potential structural fire response mechanisms associated with a proposed structural design, and making refinements where weaknesses are identified that can result in global or local failures (either in the ability to maintain the design load or in the necessary compartmentation). Specifically, if structural designs are based on structural assemblies at a scale, span, or extent that have never been fire tested, there is an increasing onus on the profession to better approximate the design's performance in fire, particularly in buildings where the consequences of collapse are significant. For example, some long-span structures have shown through calculation methods to possess unsatisfactory fire performance because of the resulting effect they have on columns in fire. By conducting specific structural fire analysis and quantifying the structure's response, guidance can then be provided to enhance structural detailing needed to improve the performance of the columns during fire. In essence the future of structural design seems to be leading toward considering fire as a design load, similar to the approach taken for wind effects, snow effects, earthquake effects, or other environmental design events.

The standard fire resistance test, along with traditional fireproofing and fire resistance methods, will likely continue to serve as a fundamental basis for the design of structures, but will need to be supplemented with quantified structural responses during real fires, as the structural response of a building not only affects the stability of the structure but also the performance of compartmentation (or fire separation). This need requires the establishment of some fundamental performance objectives for structures in fire. For example, what are the acceptable behaviors that robustly confirm stability of the structural system itself during a fire? Then, to maintain compartmentation—to stair cores, to other stories in the building, or from compartment to compartment on the same story—what fundamental performance demonstrates that this stability is being maintained?

The need for risk-based design approaches should be considered as a way forward. Currently, some specialists in this structural fire engineering field design for absolute events, unlike earthquake design, for example, which addresses likely events. Earthquake designs that satisfy such requirements are deemed to be acceptable, safe, and best practice. Such confidence is not yet available in the regulatory environment for structural fire engineers.

A significant amount of work now remains to be done to firmly establish structural fire engineering knowledge and the techniques presented here as a mainstream part of any building and fire safety regulation. In the meantime, fundamental questions must be answered and substantial work is required to establish safe and reliable design techniques within the approvals process for the authorities having jurisdiction, as well as for building insurers and other key stakeholders. All of this is deemed necessary such that real structural performance in fire is no longer omitted from the design process. The techniques described in this chapter are presented as a first step in this process.

ALTERNATIVE APPROACHES TO FIRE RESISTANCE

Traditionally, standard temperature-time relationships, such as those described in ASTM E119,[9] NFPA 251, BS 476, Part 20,[10] or ISO 834,[11] have formed the basis of standard furnace tests to determine the structural response of building elements in fire conditions. However, it is well understood that the standard temperature-time curve does not always represent real postflashover fire (Law,[12] Thomas,[13] Malhotra[14]). This is due to the number of variables that can affect the heating regime in a compartment.

Postflashover fires can be more or less severe in terms of duration, rate of heating, and peak temperature than the standard temperature-time relationship in a furnace test. In addition, real fires are a function of fuel load and geometry, compartment dimensions, thermal properties of the compartment boundaries, and the quantity of unprotected openings that allow ventilation in a postflashover fire. In addition, in Europe—and to some extent New Zealand and Australia—active fire safety systems, compartment area, occupancy type, numbers of water supplies to the compartment, provisions for fire fighters, and even smoke extraction are assigned risk factors that increase or decrease the likelihood of a flashover and its possible extent. The resulting compartment fire is a complex mix of relationships. For structural fire resistance, this fire—the design fire—is the most important input variable, as it greatly influences the structural response. It is important, therefore, to understand its origin.

However, explicitly defining temperature-time relationships as a function of a specific compartment is a relatively new phenomenon in structural fire resistance calculations (also called structural fire engineering). Initially, research work concentrated on fire resistance periods and refining these periods as a function of the compartment in question.

Historically, therefore, due to concerns with the standard furnace test temperature-time relationship, work was carried out by Ingberg, Law, and Pettersson, among others, to determine what is known as *equivalent fire resistance* or *time-equivalent* methods. For these methods, the heating effect in a compartment is based on real compartment fire behavior and therefore takes into account fuel load density, ventilation openings, compartment dimensions, and enclosure thermal properties. This allows some improvement in the grading method, based on the standard furnace test that is currently assumed in building codes worldwide.

Time-equivalent methods can be described as methods that define the thermal exposure of a particular compartment fire in terms of the duration of the *equivalent standard fire.* This is important when engineers and designers want to use published fire resistance ratings from standard tests but based on estimates of real fire exposure.

Equivalence of thermal exposure has been defined in two ways:

1. *Fire load or equal area concept.* Equal areas under the temperature-time curves
2. *Equal temperature concept.* Equal temperatures at the critical part of the structural element

The two methods give similar results where the element selected has a fire resistance on the order of half an hour or more. Samples of both methods developed in the last 80 years, which form the basis of popular calculation methods internationally, are described in the following paragraphs. What these methods provide is an overall building rating, based on building-specific compartment factors.

It is important to note that time-equivalent methods do not assess local or global structural response mechanisms. They relate only to heating effects and their relationship with the standard furnace test. In addition, time-equivalent methods typically apply to protected steelwork but have been extended to include concrete. Some of these methods have recently also been applied to unprotected steelwork and timber construction, but their use with these building materials is not well validated. For unprotected steelwork, it is important to note that in general such elements can achieve 30 minutes standard fire resistance; attempts to extend use beyond this level result in the errors observed, for example, in the Natural Fire Safety Concept study.[15]

Fire Load or Equal Area Concept

By 1918 there was a widespread concern in the fire protection and code enforcement community[16] that there was no accepted method for establishing appropriate levels of fire endurance (now referred to as fire resistance) for buildings of different sizes and occupancies. The original work had been based on "fireproofing" large commercial buildings. It was recognized that these differed significantly from residential fires but it was not understood how their severity related to the conditions in the now formulated standard fire resistance test.

The Building Code recommended by the National Board of Fire Underwriters (NBFU), 1905 edition, contained a series of tables specifying certain wall thicknesses of buildings based on the use and number of stories. Sections 106 to 108 of this code specified other criteria for "fireproof" building construction, which was generally applicable to any structure more than 55 stories in height regardless of use.

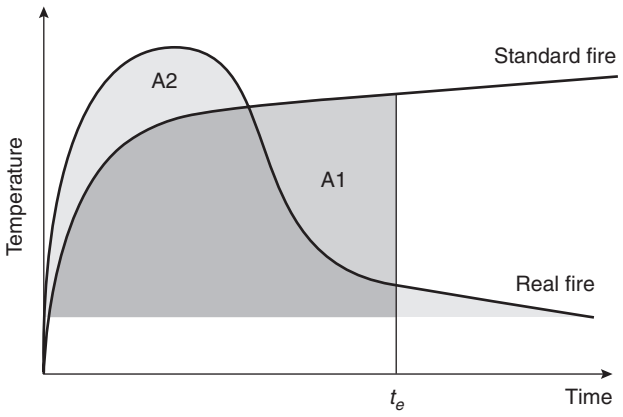

FIGURE 19.5.1 Fire Severity Concept (Source: A. H. Buchanan, *Structural Design for Fire Safety.* Copyright John Wiley and Sons Limited, 2001. Reproduced with permission.)

In order to develop a solution to this problem, in 1922 the National Bureau of Standards in the United States (now called the National Institute of Standards and Technology) investigated the nature of building fires under the direction of Simon Ingberg.[17] The main aim was to determine the intensity and duration of uncontrolled fires in particular occupancies resulting from different levels of fire load. Ingberg was also to investigate the validity of the standard time-temperature curve, which had been accepted as the basis for testing since 1918.

Ingberg investigated office and record storage type occupancies, including the effects of the building size and fire load, the effects of combustible and noncombustible flooring, and the effect of wood and steel furniture. As a result of these tests, Ingberg established a simple relationship between the average weight of combustible material within a room and the fire endurance necessary to withstand a complete burnout of the contents, known as the "fire load concept." It assumes that the area under any time-temperature curve from ignition through decay provides a comparative measure of fire severity, and that fire severity is a function of only the fire load.

Ingberg compared the area under the time-temperature curves generated in the burnout tests to an equivalent area under the standard time-temperature curve. The areas below a threshold temperature of about 300°C were not taken into account. The graph in Figure 19.5.1 shows the basis for Ingberg's work.

Ingberg developed the following relationship for time-equivalence:

$$t_e = k_1 L'' \tag{1}$$

where

t_e = t-equivalent (min)

L'' = Fire load (wood) per unit floor area

k_1 = 1 when L'' is in units of kg/m^2

k_1 = 5 when L'' is in units of lb/ft^2

Ingberg's work became widely accepted as the general basis for establishing fire endurance requirements. This method, however, neglects the effects of ventilation, fuel type, and fuel geometry on fire severity, and therefore its application and usefulness with engineered fire safety solutions is limited.

Equal Temperature Concept

The equal temperature concept is a more realistic method, where the equivalent fire severity is the time of exposure that a protected steel member would endure under the standard fire that would result in the same maximum temperature if it were exposed to a real postflashover fire. This concept was developed by Law,[12] Pettersson et al.,[18] and others and is applicable to insulating elements and materials with a limiting temperature such as wood with a charring temperature of 300°C.

The equal temperature concept is widely used, but can give misleading information if the maximum temperature of the structural element is not the limiting or failure temperature. Several factors, such as building geometry, section details, loading, connections, end conditions, continuity, and so on, can markedly influence the critical temperature for structural performance. This is discussed in more detail later in this chapter.

Kawagoe and Sekine. In 1963, after further small-scale tests and analysis, Kawagoe et al.[19] went on to show the importance of the ventilation parameter as follows:

$$\sqrt{h}\frac{A_B}{A_T} \tag{1}$$

where

h = Window height in the compartment (m)

A_B = Total area of windows (m^2)

A_T = Total area of inside compartment surfaces, including window area (m^2)

Kawagoe and Sekine also developed a formula for fire duration and defined it as the period from the beginning of temperature rise until the time the temperature drops after most of the combustible material is consumed. This time, T, is approximated as:

$$T = WA_F/5.5\sqrt{h}A_B \text{ (min)} \tag{2}$$

where

T = Time (min)

W = Fire load (kg/m^2)

A_F = Floor area (m^2)

h = Height of the window (m)

A_B = Area of the windows (m^2)

Law's Time Equivalent Method. In 1971, Law developed a time-equivalent formula based on the equal temperature concept.[12] This formula was based on small-scale compartment tests, as conducted by Thomas and Heselden,[20] and some large-scale compartment tests.[12]

The maximum temperature, which would be attained by a protected steel element in a real fire compartment, was chosen as a basis for comparison with the corresponding heating effect on the element if heated in a standard fire.

For a temperature-time curve, the maximum temperature obtained by a protected steel element in a compartment fire was calculated as:

$$\frac{d\theta_s}{dt} = \frac{\theta_f - \theta_s}{RC} \tag{3}$$

where

θ_s = Steel temperature (°C)

t = Time (sec)

θ_f = Fire temperature (°C)

R = Thermal resistance of the protective layer

C = Thermal capacity of the steel (J k^{-1})

The temperature of the heated surface of the protective material is assumed to be the same as the fire temperature. The heat transfer through the steel section can then be calculated.

For a given time-temperature curve the value RC was determined so that the maximum temperature of the protected member was 550°C. The time for the protected member to attain 550°C when exposed to the standard temperature-time curve then gives the value of time equivalent.

The best correlation was obtained from the product (L/A_v) and a term taking into account A_v and the solid surface to which heat is lost:

$$t_e = \frac{k_3 L}{\sqrt{A_v\,(A_t - A_F - A_v)}} \text{ (min)} \tag{4}$$

where

t_e = Time equivalent (min)

A_F = Floor area of the compartment (m^2)

L = Fire load (wood equivalent) (kg)

A_v = Area of ventilation opening (m^2)

k_3 = 1.3 to 1.5, depending on the stick spacing in the cribs used as fuel min m^2/kg

A_t = Area of internal envelope (walls, floor, ceiling, and openings) (m^2)

In this correlation, A_F was not included in the evaluation of solid surfaces because the floors were very well insulated. In all experiments, the openings were the full compartment height. The values of t-equivalent were found to be independent of scale and height of ventilation openings.

Law then analyzed temperature-time curves for a number of burn-out fires in larger brick and concrete compartments (approximately 3 m high) with fire loads ranging from wood cribs, furniture, and liquid fuels, and developed:[12]

$$t_e = k_4 L/[A_v(A_t - A_v)]^{1/2} \text{ (min)} \tag{5}$$

where k_4 is 1.0. This was due to the little effect fuel arrangement appeared to have in these larger-scale tests. In this correlation the floor area was included in the evaluation of solid surfaces to which heat is lost. The larger-scale data also showed no significant effect of ventilation opening height on t_e.

Law concluded that this Equation 5 was most suitable for engineering purposes for protected steel columns and went on to demonstrate that it gave good results for reinforced concrete also. She did discover that it overestimates the time prediction for tightly baled paper and cloth.

This formula is valid only for compartments with vertical openings in the walls, and cannot be used for rooms with openings in the roof.

Pettersson's Time Equivalent Method. Pettersson et al.[18] adopted Law's approach to *t*-equivalent but, instead of the experimental curves on which Law's work was based, used the family of calculated temperature-time curves for particular compartments, as derived by Magnusson and Thelandersson.[21] When the fuel load is expressed in mass (kg) of wood instead of "effective calorific value" (MJ), Pettersson's expression for *t*-equivalent is as follows:

$$t_e = 1.21L/(A_v\sqrt{h}A_t)^{1/2} \text{ (min)} \quad (6)$$

where

t_e = Time equivalent (min)

L = Fire load (wood equivalent) (kg)

h = Height of vertical opening (m)

A_t = Total area of internal envelope (walls, floor, ceiling, and openings) (m^2)

A_v = Area of ventilation opening (m^2)

Note that in his original heat balance work he excluded A_v appropriately, but for an unstated reason does not in his final equations presented in his design guide.[18] This equation includes $\sqrt{h}$ because of the input parameters in the method for calculating the temperature-time curves from Magnusson and Thelandersson,[21] on which this equation is based.

Equation 7 can be modified to take into account the thermal properties of the compartment enclosure by applying the factor k_f to each input parameter.

This yields

$$t_e = 1.21k_f^{1/2}L''A_F/(A_v\sqrt{h}A_t)^{1/2} \text{ (min)} \quad (7)$$

where

k_f = Factor applied to input parameters to take account of the thermal properties $k\rho c$ of the compartment enclosure expressed as a proportion of the $k\rho c$ for Pettersson's "standard" compartment. This standard compartment, defined in the Swedish Building Regulations in 1967, is where the surrounding structure has the thermal properties of an average of concrete, brick, and lightweight concrete of thickness 20 cm. (Note also the fire is ventilation controlled and with a cooling phase of 10°C/min.)

L'' = Fire load (wood equivalent) (kg/m^2)

A_F = Floor area of the compartment (m^2)

Eurocodes and British Standards

Eurocode 1: Actions on Structures—Part 1.2: General Actions—Actions on Structures Exposed to Fire, dated 2002,[22] has now also been adapted as a British Standard BS EN 1991-1-2:2002. It is understood that the time equivalent method defined within originates from the German standard DIN 18230, version 94.[23] The derivation of this formula has never been published but it is understood to have come from an empirical analysis of calculated steel temperatures in a large number of simulated fires computed by the German program "Multi Room Fire Code."[24] Though this German reference refers to an earlier published version of this Eurocode, the basic formulations remain and therefore this origin is believed to still apply. This method is dependent on ceiling height of the compartment but not the opening height. The fuel type assumed in the original work is unknown, although it is widely believed to be a cellulosic-type.

The time-equivalent is defined in Eurocode 1, Part 1.2[22] as:

$$t_e = q_{f,d}k_b w_f k_c \text{ (min)} \quad (8)$$

where

$q_{f,d}$ = Fire load density related to the floor area (MJ/m^2)

$$q_{f,d} = q_{f,k}m\delta_{q1}\delta_{q2}\delta_n \quad (9)$$

where

$q_{f,k}$ = Fire load density determined from a fire load classification of occupancies (see Table 19.5.1)

m = Combustion factor, which for cellulosic materials is defined as 0.8

δ_{q1} = Safety factor taking account of the fire activation risk due to the size of compartment (see Table 19.5.2)

δ_{q2} = Safety factor taking account of the fire activation risk due to the type of occupancy (see Table 19.5.3)

$\delta_n = \prod_{i=1}^{10}\delta_{ni}$ = A factor taking account of the different active fire-fighting measures such as sprinklers, detection, fire brigade, etc. (see Table 19.5.4)

k_b is a conversion factor and can be taken as 0.07 ($min\cdot m^2$ /MJ) when no detailed assessment of the thermal properties of the boundary are pursued and when q_d is given in MJ/m^2. Otherwise k_b may be related to the thermal property $b = \sqrt{\rho c\lambda}$ in accordance with Table 19.5.5.

w_f is the ventilation factor and is calculated as

$$w_f = \left(\frac{6}{H}\right)^{0.3}\left[0.62 + \frac{90(0.4-\alpha_v)^4}{1+b_v\alpha_h}\right] \geq 0.5 \quad (10)$$

where

$\alpha_v = A_v/A_f$ = Area of vertical openings A_v in the facade related to the floor area of the compartment where the limit $0.025 \leq \alpha_v \leq 0.25$ should be observed

$\alpha_h = A_h/A_f$ = Area of horizontal opening in the roof related to the floor area of the compartment

$b_v = 12.5(1 + 10\alpha_v - \alpha_v^2) \geq 10$

H = Height of the compartment (m)

For small fire compartments (defined in the Eurocode as $A_f < 100\ m^2$) without openings in the roof, the factor w_f may also be calculated as

$$w_f = O^{-1/2} A_f/A_t \quad (11)$$

where

O = Opening factor = $A_v h^{1/2}/A_t$ with $0.02 \leq O \leq 0.20$ with the default value $k_b = 0.07$ and assuming 18 MJ/kg for wood, Equation 6 becomes the same as Equation 8

k_c = A newly incorporated correction factor, which is a function of the material composing structural cross sections and as defined as $13.7 \times O$ for unprotected steel

Reinforced concrete and protected concrete remain as 1.

The basis of this method is that it should be verified that:

$$t_{e,d} < t_{fi,d} \quad (12)$$

where

$t_{fi,d}$ = The design value of the standard fire resistance of the members, assessed according to the relevant parts of the Eurocodes (Table 19.5.1 to Table 19.5.4)

Note according to the BS EN 1991-1-2[22] for "normal fire-fighting measures" such as safe access routes, fire-fighting devices, and smoke exhaust systems in staircases, the factors should be taken as 1.0. If these measures have not been foreseen but provided, then the values can be taken as 1.5 (Table 19.5.5).

New Zealand Codes

The New Zealand *Fire Engineering Design Guides*[25] gives the same empirical expression for equivalent fire severity t_e (min) as the British Standards (BS EN 1991-1-2[22]). The upper and lower k_b values have been increased by a factor of 1.3 compared to the Eurocode due to what they declare are inherent uncertainties in the Eurocode formula, the use of fuels other than wood, application to structures other than steel, and deep compartment effects. If the properties of the linings are not known, a value of $k_b = 0.09$ is suggested. This formula is based on cellulosic-type fuels. The ventilation factor limits of use are retained, although the small compartment formula in the Eurocode does not form part of the New Zealand guidance.

Comparisons

Time-equivalent methods are an improvement on the grading method in building codes worldwide, which is based on the standard fire temperature-time relationship such as ASTM E119,[9] NFPA 251, BS 476, Part 20,[10] and ISO 834.[11] This is because they attempt to account for compartment geometry, ventilation openings, fuel load density, and compartment boundary materials in addition to fuel load density, which are the key factors that affect full-scale fire development. However, the temperatures calculated on these principles are then related back to

the standard time-temperature relationship. It is also important to note that they are based on specific compartment test data, rather than generalized heat balance solutions. They are therefore not entirely representative of natural temperature-time relationships, and, as such, are not independent of the standard fire resistance test formulation.

Drysdale describes a comparison Harmathy carried out where the Ingberg,[17] Pettersson,[18] and Harmathy equations for t_e were compared.[26] Drysdale rejects Ingberg's method as radiative heat flux T^4 makes simple scaling impossible when heat transfer is dominated by radiation. He concluded that Law and Harmathy provided more conservative solutions than the others. Note that Ingberg's method ignores ventilation, unlike the other methods presented here.

Law compared results using the time-equivalent relationships by Ingberg,[17] Kawagoe et al.[19] Pettersson, et al.,[18] Harmathy and Mehaffey,[27] plus the 1993 Eurocode formula[28] with experimental data from postflashover fires in full-scale compartments.[29] These consisted of small insulated compartments, 30 m^2 area, 2.5–3 m high, with brick or concrete enclosures and larger, deeper rooms 128 m^2 in area (depth to width ratio 4:1). Law concluded Pettersson, Harmathy, and Mehaffey were the most promising methods. See Figure 19.5.2 for Law's correlation compared with experimental data.

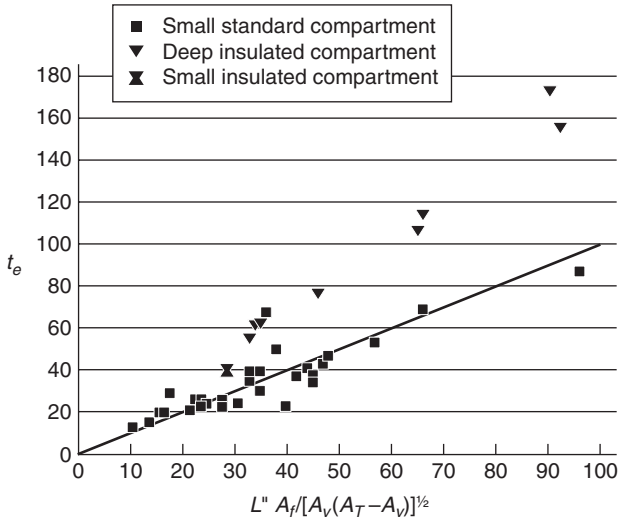

FIGURE 19.5.2 Law's Correlation Between Fire Resistance Requirements (t_e) and $L"A_f/(A_v(A_T - A_v)^{1/2}$ where
$L"$ = The fire load (kg/m^2)
A_f = The area of the floor
A_v = The area of the ventilation
A_T = The total internal surface area (m^2) of the compartment
(Courtesy of Margaret Law)

Limitations and Assumptions

There are several limitations, including the deep compartment* effect. Law examined deep compartments further, as all her derived time-equivalent formulae gave odd results when deep compartments were studied. Law also discovered that the 1993

*A deep compartment is defined by I. R. Thomas and I. D. Bennetts in *Fires in Enclosures with Single Ventilation Openings. Comparison of Long and Wide Enclosures,* 6th IAFSS Symposium, pp. 941–952, 1999 as the situation where the depth, *D,* is greater than the width, *W,* of the compartment.

Eurocode *t*-equivalent method gave poor correlation for both small and deep compartments. She concluded that the depth of the compartment has an effect on the time equivalent over and above that which can be allowed for by increase in insulation and in internal surface area A_t. Thomas and Heselden[20] had already shown that the ventilation-controlled rate of burning is affected by the compartment depth to width ratio. Recent research on this phenomenon has also resulted in the New Zealand codes recommending increased factors of safety to somehow account for this effect in their time-equivalent formula. Thomas and Bennetts[30] concluded that fire behavior and fuel mass loss rates in long and wide enclosures differ markedly if the width of the opening is less than the full width of the enclosures. However, it should be noted that they did not look at cross-ventilation. They demonstrated that mass loss in wide enclosures is greater than for deep enclosures that incorporate both full-width and partial-width openings. In their small-scale experiments the fire duration was double for deep compartments, relative to wide compartments with the same openings.

The Eurocode or BSEN formulae have caused considerable concern as Eurocode does not reference the source of the equation derivations, particularly regarding the ventilation factor, the correction factor to take account of cross section material types, as well as other factors of safety recommended for application to the calculated time-equivalent value. The Eurocode formula has also been extended to unprotected steelwork.

The k_c is defined for unprotected steel as 13.7 times the opening factor (O). Since $0.02 < O < 0.2$, this gives $0.27 < k_c < 2.7$ for unprotected steel. For small compartments $w_f = O^{-½}A_f/A_t$ and since $O = A_v h^{½}/A_t$, it can be written that the equivalent time for unprotected steel in small compartments is as follows:

$$t_e = 13.7\, q_{fd} \cdot k_b \cdot (A_v\, h^{1/2}/A_t)^{1/2} \cdot A_f/A_t$$

(fire load given as per unit floor area)

Pettersson calculated $t_e(h)$ for unprotected steel for values of opening factor ranging from 0.2 to 0.12 $m^{½}$ and various section factors (Tables 19.5.6 and 19.5.7). Law[31] compares Pettersson's time-equivalent formula with the Eurocode formula for $\varepsilon_r = 0.5$ for unprotected steel of various section factors in Table 19.5.8.

It can be seen that while the values of t_e tend to increase with increasing fuel load, they tend to decrease with ventilation factor. They are not independent of section factor. Yet when the Eurocode formula is used with $k_b = 0.055$ for Pettersson's compartment type A, for all sections, the following data is produced (Table 19.5.8).

The trends in the Eurocode are different and no explanation as to why has been provided. For unprotected steel, if the steel is assumed to be a perfectly stirred fluid, the postflashover fire temperatures are also perfectly stirred, and the temperature of the exposed surface is the same as the fire temperatures, which implies that the steel temperature is always the same as the fire temperature. Therefore, section factors of 100 m^{-1} or more would not be expected to survive a postflashover fire, but would survive a localized fire. Until suitable justification of such difference is made, it seems the original work of Pettersson or Law is best suited to this type of time-equivalent calculation.

Another limitation is that the *t*-equivalent methods do not address transient temperature gradients or associated load-bearing capacities. The ratings derived do not relate to actual frame performance in fire. These methods are quite simply refined versions of single element performance in fire, but only relative to the standard furnace test. They normally assume insulated structures only (protected steel or reinforced concrete). Although Pettersson's work does address uninsulated steel, these bare elements would not be expected to achieve a fire resistance of beyond 20 to 30 minutes.

A time-equivalent calculation does not apply if the preflashover calculations show that flashover will not occur—that is, the calculation is no longer relevant if flashover has not occurred. Then local heating effects are relevant, not temperatures in a uniformly heated compartment, as is assumed in time-equivalent analysis methods.

In addition, *t*-equivalent methods are empirical formulae developed by regression analysis using a selected number of tests or calculations. Therefore, they have been developed for a certain range of structural steel sizes and thicknesses of insulation and so may not be appropriate outside this range. The methods are used for other materials, but beyond protected steel and reinforced concrete, very little is known of the accuracy in applying the methods to other materials. Note that all *t*-equivalent methods described here involve combustible solids only.

The time-equivalence method is a simple analytical method that is generally useful in the everyday design environment due to its relative ease of use and its time and cost efficiency. However, such methods are generally incapable of considering the numerous complex structural behavior issues and are highly dependent on the parameters and assumptions chosen by the designer.

Because of the limitations and uncertainties associated with time-equivalent methods, it is important that risk factors are considered in the analysis. Using a probabilistic model, the uncertainties in the concept of safety, fire, reliability of active and passive systems, structural stability, material behavior, and so on can be incorporated into a time-equivalent analysis to envelope the expected response. In this way, a numeric measure of risk can be assessed and compared to an accepted level of risk established by the governing codes.

The accepted level of risk varies from country to country and in many cases is not explicitly documented. In Europe, the acceptable level of risk is implicitly captured in the partial safety factors found in the National Annex for each country. Similar documents are also available in the U.S. codes, New Zealand codes, and other codes around the world. A discussion of risk assessment is given by Hall[32] and Baldwin.[33]

CASE STUDY: Outlining Use of the Time-Equivalent Method. This case study is based on a study of a 50 story high-rise office building in the United Kingdom, with a combination of several structural systems (a perimeter diagrid, a secondary bracing system, and internal columns). Based on the governing codes, the sprinklered building would be required to achieve a 120 minute fire resistance rating. However, an alternate rating was proposed for the design using the time-equivalent method for justification.

The main floor plate of the building consists of an open floor plan system as seen in Figure 19.5.3 (no subdivisions proposed). Because of this open floor layout, the entire floor was considered one single fire compartment. Due to the high variability in the building geometry/design and uncertainties in identifying a representative fire for the structure, a sensitivity study was conducted to provide a range of probable design fires.

Therefore, the factors forming the basis of the time-equivalent method—that is, the fire compartment geometry, the ventilation to the fire compartment, and the other significant fire parameters—were considered in a sensitivity analysis to determine a final equivalent time of fire resistance. In addition, several fire locations within the building itself were investigated in order to ensure that a reasonable worst-case fire scenario was determined. This was as an alternative to applying the code-required fire resistance ratings for individual structural elements.

The time-equivalent method described in the Eurocode[22] was used. Combining Equations 12 and 13, the equivalent time of fire exposure can be defined as:

$$t_{e,d} = mq_{f,k}\delta_{q1}\delta_{q2}\delta_{ni}w_f k_b k_c \quad \text{(min)} \tag{13}$$

Two floor levels (5th and 44th levels) were assessed to provide an upper and lower bound estimate for the equivalent time of fire exposure. This was because level 5 had the largest floor area of 1896 m^2 with the greatest amount of glazed facade, whereas level 44 had the smallest floor area of 694 m^2 and the least amount of glazed facade.

First, a sensitivity analysis was conducted to determine a range of possible design fire loads. The characteristic fuel load ($q_{f,k}$) was 511 MJ/m^2, the compartment floor area factor δ_{q1} was valued as 1.9, and the occupancy factor δ_{q2} was valued as 1.0, as recommended by the Eurocode for office buildings with compartment floor areas less than 2500 m^2. Assuming these values as constant, the combustion factor (m), the water extinguishing factor (δ_{ni}), the automatic detection factor (δ_{ni}), and the off-site fire brigade factor (δ_{ni}) were varied to determine their impact on resulting design fire loads:

$$q_{f,d} = mq_{f,k}\delta_{q1}\delta_{q2}\delta_{ni} \quad \text{(MJ/ m}^2\text{)} \tag{14}$$

Based on this sensitivity analysis a design fire load ranging from 270 to 971 MJ/m^2, as presented in Table 19.5.9, was obtained.

Next, a sensitivity analysis was conducted for each design fire load to determine a range of time-equivalent fire exposures based on the variation of the ventilation factor (w_f) in the following equation:

$$t_{e,d} = q_{f,d}w_f k_b k_c \quad \text{(min)} \tag{15}$$

The k_b and k_c terms were assumed constant at 0.07 min·m^2/MJ and 1.0, respectively.

Four different ventilation factors were determined by varying the area of ventilation openings in the facade from 25 percent to 100 percent. It was necessary to assess the lower levels of glazing failure (below 50%) due to the approving authority's concern with the concept of glazing breakage in fire and their lack of certainty that this would occur. The maximum openings for the 5th and 44th levels were 498 and 305 m^2, respectively. Note that there were no horizontal openings in the compartment.

The ventilation factor was calculated by the following equation taken from the Eurocode:

$$w_f = \left(\frac{6}{H}\right)^{0.3}\left[0.62 + \frac{90(0.4-\alpha_v)^4}{1 + b_v\alpha_h}\right] \geq 0.5 \tag{16}$$

Based on this sensitivity analysis, a range of 16 different equivalent times of fire exposure were determined and are presented in Table 19.5.10 and Figure 19.5.4 for levels 5 and 44 of the building investigated.

The results of the time-equivalent sensitivity study range from a fire resistance rating of 15 to 138 minutes. The sole value greater than 90 minutes was an equivalent time of 138 minutes. This value occurs when the reduction in risk of a flashover due to active fire protection methods is not incorporated, but only

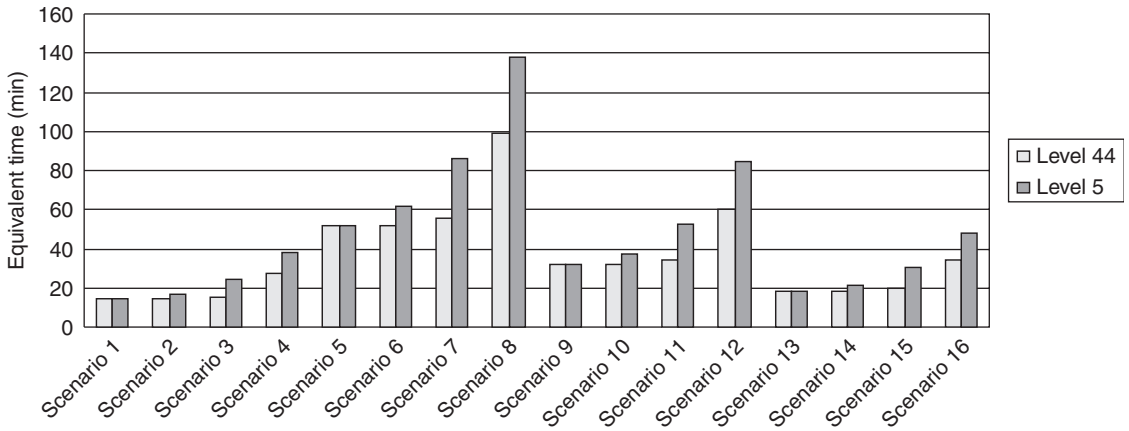

FIGURE 19.5.4 Graph of the Output Data from the Sensitivity Study (Source: Arup)

if a low glazing failure quantity is also assumed to occur. As it was agreed with the approving authorities that such a low level of glazing failure was not practically possible at the fire temperatures expected without active fire protection intervention, this value was deemed overly conservative.

The high variability in the upper and lower bound values illustrates the importance of performing such a sensitivity study, in order to appreciate the potential fire resistance ratings for a structure when using the time-equivalent method.

A reduction in the fire resistance of the building from 120 minutes to 90 minutes was proposed on the basis of this study, because the majority of cases fell well below this value.

DETERMINING A DESIGN FIRE FOR A STRUCTURAL ANALYSIS

Throughout the remainder of this chapter, as specific structural analysis techniques are presented, the important role of the heating regime on the structural element or elements is clear.

Specific references are provided to direct the reader to useful analytical models and formulae to represent fire.

Issues Involving Design of Fire Component

Before more detailed information is presented, it is useful to consider the issues involved with the fire component of a structural design. Unlike design basis fires for smoke control systems or as part of developing time to untenable conditions for purposes of egress, structures are usually most severely affected by postflashover fires. This is when the fire has moved beyond the incipient and growth phase to a point where it is consuming essentially all combustible contents of the enclosure. The resulting peak temperatures, duration, and overall fire severity are then a function of the available combustibles and the ventilation openings into the space. It is these postflashover fires that normally form the basis of a structural fire assessment.

When contemplating the occurrence of a postflashover fire, the sequence of events that must occur to allow such an event to take place is of importance. For example, in a fully sprinklered building, failure of the sprinkler system would have to be assumed to create a flashover condition. Another event is the effect of fire-fighting operations on the occurrence of flashover. Whatever assumptions are made, it is important to bear in mind the risks associated with such assumptions and the different consequences that may result depending on the building height, scale of occupancy, fuel content, use, and compartment extent. That is, the taller the building, the greater the consequence of failure of the structure, and so on.

Addressing Postflashover Events

Various methods are available to designers to address such a postflashover event, including the use of the standard temperature-time relationship on which the furnace tests are based; parametric temperature-time relationships derived from specific postflashover fire tests; or temperature-time relationships derived from resolving the heat balance system within a compartment.

The important question, then, is whether the temperature-time regime proposed represents (or even should represent) an absolute worst case or a reasonable worst-case scenario. In the Eurocodes, for example, designers are advised to use risk-based factors to apply to the fuel load content assumed in a compartment, such that the resulting heating regime is not absolute but also addresses the consequence of failure, the likelihood of occurrence of the fire, and the role of active fire safety systems (e.g., sprinklers) on the probability of a severe fire in a building.

There are concerns with the limitations of parametric fires specifically, as the equation now proposed, for example in the Eurocode, is in essence the result of a regression analysis of specific test data. How to justify the use of this outside the limits of the original test data remains an unresolved subject in the design domain. Although this is the case, engineers are relying on additional safety factors to ensure that design remains on a reasonably conservative side. The more theoretical approaches based on heat-balance relationships, such as Pettersson's, are less popular with code writers, but it may be prudent to revisit such approaches in order to resolve the design basis fire problem for structural fire engineering.

However, adopting a postflashover fire condition as a basis for design is not always the correct approach, as in the case, for example, of very large open spaces with specific pockets of fuel, such as in an airport terminal, where a postflashover fire is unlikely to occur. In such an arrangement, a severe localized fire may expose only one or two columns supporting a long-span structural roof system. For such design cases, specific formulae for local fire and smoke effects are available.[34–36]

Finally, if the structure in question is external to the building, the heating that results from internal and external flaming adjacent to the structural elements becomes the basis for design. Again guidance is provided in the following section on useful formulations to create temperature-time regimes for such events.

Once the design fire temperature-time regime is defined, the remaining steps in a structural fire assessment are possible. The following sections provide information on this. It is recommended that the authorities having jurisdiction are consulted and approve the design fire formulated prior to any time-consuming structural analysis.

SINGLE STRUCTURAL ELEMENT ANALYSIS

The analysis of a single structural element in isolation from the rest of the structural frame has formed the basis for structural fire engineering for many years, mainly because it is comparable with a standard furnace test and excludes calculations based on the nonlinear response of a whole frame or a significant subassembly to fire, both of which require extensive computations.

Single Element Analysis Defined

Single element analysis is useful as a first check of structural capacity at elevated temperature as a basis for design or before conducting a more complex analysis. It typically involves comparing the structural load that the member has to carry in the fire condition with the capacity of the member at elevated temperature. Axial force, bending, shear, and buckling, including lateral torsional buckling, all need to be considered as appropriate. The capacity of the associated connections also needs to be checked.

Single element analysis is a fast, effective technique that can bring substantial value to a design as it allows an understanding of the overcapacity or undercapacity of the member in the fire limit state. This can be used to formulate adequate fire resistance ratings and protection thicknesses for specific elements or to inform a change to the structural design to allow adequate capacity without any added fire protection. Using single element analysis is preferable for isolated structural element concerns in a building, rather than for forming a uniform design approach for all elements in a building. This is because single element checks cannot capture the full frame response, which can mean, in some construction forms, significant weaknesses in fire performance.

Specifically, it is not typical to consider thermal expansion in single element calculations; therefore, the forces experienced by the structural element in a fire when restrained by adjacent members in a structural frame are not adequately considered. However, in general, single element calculations can be assumed to be conservative because alternative load paths that can be present in a real frame during a fire are neglected.

Single element analysis techniques are codified in many countries worldwide. The approach is commonly applied to concrete, steel, and wood members. As with all structural fire engineering, single element analysis is generally based on a three-stage calculation process:

1. Definition of credible design fires
2. Heat transfer analysis to the structural member from the design fires
3. Structural analysis at the elevated member temperature calculated from the heat transfer

Design tools for heat transfer and structural analysis vary in complexity from empirical correlations, look-up tables, nomograms, and hand/spreadsheet calculations, to simple finite element analysis. The tools adopted by an engineer depend on the failure criteria to be identified. For example, a critical steel temperature of 1022°F (550°C) for column members may be sufficient as the basis of design; alternatively, determining the residual strength/stiffness could be more appropriate. However, a simple temperature comparison may not always be appropriate. In columns and beams that are unrestrained on their top flange, instability events such as buckling also need to be considered, because they occur at lower temperatures than the yield temperature of the constituent material. Guidance exists in several countries worldwide on how to approach this problem; several are identified in the following sections.

Design Fires

One approach to the design fire is to simply assume a heating regime in the compartment of interest identical to the standard temperature-time curve (e.g., ISO 834,[11] BS 476,[10] ASTM E119,[9] NFPA 251). Alternatively, a more rigorous approach to the heating regime from the design fire can be taken. The choice of design fire then depends on the location of the structure in relation to the fire compartment, available fuel load, available ventilation, compartment dimensions, and compartment enclosure material properties. Figure 19.5.5 produced for the One Stop Shop in Structural Fire Engineering website in the United Kingdom (MACE) highlights the range of design fires possible.

In addition, for countries outside the United States, it depends on whether failure of sprinklers must be assumed when calculating the fire for determining structural capacity of a single structural element. For example, external structures may only be exposed to flaming through specific window openings. In tall spaces with well-defined and specific locations for fire load, a local fuel-bed-controlled fire adjacent to a critical piece of structure might be appropriate as the basis of design. In areas of high fire load with ceiling heights of 3 to 4 m, a postflashover fire is likely to be the most appropriate fire case. Alternatively, the standard fire heating regime can be selected to carry out a comparative analysis of the structural element relative to code-based fire resistance recommendations.

Empirical equations and complex computer codes such as fire dynamics simulator (FDS) exist to calculate external fire exposures. A useful empirical approach is presented by Law and O'Brien.[37] Note this was also published in the United States by the AISC. FDS, which is well documented elsewhere,[38] can also be used to formulate, at a reasonably complex level, temperature changes with time for external flaming.

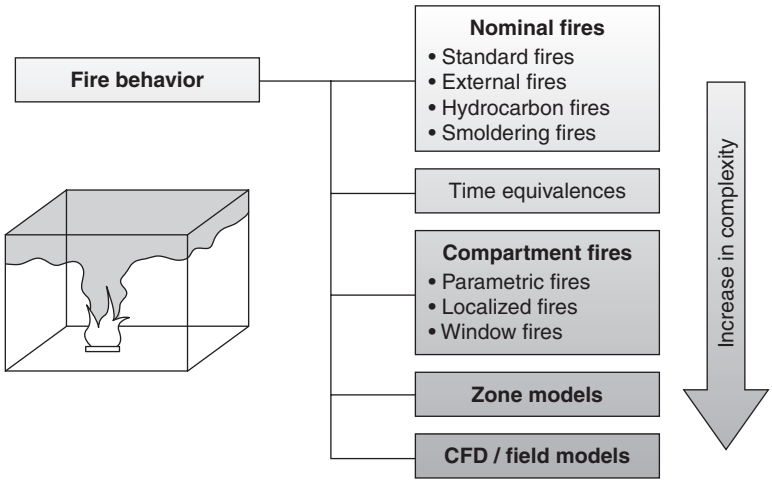
Empirical equations are available for considering local fire cases. In the United Kingdom, TM19[34] provides empirical correlations commonly used in the United Kingdom. The *SFPE Handbook of Fire Protection Engineering*[35] also describes correlations by many researchers, and these are used worldwide. The correlations generally enable the user to calculate flame heights, plume temperatures at various heights, and temperatures along ceiling jets. These data can then be used to calculate the heating effect to and through the structural element for the duration of the fire.

Many deterministic models of postflashover fires have been developed, starting in the 1960s. All postflashover models are based on the assumption that the gas temperature in the compartment is uniform. Walton and Thomas[39] provide a review of many of the available models in the *SFPE Handbook of Fire Protection Engineering.*

The models most often used in design internationally include the parametric temperature time curve given in Eurocode 1, Part 1.2[22] and the heat balance model developed by Magnusson and Thelandersson[21] (Figure 19.5.6). Note that in the United Kingdom, EC1-1-2 has been amended and adopted for use as BSEN1991-1-2:2002. Each country in Europe has similarly made various amendments based on local concerns and market, presented in National Application Documents (NAD) to the main Eurocode. This is true for each material type (steel, concrete, wood, aluminum) and for each calculation procedure or approach.

Computer zone models such as Ozone (University of Liege, Belgium) and CFAST (NIST) will also provide temperature-time curves for postflashover fires. All of the models developed to calculate postflashover fires are only strictly applicable for relatively small compartments, close to square in plan. They are not strictly applicable to large open plan spaces commonly found in real buildings, but they are the only tools available to engineers at the present time. For example, a typical commercial office floor in a tall building in London is approximately 1500 to 2000 m^2 per story, yet the EC1-1-2 limits compartment areas to 500 m^2. As such, the design theory continues to fall behind commercial design requirements and concerns.

The alternative is to use computational fluid dynamics (CFD) codes,[40] but these were originally developed for smoke movement studies and, therefore, consider small fuel-bed-controlled fires in large spaces. Work in defining realistic postflashover fires for use in large or rectangular spaces is ongoing and is considered urgent. Current CFD models will tend to overpredict compartment temperatures and must therefore be used with care when forming the basis of actual design. It is worth noting that NFPA's Technical Committee on Hazard



Fire Model	Nominal Fires	Time Equivalences	Compartment Fires		Zone Models		CFD / Field Models

and Risk of Contents and Furnishings has recently initiated a project to better define fire loads for structural fire resistance calculations.

Heat Transfer

Once a temperature-time regime for the space containing the structural element or, in the case of a local fire or external fire, for the area immediately surrounding or adjacent to the structural element, the structural temperatures can be calculated using heat transfer equations. Various empirical and analytical equations exist in Europe; specifically, the lumped mass heat transfer equations to calculate average section temperatures in Eurocode 1, Part 1.2[22] and Eurocode 3, Part 1.2[41] or Law and O'Brien's[37] view factors to calculate radiative heat transfer to elements remote from a fire are typically used. All equations in codes and guidance documents are very similar because each one has to consider conduction, convection, and radiation in accordance with the principles of heat transfer.

For heat transfer analysis, the nonlinear values of conductivity, specific heat, density, and moisture content of the constituent materials are required to calculate heat transfer. Where available, these values should vary with increasing temperature to obtain an accurate result.

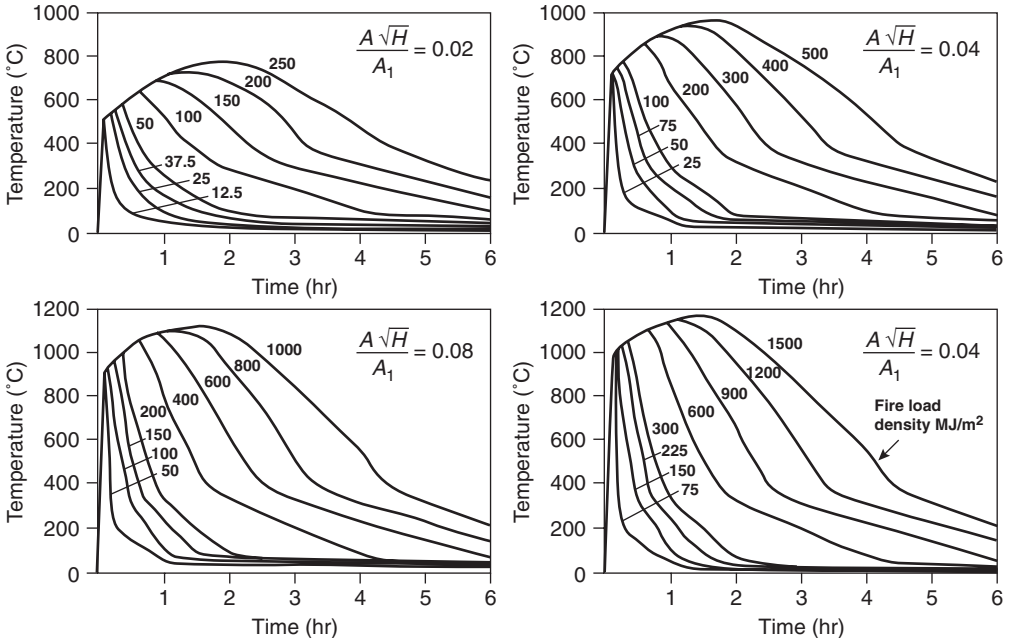

FIGURE 19.5.6 Postflashover Temperature-Time Curves (Courtesy of Swedish Institute of Steel Construction)

For single structural element analysis, some analytical design tools require the use of strength and stiffness properties at elevated temperatures. Where this is the case it is highlighted in the text in the following sections. Most international material codes provide values for stress-strain and Young's modulus with increasing temperature.

APPLICATION OF SINGLE STRUCTURAL ELEMENT ANALYSIS TO STEEL

There are numerous methods applicable to steel elements because the steel industry has spent many years of research optimizing steel design for fire. The main reason is that passive fire protection can significantly increase the cost of a steel frame solution. However, with modern fire protection materials, options for off-site application, particularly of intumescents, are on a rapid rise of use, mainly in Europe. These new approaches, which bring considerable time saving to a construction project and ensure a high quality of application and finish, along with performance-based design methods to optimize fire protection arrangements and thicknesses, mean steel frame solutions are cost effective and very popular in the United Kingdom, as well as in cities where high-rise construction is in demand internationally (e.g., Singapore, Beijing, Dubai).

Some steel-specific calculation methods follow.

Section Factor

The *Hp/A concept,* or *section factor,* is a key variable in single element analysis of steel members in fire. It provides a simple relationship between the surface area of the section exposed to fire and its cross-sectional area or thermal mass. The rate of temperature change in a steel section is a function of this relationship. Consequently, the concept is used by fire protection manufacturers as a factor in determining and specifying the necessary thickness of fire protection material for a particular member size. The value varies if the section is sprayed with fire protection or boxed, as shown in Figure 19.5.7.

Consider a unit length of a steel element where the end connections are ignored. A steel section with a larger surface area will receive more heat than one with a smaller surface area. Moreover, the greater the volume of the section, the greater is the heat sink. Typical values of section factor for structural steel members commonly used in building design are between 100 to 250 m^{-1}. At values of about 50 m^{-1}, a beam section can be assumed to have about 30 minutes inherent fire resistance[42] as a single element considering its thermal mass only.

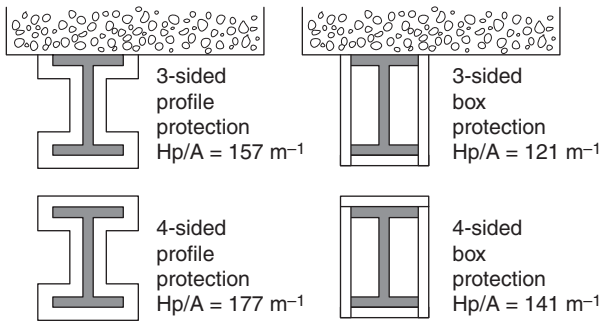

FIGURE 19.5.7 The Section Factor Concept (Courtesy of CORUS)

BS 5950-8[42] in the UK and Eurocode 3, Part 1.2[41] describe the Hp/A concept and how to calculate it for different steel sections and protection arrangements. Note that in the United States, the section factor is represented by the *W/D* (average weight/heated perimeter) *concept* where *W* is in pounds/ft and *D* is given in inches.

Section factors for common structural steel shapes are available from steel distributors worldwide, such as CORUS (the largest steel producer in Europe) and the Heavy Engineering Research Association (HERA), a nonprofit research organization dedicated to the needs of the metals-based industries in New Zealand. The American Institute of Steel Construction and various building codes provide reference to such information in the United States.

Once the section factor is known for a specific section, the average steel temperature development can then be evaluated using relatively simple lumped mass heat transfer formulae for protected and unprotected internal steelwork. The heat transfer analysis is based on the net heat flux to the surface of the member, including convection and radiation effects and conduction through the fire protection material and /or the steel. Equations are provided throughout the literature including the *SFPE Handbook of Fire Protection Engineering* and the following design codes: BS 5950-8,[42] EC 1-1-2,[22] and EC 3-1-2.[41] The lumped mass equations do not calculate temperature gradients through the depth of a steel section; they should, therefore, not be used when this is important for design—for example, if a protected column could fail as a result of thermal bowing. Heat transfer and structural stability have to be checked by finite element analysis or stability of the frame proven by showing the single element can be removed.

Note that the IBC[43] in the United States has many empirical correlations based on the *W/D* ratio to allow engineers to calculate the fire resistance of a particular steel section protected with different materials, including concrete, masonry, and type X gypsum board. It does not currently provide analytical methods for heat transfer analysis. *NFPA 5000®, Building Construction and Safety Code®,* allows for the use of analytical methods to determine the fire resistance of building assemblies. Specific reference is made to ASCE/SFPE 29, *Standard Calculation Methods for Structural Fire Protection,* and ACI 216.1/TMS 0216.1, *Standard Method for Determining Fire Resistance of Concrete and Masonry Assemblies.*

Fire Limit State Factors

Traditionally, single element analysis assumed failure of a steel member occurred at a temperature of 1022°F (550°C). This is because fire protection is typically applied to steel members to limit the temperature rise to 1022°F (550°C) for a prescribed fire resistance period and because steel has lost about 40 percent of its design strength at 1022°F (550°C). (Note that in more recent years in the United Kingdom, a limiting temperature of 620°C is now used for beams, with columns remaining at the traditional 550°C. It is important to ascertain for the specific fire protection being reviewed as part of the single element analysis what limiting temperatures have been assumed. For unprotected members, the limiting temperature should be clearly defined and used as the basis of the capacity checks.)

Often designers would not consider the load or structural actions on a steel member but simply assume failure at 1022°F (550°C). This was generally conservative, but analytical methods are now available to define critical steel temperatures more accurately, considering load, residual capacity of strength and stiffness, and structural failure mechanisms. What this means is that for some cases a higher limiting temperature is possible, but for others, a lower temperature should be assumed.

To determine the limiting steel temperature, load combinations for buildings exposed to fires must be considered. An important part of structural fire engineering is defining the applied load assumed to act on the structure during a fire event. It is common practice to assume that a fire is an unusual event, and, as such, that the safety factors applied to characteristic dead load, wind load, and live load can be reduced. (Dead load is a load of constant magnitude and position that acts permanently, including self-weight. Live load is load on a structure or member, other than wind load, produced by the external environment or the intended occupancy or use.) In general, dead load (DL) is multiplied by 1.0 and live load (LL) is multiplied by a factor ranging from 0.3 to 0.8, depending on the building occupancy type.[42]

Different countries adopt slightly different factors as discussed below. In the UK and Europe, partial safety factors for accidental loads in structural steel design are given by BS 5950-8[42] and Eurocode 0,[44] respectively, for the fire limit state. Table 19.5.11 shows the values for load factors at the fire limit state in BS 5950-8.[42]

The New Zealand Standard NZS 4203[45] adopts 1.0 DL + 0.6 LL or 1.0 DL + 0.4 LL for fire limit state. The live load factor 0.6 is used for storage occupancies and 0.4 for other

TABLE 19.5.11 Load Factors for γ_f at the Fire Limit State

Load	γ_f
Dead load	1.00
Imposed loads:	
a) Permanent:	
1) Those specifically allowed for in design, e.g., plant, machinery, and fixed partitions	1.00
2) In storage buildings or areas used for storage in other buildings (including libraries and designated filing areas)	1.00
b) Nonpermanent:	
1) In escape stairs and lobbies	1.00
2) In offices for general use	0.50
3) All other areas (imposed snow loads on roofs may be ignored)	0.80
Wind loads:	
a) Design for boundary conditions to control external fire spread	0.00
b) All other cases	0.33

occupancies. The Australian Standard AS 1170[46] adopts the same factors as New Zealand for live load but a slightly higher factor (1.1) for dead load.

Ellingwood and Corotis[47] present a methodology for determining loads and load combinations for use in fire-resistant structural design in the United States. Loads and load combinations were found by using probabilistic load modeling techniques and modern load survey results. Since significant fires are rare, it was found that a reduced nominal live load combined with the structural action due to fire is appropriate for design. The load combination that they found is:

$$U_n = D_n + 0.5L_n + F \tag{17}$$

where D_n and L_n are the dead and live loads from the ANSI Standard A58.1[48] and F is the structural action due to fire.[47] ASCE 7-05, *Minimum Design Loads for Buildings and Other Structures,*[49] has adopted load combinations based on the work by Ellingwood and Corotis but applied a factor of 1.2 to dead load and a factor of 0.2 to wind load.

Single Element Calculation Methods Used in the United Kingdom and Europe

BS 5950-8[42] and the Eurocode series[22,41] are the main references for structural fire engineering of steel members. Both codes define methods for heat transfer analysis and single element structural analysis techniques. The codes also provide detailed information on the thermal and mechanical properties of steel at high temperatures necessary to conduct a single element calculation for a steel member.

A key factor in the introduction of BS 5950-8 was a series of loaded furnace tests conducted in the United Kingdom in the 1990s.[50] The tests showed that if a member was carrying less load than assumed in ambient design, then its failure temperature was shown to increase from the traditional 550°C typically assumed. As a result of these tests, BS 5950-8 was published and included the concept of the limiting temperature method. The limiting temperature method, also called the critical temperature method, relies on reduced dead and live loads in fire conditions (relative to the cold temperature design), as defined above, and allows the user to calculate a specific limiting temperature for the structural element on this basis, using the actual loads of the cold temperature structural design. Therefore, the resulting limiting temperature for the element is building-specific.

The limiting temperature method or critical temperature method therefore provides a simple way of relating the critical temperature to the load that the member actually supports in fire conditions. It does not require the engineer to consider reduced strength and stiffness properties at high temperature.

This approach has been commonly adopted in the United Kingdom, Europe, New Zealand, and Australia, where limit state design is used. In North America, however, working stress design is still preferred. This means that, in fire design, the structure's full dead and live design loads are assumed.

For beams under bending and having three or four sides fully exposed to the standard fire or to natural fires, BS 5950-8[42] defines the load ratio (R) as:

$$R = \frac{M_f}{M_c} \tag{18}$$

where M_f is the maximum bending moment under fire conditions (e.g., 1.0 DL + 0.5 LL in an office occupancy) and M_c is the bending moment capacity of the beams at ambient temperature.

If the beam fails by yielding of the steel, M_c is equal to the plastic bending moment capacity of the cross section of the beam. If lateral torsional buckling (LTB) governs design, M_c is the lateral torsional buckling capacity of the beam.

A similar equation is provided for columns or members in tension. For columns, axial load and bending in both directions is also considered.

All steel members lose strength in a similar manner, but because of aspects such as temperature gradients and instability effects (e.g., buckling) at elevated temperatures, it is not always appropriate to apply the same strength reduction to structural members as are applied to the steel itself. Therefore, BS 5950: Part 8 gives limiting temperatures for different types of member for a range of load ratios shown in Table 19.5.12.

The limiting temperature method is simple to use. However, if temperature distribution in a steel beam for the specific design fire is shown to be nonuniform and the beam is prevented from lateral torsional buckling, it may be more beneficial to use a more detailed method to calculate the bending capacity of the beam. Such calculations may be carried out using the bending moment capacity method in accordance with BS 5950–8.

For this approach the beam is divided into a number of sections (Figure 19.5.8) of approximately the same temperature. The number of elements will depend on the complexity of the member and its temperature gradient. The bending moment ca-

TABLE 19.5.12 Limiting Temperature for Design of Protected and Unprotected Hot Finished Members

	Limiting Temperature (°C) at a Load Ratio Of						
Description of Member	*0.7*	*0.6*	*0.5*	*0.4*	*0.3*	*0.2*	*0.1*
Members in compression, for a slenderness λ[a]:							
≤ 70	510	540	580	615	655	710	800
> 70 but ≤ 180	460	510	545	590	635	635	635
Noncomposite members in bending supporting concrete slabs or composite slabs:							
Unprotected members, or protected members complying with item (a) or (b) of 6.3[b]	590	620	650	680	725	780	880
Other protected members	540	585	625	655	700	745	800
Composite members in bending supporting concrete slabs or composite slabs:							
Unprotected members, or protected members complying with item (a) or (b) of 6.3[b]							
i) 100% degree of shear connection	550	580	610	645	685	470	840
ii) 40% degree of shear connection	575	600	635	665	700	760	865
Other protected members							
i) 100% degree of shear connection	495	530	570	610	650	705	785
ii) 40% degree of shear connection	530	560	595	630	675	725	795
Members in bending not supporting concrete slabs:							
Unprotected members, or protected members complying with item (a) or (b) of 6.3[b]	520	555	585	620	660	715	810
Other protected members	460	510	545	590	635	690	770
Members in tension: all cases	460	510	545	590	635	690	770

Note: For beams supporting a composite of slab the limiting temperatures only apply when the voids between the top of the beam and underside of the steel deck are filled with noncombustible void fillers. For guidance on limiting temperatures when void fillers are not used, see Association of Specialist Fire Protection (ASFP), *Fire Protection for Structural Steel in Buildings,* 3rd ed., ASFP and Steel Construction Institute, Hampshire, UK, June 2004.

[a]λ is the slenderness, i.e., the effective length divided by the radius of gyration.

[b]The 6.3 refers to the limiting strain level in the steel and the corresponding strain in any fire protection material. The following strains should not be exceeded: (a) composite members in bending that are unprotected or protected with fire protection materials that have demonstrated their ability to remain intact at a strain of 2.0 percent; (b) noncomposite members in bending that are unprotected or protected with fire protection materials that have demonstrated their ability to remain intact at a strain of 1.5 percent; (c) members not covered in (a) or (b) with a strain of 0.5.

pacity of the cross section is calculated according to the reduced strength and stiffness of steel at the temperature of these sections. See Figure 19.5.7 and the SCI 080[51] for an example.

The bending moment capacity method requires more calculation work than the limiting temperature method. The benefit of using the more elaborate method is to explore possible benefits of the nonuniform temperature distribution in the cross section of the beam, particularly to optimize fire protection or to justify the use of unprotected steel.

EC3-1-2[41] gives two methods to calculate the bending capacity of a steel beam using reduced strength and stiffness properties for steel at high temperature. The first is identical to the bending moment capacity method in BS 5950-8,[42] which is described in the previous section.

Since this method requires many calculation steps, EC3 gives an alternative method that is simpler to use. In this simple method, the design bending moment resistance of the beam is given by

$$M_{fi,\theta,Rd} = \frac{k_{y,\theta} \cdot M_{Rd} \cdot \dfrac{\gamma_{m1}}{\gamma_{m,fi}}}{k_1 \cdot k_2} \tag{19}$$

where M_{Rd} is the bending moment capacity of the cross section ambient temperature and $k_{y,\theta}$ is the reduction factor in the effective yield strength of steel at the maximum temperature in the cross section. Adaptation factors k_1 and k_2 are used to account for nonuniform temperature distribution through the depth and along the length of the steel beam. γ_{m1} and $\gamma_{m,fi}$ are partial safety factors, which vary per country.

Although the bending resistance of a steel beam is usually controlled by the plastic bending capacity of the cross section, it is sometimes necessary to consider the lateral torsional buckling

(LTB) resistance of a steel beam in fire. In EC3, the lateral torsional buckling resistance of a steel beam is calculated the same way as at ambient temperature.

In EC3-1-2, calculations for the strength of a column in fire follow the procedure for design of cold columns in EC3, Part 1.1. An equation to calculate the column slenderness conditions under fire is given a buckling curve *c,* which is to be used to determine the reduced values for flexural stiffness. Although there are four column-buckling curves for column design at ambient temperature, for fire safety design in EC3-1-2, only column curve *c* is used regardless of the type of cross section and axis of buckling. Column buckling curve *c* gives relative conservative values of column buckling resistance. Reasons for using this low buckling curve in fire include the more severe influences of initial imperfections and additional bending moments in the fire case, due to possible nonuniform temperature distributions.[52] Application of BS 5950-8 for a postflashover design fire is presented in the following case study of the Rem Koolhaas CCTV Building in Beijing.

CASE STUDY: Rem Koolhaas CCTV Building, Beijing, China. At the request of the approving authorities in China, the fire resistance of the CCTV (Central China Television) building, Beijing, was calculated using performance-based engineering, despite the fact that that structure was proposed to be fully protected to code. This request was made because the structure was highly innovative, completely asymmetric, and, therefore, the approving authorities wanted to check that the performance was adequate in a real fire.

The CCTV building is a high-rise office building (Figure 19.5.9) with an internal structure consisting of a composite steel and concrete frame. The exterior structure consists of a lateral bracing system formed with tubular structural elements. This exterior lateral stability system comprises a series of axial members at many different orientations, forming a structural role as well as an architectural role. Each member is designed to carry load in axial compression and/or tension.

In collaboration with the structural engineer, the most highly loaded columns and bracing members were identified and checked against their respective failure criteria at the fire limit state using the limiting temperature method in BS 5950-8.[42] All of the steel members were to be protected to not exceed 540°C at the end of 2 or 3 hours heating, dependent on the prescriptive rating of the member in accordance with the local code.

In almost all cases the limiting temperature was shown to be greater than 540°C and therefore deemed to have passed the performance criterion. However, some members were considerably heavily loaded in compression, thereby lowering their limiting temperature to just below 540°C (see Table 19.5.13). A further check on stability was carried out by removing the critical member from the cold design structural model and assessing the performance of the rest of the frame. In all cases loads were able to redistribute to adjacent members without causing failure of adjacent members.

In order to carry out the analysis, credible postflashover design fires were proposed and calculated in accordance with

the parametric equation in EC1-1-2, assuming no reduction of the fuel load as a result of sprinklers or other active systems (the parametric temperature-time curve and its limitations are discussed later in this chapter in the section "Use of Advanced Analysis in Global Structural Response to Fire"). The heat transfer from these design fires to the protected steel elements were then calculated using the lumped mass heat transfer equations in EC1-1-2 and EC3-1-2.

For the design fire case, all of the members passed their limiting temperature criterion because the design fires, although sometimes hotter than the standard fire, were of shorter duration than the standard fire resistance period required. The protected members, therefore, reached lower temperatures in response to the design fires than the 540°C at the end of the standard fire resistance test and also did not reach their limiting temperature.

Single Element Calculation Methods Used in Australia and New Zealand

Structural fire design is a rapidly developing subject in Australia and New Zealand. The New Zealand and the Australian standards are referenced in their building codes (AS 1170 and NZS 4203). The following fire engineering approach was developed in New Zealand and modified for Australia, but is still very similar. As with British and EC standards, the Australian and New Zealand standards determine a fire limit state load combination for fire emergency conditions.

Standards AS 4100[53] and NZS 3404[54] present a limiting temperature method. The simple design method is based on determining the limiting temperature of the steel member under consideration. The limiting steel temperature is the temperature at which the steel member would be expected to yield considering the strength of the steel and load ratio (load in fire/design capacity at ambient temperatures) of the member. The limiting temperature is directly related to the variation of material properties at elevated temperatures. The yield-stress ratio at elevated temperatures and Young's modulus degradation curve at elevated temperatures used in Australia and New Zealand is presented in Figure 19.5.10.

The standards specify the formula from European Convention for Constructional Steelwork[55] to predict the fire resistance time for protected and unprotected steel. Times are based on exposures to standard fire or on an equivalent time exposure.

Single Element Calculation Methods Used in the United States

ASCE/SFPE Standard 29-99, *Standard Calculation Methods for Structural Fire Protection,* provides calculation methods to find the fire resistance of selected structural member and barrier assemblies using structural steel, plain concrete, reinforced concrete, and wood. These methods are intended to produce fire resistance rating times equivalent to those found from ASTM E119, *Standard Test Methods for Fire Tests of Buildings Construction and Materials,* and to NFPA 251. Therefore, the results obtained from the calculations should be used in place of test results.

Chapter 5 of this standard covers the methods for determining the fire resistance of structural steel construction. It describes analytical procedures for determining the fire resistance rating of protected columns, beams, girders, and trusses.

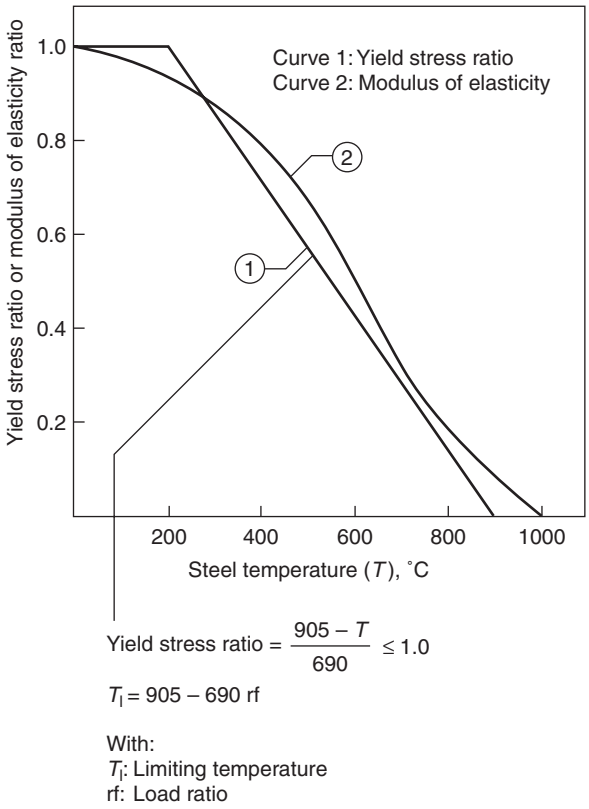

FIGURE 19.5.10 Australian and New Zealand Load Ratio and Limiting Temperatures Standards (Source: A. H. Buchanan, *Structural Design for Fire Safety.* Copyright John Wiley & Sons Limited, 2001. Reproduced with permission.)

The standard also provides calculation methods to find the fire resistance of structural steel beams and girders that differ in size from that specified in approved fire-resistant assemblies, as a function of the thickness of fire protection material and the weight (W) and heated perimeter (D) of the beam or girder. The W/D ratio is similar to the Hp/A concept used in the UK and Europe in that it is an indictor of heating rate.

The calculation methods apply to structural steel beams and girders protected with spray-applied cementitious or mineral fiber materials and a W/D ratio of 0.37 or greater (0.022 in SI units). In addition, the thickness of fire protection material is not to be less than ⅜ in. (9.5 mm). For beams and girder meeting these criteria, the thickness of fire protection material can be found using the following equation:

$$h_2 = \left(\frac{W_1/D_1 + 0.60}{W_2/D_2 + 0.60}\right) h_1 \qquad (20a)$$

where

h = Thickness of spray-applied fire protection material (in.)

W = Weight of the structural steel beam or girder (lbs per linear ft)

D = Heated perimeter of the structural steel beam or girder (in.)

In SI units:

$$h_2 = \left(\frac{W_1/D_1 + 0.036}{W_2/D_2 + 0.036}\right) h_1 \qquad (20b)$$

where

h = Thickness of spray-applied fire protection material (mm)

W = Weight of the structural steel beam or girder (kg per m)

D = Heated perimeter of the structural steel beam or girder (mm)

Subscript 1 refers to the beam and fire protection thickness in the approved assembly and subscript 2 refers to the substitute beam or girder and the required fire protection thickness.[56]

The ASCE standard also provides a method for dealing with structural steel trusses. Although analytical tools for steel fire design are not included in the codes and standards in the United States, the *SFPE Handbook of Fire Protection Engineering* includes a chapter dedicated to analytical methods for determining fire resistance of steel members. This chapter describes three types of calculation methods used to determine fire resistance of steel structural members. Empirical correlations are given based on the analysis of data from performing the standard test, heat transfer analyses to determine the time required for the structural member to attain a predetermined critical temperature or to provide input to a structural analyses, and structural analyses similar to those conducted for structural engineering purposes, except that the material properties are evaluated at elevated temperatures.[57] Methods developed by Lie and Stanzak to calculate the critical temperature of beam and column sections are presented. As with the methods described in other countries, the members are generally assumed to be simply supported and unrestrained.

Milke[57] provides examples throughout the description of each method to illustrate the procedure. The section also provides various methods of protection used for steel structural members.

Calculation Methods Applicable to Steel Elements Exposed to Local Heating

In general, the single element structural checks discussed in the previous section for steel members exposed to postflashover fires can also be applied to steel elements exposed to local heating. This equivalence is because once the temperature of the steel section has been established by heat transfer, the same structural checks considering load ratio and limiting temperature or the reduction in strength and stiffness of the constituent materials are conservative, unless temperature gradient is an issue for stability (e.g., columns).

In the case of local fires, the heat transfer calculation is slightly more sophisticated than the lumped mass heat transfer calculations used in a postflashover fire presented previously. Lower emissivity values and view factors need to be used to calculate heat transfer from radiation when the flames (external through a window or door) or fire are remote from the steel

member. For example, if a local fire is located under a floor slab supported by steel beams but the flames are not high enough to touch the steel, then the effects of convective and radiative heat transfer are reduced compared to a member in a compartment engulfed in a postflashover fire. In this case convective heat transfer to the steel member is a result of the temperature of the hot gases/smoke in the plume above the fire. Radiative heat transfer is largely dependent on the distance of the fire from the steel and is evaluated by using view factors.

Care should be taken when columns are likely to be exposed to a thermal gradient. In this instance the applicability of single element checks has not been validated. The gradient may result in significant thermal bowing and out-of-straightness that should be considered. For example, overall stability of the frame could be checked by removing the member from the ambient structural model that most structural engineers now generate for cold design and checking the resulting stability of the frame. The deflected shape of the structure is less important for fire limit state design, but the stresses generated in the rest of the frame, including the connections, should be shown as less than that required for failure. Once this assessment has been made, a single element approach is acceptable.

One form of local heating is external flaming from a compartment fire through openings or windows. Annex B of EC 1 gives thermal actions for external members. The equations and methodology in EC 1 are based on the external structural steel calculations originally developed by Law and O'Brien.[37]

The calculations consider the different fire exposure experienced by external structural members as compared to the same members in a fire compartment. The concept is shown in Figure 19.5.11. The calculations account for the following:

- The fire being within an adjacent compartment
- No heat buildup because the member is outside
- Cooling from surrounding air
- Heating based on flame size and position of member with respect to the facade
- Radiative heat flux from the fire compartment
- Radiative and convective heat flux from the external flames through the windows
- Radiative and convective heat loss from the steelwork to the ambient surroundings
- Size and location of the structural steelwork
- Through-draft conditions

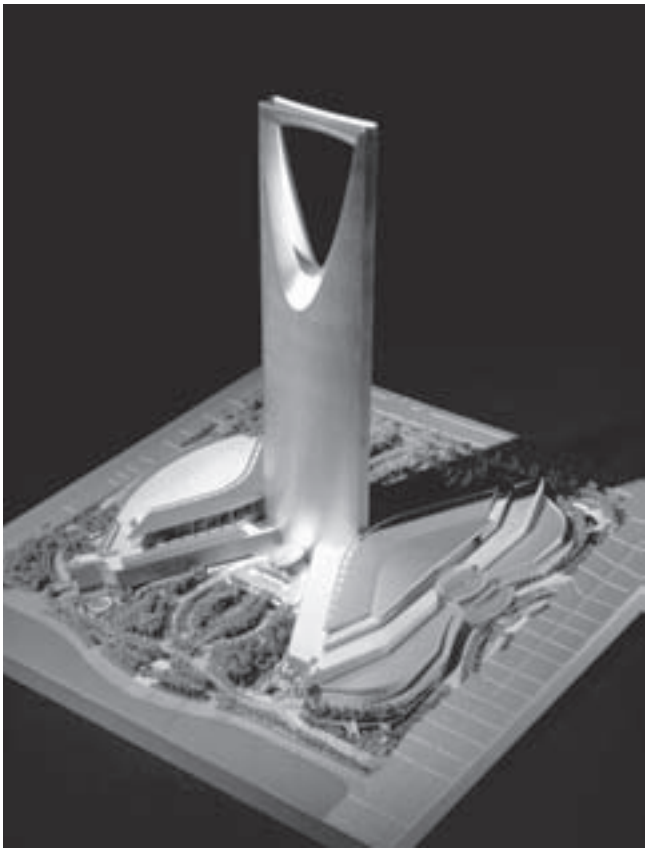

FIGURE 19.5.12 The Kingdom Centre, Riyadh, Saudi Arabia (Courtesy of Ellerbe Becket, Inc.)

CASE STUDY: Kingdom Centre, Riyadh, Saudi Arabia. The Kingdom Centre in Riyadh, Saudi Arabia, is an example of the application of Law and O'Brien's original external steel work calculations to an external flame–only design fire. The building is mainly office use with some retail and extends from grade to 180 m. At 180 m to 290 m, there is a raised observation deck (located at 290 m), a supporting structure containing lift/stair cores, and a steelwork "necklace." The observation deck, its supporting structure, and the nonstructural necklace are referred to as the "sculpture" (Figure 19.5.12 and 19.5.13).

The building structure was designed to meet the requirements of the Uniform Building Code, 1994. By code, it required a 3 hour rating, which meant the sculpture, which was not to contain any occupied floors other than the observation deck at the top, would be protected with passive fire protection. This passive fire protection requirement, however, had a negative impact

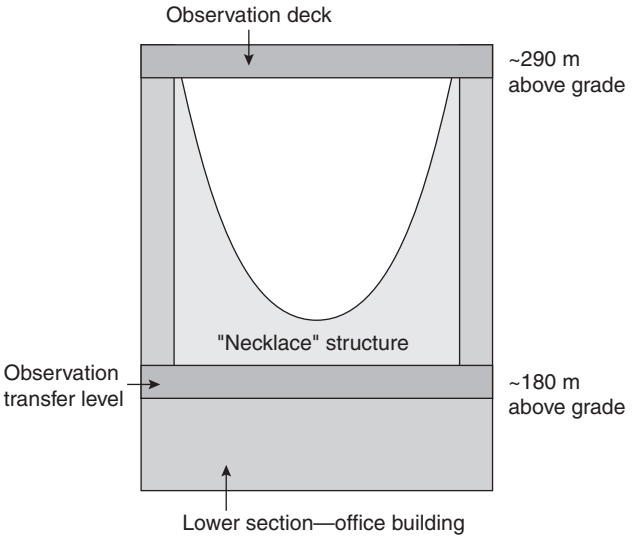

FIGURE 19.5.13 The Sculpture (Source: Arup)

on the aesthetic value of the sculpture and the construction program. In addition, the fire protection appeared to be redundant as it would be providing protection in an area of low fire load. A fire engineering study was, therefore, performed to reduce the areas of passive fire protection to the sculpture structure.

A number of fire scenarios were considered; failure was defined as a critical steel temperature of 550°C, when steel has lost about 40 percent of its ambient strength. This is conservative because it does not take advantage of the limiting temperature method presented previously, in which higher critical temperatures could have been calculated based on a reduced dead load, live load, and wind load at the fire limit state. For the sculpture this could have meant higher limiting temperatures of 600 to 700°C.

One of the fire scenarios considered for this project was the flame projection through the proposed windows and the resulting heating of the external steel members in proximity to the windows due to a postflashover fire on an office level. The flame projection (see Figure 19.5.14) from the office was determined for a range of ventilation conditions, and the heat transfer from the flames to the steel was calculated for the worst-case condition of flame length and temperature.

It was found by iteration that, at a vertical distances of greater than 10 m above the window opening, the heat flux from the flames would not heat the steel members to above 550°C, even after infinite exposure time. The steelwork immediately above the office floors was therefore protected for a height of 10 m, but the remainder of the structure above, including the observation desk, was unprotected. On the observation deck, credible local fires—for example, a large baggage fire—were investigated, assuming the same critical steel temperature of 550°C for failure criterion. Lower temperatures were shown as a result of heat transfer using the equations from the fire to the steel elements based on the work of Milke[57] from the *SFPE Handbook of Fire Protection Engineering.*

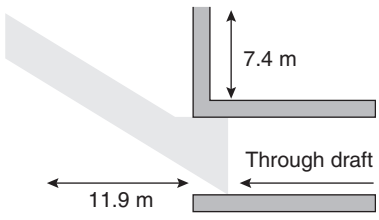

FIGURE 19.5.14 Summary of Flame Projection Calculations for the Office Level (Source: Arup)

Role of Connections in Single Element Design

Calculating the fire resistance of single members is only an acceptable design solution when the connections between the members are also considered. The fire resistance of connections in a steel frame is generally not well understood. The University of Sheffield in the United Kingdom has conducted some of the most significant research in this field.[58]

In addition, Scott, Lane, and Gibbons[59] discuss the behavior of connections in response to whole frame behavior and provide some insight into likely favorable and nonfavorable connection arrangements when considering the axial (compression and tension) forces placed on a connection as beams expand, pull, and push on connections in fire. Rotter et al.[60] state that connections should be designed for the tensile pulling force in the cooling phase of a fire when deflected steel beams try to contract to their original position but, because of plastic strains in the steel beam, cannot.

However, with respect to design recommendations in codes for single element analysis, it is generally assumed that a connection will be designed for ambient loads and then protected to the same standard as the adjoining member. If the adjoining member has been overdesigned so that it has more fire resistance, then the connection should also be overdesigned. This is always the approach when using the single element approach to design discussed in this chapter.

EC 3[41] and BS 5950-8[42] state that the fire resistance of a bolted or a welded connection may be assumed to be sufficient, as long as the fire protection on the connection provides the same thermal resistance to the joint as the fire protection on connecting members and the utilization of the joint is equal or less than the maximum value of the utilization of any of the connected members. BS 5950[42] further states that if the utilization of the connection is higher than the utilization of the connecting members, the protection to the connection should be increased to ensure that the connection does not fail first.

APPLICATION OF SINGLE STRUCTURAL ELEMENT ANALYSIS TO CONCRETE

The simplest and most common method of designing concrete structures in fire is to ascertain the required thickness and cover to reinforcement for the necessary fire resistance period, as spec-

ified in tabulated data in codes worldwide. When these tabulated data are applicable and are followed in the design of a concrete element, spalling prevention is generally assumed to heave been adequately addressed. There are a number of analytical methods to calculate the fire resistance of concrete members based on their capacity in fire, but the phenomenon of spalling must also be addressed when using these approaches.

Spalling

Detailed analysis of concrete members' response to fire, including the effect of spalling throughout the fire duration, is difficult due to the complexity of the factors that cause spalling and their nonlinear and unpredictable response to heat. Spalling prevention must therefore be demonstrated as provided prior to detailed analysis of concrete elements. Before the range of single element calculation methods available internationally for concrete are presented, a discussion of spalling and how it is treated by design codes in various countries is given.

Spalling is a complex process and, in general, not well understood, even by experts in the field. There are various different kinds of spalling (aggregate splitting, explosive, surface, corner separation, sloughing off, and cooling spalling). The most detrimental to a structural member in fire is explosive spalling. Explosive spalling (Figure 19.5.15) can occur at temperatures as low as 100°C and in some cases can fully expose the reinforcement to the full heat of a fire. Explosive spalling is thought to be primarily associated with evaporation of water in the concrete pores and the associated buildup of pore pressures. However, restraint to thermal expansion, the heating rate of the fire, the strength of the concrete, and the dimensions of the section also contribute.[61]

The risk of explosive spalling can be reduced by choice of aggregate, by limiting the concrete strength and moisture content where possible, and by the addition of polypropylene fibers. Arup Fire[61] conducted a research project to define the risk of spalling in normal weight-reinforced concrete exposed to hydrocarbon fires for the health and safety executive in the United Kingdom. Risk values (1 to 5) were assigned to all of the variables affecting spalling of concrete in a fire—for example, moisture content, restraint, and aggregate type. Risk categories associated with the combined or additive risk values for a particular concrete were assigned spalling rates defined by Arup Fire from evidence in the literature.

FIGURE 19.5.15 Example of Explosive Spalling of Concrete (Source: Arup)

Spalling Prevention Measures Used in the United Kingdom and Europe

BS 8110, Part 2[62] presents a tabulated approach to specifying cover and thickness of section required for different fire resistance periods for a range of concrete elements. Lennon[63] gives the background to these data and reports on spalling observed during standard fire tests and the adequacy of this guidance for cover to reinforcement given in the United Kingdom. Section 4 of BS 8110-2[62] gives additional measures necessary to reduce the risks of spalling at elevated temperatures. It is recommended that these additional measures also be implemented when the cover to reinforcement exceeds 40 to 50 mm.

The British standard discusses the key factors believed to influence spalling. It states that rapid rates of heating, large compressive stresses, or high moisture contents (over 5% by volume or 2% to 3% by mass of dense concrete) can lead to spalling of concrete cover at elevated temperatures, particularly for cover to reinforcement of thicknesses exceeding 40 to 50 mm. In addition it states that concretes made from limestone aggregates are less susceptible to spalling than concretes made from aggregates containing a higher proportion of silica, quartzites, and granites. Concrete made from manufactured lightweight aggregates are found to rarely spall.

Recommendations are given to designers to protect the concrete against spalling when the cover to reinforcement exceeds 40 to 50 mm. Acceptable measures are proposed as follows:

- An applied finish by hand or spray of plaster, vermiculite, and so forth
- The provision of a false ceiling as a fire barrier
- The use of lightweight aggregates
- The use of sacrificial tensile steel

The code states that welded steel fabric as supplementary reinforcement is sometimes used to prevent spalling; it is then placed within the cover at 20 mm from the concrete face.

General design rules concerning spalling are also mentioned in EC 2-1-2,[64] giving recommendations to limit explosive spalling and falling off of concrete. The main parameter considered by this design guidance is the moisture content. The code states that explosive spalling is unlikely to occur when the moisture content of the concrete is less than a certain amount with respect to the weight. This parameter is called k and is given as a percentage. The allowable percentage for each European nation is given by each individual National Annex. However, the recommended base value in EC 2-1-2[64] is 3 percent by weight of moisture content. (The United Kingdom has adopted 3%).

For normal-weight concrete, when using tabulated data to design section thickness and cover to reinforcement for the standard fire, the European code states that there is no further check required for spalling.

For beams, slabs, and tensile members, if the moisture content of the concrete is more than k percent by weight, the influence of explosive spalling on load-bearing function R may be assessed by assuming local loss of cover to one reinforcing bar or bundle of bars in the cross section and checking the reduced load–bearing capacity at the resulting high temperatures.

A specific section in the Eurocode addresses high strength concrete. For concrete grades C55/67 to C80/95 (where the two numerical values given after the C refer to the strengths measured in a cube and cylinder test), the rules as already described apply, provided that the maximum content of silica fume is less than 6 percent by weight of cement.

For higher contents of silica fume, further spalling prevention measures are proposed. For concrete grades $80/95 < C < 90/105$, spalling is deemed as likely in any situation for concrete exposed directly to the fire and at least one of the following methods should therefore be provided:

- *Method A.* A reinforcement mesh with a nominal cover of 15 mm. This mesh should have wires with a diameter greater than or equal to 2 mm with a pitch less than or equal to 50 × 50 mm. The nominal cover to the main reinforcement should be greater than or equal to 40 mm.
- *Method B.* A type of concrete for which it has been demonstrated (by local experience or by testing) that no spalling of concrete occurs under fire exposure
- *Method C.* Protective layers for which it is demonstrated that no spalling of concrete occurs under fire exposure
- *Method D.* Include in the concrete mix more than 2 kg/m³ of monofilament propylene fibers

Spalling Prevention Measures Used in New Zealand and Australia

The concrete code used in Australia is AS3600.[65] The existing code contains only a cautionary note about spalling, with no actual guidance; it reads as follows:

> SAA is not prepared at present to specify requirements for the prevention of spalling of concrete from beams or columns exposed to fire. However, reference may be made to Clauses 4.1.6 and 4.1.7 of BS8110 part 2, in relation to this matter.

The whole code is currently being redrafted. The reason for this exercise is to increase the maximum concrete grade addressed by the code and therefore more easily used in design from 65 MPa to 100 MPa. This further increases the risk of spalling. The current draft in circulation includes no guidance on spalling and the intention is to include some technical advice to prevent spalling, in the commentary only.

Spalling Prevention Measures Used in the United States

In the United States, the building codes and ACI Manual of Concrete Practice are silent on spalling prevention measures for fire other than specifying minimum levels of cover to reinforcement. In the *SFPE Handbook of Fire Protection Engineering,* Fleischmann and Buchanan[66] briefly discuss the merits of adding fine polypropylene fibers to the concrete mix but do not specify quantities for design.

Calculation Methods Applicable to Concrete Structures

In all the analytical methods presented here to determine the capacity of concrete elements in fire, engineers should also satisfy themselves that spalling has been adequately addressed by the design, through the meeting of tabulated code requirements for dimensions of section and cover or by prevention measures.

When designing concrete elements for fire protection, well-detailed reinforcement with adequate tying will generally perform well in that loads can be redistributed. It has been shown that continuity will enable redistribution of moments to hogging areas where steel is remote from the fire, enhancing the fire resistance of a slab or beam; if this is considered in design, however, then the detailing must allow for it.

Axial restraint will allow arch/membrane action to occur; some single element design methods take this into account to further increase the fire resistance that can be assumed to be achieved by a section in design, although it should be noted that this may also then increase the likelihood of spalling.

Calculation Methods for Concrete Used in the United Kingdom and Europe

The tabulated data in BS 8110 are based on furnace test data from the 1950s and are therefore relevant to design fire cases where a postflashover fire is assumed. Tables tend to be related to element type; tables for columns and beams, for example, are different. Similarly, separate tables exist for prestressed members as opposed to ordinary reinforced sections in BS 8110. The prestressed data are based on data for precast elements and their application, therefore, to modern posttensioned slabs is questionable, particularly bonded systems with very little passive reinforcement and the protection of anchorages in unbonded construction. Similar tables are available in Eurocode 2, Part 1.2, and these are also assumed to be applicable to the design fire case where flashover has occurred in the compartment containing the structural elements.

Both BS 8110-2 and EC2 give material properties for reinforcement, prestressing steel, and concrete at elevated temperature. These can be used for detailed analysis to determine the capacity of single concrete elements at elevated temperatures. Again a three-step process (design fire, heat transfer, capacity calculation) is required for concrete. When calculating heat transfer, there are no simple equations that can be used because the conductivity of concrete is low and concrete sections are thermally thick. Consequently, either predefined nomograms drawn for particular sections in response to the standard fire can be used, or a finite element heat transfer analysis is required to calculate the temperature gradient through the depth and/or along the length of a concrete section.

The most commonly applied design tool for concrete members in a compartment with a postflashover fire is the 932°F (500°C) isotherm method or reduced cross section method orig-

inally developed by Anderberg.[67] The approach is recognized by EC 2-1-2[64] and illustrated in Figure 19.5.16.

It is assumed that any concrete at a temperature greater than 500°C will not be able to support load in fire. Any concrete at a temperature less than 500°C can be assumed to have its full ambient design strength. These simple rules and the reduced strength of reinforcement are used to calculate the residual capacity of the section in response to fire. If this residual capacity is sufficient to carry the loads, factored for the fire limit state, the section is deemed to be acceptable.

Data are available in EC2 to predict the location of the 500°C isotherm in various sections at 30, 60, 90, and 120 minutes of the standard fire, usually in the form of nomograms. Alternatively, engineers can calculate a credible design fire and subsequent heat transfer through the particular concrete element to actually predict the isotherm. The methodology is generally applied to beams and columns, although it can also be applied to slabs, provided the section is not too thin that almost the entire section is at 500°C and, therefore, has to be ignored.

In addition to the 500°C isotherm method, Annex B of EC2-1-2 also provides the zone method for calculating the resistance to bending moments and axial forces. The zone method is recommended for use with small sections and slender columns fully engulfed in a postflashover fire, but is only valid when the standard fire is used as the design fire case.

The zone method requires more calculation but is of benefit to smaller sections because some strength in the concrete is considered even at high temperatures. The zone method splits the member into three or more zones of near equal temperature; then the material properties at elevated temperature are used to calculate that particular section capacity. A zone of damaged concrete at the surface is calculated and ignored in the capacity check. The capacity of the reduced section is then calculated by summing the capacity of each remaining zone.

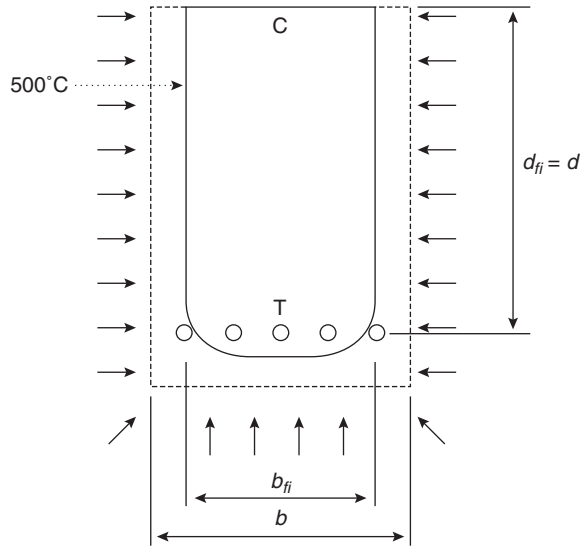

FIGURE 19.5.16 500°C Isotherm Method (Courtesy of British Standards Institute. Permission to reproduce extracts from British Standards is granted by BSI. British Standards can be obtained from BSI Customer Services, 389 Chiswick High Road, London W4 4AL. Tel: +44 (0)20 8996 9001. email: cservices@bsi-global.com.)

For shear, torsion, and anchorage, Annex D provides a simplified calculation method, although failure of concrete is rare in this respect. Shear can be a problem in precast, pretensioned slabs with narrow webs.[68]

Simplified methods for the design of beams and slabs where the loading is predominantly uniformly distributed and where the design at normal temperature is based on linear analysis are provided in Annex E of the Eurocode. A method for simply supported slabs and beams and a method considering redistribution of load for continuous members are also provided. When considering the redistribution of load in continuous members in fire, the curtailment length of the reinforcement over the supports should be checked because the point of contra-flexure will have changed. A formula to calculate the required length is given by EC2.

The Eurocode does not provide a simplified calculation method for the analysis of axially restrained slabs/beams, unlike methods presented in the *SFPE Handbook of Fire Protection Engineering*.[66] This is conservative as restraint induces thrust, which will enhance the members' fire resistance because the thrust acts as additional reinforcement.

Calculation Methods for Concrete Used in New Zealand and Australia

The Australian Concrete Design Code, AS 3600,[65] provides dimensions for concrete sections to achieve periods of fire resistance like all other codes, assumed as applicable for postflashover fire conditions. In Section 5.9 of the code it states that fire resistance may be predicted by methods of calculation provided the relevant properties of materials at elevated temperature are used. New Zealand's NZS 3101 has a similar approach.

Calculation Methods for Concrete Used in the United States

Tabulated data for cover and thickness of concrete elements are given in building regulations ACI 216.1-97 in the ACI *Manual of Concrete Practice*[69] and ASCE/SFPE 29-99.[56] The main differences between U.S. data and tabulated data elsewhere are that U.S. codes differentiate between aggregate type, recognizing that carbonate concretes spall less than siliceous concretes. Dimensions and cover are given for restrained and unrestrained slabs and beams as a consequence of the restrained furnace test in ASTM E119. The data for prestressed members differ from the data for ordinary reinforced members.

Fleischmann and Buchanan[66] present analytical methods for determining the fire resistance of concrete members in the *SFPE Handbook of Fire Protection Engineering*. The chapter presents temperature nomograms for slabs and beams in the standard fire and equations for calculating the fire resistance of simply supported slabs and beams, continuous unrestrained flexural members, and those restrained against thermal expansion.

Continuous unrestrained members have longer fire endurance than simply supported members because they can redistribute moments. Usually the redistribution of moment through the depth

of the member results in failure of the negative moment reinforcement over the supports. The chapter states that the American Concrete Institute warns against increasing this reinforcement as this could result in compression failure of the member, which is not desirable. Limitations are therefore placed on the negative reinforcement to ensure flexural failure in design. Equations to calculate the flexural strength at any point are given.

Equations are also given to account for the thermal thrust force that will occur in the axis of members heated from below and restrained from thermal expansion. The effect of the thermal thrust is the same as prestressing a concrete beam or slab. Therefore, the line of thrust can be considered a fictitious line of reinforcement in flexural design. To calculate the thrust moment, the midspan deflection must be calculated. Fleishmann gives an approximate equation for deflection.

Similar calculations to those presented by Fleischmann and Buchanan[66] are presented in ACI 216R-89, ACI *Manual of Concrete Practice.*[69]

Calculation Methods Applicable to Concrete Elements Exposed to Local Heating

As for steel design, local fires and external flaming can be considered as credible design fires to be resisted by the concrete element, in lieu of a standard fire or postflashover design fire, depending on the fuel load arrangement, quantity, and location (as outlined earlier, TM19[34] and Law[37] are useful references to determine such fire cases).

Heat transfer to concrete is more complex and will generally require a finite element computer code to calculate the temperature gradient through a concrete section.[68]

Spalling prevention measures should be addressed by the design if the concrete is exposed to direct flame impingement or if the concrete temperature in the cover to reinforcement exceeds 100°C. However, if overall frame stability can be shown when a single critical element is lost, then spalling prevention is not required. The capacity of the element in these local or external heating regimes can then be checked using the methods outlined from BS8110 Part 2 or EC2.

APPLICATION OF SINGLE STRUCTURAL ELEMENT ANALYSIS TO COMPOSITE STEEL AND CONCRETE MEMBERS

Composite steel and concrete members are generally concrete slabs connected to steel beams via shear studs, hollow steel sections filled with reinforced concrete, or hot rolled steel sections encased in concrete, all of which are designed at ambient temperature, taking into account composite action. In some cases steel hollow sections are filled with concrete to provide fire resistance, but the concrete fill is ignored by the ambient design. In this case there may be no composite action, and the concrete simply acts as heat sink, in which case there is a limit to the fire resistance that can be achieved (30 to 60 minutes maximum).

Composite steel frame construction generally has excellent fire resistance properties as a single member and as a whole frame. The main reason for this good performance is that when the steel member becomes hot and weak, there are alternative paths for the load into the colder concrete slab in a composite floor or the concrete core of a composite column.

As a consequence of the concrete, composite members experience large gradients through their depth; therefore, to obtain an accurate representation of this temperature gradient during a fire, a heat transfer analysis using a finite element method is usually required. A 2D analysis is sufficient if it is safe to assume there would be no gradient along the member.

For composite slabs it is reasonable to assume an average steel temperature from the fire for the entire protected or unprotected beam section, because it is the gradient between the steel beam and the concrete slab that tends to define performance. In this case, the simple lumped mass heat transfer equations can be used to calculate the average steel temperature. However, increased fire resistance could be achieved if the temperature gradient in the beam is also calculated.

As for all single element methods, the design fire must first be established (a standard fire; a postflashover fire calculated using, for example, a parametric equation; a local fire; or an external fire case). The heat transfer from this fire through the structural element can then be determined using a finite element analysis. Predefined nomograms based on standard furnace tests can also be used to obtain the temperature gradient. The capacity assessment methods, as follows, can then be used.

Composite Beams, Slabs, and Columns in the United Kingdom and Europe

The limiting temperature method discussed in the context of steel members previously can also be used for composite beams. The difference with the design methods for steel beams is that if the beam fails by yielding of the steel, M_c is equal to the plastic bending moment capacity of the cross section of the composite beam (steel and concrete). BS 5950-8[42] and Eurocode 4, Part 1.2,[70] therefore, give specific values for limiting temperature of composite steel beams.

An essential part of composite beams are the shear connectors or shear studs, which transfer the forces from steel beam into the concrete slab and vice versa. EC4-1-2[70] states that the design shear resistance in fire situation can be determined in accordance with the cold design in EC4-1-1,[71] except that in the fire circumstances, the variation of material properties with temperature and the different partial safety factor should also be taken into account. The temperature of the stud connector and concrete may be taken as 8 percent and 40 percent, respectively, of the temperature of the upper flange of the beam. Note BS 5950–8 does not consider the temperature of the shear stud.

However, both BS 5950-8 and EC4-1-2 differentiate between partial and full shear connection. Note that the limiting temperatures for partial shear connections are higher than for the 100 percent shear connection (Table 19.5.14) due to the fact that the partial shear connection determines the capacity of the beam. The shear connections remain relatively cold, because the studs are in the concrete slab. The limiting temperature for the rest of the cross section might therefore be higher. For the 100 percent shear connection, temperatures of the lower flange are determined to find the capacity of the composite beam in fire.

In addition to providing design methods for conventional composite beams, both design guides also present design meth-

TABLE 19.5.14 Limiting Temperature of Composite Beams

Description of Member		Limiting Temperature (°C) at a Ratio Of *0.7*	*0.6*	*0.5*	*0.4*	*0.3*	*0.2*
Unprotected, or protected with fire protection that can undergo large strains	100% shear connection	550	580	610	645	685	740
	40% shear connection	575	600	635	665	700	760
Other protected members	100% shear connection	505	540	575	620	660	715
	40% shear connection	535	565	605	640	675	736

ods to determine the capacity of partially encased composite beams (as would occur when shelf angle floor beams are used and some of the beam is embedded in the slab).

When calculating the load-bearing resistance of a composite slab in fire using a single element approach, it is often assumed that it is one-way spanning, being effective only in the direction of the concrete rib. This is in contrast to the much stronger mechanism that occurs in reality—tensile membrane action—discussed later in this chapter in the subsection "Analytical Methods to Quantify Tensile Membrane Action in Fire." Consequently, a single element approach will tend to be on the conservative side.

For a continuous slab, a plastic design method may be used as defined in EC 4.[70] In this method, plastic hinges are assumed at the support and locations of the maximum bending moment in the slab. In order to guarantee sufficient deformation capacity for continuous slabs, there are limitations on the minimum amount of reinforcement at supports and midspan.

In sagging bending, since the temperature rise on the unexposed side of the slab is generally required to be below 284°F (140°C) to fulfill the insulation requirement in standard fire resistance testing, the concrete in compression can be assumed to be cold. Its cold strength may be used when calculating the sagging bending moment capacity of the slab. Contributions from the steel decking are usually ignored because the decking will be unprotected and might debond when under direct fire attack. Reinforcement in the ribs generally provides the tension force in fire. (See Figure 19.5.17 for visualization of the design method.) To calculate this tension force, the temperature distribution through the composite slab is required and can be obtained from calculation using finite element heat transfer models or nomograms provided in Eurocode 4.

Under a negative bending moment (Figure 19.5.18) in a continuous slab, the compression face of a composite slab is exposed to fire where there is a steep temperature gradient. When calculating the negative moment capacity, the composite slab, including the concrete ribs, should be divided into a number of layers, each of approximately the same temperature. The contribution of each layer should be evaluated separately using the reduced strength and stiffness properties of the materials and then integrated to give the total slab resistance. To simplify this calculation, a ribbed or trapezoidal slab may be converted into a flat slab with an effective flat slab depth, with its corresponding temperature distribution. This temperature distribution can be calculated using nomograms for the standard fire or finite element analysis for any fire type.

Composite Beams, Slabs, and Columns in New Zealand and Australia

In New Zealand and Australia, the limiting temperature method is used for composite beam members. Performance-based design assuming reduced strength and stiffness of composite columns and other structural members can also be performed within the performance-based framework in both New Zealand and Australia.

Composite Beams, Slabs, and Columns in the United States

Fleishmann and Buchanan[66] briefly discuss composite steel–concrete construction in the *SFPE Handbook of Fire Protection Engineering* but simply cross-reference Eurocode 4 for detailed analysis. ASCE/SEI/SFPE 29-99[56] provides empirical correlations to calculate the benefit of increased thermal mass when steel sections are filled or encased with concrete.

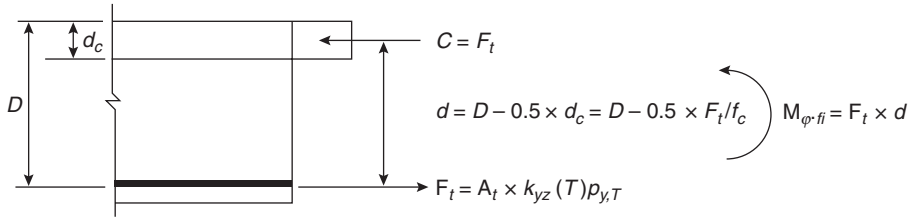

FIGURE 19.5.17 Calculation Method for Sagging Moment Capacity (Source: Arup)

$$\frac{1}{z} = \frac{1}{\sqrt{u_1}} + \frac{1}{\sqrt{u_2}} + \frac{1}{\sqrt{u_3}}$$

where u_1, u_2, u_3 are axial distances (mm) of the reinforcing bar to the profiled steel as specified in figure.

Additionally to the limitations given in the table, the use of this table is restricted to:

u_1 and $u_2 \geq 50$ mm

$u_3 \geq 35$ mm

Relation fire duration - temperature of the reinforcing steel

Standard Fire Resistance	*Temperature of Reinforcing Steel (°C)*
R 60	$\theta_z = 1175 - 350\ z \leq 810°C$ for $(z \leq 3{,}3)$
R 90	$\theta_z = 1285 - 350\ z \leq 880°C$ for $(z \leq 3{,}6)$
R 120	$\theta_z = 1370 - 350\ z \leq 930°C$ for $(z \leq 3{,}8)$
R 180	$\theta_z = 1490 - 350\ z \leq 1000°C$ for $(z \leq 4{,}0)$
R 240	$\theta_z = 1575 - 350\ z \leq 1500°C$ for $(z \leq 4{,}2)$

Calculation Methods for Concrete-Filled Hollow Steel Sections

Various existing calculation methods provide a cost-effective way to obtain columns with a high load-carrying capacity at ambient temperature and high fire resistance (Figure 19.5.19) without the addition of passive fire protection to the steel. When the column is designed as composite at ambient temperature and in fire the concrete filling has several beneficial effects. The concrete will act as a heat sink to slow the temperature rise of the steel column; the reinforced concrete can bear some or all of the axial load as the steel weakens; and the reinforced concrete fill can provide lateral stability to inhibit local buckling of the steel shell.

In some instances the hollow steel section is filled with concrete only and no benefit is taken from composite action in design, in which case the concrete simply acts as a heat sink. Low fire resistance periods of 30 to 60 minutes can be achieved.[72]

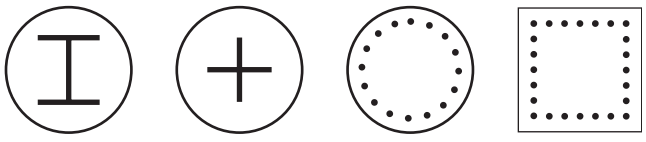

FIGURE 19.5.19 Example of Composite Column Sections (Source: F. Kettner, "Investigations on the Load Bearing Behavior of Composite Columns Under Fire Conditions," *1st International Ph.D. Workshop on Fire Protection Science and Engineering,* Hanover, Germany, 2005)

Composite Column Design Approaches

EC4-1-2 Design Approach. EC4-1-2 gives a more rigorous and detailed approach to composite column design than any other code worldwide. It introduces three design procedures for composite columns: (1) tabulated data, (2) simple calculation model, and (3) advanced calculation models.

The application of the tabulated approach is for a limited range of load ratios and steel section size and is only applicable to columns with a buckling length of less than 4.5 m. A more detailed calculation method is given in Annex H of EC4-1-2.[70] In this case the maximum buckling length permissible in order for the calculation to be valid is still 4.5 m as a consequence of the furnace tests the methodology is based on, but any section and any load ratio can theoretically be designed using this approach.

EC 4 also permits advanced analysis; a number of researchers have created software (Kettner,[73] CEC,[74] SCI,[51] and CORUS[72]) to calculate and extend the application of EC4-1-2 Annex H.[70] The software is still based on single element analysis but allows an accurate calculation of the through-depth thermal gradient and resulting differential strains in the steel casing, concrete, and reinforcement. Each code is based on an iterative process to obtain the squash load and rigidity of the composite column in fire. The calculation involves the determination of the temperature distribution in the cross section and the consequent residual rigidity (EI). The Steel Construction Institute (United Kingdom) and CORUS steel have produced software to make this calculation easy to use in design but this is also limited to a column buckling length of 4.5 m.[75]

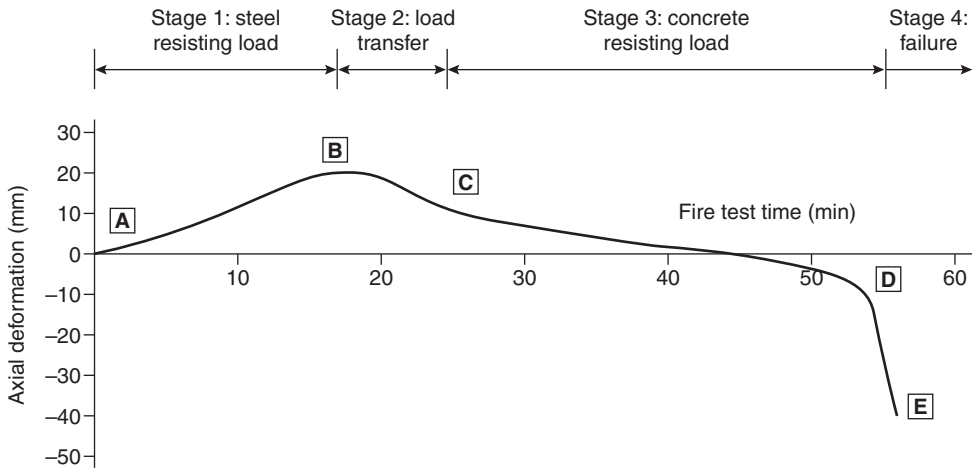

FIGURE 19.5.20 Axial Deformation Response as a Function of Time for a Typical Concrete-Filled Tube (Courtesy of V. K. R. Kodur and John C. Latour, National Research Council of Canada)

Canadian Fire Tests. In Canada a body of work exists on the response of concrete-filled steel sections. Over a number of years, the National Research Council of Canada (NRCC) carried out numerous fire tests on unprotected concrete-filled steel columns. The fire tests were carried out in a specially constructed fire testing furnace at the National Fire Laboratory.[76] The Canadian fire tests included different dimensions and thickness of circular and square hollow sections, a variety of concretes (plain, bar reinforced, high strength, and steel fiber reinforced with either siliceous or carbonate aggregates), and different levels of applied loads.[77–79] All the test columns were 3810 mm and the column ends were rotationally restrained at the ends. All fire tests were carried out with unprotected steel sections and fire exposure according to ASTM E119.[9]

Figure 19.5.20 shows a typical response of the recorded axial deformation-time relationship. It can be divided into four parts: (1) a phase of steady increase in the column expansion (A-B) is followed by (2) a sharp contraction (B-C) and (3) then gradual contraction (C-D) in the column axial deformation. (4) The columns experience another sharp contraction (D-E) before failure.

This type of behavior may be explained by considering the temperatures and resistances of the steel tube and concrete. Fire tests by others[74] on unprotected concrete-filled columns show similar results.

A design method for the calculation of the fire resistance of concrete-filled hollow steel columns was included in Appendix D of the National Building Code of Canada beginning with the 1995 edition and then later in a joint publication of the American Society of Civil Engineers and the Society of Fire Protection Engineers.[56]

CASE STUDY: Auditorium. The following case study demonstrates a single element analysis of unprotected circular hollow section (CHS) columns in a steel sway frame. The columns form part of the primary structural frame of an auditorium. The aim was to determine if the unprotected columns could achieve their necessary fire resistance rating as a result of composite action with reinforced concrete filling. The local code required a fire resistance rating of 2 hours, except where the columns support the roof, in which case a reduction to 1 hour was acceptable.

The simplified single element approach in Eurocode 4 for nonsway frames was deemed applicable for the sway frame of the auditorium because it was determined that the overall lateral stability could be provided by the global performance of the steel frame with four adjacent columns removed. Based on the fire load in the auditorium it was shown that only four columns are expected to be affected by fire simultaneously. Therefore, four adjacent columns were removed from the structural engineer's model and the stability of the frame in wind was shown to remain adequate. As global lateral stability was justified, the capacity of the columns under gravity loading in fire could be assessed individually.

The inherent fire resistance of the columns under axial load was checked in accordance with the simplified guidance in Eurocode 4 for single elements in a nonsway frame. The heating regime was assumed to be the standard temperature-time curve.[9] The calculations were performed using a combination of software developed by the steel producer CORUS[72] and spreadsheet calculations. The software assessed the temperature gradient in the section and then the capacity of the composite column using the properties of steel and concrete at elevated temperatures. It also considered the differential strains between the cool concrete and the hot steel casing. The resulting capacities were incorporated into a spreadsheet and compared to the demands.

The columns were analyzed with up to 6 percent reinforcement within the concrete fill with 1 in. (25.4 mm) cover throughout. The column capacities produced by the software were used to calculate the utilization (ratio of load to capacity) at 60 and 120 minutes of the standard fire for each column member. Failure was defined as a load ratio greater than one.

The effective length of the columns was assumed to be 1.0 and the safety factors applied to dead, snow, and live loads were taken as 1.0. These values are considered conservative because Eurocode 4 allows a reduction of 0.7 to 0.85 times the actual column length and a reduction in live load of 50 percent. These

reductions are permitted because a hot column will be restrained by the cold structure at its ends and the ambient design live load is unlikely to be achieved in reality. It was shown that all columns met the code required rating.

APPLICATION OF SINGLE STRUCTURAL ELEMENT ANALYSIS TO WOOD ELEMENTS

Pyrolysis Behavior of Wood

The pyrolysis behavior of wood (Figure 19.5.21) is that of a charring material that deposits residue as it burns. This residue helps prevent further pyrolysis; it does, however, result in some loss of section. The thermal and mechanical properties of wood vary with respect to heat flux/exposure, exposure time, moisture content, wood species, and density.

Wood performance in fire is complex to predict. Heat transfer through this material is affected by phase change of moisture as well as opening/cracking of the increasing char layers, which then generate new paths for heat transfer. The mechanical properties of wood are known to be dependent on creep, moisture, the direction of the grain, and the presence of knots and other discontinuities.

However, fire is a short-term event; therefore, creep is of less concern. Indeed, because fire is a short-term event, BS 5268, Part 4[80] and other design codes allow the long-term stress values used for ambient design to be increased when checking the cold residual section after charring in fire design—that is, the strength properties of the cold residual section are assumed to be better in fire than ambient because the member will only carry the load for a short time. Due to charring, design codes generally recommend the reduced cross section method to calculate the residual capacity in fire in order to determine available fire resistance.

As for steel and concrete, the design fire must be first ascertained (standard fire, postflashover design fire, local fire, or external fire). However, unlike steel and concrete, a heat transfer analysis to determine the wood section temperature for the fire duration is not always required because most design methods assume the charred material should be ignored and the rest of the section has its full ambient design strength. Specific capacity checks, assuming the same equations as used at ambient, as outlined in the following sections can then be utilized.

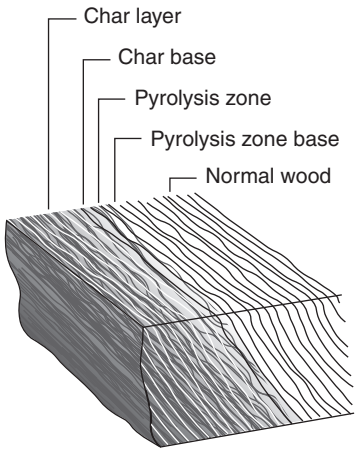

FIGURE 19.5.21 Charring of a Wood Section (Source: A. H. Buchanan, *Structural Design for Fire Safety.* Copyright John Wiley & Sons Limited, 2001. Reproduced with permission.)

Calculation Methods for Wood Used in the United Kingdom, Europe, Australia, and New Zealand

In the UK, BS 5268, Part 4[80] provides simple rules for designing wood members for fire. It treats solid members and glulams (glued laminated wood sections) in the same way, provided the glulam is laminated with certain phenolic and amnioplastic synthetic resin adhesives. Table 1 in the code lists charring rates to calculate the residual section of a wood member as a function of exposure of density. For example, the table has a higher char rate for western red cedar and a lower char rate for hardwoods with a density of 650 kg/m^3 or greater at 18 percent moisture content.

If wood sections are built up with metal fasteners, the charring rates given in BS 5268[80] can only be used on the whole section if the metal fasteners are fully protected against heat from the fire. Metal fasteners can be protected with passive fire protection or embedded in the wood so that they remain within the residual section (section not affected by charring).

To assess the fire resistance of a wood section, the following steps are proposed:

1. Calculate the residual cross section by subtracting the appropriate amount of lost wood, based on the defined charring rate for the fire resistance period under assessment. If the section has exposed corners, then rounding needs to be taken into account – that is, the corner will char more because it is exposed to heat on two sides.
2. Calculate the capacity of the resulting reduced section using cold design checks but assuming 2.25 × permissible long-term dry stresses.
3. For flexural, check that the deflection of the resulting reduced section does not exceed L/20 and does not impact the stability or integrity of other parts of the construction.
4. Check the stability in members subject to buckling, for example, columns or beams unrestrained by a slab.

Where connections are traditional wood joints, the same charring rates as for the main member can be adopted and its capacity in shear can be checked as it would be in ambient design.

The Hp/A of the wood section is important because fire-rated construction, for example, a ceiling, will shield wood sections and can have a significant impact on the resulting area of residual section for fire design. Figure 19.5.22 illustrates this concept. With shielding, considerably more area of residual section is possible, thereby increasing the fire resistance of the section.

Similar methods are given in Eurocode 5, Part 1.2[81] and design codes in Australia (SAA[82]) and New Zealand (NZS 3606[83]). The main difference is that BS 5628 and the methods in New Zealand ignore any reduction of wood strength below the char line (see Figure 19.5.21) whereas EC5 and SAA recommend considering it.

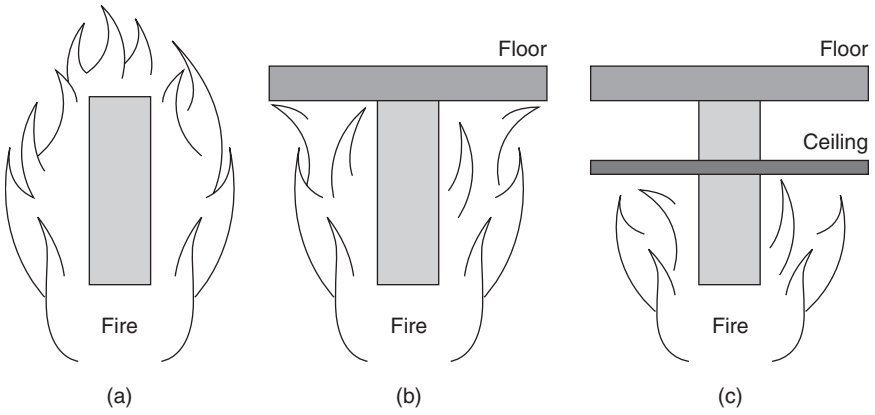

FIGURE 19.5.22 Heated Perimeter of a Wood Beam Shielded by a Fire-Rated Ceiling (Source: A. H. Buchanan, *Structural Design for Fire Safety.* Copyright John Wiley & Sons Limited, 2001. Reproduced with permission.)

Calculation Methods for Wood Used in the United States

White,[84] in Section 4, Chapter 11, of the *SFPE Handbook of Fire Protection Engineering,* discusses analytical methods for determining fire resistance of wood members. He reports on theoretical models for wood charring, many of which are based on the conservation of energy equation. The balance is between the heat stored in the wood, conduction away from or into the wood, and the fire and the energy absorbed when the wood undergoes pyrolysis. White also gives properties for wood at elevated temperatures and empirical models to calculate charring and the capacity of the residual cross sections.

For heavy wood members, ASCE/SFPE 29-99[56] provides analytical methods for calculating the fire resistance time (t) of beams and columns. The equations typically include load factor (z), initial dimensions of the section (b,d), and a constant (γ) with the units min/mm or min/in.

An example for beams exposed to fire on four sides is given in Equation 21.

$$t = \gamma z b \left[4 - 2\left(\frac{b}{d}\right)\right] \tag{21}$$

ASCE/SFPE 29-99[56] also presents values of fire resistance for various components of light frame wood construction. The additive method of calculation is proposed, which simply means adding together the fire resistance times assigned to each component as given in the code. For a stud wall, for example, the fire resistance time is equal to the total of all of the membrane elements on the fire exposed face plus the fire resistance time of the stud framing elements; the membrane on the unexposed face is ignored in the calculation.

Assessing Wood Connections in Fire

The collapse of traditional wood connections in fire scenarios is preceded by distinctive cracking and hissing noises due to the stresses in the wood. Visible deflections also become apparent before collapse, providing the fire services with notification that collapse is imminent.

New construction techniques involving steel connectors such as bolts or steel plates mean that the traditional bending and compressive forces in the wood joints have been largely replaced by localized shear forces surrounding the steel connectors.

Shear failure occurs when the lining within the wood section becomes heated and begins to act like a supercooled liquid. This change occurs at relatively low temperatures (~120°C) and causes the shear strength of the wood to change. This shear failure poses a catastrophic collapse mechanism during a fire because no prior warning of collapse is given under these circumstances. This area of fire engineering is being investigated by a number of researchers.[85,86] For now, metal connectors should be protected.

CASE STUDY: Residential Development, England. The following case study shows the application of single element calculation methods for wood using BS 5268 at a residential development in England. A structural assessment was undertaken of the existing wood beams within an old mill in the United Kingdom being converted to apartments. The structure required 60 minutes fire resistance according to the UK Building Regulations.

At ambient design, the wood members were being retrofitted with two steel plates, one on each side of the full length of the beam to resist bending. The beams were 190 mm wide by 390 mm deep plus partially shielded by a fire-rated ceiling 110 mm through its depth. The method in BS 5268[80] was used, assuming a total amount of charring of 40 mm for 60 minutes of the standard fire.

As an initial calculation, the residual section capacity after this section loss due to charring was calculated (Figure 19.5.23), assuming no benefit of the steel plates. This was done to determine if the steel plates might be left unprotected. The area of beam above the ceiling was assumed to not char because it is shielded from a fire. It was therefore assumed that the beam

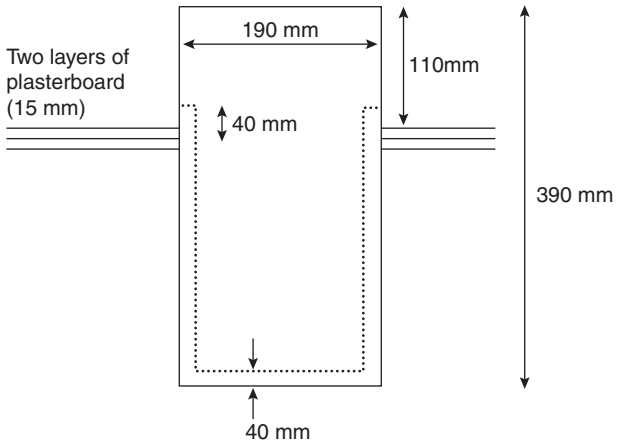

FIGURE 19.5.23 Residual Section After Char (Source: Arup)

would char on all three sides. The shear and bending capacity were checked, assuming the full strength of the residual cross section as permitted by BS 5268 [80].

From these assessments it was confirmed that the existing section would need additional provisions for 60 minutes fire resistance because the reduced section failed in bending. The following recommendations were therefore made:

- The wood section size to be extended to 430 mm deep from 390 mm, providing 40 mm sacrificial wood on the underside of the beam only (Figure 19.5.24)
- To provide two 280 mm × 12 mm S275 steel plates such that they extended the full depth of the exposed part of the beam, including the 40 mm additional depth proposed
- To protect the steel plates and bolt faces to a 60 minute applied fire protection, using a 550°C limiting temperature
- All connections exposed within the apartments to have 60 minutes applied fire protection because they are steel

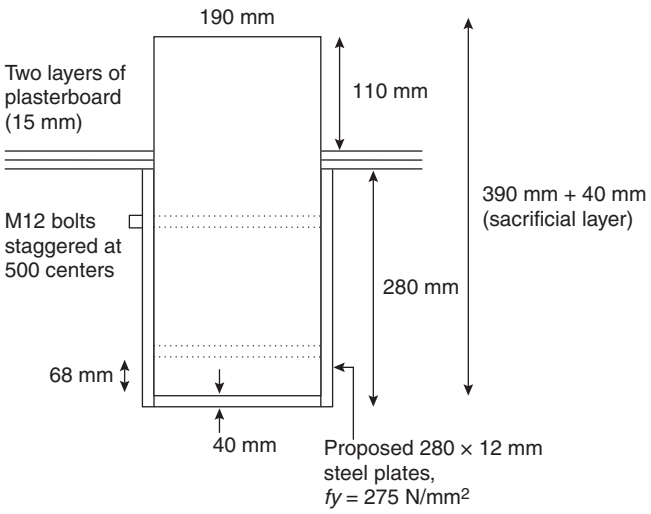

FIGURE 19.5.24 New Proposed Design Solution (Source: Arup)

The capacity of the new proposed section was shown to be adequate.

APPLICATION OF SINGLE STRUCTURAL ELEMENT ANALYSIS TO ALUMINUM

The sole design guidance available for the fire design of aluminum is Eurocode 9, Part 1.2, published in 2000.[87] In general the methods and principles are the same as for steel and the code looks very similar to EC3-1-2. Specific material properties (thermal and mechanical) at elevated temperatures are included.

USE OF ADVANCED ANALYSIS IN GLOBAL STRUCTURAL RESPONSE TO FIRE

Advanced Analysis Techniques

The current state of the art for structural fire assessments is to use advanced analysis techniques (Figure 19.5.25). These allow designers to quantify the global and local structural mechanisms throughout the duration of a fire. Therefore the stability of the structure in a severe fire can be determined, along with the quantification of the compartmentation response.

Such analysis can be used to assess a cold temperature structural design in specific fire events to determine if there are any particular areas of strength or, more importantly, weakness in the fire limit state. Fire-related responses are very different from any other form of cold temperature structural design concerns. So this form of analysis can prove a very useful tool to allow economical enhancements to be made to the areas of the structure underperforming in fire. For example, perhaps increasing the bottom flange thickness of a long span cellular beam is a more robust design measure in fire than applying thin-film intumescent paint.

Advanced analysis techniques also allow the development of refined passive fire protection strategies such that, in the case of steel structures, applied passive fire protection is proposed and installed in areas of the structure that require it, rather than providing "blanket" coverage, with its associated ongoing maintenance concerns throughout the lifetime of a structure. Of particular use is the ability, based on advanced analysis techniques, to quantify if compartmentation is being maintained, particularly at areas of concern, such as at egress stairs or fire fighter enclosures.

Advanced analysis models have undergone substantial validation for steel construction forms. Greater full-scale validation tests are now needed for other construction forms. Real-fire experience such as the Torre Windsor* in Madrid, Spain, on Feb-

*On the evening of Saturday, February 12, 2005, a fire broke out in the 32 story Windsor Tower, one of the tallest buildings in Madrid's commercial and banking center. The unsprinklered building had a concrete central core and a typical floor slab construction reinforced by bidirectional ribbed slabs spanning onto composite beams. Fire spread from the 21st floor, causing collapse of floors above the 17th, with significant deformation but no collapse of floors below the 17th.

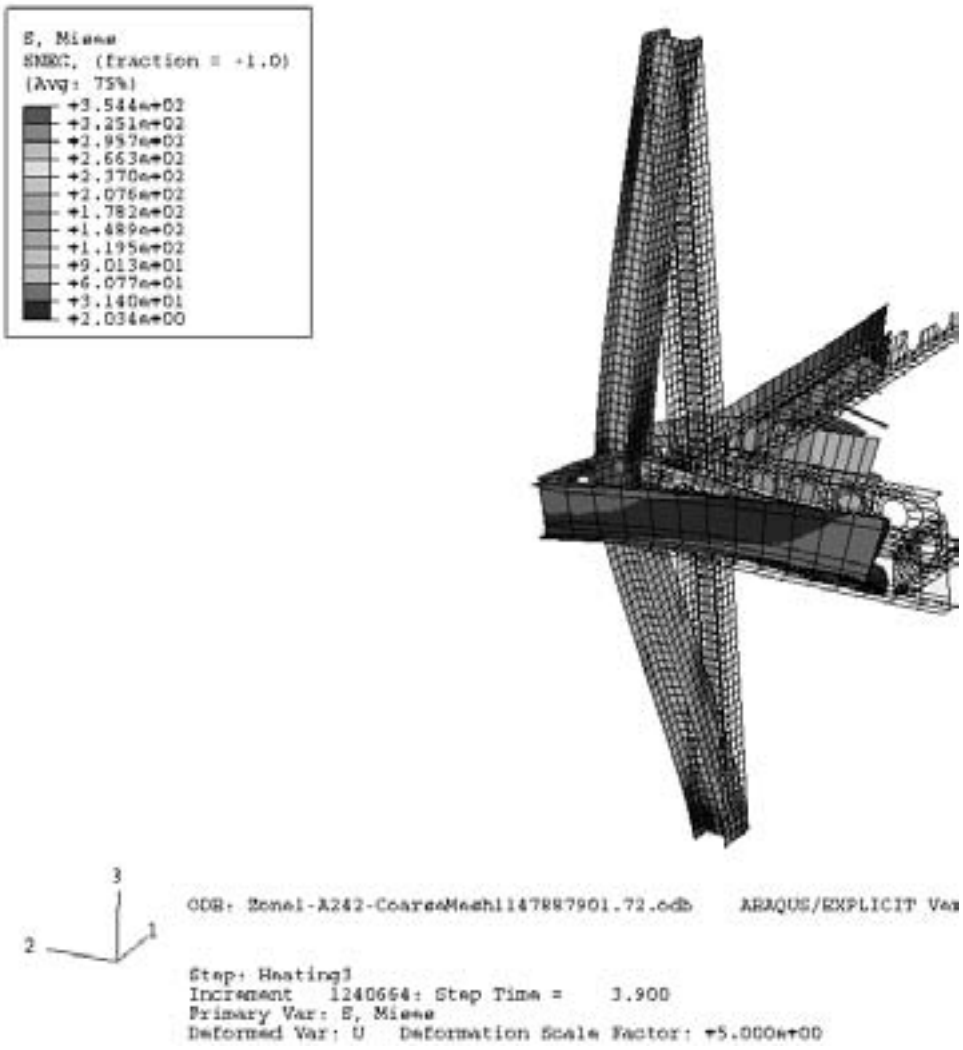

FIGURE 19.5.25 Example of Column Lateral Displacement from Advanced Analysis (Source: Arup)

ruary 12, 2005,[61] will provide substantial information on real performance of concrete structures. But a specific program of validation would be of great benefit for concrete, timber, and the increasingly popular long-span cellular beam construction forms.

This section addresses existing design methods, as well as a methodology for applying advanced finite element analysis techniques to real building design. This four-step technical process must always be accompanied by close consultation with the authorities having jurisdiction, and any other primary stakeholders, to ensure its real value is brought to a design.

Advanced analysis of steel/composite steel frames in fire was initiated in 2000. The Cardington experiments[6] and finite element modeling of the tests that followed[88–90] resulted in a number of design approaches for composite steel frame construction, taking advantage of tensile membrane action during high deflections in a fire. Two approaches are available: (1) design methods based on analytical methods derived from the Cardington data or (2) advanced thermomechanical analysis of the full structure using finite element analysis.

Analytical Methods to Quantify Tensile Membrane Action in Fire

In 2000, the Steel Construction Institute (SCI) in the United Kingdom produced relatively simple design guidance[91] based on work carried out by Bailey et al.,[92] as well as observations of the Cardington frame fire tests and similar building fire tests carried out in Australia and Europe. The guide is designed to allow secondary beams in composite steel-framed structures to be left unprotected, while achieving code-recommended fire resistances by capturing the strength enhancement of the composite slab in tensile membrane action. This occurs due to the high deflections in the slab during a fire.

Recommendations given in the new guide are restricted to structures that are similar to the Cardington eight-story

composite steel frame—that is, nonsway frames with composite steel decks. The slab should comprise steel decking, reinforcing mesh, and normal-weight or lightweight concrete. The profile of the slab can be trapezoidal or re-entrant. The floor beams should act compositely (including the edge beams) and be designed to BS 5950 Part 3 or EC 4.[70] This method, therefore, does not apply to fabricated beams or beams with large openings, precast concrete slabs, or slim-floor construction. Slim-floor construction is a proprietary product in the United Kingdom where the beams are partially embedded in the depth of the concrete slab to achieve fire resistance with reduced passive fire protection on the steel.

The design method, derived from the principles of yield line theory for slabs, is simplified into a set of look-up tables that state whether a particular design will pass or fail given a certain combination of variables of beam span, reinforcement mesh, slab profile, and load. The design data assume the standard fire exposure (Figure 19.5.26) only. However, the full theoretical model[92] can be implemented with natural fire curves if created specially on a spreadsheet-based tool.

The maximum fire resistance that can be achieved using the guide is restricted to 60 minutes. Rules and guidelines for maximum spans, layout configurations, allowable deflections, and construction details are based on providing a final solution that brings no increased threat to the life safety of the occupants or fire fighters. Property protection is not addressed by U.K. legislation.

Excessive deflections that can occur in a fire should, therefore, be limited to prevent compartmentation breach. This ensures that the fire would not be able to spread horizontally or vertically as a result of deflections imposed by the heating regime. The guidance for the detailing of the slab to achieve adequate tensile membrane action in the fire limit state is, therefore, on this basis.

The method requires the building floor to be split into square or rectangular design zones (see example in Figure 19.5.27) or panels with each panel incorporating a number of unprotected beams surrounded by a square or rectangle of fully protected beams. The spans are restricted to 9 m. The edges of each panel must be vertically supported for the duration of the fire. Catenary action of the beams is conservatively ignored, although a revised version has recently been published that includes catenary of the beams. As a result of the slab membrane forces, beams at the boundaries of the floor design zones receive additional loading due to forces transferred from the slab, thus increasing the load ratio. This increase is addressed in the final design guidance provided.

Failure is defined in terms of a maximum allowable vertical displacement (L/30) and limits mechanical strains by assuming a maximum allowable stress for the reinforcement of $0.5f_y$. The equation for allowable vertical displacements should always give conservative results because of the various assumptions made and the fact that there was no failure observed in any of the Cardington tests.[6]

The enhancement in load-carrying capacity as a result of tensile membrane action is restricted by this limit. It is impossible to know how overconservative this method is because failure was not observed in the tests to validate the failure criterion assumed by the analytical model. Global failure can be modeled by finite element analysis; therefore, overconservatism can be avoided using a finite element approach. The method also includes options to enhance the strength of the slab if the load capacity is determined to be less than the applied load in the fire limit state, for instance, by increasing the mesh size or slab depth.

In 2005 the method was extended to include orthotropic reinforcement, recognizing that structural bays are sometimes longer in one direction and therefore require an orthotropic reinforcement mesh. The new method also includes catenary action of the steel beams, which was conservatively ignored in the earlier approach.

Usmani and Cameron[93] also developed a new concept for determining the limit capacity of rectangular reinforced concrete slab panels subjected to fire in tensile membrane action. In the context of performance-based design, this additional capacity of composite decks or reinforced concrete slabs can be exploited for providing structural stability in fire, given that a quantitative estimate of this capacity can be reliably made.

The difference between Usmani and Cameron's approach compared with the Bailey method is that the deflected shape of

the reinforced concrete slab is estimated using a cubic function before a calculation of tensile membrane effects is carried out. Usmani and Cameron[93] propose a three-stage process. First, the temperature distribution over the depth of the slab is estimated for a given fire scenario. Then, the deflected shape of the reinforced concrete slab and its membrane stress state is determined using an analytical method. Finally, an energy-based method is used to determine the maximum load that the slab could carry based on the geometric form and stress state determined in the previous steps. Failure is defined as a rupture of the reinforcing mesh at a given mechanical strain. There is no limit placed on deflection.

Heavy Engineering Research Association (HERA), a nonprofit research organization dedicated to the needs of the metals-based industries in New Zealand, has also published a design procedure to capture tensile membrane action in fire.[94] The design approach predicts the strength re-enhancement required from tensile membrane action to support the load based on work by Wang.[95] As tensile membrane action is a function of the maximum deflection of the slab and the extent of strength re-enhancement required is known, this is used to determine the slab deflection at elevated temperatures associated with the required level of strength reenhancement. Limits are applied to prevent undesirable failure of the slab and secondary beams—for example, fracture of the reinforcement. The guide considers all aspects of the frame, including pulling in of the columns when the slab is at high deflections in tensile membrane action, which is not addressed by Bailey[92] or Usmani and Cameron.[93]

All of the analytical methods presented require primary and edge beams to be protected. The protection reduces the edge/primary beam deflections and will generally allow the frame to survive longer in a fire. If the edge beams are unprotected, the relative displacement of the floor slab between the outside edges and the middle of the compartment would be smaller, reducing the development of tensile membrane action. It is important to note, however, that in order to address long-span floor systems and the stability of the columns, a finite element approach is required.

CASE STUDY: No. 1 Bradford Interchange, United Kingdom. The following case study uses the Bailey method to optimize the passive fire protection layout at No. 1 Bradford Interchange, United Kingdom.[96] Two design options were calculated, both of which allow unprotected secondary steel beams but consider different solutions for the slab profile and size of mesh reinforcement.

The office use building is four stories high. The structure is a composite steel frame with two configurations for the structural bays. The first is a 9 m × 7.5 m bay. Secondary beams are 9 m with secondary beam centers at 3.75 m. The second configuration is a 6 m × 7.5 m bay. Secondary beams are 6 m with secondary beam centers at 3.75 m. A typical structural bay is illustrated in Figure 19.5.28.

The structural bays described in Figure 19.5.27 are appropriate floor design zones for assessment using Bailey's method because they are rectangular and bounded by beams on all sides. Each zone contains beams spanning in one direction only. The columns are on the boundary of the zone—not within the zone—and all the beams connected to the columns are protected to 60 minutes fire resistance.

The calculations were carried out using a spreadsheet based on the original theory by Bailey,[92] rather than the tabulated data presented in the SCI guide.[91] The results were compared with the look-up tables in the SCI guide for consistency; although the

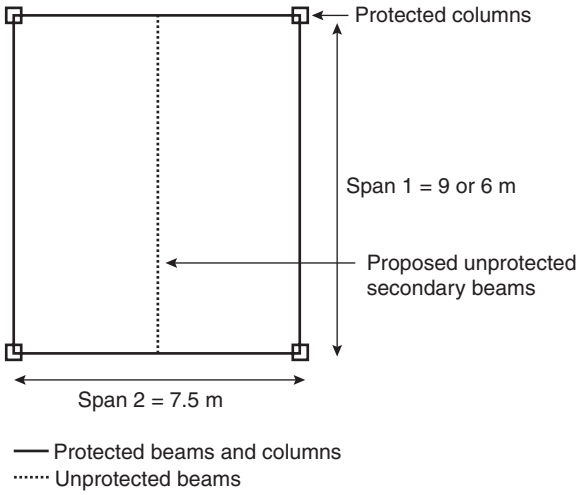

FIGURE 19.5.28 Schematic Plan View of a Structural Bay at Bradford Interchange (Source: Arup)

look-up tables are considered to be more conservative because the results are rounded up, they compared well.

The results of the design calculations for the 9 m span bay are given in Table 19.5.15. The use of re-entrant deck provides significantly better fire resistance because the ribs of the profile deck are bigger than in a trapezoidal deck, and therefore the reinforcement remains cooler. The reinforcing mesh required in a re-entrant deck slab is therefore less compared with the same design assuming a trapezoidal deck.

TABLE 19.5.15 Design options 9 m × 7.5 m Bays

	Option 1	*Option 2*
Span 1 (m)	9	9
Span 2 (m)	7.5	7.5
Unfactored dead load (kPa)	4	4
Unfactored live load (kPa)	4 + 1 = 5	4 + 1 = 5
Secondary beam spacing (m)	3.75	3.75
Mesh size	A393	A252
Slab profile	Trapezoid	Re-entrant
Reinforcement depth* (mm)	40–45	65
Concrete strength, f_{cu} (N/mm^2)	30	30
Concrete type	NWC	NWC
Secondary beam moment capacity (kNm)	640	640
Load ratio on edge beams parallel to secondary beams	0.33	0.32
Limiting temperature (Table 5 BS 5950 Part 8)	725	725
Resize edge beams for additional load?	No	No
Applied load at the fire limit state (kPa)	8	8
Capacity (kPa)	9.12	8.08
Capacity-load (kPa)	1.12	0.08

*The depth to reinforcement is measured from the top surface of the slab.
Source: Arup.

The location of the reinforcing mesh in the depth of the slab is critical to the design. Option 1 assumes a trapezoid deck with A393 mesh (a square mesh with 10 mm diameter bars at 200 mm pitch, providing an area of reinforcement equal to 393 mm^2/m); option 2 considers a re-entrant deck with A252 mesh (a square mesh with 8 mm diameter bars at 200 mm pitch, providing an area of reinforcement equal to 252 mm^2/m).

The additional load at the fire limit state on the edge beams parallel to the unprotected secondary beams is listed in Table 19.5.15 as a load ratio. The corresponding critical temperature in BS 5950, Part 8[42] is also listed. Where the critical temperature is less than 620°C (the normal assessment temperature for fire protection materials for beams), the beam must then be resized to incorporate a higher load-carrying capacity. In this case study, the critical temperatures for each beam size in each design option are all greater than 620°C; therefore, the beams did not need to be resized.

The method relies on good structural detailing; therefore, the following was written on the construction drawings:

1. All the steel beams should be composite with the slab through the use of shear studs.
2. The reinforcing mesh should be properly lapped and anchored in all areas of the slab as required for ambient design.
3. The location of the reinforcing mesh in the depth of the slab is critical to the design and should be marked on the construction drawings. For a trapezoid deck with A393 mesh, it should be 40 mm to 45 mm from the top surface of the slab. For a re-entrant deck with A252 mesh, it should be 65 mm from the top surface of the slab.
4. The mesh reinforcement should conform to the ductility limits of BS 4482[97] and BS EN 10080[98] for type B reinforcement. These limits are consistent with 12 percent elongation at failure.
5. Any cellular beams, including the beams immediately adjacent in the bay, are to be fire rated (i.e., no fire engineering).
6. All beams above a compartment wall (parallel or crossing the wall) should be fire protected to at least the same fire resistance standard as the compartment wall.

The use of Bailey's design method shows that unprotected steel secondary beams at Bradford Interchange were acceptable under the U.K. Building Regulations, which address life safety, while achieving structural stability for a 60 minute rating.

Design Methods Based on Finite Element Analysis

As a consequence of the Cardington Frame fire tests[6] and the savings that can be brought to a steel design project by using global structural analysis, composite steel frame structures are the most common construction form modeled using finite element techniques by design consultants. Performance-based

codes in the United Kingdom, Europe, Hong Kong, Australia, and New Zealand state that design considering credible design fires, thermal heat transfer, and structural analysis using advanced finite element methods is an acceptable approach to fire design. There is currently no such guidance document in the United States. However, organizations like SFPE, NFPA, NIST, and AISC are gradually funding research and drafting documents that will assist engineers in carrying out structural fire engineering using finite element analysis in the future. It is expected that this process will take a number of years to enter the design domain.

Since the collapse of the World Trade Center towers, the finite element analysis technique is being increasingly used as a design tool to bring greater robustness to the response of a structure to fire. This is the only method that allows the quantification of the strengths and weaknesses in a cold temperature structural design to be quantified and identified; it can provide invaluable information to the structural team to allow changes to be made to enhance the performance of the cold temperature structure in the fire limit state. Currently almost no data exist for concrete or wood structures at a level that exists for steel structures. Hence finite element methods remain underutilized with these forms of construction.

In general, structural fire design codes will not provide guidance on how to perform an advanced structural fire analysis using finite element methods. They do, however, set out the principles that should be followed. They tend to state that the structural performance of steel may be assessed using calculation models that consider the fire exposure, thermal response, and structural response, provided that the models are based on acknowledged principles and assumptions of the theory of heat transfer and structural mechanics. Further, they stipulate that the governing elevated temperature response of thermal expansion and geometric nonlinearity have to be included in a structural model.

When using finite element analysis, a four-step process is recommended:[99] (1) determine credible design fires, (2) calculate the heat transfer from these fires to the elements in a representative structural model, (3) quantify the mechanical response of these elements for the duration of the fire, and (4) determine strengths and weaknesses in the global response of the structure when considering stability and compartmentation.

Typically, stability is deemed to be maintained once the columns continue to carry their design load for the duration of the fire and runaway failure of the beams or slab does not occur.[99] Note that an alternative view to this is to simply design to prevent deflections beyond that allowed in the standard fire test (L/20 as an example in the United Kingdom[10]).

For compartmentation, an assessment of strain in the slab and adjacent to protected escape stairs or, in countries such as the United Kingdom, adjacent to fire-fighting cores is necessary to ensure severe cracking is not causing breach of integrity or insulation.

Various methods, such as Eurocode 1, Part 1.2[22] or those described in the *SFPE Handbook of Fire Protection Engineering,* exist to determine design fires. However, their limitation, due to the small-scale nature of the testing carried out, means realistic compartment sizes as used in real buildings have not yet been validated. For empirical methods, this remains a concern. It is essential that a factor of safety is introduced in the design fire to overcome this concern. Methods based on a theoretical heat-balance approach are, therefore, preferred for adoption in compartment sizes that exceed the limits of empirical methods (i.e., the parametric equation in the Eurocode, derived from specific experimental data sets from Franssen,[100] NFSC1,[15] and NFSC2[101]).

An alternative approach is to assume the heating regime follows the standard temperature-time relationship as would be utilized in a furnace. However, when this is used, no cooling phase is incorporated, and so the specific structural response in this phase is then ignored. This can in some cases result in a nonconservative design, especially of connections that can fail in cooling as contracting beams pull on the connections.

One example of a methodology when using a finite element method is outlined in Eurocode 3. It gives similar performance-based objectives to other codes but also specific details about what should be included in advanced calculation methods. For example, when conducting a calculation of mechanical response, it states the following requirements, among others:

- The effects of thermally induced strains and stresses, both due to temperature rise and due to temperature differentials, should be considered.
- The deformations at ultimate limit state implied by the calculation method should be limited to ensure that compatibility is maintained between all parts of the structure.
- The design should take into account the ultimate limit state beyond which the calculated deformations of the structure would cause failure due to the loss of adequate support to one of the members.

Eurocode 3 also explicitly asks for validation of the computer model being used for the assessment, with whole frame fire tests.

In the United Kingdom, a new guide is being produced by the Institute of Structural Engineers that will identify the best practice for creating and using finite element models, plus suggested failure criteria to assess structural and compartmentation response in fire.

In Australia, the performance-based design framework permits structural fire engineering analysis using advanced modeling techniques. This is as a result of a series of full-scale fire tests to determine which elements were critical to the stability of the Williams Street building in Melbourne, Australia, as well as those elements critical for ensuring adequate protection during egress and fire fighting—for example, detailing of connections at protected cores.[102]

In Hong Kong and China, the finite element approach is not specifically codified, but is possible via performance-based options for design in the building codes there. However, currently the approach is most widely used in the United Kingdom.

In the United States, performance-based design is also permitted as an alternate means to the prescriptive requirements of the building codes; therefore, a finite element approach is permitted if the basis for the design can be agreed with the approving authorities. The finite element approach is not codified in the United States.

An alternative approach to this quantitative method for assessing structural response to fire is to use a risk-based method, such as outlined by Fontana. The main objective of Fontana's work is to develop a fire risk assessment framework that takes into account both risks associated with property damage and risks associated with injuries and fatalities. A generic model is developed, taking into account fire relevant parameters such as fire load, ventilation, and so on. The causal interrelations are modeled with Bayesian networks. The generic model is used for the calibration of already existing fire risk assessment frameworks—for example, the Swiss SIA Documentation 81.[103]

CASE STUDY: Kings Place Building, London, England. The following case study outlines the key steps and major considerations for a whole frame analysis using finite element analysis. The Kings Place building in London, England, is a composite steel-framed structure with eight stories above ground and three basement levels. The composite floors are constructed using 130 mm deep composite slabs with profiled steel decking attached by shear connectors to steel beams with circular web penetrations. The columns are universal steel column sections with two changes in size (at floor 2 and floor 6). Steel beam spans are 9 m or 12 m.

A finite element analysis of the structure was proposed in order to determine the response of the structure to fire. The aim of this nonlinear finite element analysis was to determine an optimized fireproofing strategy, along with an understanding of the strengths and weaknesses in the cold temperature design. This would allow specific advice to be determined for the structural team to incorporate enhancements, if required, specifically for the fire limit state.

Specific aims of the nonlinear analysis were to investigate the required fire rating of the structural elements and to determine if secondary steel beams could be left unprotected when only the columns and primary structure (edge beams and beams connected to columns) are protected. Based on the life safety requirements of the building regulations in the United Kingdom, acceptance criteria for the data produced by the analysis were structural stability (columns maintain their load-carrying capacity throughout the fire duration and no runaway deflections in beams or floors), compartment integrity, and compartment insulation (assessment of strain in the slab and adjacent to fire-rated enclosures to prevent any cracking).

For addressing the fire ratings, all structures forming the fire-fighting shafts were considered to remain at the standard 120 minutes. The time-equivalent method, as defined in BSEN 1991-1-2,[22] was then used to determine an overall building rating, utilizing risk factors that address only compartment size, occupancy type, and sprinkler provision. This resulted in an equivalent fire resistance rating of 90 minutes, based on calculation for an assumed compartment area of 4081 m², with a compartment height of 3.68 m, and percentage glazing failure of 100 percent. A sensitivity study considering 100 percent or 50 percent of the glazing breaking as well as the influence of reducing the floor area of the compartment involved in the fire was studied to obtain the longest period of fire resistance. This rating was utilized as the basis of the first model run, when any protected elements proposed that did not form part of the fire-fighting shafts and all compartment floors were assumed to be protected to a 90 minute standard. Should the finite element analysis reveal any concerns with this rating assumption, alterations could then be made. This is necessary as time-equivalent methods do not incorporate any form of structural response; they are purely simple methods based on possible heating regimes in a compartment only.

As a first step in the structural fire analysis, an assessment of credible design fires was necessary. This resulted in two design fires, quantified using the parametric equation in BS EN 1991-1-2:[22]

- *Short/hot fire.* Assuming 100 percent glazing failure to allow ventilation in the postflashover fire state, with a flashover fire acting over the whole floor plate. The peak temperature is about 1200°C.
- *Standard fire.* A long/cool fire relative to the parametric temperature-time curve described above, as specified in BS 476.[10] This was at the request of the approving authorities.

A short/hot fire, which results when the fire is well ventilated, was considered because of its high peak temperatures and its short duration, which together are known to induce large thermal gradients within structural elements, and also because it includes a cooling phase. The standard fire was chosen to investigate the effects of a longer-lasting fire, with a constant increase in temperature—that is, no cooling phase. All other credible postflashover fire scenarios, based on possible ventilation provision to the specific compartment dimensions and boundaries, were considered to fall within the boundaries of the two cases adopted.

The next step was to calculate the heat transfer from these fires to the structural elements in the proposed representative structural model. Different approaches were followed with regard to the concrete and steel materials. The heat transfer for the concrete slab was modeled using a 1D heat transfer model in ABAQUS 6.5.4.[104] The slab is modeled as a flat slab of equivalent thickness, although ribs in the dovetail slab are ignored. The same assumption is used in the structural model. This reflects the approach given in Section 4.4 of EC 4, Part 1.2.[70] Input data to the heat transfer model complied with the recommendations for siliceous concrete material properties in EC 2.[64] Moisture content in the concrete was ignored.

The heat transfer calculations for the steelwork were conducted using the lumped mass heat transfer model in EC 1, Part 1.2[22] and EC 3, Part 1.2[41] for the unprotected steel beams and protected columns. Material properties for the protection material were provided by the manufacturer and for the steel the values of conductivity, specific heat, and density in EC3, Part 1.2, were assumed.

In order to create a representative structural model, that is, a model with enough elements within it that it represented the full building, various modeling assumptions were made. When considering a single-story fire, the third floor was deemed to be the worst-case floor scenario in the building due to the highest column load ratio occurring on this floor. Therefore, it was con-

sidered to be representative of the entire floor plate on any story from Level 1 to Level 8 (Figure 19.5.29).

Worst-case boundary conditions were assumed for the structural models of each zone (see Figure 19.5.29). This means the resulting structural fire responses observed are on the conservative side, as less reliance is placed on the overall floor continuity available in the model.

The boundary conditions assumed for Zone 1 makes the portion of the building weaker with respect to the real case. The edge beam condition on the north side does not take advantage of continuity of the floor plate. Furthermore, the two symmetry conditions discount the model from the beneficiary effect of the concrete core and the continuity of the floor plate on the south side.

The boundary conditions of Zone 2 make the model act as an infinitely long strip of structural bays. In reality it is six bays long, and three of these are connected to structure that wraps around the core.

Zone 3 does not have boundary conditions. It has been considered as a structure itself, neglecting the decks that connect it to the rest of the building.

BS 5950-8[42] has been used to determine the factored design loads for the structural elements in the fire limit state. The factored gravity (1.0) and live load (0.5) were applied to the model throughout the analysis, using the applied loads provided by the structural engineers.

The materials adopted to represent the steel and concrete of the composite frame were taken from the appropriate Eurocodes (Table 19.5.16). Thermal expansion and full degradation of the stress-strain curves with temperature are allowed.

All connections were modeled in such way that they could not fail. For this reason the connection forces were checked at key stages in the fire to determine if the connection was being pulled in tension by the beam. (The protected steel-steel and steel-concrete core connections will therefore be designed on site to resist a tensile pull force of 60 kN when at a temperature achieved at 90 minutes of the standard fire, when protected.)

The software used to perform the finite element analyses (FEA) was ABAQUS.[104] The software is used throughout the world for stress, heat transfer, and other types of analysis in mechanical, structural, civil, and related engineering applications.

TABLE 19.5.16 Material Properties

Material	*Grade*	*Model*
Steel (frame)	S355	Eurocode 3
Lightweight concrete (slab)	C35	Eurocode 2 with tensile strength equal to 5% of the compressive strength
Reinforcing mesh		A252, steel mat, 8 mm bars, spacing 200 mm

Source: Arup.

The code has been validated extensively for many engineering problems and in particular by University of Edinburgh[7] and British Steel (now CORUS)[5,6] to model composite steel and lightweight concrete structures in fire.

The performance of all the models under the effects of the short/hot fire was found to be acceptable; stability and compartmentation were maintained throughout the duration of the fire. For the standard fire, however, various issues with respect to the response arose, as described in the following sections.

The main differences between the two fires are the length of the heating phase, the maximum temperature, and the cooling phase. The standard fire does not have a cooling phase; therefore, the elements are heated up throughout the analysis, with a steep initial increase and a rather flat evolution for the rest of the time. Eventually, in the standard fire, the elements reach hotter temperatures than in the short/hot fire, and this results in larger deflections as a consequence of more thermal expansion and also weaker material strengths, therefore leading to reduced structural performance. This would also be true of a parametric fire with limited ventilation—for example, 25 percent glazing failure.

An important outcome of the study was the finding that the Zone 1 model failed when subjected to the standard fire. Structural failure is assumed because rapid downward vertical displacement of the columns was observed. After the initial downward movement due to the load given by the above floors, the columns began to elongate when heated. The displacement reached values of about 25 mm before inverting its trend. At about 80 minutes, all the columns showed vertical runaway with a rapid increase in the downward movement while the temperature was still rising (Figure 19.5.30).

The column capacity is undermined by the lateral movement of the elements at the floor level causing bending stresses and P-Delta moments. Due to large thermal elongation of the long-span beams connected to the columns, and consequently large displacements, the column elements were required to sustain loads and actions they were not designed for in cold temperature conditions. Additional stresses/strains, along with material degradation, therefore undermined the structural stability. The structural model was considered unsafe under the effects of fire, and therefore methods of increasing the robustness were investigated.

A number of options are available to increase the robustness of the structure, such as increasing the column size, increasing the strength of the slab by adding more reinforcement,

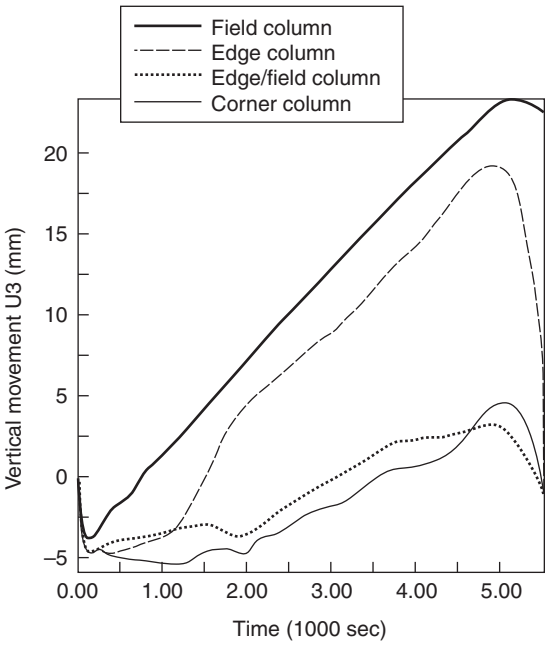

FIGURE 19.5.30 Vertical Displacement of Columns over Time During Standard Fire (Source: Arup)

keeping the 12 m span beams cooler with additional fire protection, or increasing their load-bearing capacity by increasing the member size. In this project the latter choice was adopted in order to reach the best performance/cost-effective solution. Therefore, the bottom flange of the 12 m span secondary protected beams connected to the columns was increased from 16 to 25 mm. This means less reliance on fire protection and greater reliance on the structural system itself. This is considered to be a more robust approach as it is not reliant on maintenance.

When the Zone 1 analysis was carried out to check that the improvements adopted in the model were significantly changing the response of the structure, it was determined that the change meant no column failure and therefore greater robustness in the building. Throughout the fire, the columns exhibited a steady elongation along with the increasing temperatures (Figure 19.5.31). No vertical runaway was recorded in this case, and therefore the columns can be expected to maintain their stability.

Figure 19.5.32 shows the deflection contour of the slab at the end of the fire. The maximum deflection is 1600 mm at the mid-span of the corner bay. The stability of the structure is maintained thanks to the tensile membrane action developing within each structural bay.

A thorough investigation was made with regard to the total strains exhibited by the model. The software itself does not model reinforcement rupture, and therefore identification of this failure mode had to be considered by plotting the plastic strains in the structure.

Due to the high value of deflection, relatively large total strains are observed across the protected secondary beams, axis

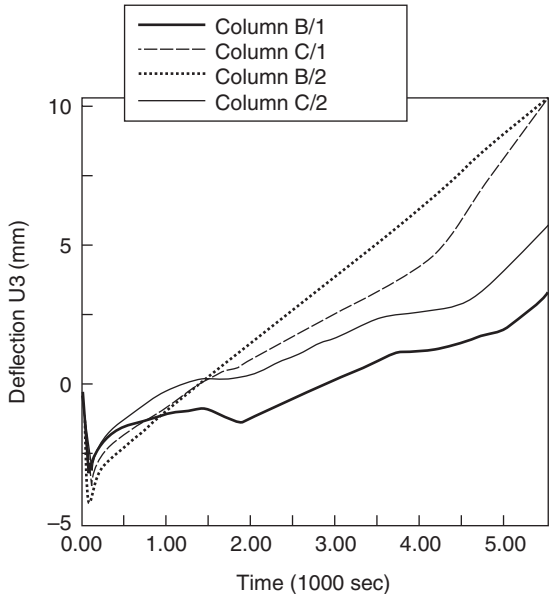

FIGURE 19.5.31 Vertical Displacement of the Column (Elongation) (Source: Arup)

C. The maximum observed strain is about 30 percent in the top of the slab and 25 percent in the reinforcement mesh (Figure 19.5.33).

It is assumed that these strains are likely to cause cracks at the top face of the composite slab. In addition, it is possible that the reinforcement may rupture locally over the support. To ensure stability is maintained, additional reinforcement was therefore proposed for the ribs of the dovetail profile over the protected primary beams.

For the Zone 2 model in the standard fire, there was generally better response than in Zone 1, mainly because Zone 1 represents the corner of the building and as such has two exterior edges, whereas Zone 2 represents an edge bay, which has more redundancies. However, as per the Zone 1 model, relatively large strains were observed at the core to slab interface. This has implications for compartmentation rather than stability. The connection between the concrete core and the dovetail slab was realized for this building using pull-out rebars that bond the core and the slab together. The concrete does not give continuity to the connection because it is poured in different stages, although a friction interaction might be assumed when the slab is heated and the edges are in close contact.

Given the aforementioned connection detail, the finite element model assumed a pinned connection between the concrete core and the slab. It is proposed that this assumption conservatively represents the connection at the early stages of the fire and better represents the behavior of the structure later in the analysis when the concrete slab may be cracked.

As highlighted in Figure 19.5.34, large strains up to a magnitude of 20 percent (neglecting the strains affected by the boundary conditions at the edges of the model) evolved at the concrete core, on the bottom side of the slab.

Initially, the underside of the slab will expand due to thermal elongation. Thus, high compressive strains will rise at the boundary with the slab pushing against the concrete core. Later, when the structural bays begin to deflect more, the edge of the slab will rotate significantly and concrete crushing is likely to occur on the lower portion and significant tension can be expected to develop in the rebars (Figure 19.5.35).

Compartmentation could be maintained due to geometrical rotation of the section, which is expected to tighten the lowermost portion of the concrete slab to the core. In addition, the rise in temperature throughout the extent of the fire will cause

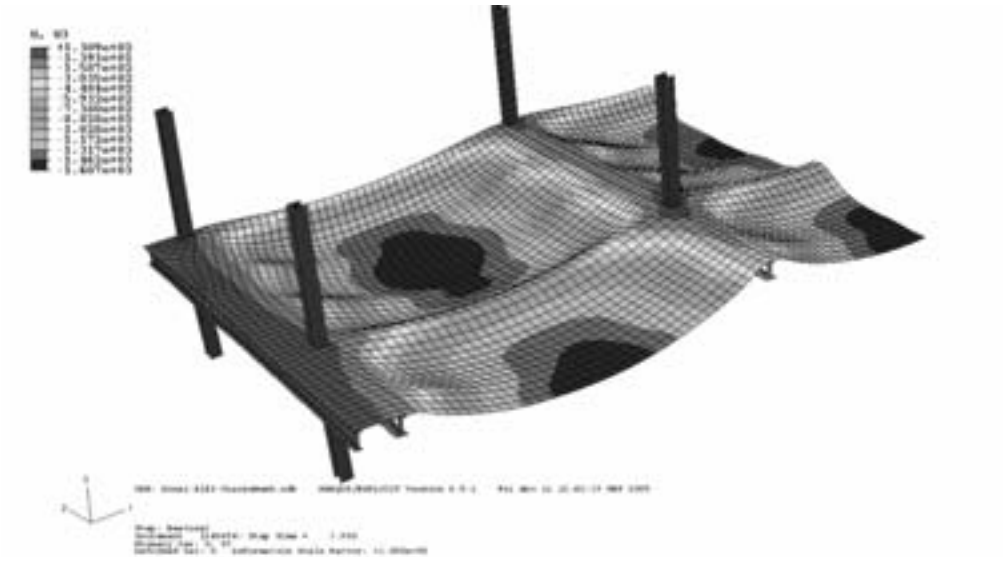

FIGURE 19.5.32 Deflection Contour at the End of the Fire (Source: Arup)

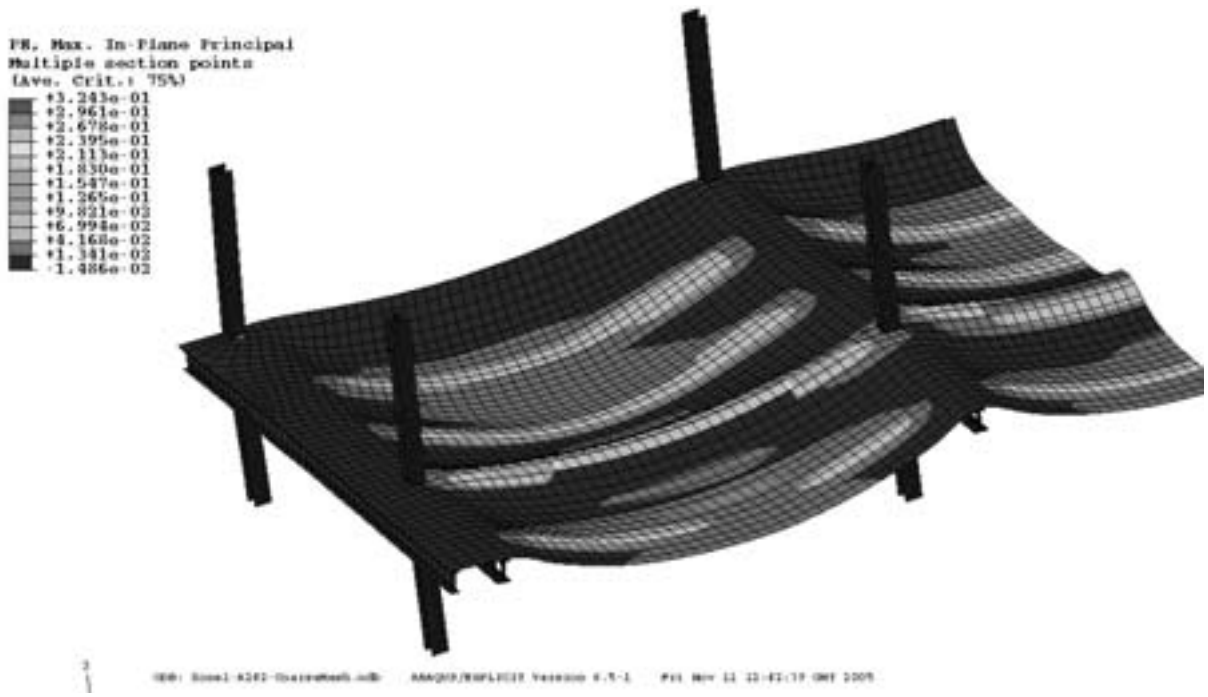

FIGURE 19.5.33 Maximum In-Plane Plastic Strains in the Reinforcement Mesh, Shorter Span Direction (Source: Arup)

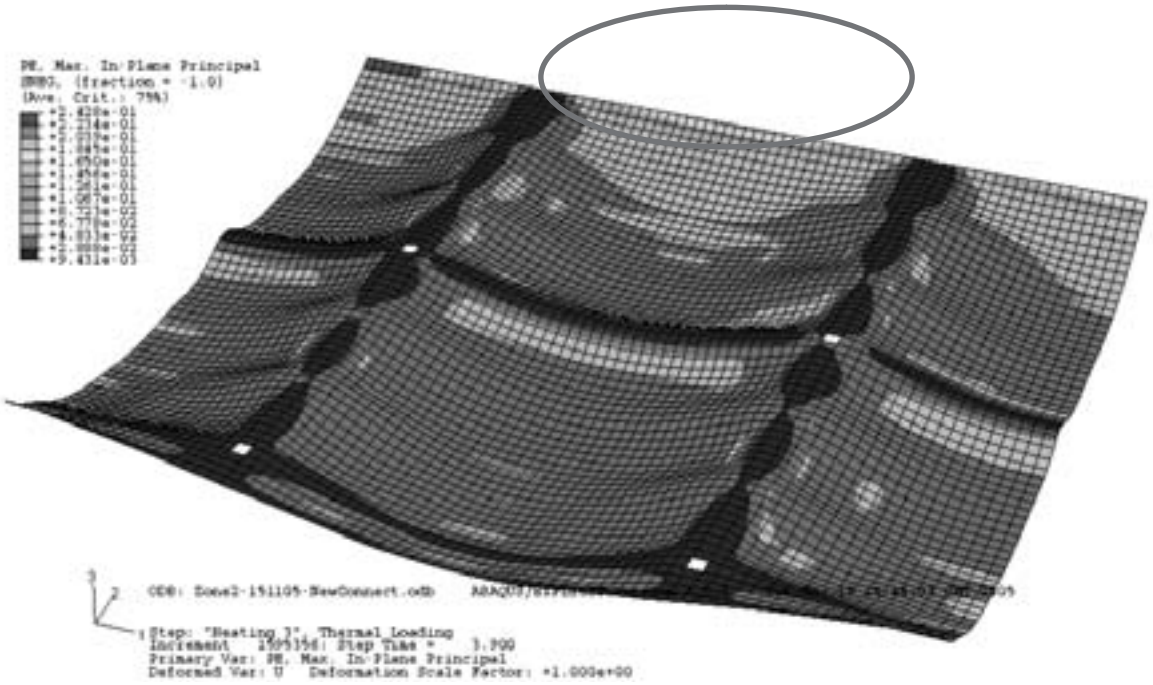

FIGURE 19.5.34 Maximum Resulting Plastic Strain on the Underside of the Slab at the End of the Fire (Source: Arup)

large elongation in the concrete, which will eventually help in closing the gap.

This interpretation of the matter is merely based on an understanding of the behavior of materials at high temperature and the likely structural response of an assembly in fire. Many factors, such as friction, concrete to steel bond, rebar anchorage, and temperature distribution are involved. Hence, a clear understanding of the phenomenon is not straightforward and to

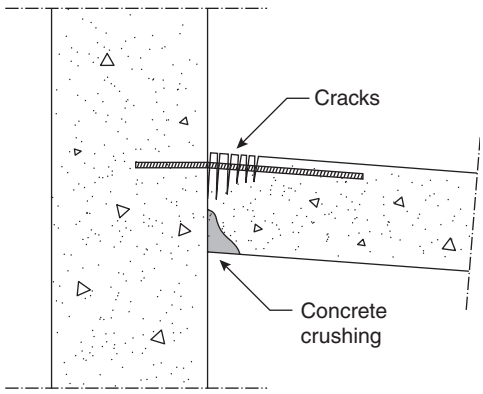

FIGURE 19.5.35 Likely Deformed Shape of the Structure at the Core Connection (Source: Arup)

obtain a more accurate understanding, specific detailed research is required. Detailing of connections and interfaces is becoming more and more important as the understanding of structures in fire evolves. It is important to note that this form of response is also true of fully protected structures.

Whether the current situation will cause a gap at the core to slab interface is highly debatable. On this subject, the approving authority has put forward a request for making further provisions to ensure compartmentation. To limit the effect of strains, a steel angle or similar vertical support was requested at the concrete core-to-floor interface to allow the slab to slide over the angle during a fire (Figure 19.5.36). The angle is fire protected and the length of the horizontal flange is at least 70 mm to accommodate an estimated horizontal displacement of the slab of 60 mm.

The analysis presented here was used to determine whether the structure could withstand an agreed set of credible design fires when secondary steel beams are left unprotected. This approach allowed a full quantification of the structural response of the building to fire.

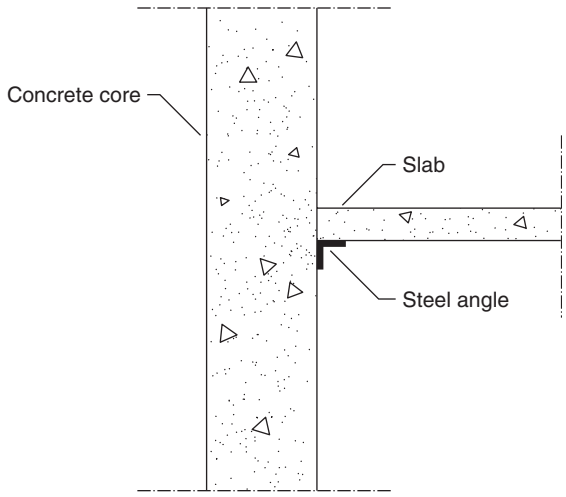

FIGURE 19.5.36 Detail of the Connection Between Slab and Concrete Core (Source: Arup)

The Kings Place case study has given rise to some important issues when considering stability and compartmentation of composite steel-framed buildings with long-span cellular beams. Leaving the secondary beams unprotected relies on secondary load-bearing mechanisms exhibited by the composite floor at the fire limit state. Minor mitigation measures were adopted to improve the structural performance in lieu of fire protection, including adding reinforcement locally and increasing the thickness of the lower flange of critical primary beams. Both are considered more robust than applied passive fire protection.

To improve compartmentation, a protected steel angle was proposed for the core walls to provide vertical support to the slab and allow the slab to slide over the angle during a fire. This provision is believed to avoid the fire breaching the floor-to-floor compartmentation of the building. The finite element analysis allowed such alterations to be determined.

This case study highlights the importance of checking that the cold temperature structural design has no intrinsic structural weaknesses in fire.

Advanced Analysis of Concrete Structures

Calculation of the whole frame response of concrete frames to fire is possible using finite element analysis. Eurocode 2 contains a method that specifically addresses concrete. However, none of the computer codes that currently exist and are used in fire design explicitly calculate spalling. Therefore the thickness of spalled material must be assumed and generally removed at the start of a structural or heat transfer analysis.

Most of the research in this field with regard to modeling concrete frames or sub-assemblies has been carried out in Europe, with some work in the United Kingdom after the full-scale Cardington frame fire test.[6] Most of the concrete finite element models in Europe have been validated against single element tests.[105,106]

Modeling tension cracking cannot be done without a code that includes fracture mechanics, which most do not because this calculation is labor intensive. In general, a smeared crack model is used to indicate areas of high tensile strain, which indicate that cracking will have occurred. Spalling is also an unknown; therefore, accurate concrete models are difficult to achieve.

The same four-step approach outlined for steel structures undergoing a finite element analysis can be used. Computer programs specifically written to quantify concrete frame response to fire include CONFIRE,[107] TCD,[108] FIRES-T3,[109] and SAFIR.[100]

As for any frame analysis in fire, concrete-specific codes must model nonlinear behavior of the structural elements and material properties, as well as include full degradation of material properties with temperature. An accurate representation of thermal gradients varying with time is particularly important for concrete elements as a consequence of concrete's poor conductivity. Nonlinear material properties of density, specific heat, and conductivity are required in a finite element model

of the concrete structural element's cross section to calculate through-depth temperature gradients. If moisture content is ignored this will give conservative results because there will be no thermal lag as a result of latent heat of evaporation at 100°C. A temperature-time curve representing the design fire and associated boundary conditions (convection coefficient and emissivity) can then be applied to the appropriate faces of the finite element model. Design fires can be determined, as outlined earlier in this chapter.

Calculating the whole frame response of concrete frames to fire is rarely carried out in design. The main reason for this is the lack of full-scale test data to validate the use of finite element methods with concrete materials.

Of particular interest in the United Kingdom currently is the performance of prestressed concrete frames in fire, as they may be more susceptible to fire because the slabs are thinner, the prestressed tendons tend to be weaker than ordinary reinforcement at elevated temperature, and thermal expansion may reduce prestress. This results in an overall reduced level of performance. However, this remains to be confirmed.

Tabulated data exist for the dimensions and cover to reinforcement for prestressed slabs exposed to the standard fire, but they are based on limited test data. Ideally, a full-scale fire test of a concrete frame comprised of prestressed slabs/beams is desirable to check the tabulated data when the slab is restrained as in the real case; more spalling may occur because of this restraint. The test should be designed to identify alternative load paths such as compressive and tensile membrane action, which may support the load if prestressing is reduced by the tendons expanding in a fire. The test should also measure the reduction in prestress, if any, during the fire.

Advanced Analysis of Wood Elements

Design of wood elements in fire is also generally achieved by single element analysis throughout the world. However, Eurocode 5, Part 1.2[81] acknowledges that advanced models can be used for heat transfer analysis and or mechanical response. The complex phenomena associated with wood response to fire, as highlighted when single element methods of design were discussed, are also an issue for whole frame response; the recommendations in EC5-1-2[81] for conducting advanced analysis recognize these. For instance, it states that the thermal response model should take into account the variation of the thermal properties of the material with temperature, including phenomena such as increased heat transfer due to mass transport (e.g. due to the vaporization of moisture) or increased heat transfer due to cracking, which causes heat transfer by convection and/or radiation.

In advanced calculation methods for the structural response EC5-1-2[81] states that the user should take into account the changes of mechanical properties with temperature and moisture. In particular, the effects of transient thermal creep and transient states of moisture should be taken into account. One way of doing this is to use the mechanical properties of wood given in Annex B of EC5-1-2,[81] which include the effects of thermal creep and transient states of moisture. As for the advanced analysis of any structural frame, EC5-1-2[81] states that the structural response model should take into account the effects of nonlinear material properties and nonlinear geometry.

SUMMARY

This chapter outlined some of the design techniques available to assess structural fire resistance, with a specific focus on international approaches. The initial emphasis on the heating regime, which resulted in alternative approaches to fire resistance, was summarized. These do not address structural performance; rather, they address only heating regimes in real compartments and their duration relative to the standard fire resistance heating regime.

The three different forms that fire can take when forming the basis of a structural design include postflashover fires, local fires, and external fires. Guidance was provided on when these very distinctive scenarios are appropriate. Although work remains to be done on addressing the fire scenario in a risk-based framework appropriate for structural design, several design options are available for real building performance. Determining a fire scenario for a structural analysis should, therefore, serve as a useful framework for understanding the issues surrounding the most important parameter in structural fire assessments.

Specific design methods allow single structural element response to elevated temperatures to be quantified. Single structural element analysis techniques provide useful understanding of single element strength in fires under the reduced loading conditions associated with the fire limit state. They do not, however, incorporate any thermal expansion effects, which is one of the most important parameters that govern full-frame structural response.

The chapter concludes with a discussion on methodologies for using advanced structural fire models, as well as some current design methods derived from full-scale testing available in the public domain. Such techniques allow quantification of structural mechanics in elevated temperatures, including significant parameters such as degradation of strength and the alteration in geometry that takes place in a fire. A formal process for design and approvals within a risk-based framework is suggested as a useful way forward for the profession, along with the creation and education of skilled structural fire engineering professionals trained to address this essential component of robust design for all structural forms.

ACKNOWLEDGMENT

The author was assisted in the production of this chapter by her Arup colleagues Dr. Susan Lamont and Ms. Darlene Rini, both of whom are structural fire engineering specialists.

20.1 Assessing Life Safety in Buildings
20.2 Board and Care Facilities
20.3 Hotels and University Housing
20.4 Apartment Buildings
20.5 Lodging or Rooming Houses
20.6 One- and Two-Family Dwellings
20.7 Manufactured Housing
20.8 High-Rise Buildings
20.9 Assembly Occupancies
20.10 Mercantile Occupancies
20.11 Business Occupancies
20.12 Educational Occupancies
20.13 Day-Care Occupancies
20.14 Detention and Correctional Occupancies
20.15 Health Care Occupancies
20.16 Storage Occupancies
20.17 Library and Museum Collections
20.18 Industrial Occupancies
20.19 Motion Picture and Television Studios and Soundstages
20.20 Occupancies in Special Structures

Section 20 of the *Fire Protection Handbook*® describes fire protection requirements and operating features for individual occupancies covered by NFPA *101*®*, Life Safety Code*®, and *NFPA 5000*®*, Building Construction and Safety Code*®. Many of the chapters also discuss the characteristics of the occupants typically found in the occupancies.

Chapter 1, "Assessing Life Safety in Buildings," sets the stage for the chapters that follow by previewing life safety concepts, goals, objectives, strategies, and tools such as the Fire Safety Concepts Tree and fire safety evaluation systems.

The next chapters deal with types of residential facilities. Chapter 2, "Board and Care Facilities," examines what makes alcohol and drug rehabilitation facilities, shelters, assisted living facilities, and other board and care facilities so susceptible to fire and loss of life and what must be done to improve the fire record. Chapter 3, "Hotels and University Housing," has undergone a major revision for the 20th edition. Chapter 4, "Apartment Buildings," also addresses residential condominiums. Chapter 5, "Lodging or Rooming Houses," provides information for facilities providing sleeping accommodations without separate cooking facilities for up to 16 persons who are capable of self-preservation.

The next two chapters also cover types of residences. Chapter 6, "One- and Two-Family Dwellings," concentrates on one- and two-family dwellings, defined as residential structures that contain not more than two dwelling units. Chapter 7, "Manufactured Housing," covers manufactured homes and their construction, fire safety features, installation, and associated utilities.

Chapter 8, "High-Rise Buildings," describes some of the code provisions and special features of the high-rise building, as well as presenting historical data on high-rise building fires.

Chapter 9, "Assembly Occupancies," addresses the fire safety issues of assembly occupancies, which generally can be defined as rooms, spaces, or structures in which groups of people gather for a purpose, such as deliberation, worship, entertainment, or to await transportation. Chapter 10, "Mercantile Occupancies," covers shopping malls and other shops and stores. Chapter 11, "Business Occupancies," includes a discussion of staged and total evacuation.

In previous editions of this handbook, information on educational occupancies and day-care occupancies were combined into a single chapter. In this edition, Chapter 12, "Educational Occupancies," addresses educational occupancies, which are generally defined as facilities in which six or more persons gather for purposes of formal or structured instruction through the twelfth grade. Chapter 13, "Day-Care Occupancies," addresses structures in which four or more clients receive care, maintenance, and supervision by other than their relatives or legal guardians for fewer than 24 hours per day.

Gregory E. Harrington, P.E., is principal fire protection engineer with NFPA's Building Fire Protection and Life Safety Division.

Chapter 14, "Detention and Correctional Occupancies," covers fire safety concerns in buildings and facilities in which persons are restrained for security purposes by locks they do not control.

Chapter 15, "Health Care Occupancies," describes fire protection needs in a variety of facilities that care for nonambulatory patients who are incapable of self-preservation.

Chapter 16, "Storage Occupancies," addresses fire protection for storage and warehouse operations, where intense fires can develop rapidly. Chapter 17, "Library and Museum Collections," summarizes the unique fire safety concerns, including damage limitation, in cultural properties such as historic buildings and sites.

Hazard assessment and prefire planning are among the topics considered in Chapter 18, "Industrial Occupancies." Chapter 19, "Motion Picture and Television Studios and Soundstages," includes a discussion of pyrotechnics before a proximate audience.

The section closes with Chapter 20, "Occupancies in Special Structures." For purposes of this chapter, special structures include limited access and underground structures, mall buildings, open parking structures, special amusement structures, piers and wharves, water-surrounded structures, membrane structures and tents, grandstands, towers, and open structures.

Chapter 1

Assessing Life Safety in Buildings

Life Safety Concepts
Life Safety Goals and Objectives
Characteristics of Occupants
Life Safety Strategies
Life Safety Assessment Tools

Key Terms

egress, evacuation capability, fire prevention, Fire Safety Concepts Tree, Fire Safety Evaluation Systems (FSES), fire scenario, life safety assessment, life safety concept, occupancy classification, occupant characteristics, occupant load, performance-based approach, travel distance, untenable condition

Assessment of life safety is the process of estimating the quality of security against fire and its effects. There is no universally accepted method of assessing life safety from fire in buildings. Life safety is a concept, and no formula can identify or guarantee that a building is safe from fire.

First of all, assessment requires an understanding of the fundamentals of the life safety concept. Life safety goals and objectives need to be reviewed and then an evaluation can be made of the parameters that create hazards to life and those that tend to offset or control a portion of the life hazard. A wide variety of tools have been devised to relate these parameters so as to assess life safety in buildings.

Every general type of fire safety practice and fire protection strategy discussed in this handbook may apply to life safety in buildings. Specific additional information that can be helpful in a life safety assessment is identified throughout this chapter.

See also Section 2, Chapter 1, "Physics and Chemistry of Fire"; Section 4, Chapter 1, "Human Behavior and Fire"; Section 4, Chapter 2, "Calculation Methods for Egress Prediction"; and Section 6, Chapter 2, "Combustion Products and Their Effects on Life Safety."

LIFE SAFETY CONCEPTS

Concern for life safety implies avoiding exposure to harmful levels of products of combustion. This goal is usually achieved by controlling the fire process or by separating endangered individuals from the harmful effects of fire by time, distance, or shielding. Thus, life safety is accomplished if endangered individuals can move away from potential danger or if harmful effects of fire can be delayed indefinitely from reaching people in the building.

Details of the fire's development, along with characteristics of exposed occupants, determine the magnitude of the hazard. In addition, specific safety measures may be employed to reduce the hazard. Understanding the interrelationships of these components is the first step in assessing life safety from fire in buildings.

Importance of Time

As a fire develops over time, smoke and heat build up to create an environment that is hazardous to life. The rate at which the environment deteriorates is difficult to predict, because a great many variables are involved. Figure 20.1.1 is a generalization of the way life hazard increases over time. At the time of ignition (lower left corner), the environment is normal. Most fires develop slowly, so the initial hazard is small. Eventually, fire intensity will increase more rapidly, building up the level of dangerous products of combustion.

After some period of time, the accumulation of products of combustion reaches a level at which the fire will be discovered by the occupants through sight or smell or by automatic fire detectors. The level of hazard at which discovery occurs corresponds to a specific time in the course

John M. Watts, Jr., Ph.D., is director of the Fire Safety Institute, a not-for-profit information, research, and educational corporation located in Middlebury, Vermont. He also serves as editor of NFPA's quarterly scientific journal, *Fire Technology.*

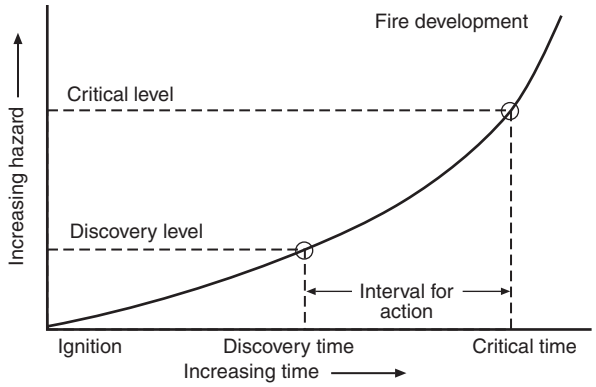

FIGURE 20.1.1 Representative Rate of Deterioration of the Environment as a Fire Progresses and the Interval of Time Available to Take Action to Prevent Death or Injury

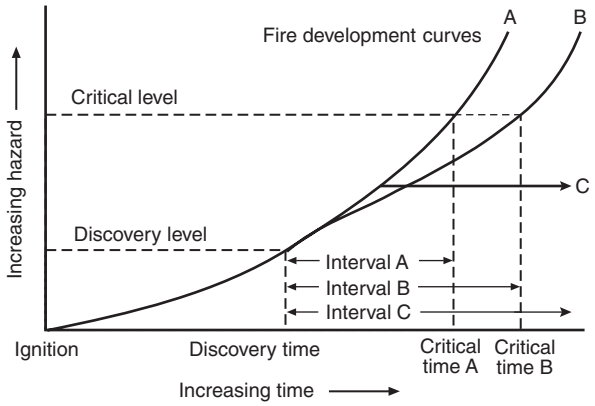

FIGURE 20.1.2 Difference in Deterioration Rates Between a Faster-Developing and a Slower-Developing Fire and Resulting Impact on the Interval for Action

of the fire. Figure 20.1.1 indicates a discovery level and a corresponding discovery time. If no actions are taken after discovery, eventually, the hazard will increase to a level that is lethal or incapacitating. In Figure 20.1.1 this is shown as the critical level and there is a corresponding critical time.

Fire Hazard

The critical time depends on the interaction of three sets of conditions: (1) elevated environmental temperatures, (2) toxic conditions resulting from pyrolysis or combustion products, and (3) preexisting or current psychophysiological attributes of the occupants. Elevated temperatures can cause burns or heat stress ranging from trivial to lethal. Specific chemical pyrolysis or combustion products, decreased oxygen concentration, or particulate smoke can cause toxic effects. The clinical consequences of these physical conditions also will reflect the psychophysiological conditions of the occupants. For example, preexisting heart disease has been established as a contributory factor in fire deaths.[1] Assessment of the variable interactions of these three sets of conditions is, obviously, extremely complicated.

Interval for Action

The interval between discovery and criticality is the time available to undertake action to prevent occupants from being exposed to the critical hazard level. This action may take various forms, such as activation of automatic equipment, evacuation of occupants, or both. Lowering the hazard level where discovery occurs, such as by automatic fire detection, will have a corresponding decrease in the time to discovery and, therefore, will increase the interval of time available for action. On the other hand, occupants with greater susceptibility and, hence, a lower personal critical level will have less time to react.

Fire growth and hazard are not the same in every fire. If conditions are insufficient to sustain a fast-spreading fire, the rate of deterioration of the environment is reduced, resulting in a decreased slope of the fire development curve. Figure 20.1.2 shows three different fire development curves. Curve A is the same fire as in Figure 20.1.1. Curve B represents a slower-developing fire than curve A. The curve starts at the same point of ignition but does not curve upward as quickly as curve A. This means it takes longer to reach the critical hazard level and, thus, has a resultant increase in the interval of time available for action. This could be affected by a decrease in the surface area or combustibility of interior finish materials.

Alternatively, curve C might represent the effect of a smoke control system or sprinkler system, which are two active systems that can stop or even reverse the developing severity of the fire. Curve C begins with ignition and then grows at the same rate as curve A, but at some point after discovery, the system is activated and it maintains the atmosphere below the critical level for an indefinite period of time.

LIFE SAFETY GOALS AND OBJECTIVES

Life safety goals and objectives identify what it is that we want to achieve. The primary difference between goals and objectives is that objectives are more specific to the problem being solved. Goals are always qualitative, whereas objectives may also be quantitative.

Life Safety Goals

A goal is a broad, qualitative expression of the overall, primary concern. Goals are nonspecific and are potentially measurable although only on a qualitative basis. They are stated in terms of conditions that are intrinsically desirable and do not rely on assumptions.

Goals relating to life safety are the most common and arguably the most important in fire and other emergency situations. The public trusts the built environment (that is, anyone involved in constructing buildings, structures, and other facilities—designers, engineers, code officials, and the like) to maintain some level of safety or protection from adverse conditions. Therefore, maintaining the health, safety, and welfare of building occupants is a basic goal.

NFPA *101*®, *Life Safety Code*®, has three stated goals to reduce the adverse impact of fire on people:

- Protection of occupants not in contact with the initial fire development
- Improvement of the survivability of occupants in contact with the initial fire development
- Provision of reasonably safe emergency crowd movement

Life Safety Objectives

A life safety objective is a requirement of the fire development, building, or occupants that needs to be accomplished in order to achieve a life safety goal. Objectives provide a greater level of qualitative detail than goals, are stated in more specific terms than goals, and are measured on a more quantitative rather than qualitative basis. In general, objectives define a series of actions necessary to make the achievement of a goal much more likely. If each life safety objective is accomplished for a building, then that building can be said to meet the life safety goals.

NFPA *101* has three objectives that address occupant protection, structural integrity, and system effectiveness:

- A structure shall be designed, constructed, and maintained to protect occupants who are not intimate with the initial fire development for the time needed to evacuate, relocate, or defend in place.
- Structural integrity shall be maintained for the time needed to evacuate, relocate, or defend in place occupants who are not intimate with the initial fire development.
- Systems utilized to achieve the goals shall be effective in mitigating the hazard or condition for which they are being used, shall be reliable, shall be maintained to the level at which they were designed to operate, and shall remain operational.

Life safety goals and objectives identify the fundamental purpose of assessing life safety in buildings. Meeting these goals and objectives is what the assessment is intended to help achieve.

CHARACTERISTICS OF OCCUPANTS

The most difficult component of life safety to evaluate is the population at risk (i.e., the occupants of the building). The difficulty is due to wide variations among building occupants. It is necessary to assess their susceptibility to fire and fire products and their ability to undertake and follow procedures necessary for their safety (i.e., anticipated response to a fire emergency). Indications of these abilities may be found in physical and mental characteristics of the occupants, as individuals and as a group. Four categories of occupant characteristics influence the ability to survive in a fire: (1) location, (2) response, (3) number, and (4) staff.[2]

Location

Assumptions generated by committees responsible for the development of NFPA *101* performance-based design option regarding the location of occupants dealt more with the density or concentration of people within a space rather than the actual location of individual occupants. However, the location of individual occupants may be inferred from the stated assumptions. For example, the Technical Committee on Board and Care Facilities assumed "full occupancy" and the Technical Committee on Residential Occupancies assumed "high-density (people per room) properties." These assumptions indicate that the maximum travel distance from any occupiable room or space within the building must be considered when designing and analyzing potential building designs.

The present prescriptive requirements in NFPA *101* and *NFPA 5000*®, *Building Construction and Safety Code*®, identify the location of occupants in regard to compliance with maximum allowable travel distances. Table 20.1.1 lists travel distance limits by type of occupancy and sprinkler protection as prescribed in NFPA *101* and *NFPA 5000.* These codes specify that the travel distance to an exit must be measured from the most remote point subject to occupancy. This has been interpreted as an assumption necessary for performance-based design as follows: "In every normally occupied room or area, at least one person shall be assumed to be located at the point most remote from the exit(s)." Although consistent with the prescriptive code, this is a conservative assumption and not necessarily representative of expected normal human behavior.

Another aspect of occupant location is the remoteness of exits when more than one is required. This is to ensure that multiple exits are not simultaneously blocked by a single fire. Current codes rely on a rule that says exits should be a straight-line distance apart not less than one-half the length of the maximum overall diagonal dimension of the building or area served. The rationale for this "one-half diagonal rule" is not obvious. There is no physical or logical reason to relate a building diagonal to the emergency egress of people. Furthermore, this approach permits configurations in which the exits might not intuitively be considered remote. For example, consider a space with a length of 100 ft (30.4 m) and a width of 60 ft (18.2 m) with both its exits at one of the narrow ends.

Remoteness of exits may be more logically a function of direction of travel than separation distance. A measure of this concept would be the angled distended between lines corresponding to routes from any point in a room or space to the exits or exit accesses. Figure 20.1.3 illustrates a situation where if the travel paths to two exits are different by at least 30°, the exits may be considered remote. That is, if the exits were closer together, the angle of remoteness would be less than 30°. There are also ways this concept can be adapted to include a common path of travel limitation.[3]

Response

In a performance evaluation of life safety, assumptions need to be made regarding the expected distribution of characteristics of a population appropriate to the use of the building. The four basic characteristics (i.e., sensibility, reactivity, mobility, and susceptibility) comprise a minimum, exhaustive set of mutually exclusive performance characteristics of people in buildings that can affect a fire safety system's ability to meet life

safety objectives. They are briefly described in Table 20.1.2. In application, as with the use of computer evacuation models, assumptions may address a larger number of factors that are components of these basic performance characteristics.

Furthermore, occupant response assumptions vary depending on the type of facility being analyzed. For example, the committee dealing with theaters, nightclubs, concert halls, sports arenas, and so on assumed that patrons may be intoxicated. This

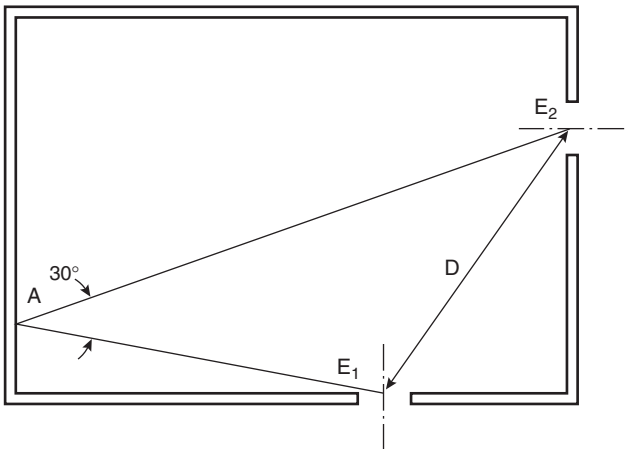

FIGURE 20.1.3 Travel Paths from Point A to Two Exits, E_1 and E_2, with 30° Difference (D = Safe separation distance)

assumption would affect the patrons' sensibility, reactivity, most likely their mobility, and possibly their susceptibility. Other occupancy committees made assumptions that fall into only one of the categories of Table 20.1.2: detention and correction facilities by their very purpose impair the mobility of the occupants; specific kinds of health care and board and care facilities may involve persons with limited sensibility, persons with limited reactivity, or persons having a wide range of susceptibility; and so on.

TABLE 20.1.2 Occupant Response Characteristics

Characteristic	*Description*
Sensibility	Sensibility to physical cues. Ability to sense the sounding of an alarm. May also include discernment and discrimination of visual and olfactory cues in addition to the sounds of the fire itself.
Reactivity	Reactivity is the ability to correctly interpret cues and take appropriate action. May be function of cognitive capacity, speed of instinctive reaction, or group dynamics. May need to consider reliability or likelihood of a wrong decision as in the influence of familiarity with the premises on wayfinding.
Mobility	Mobility is speed of movement. Determined by individual capabilities as well as crowding or congestion phenomena, such as "arching" at doorways.
Susceptibility	Susceptibility to products of combustion. Metabolism, lung capacity, pulmonary disease, allergies, or other physical limitations that may affect survivability in a fire environment.

There also may be a dynamic component to occupant response assumptions. Any facility in which occupants may be sleeping requires different sensibility and reactivity assumptions when occupants are expected to be awake than when occupants are expected to be sleeping.

One type of occupant response assumption that the occupancy committees made that is difficult to categorize has to do with an occupant's familiarity with the facility being analyzed. For example, occupants of an office building were assumed to have a high degree of familiarity with the building in which they work, whereas patrons in an assembly occupancy were assumed to be unfamiliar with their surroundings. Is "higher familiarity" manifested as greater mobility? Presumably, a higher degree of familiarity with a facility results in more correct decisions about the safest path to take to reach a place of safety and, therefore, an effectively higher degree of mobility. Certainly an argument may be made that those having less familiarity with a facility's exit locations and egress routes will have a lesser degree of mobility (i.e., take a longer time to evacuate). However, not enough is currently known to make an estimation of how much mobility should be degraded to account for poor decision making while evacuating a building.

Number

A critical factor in human behavior in fire is the number of occupants in a given space. NFPA *101* and *NFPA 5000* identify figures for the average maximum density of occupancy for the existing classifications. Table 20.1.3 shows occupant load factors for types of occupancies and functional spaces within the occupancies as prescribed in NFPA *101* and *NFPA 5000*. These figures represent acceptable estimates in the absence of preferable data.

Staff

When trained employees are explicitly or implicitly included as part of the fire safety system, assumptions regarding their capability need to be identified and documented. For example, in hospitals, staff characteristics such as number, location, quality, frequency of training, and so on should be considered. An aspect that is often overlooked is the potential effectiveness of staff in assembly occupancies such as art galleries and museums. Although staff may be present in a given occupancy, they often are not considered part of the fire safety system. A case in point is in most mercantile occupancies where staff are trained to aid customers in sales, not necessarily evacuation.

Additional information on human behavior in fire is found in Section 4, Chapter 1, "Human Behavior and Fire," and in the *SFPE Engineering Guide to Human Behavior in Fires.*[4]

NFPA 101A, *Guide on Alternative Approaches to Life Safety,* addresses some characteristics of occupants. The chapter on "Evacuation Capability Determination for Board and Care Occupancies" describes a method for determining evacuation capability for a specific type of occupancy. This method calculates an evacuation capability score using information on residents, staff, and vertical egress travel required. Rating of residents assesses several characteristics of occupants that are particularly important to board and care occupancies. Table 20.1.4

Mall buildings[d]	Per factors applicable to use of space[e]	Per factors applicable to use of space[e]

Note: The occupant load is the maximum probable number of occupants present at any time.

[a]All factors are expressed in gross area unless marked "net."

[b]For the purpose of determining occupant load in mercantile occupancies where, due to differences in grade of streets on different sides, two or more floors directly accessible from streets (not including alleys or similar back streets) exist, each such floor is permitted to be considered a street floor. The occupant load factor is one person for each 40 ft^2 (3.7 m^2) of gross floor area of sales space.

[c]For the purpose of determining occupant load in mercantile occupancies with no street floor, as defined in Section 3.3.239 of NFPA *101,* but with access directly from the street by stairs or escalators, the floor at the point of entrance to the mercantile occupancy is considered the street floor.

[d]For any food court or other assembly use areas located in the mall that are not included as a portion of the gross leasable area of the mall building, the occupant load is calculated based on the occupant load factor for that use as specified in this table. The remaining mall area is not required to be assigned an occupant load.

[e]The portions of the mall that are considered a pedestrian way and not used as gross leasable area are not required to be assessed an occupant load based on this table. However, means of egress from a mall pedestrian way are required to be provided for an occupant load determined by dividing the gross leasable area of the mall building (not including anchor stores) by the appropriate lowest whole number occupant load factor from Figure 7.3.1.2(a) or Figure 7.3.1.2(b) of NFPA *101.*

Each individual tenant space is required to have means of egress to the outside or to the mall based on occupant loads calculated by using the appropriate occupant load factor from this table.

Each individual anchor store is required to have means of egress independent of the mall.

NA = Not applicable.

Source: Table 7.3.1.2, NFPA *101,* 2006 edition.

summarizes these characteristics and illustrates that for some types of building use more detailed information on occupants is necessary.

Surrogate Descriptors

Occupant age is often used as a surrogate descriptor for characteristics that determine life safety risk. Relatively easy to identify, age is often directly associated with characteristics such as mobility, awareness, and knowledge. Statistics showing that the very young and the very old suffer higher fatality rates from fire indicate variation of life risk with age.

NFPA *101, NFPA 5000,* and other model building codes categorize building use or occupancy classifications to simplify the application of regulations governing construction, fire protection, and other life safety requirements. In application, occupancy class, once determined, becomes the basis for most code requirements. In effect, we use occupancy classification as a surrogate for life safety risk. This generalization is inadequate for more performance-based assessment of life safety in buildings. NFPA *101* and *NFPA 5000* categorize buildings using the following occupancy classifications:

- Assembly
- Educational
- Day care
- Health care
- Detention and correctional
- One- and two-family dwellings
- Lodging or rooming houses
- Hotels and dormitories
- Apartment buildings
- Residential board and care
- Mercantile
- Business
- Industrial
- Storage

NFPA *101* further classifies occupancies as either new or existing.

TABLE 20.1.4 Risk Factors for Rating Evacuation Capability of Residents in a Board and Care Occupancy (as addressed in NFPA 101A)

Risk Factor	*Description*
Risk of resistance	During an emergency evacuation, the resident might resist leaving the facility
Impaired mobility	Physical ability of the resident to leave the facility
Impaired consciousness	A resident could experience partial or total loss of consciousness in a fire emergency
Need for extra help	Possibility that more than one staff member might be needed to evacuate the resident
Response to instructions	Resident's ability to receive, comprehend, and follow simple instructions during a staff-directed evacuation
Waking response to alarm	Fire alarm might fail to awaken the resident

LIFE SAFETY STRATEGIES

Ideally, building design considers the risk factors associated with occupants and fire, and it includes safety features to mitigate the risks. The discussion in this chapter is intended as a synthesis of the various safety measures that may be applied to reduce the danger of fire to occupants. Major categories of safety strategies have been identified by NFPA 550, *Guide to the Fire Safety Concepts Tree,* as (1) prevent fire, (2) manage fire, and (3) manage exposed (occupants). A simplified portion of the Fire Safety Concepts Tree showing the relationships of these strategies is presented as Figure 20.1.4.

Fire Prevention

No harm can come from fire if no fire takes place. Fire prevention, therefore, has the potential to eliminate the need for other fire safety measures. However, no fire prevention strategy is ever totally effective, so it is not prudent to rely on fire prevention alone.

Fire prevention considerations relate to heat energy sources, fuels, and the mechanisms that bring them together. For example, major potential ignition energy sources, such as electrical power, can be controlled largely through regulation, such as by following the requirements of NFPA 1, *Uniform Fire Code™,* and NFPA 70, *National Electrical Code®*. In addition, some fuels, such as flammable liquids and interior finish, also may be addressed by codes and standards. However, not all energy sources or all fuels can be regulated. This is also true of people, the primary causal factor of ignition. Assessment of the probability of

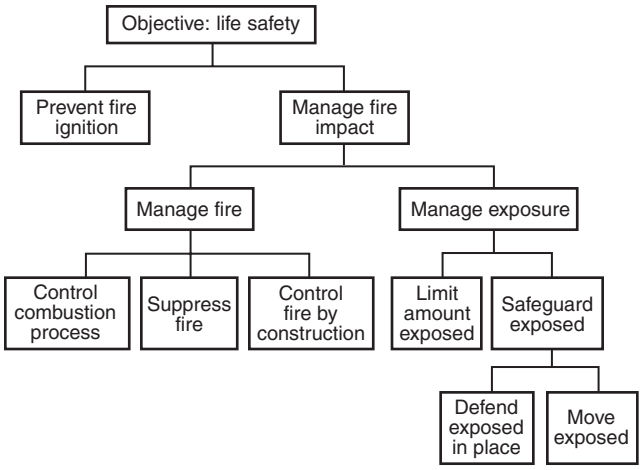

FIGURE 20.1.4 Simplified Portion of the Fire Safety Concepts Tree

fire occurrence involves analysis of ignition potential, especially in relation to the activities of building occupants, and of factors that will decrease the likelihood of ignition.

Fire Management

Since it is impossible to avoid all ignitions, managing fires that occur also is important. The strategies of fire management may be seen as reducing the slope of the fire development curves portrayed in Figures 20.1.1 and 20.1.2. These approaches strive to control the rate of smoke and heat production by altering fuel and/or the environment, controlling the combustion process by manual or automatic suppression, and controlling the products of combustion through venting and/or containment.

Objectives of the "manage fire" strategy are to reduce risks associated with fire growth and to reduce fire and smoke spread. Together, these reductions diminish the impact of a fire on building occupants.

Occupant Management

This life safety strategy (manage exposed) is the most complex, dealing with the risk factors of both fire and people. Occupant management involves undertaking emergency action appropriate to expected fire development and to characteristics of the occupants.

To initiate occupant management action, there first must be detection and alerting activities. Automatic equipment may perform these functions. Actions for managing exposed persons involve evacuation, refuge, or rescue. Evacuation is the most common approach when occupants are alert and mobile. In other cases, areas of refuge from fire and smoke within a building are employed, along with movement assisted by emergency personnel.

LIFE SAFETY ASSESSMENT TOOLS

The components of a generalized approach to assessment of life safety from fire in buildings are shown in Figure 20.1.5.

Step 1 is to identify the expected fire. This is depicted by the boxes to the left of the centerline in Figure 20.1.5. The expected fire is determined by the fire hazards that are present in the building, fire prevention measures implemented to prevent specific hazards from occurring, and fire management activities to control the severity of a fire if it does occur. The expected fire is input to step 2.

Step 2 is to the right of the centerline in Figure 20.1.5. The expected fire from step 1 is considered in conjunction with occupant risk factors and management of exposed occupants. This analysis produces a life safety assessment.

Step 3 is a return to the beginning to consider other expected fires or enhanced fire safety strategies. Thus, improving life safety in buildings is an iterative process of matching hazard and safety factors.

Specific techniques can be used in an assessment of life safety from fire in buildings including codes, exit analysis, fire safety evaluation systems (FSES), fire scenarios, evacuation models, and performance-based evaluation.

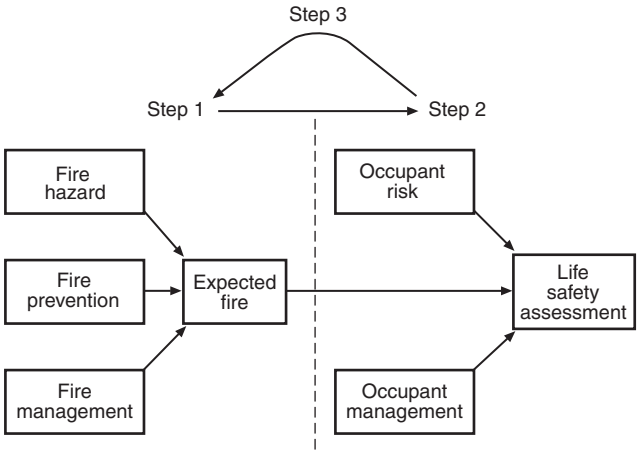

FIGURE 20.1.5 General Approach to Assessing Life Safety in Buildings

Codes

In the United States, NFPA *101* is the most widely used code for life safety from fire in buildings. The code has its origins in the 1912 *Exit Drills in Factories, Schools, Department Stores, and Theaters* that evolved as a result of the Triangle Shirtwaist factory fire in New York City that killed 146 workers in 1911. Requirements for factories and other occupancies were combined with specifications for building construction and automatic fire protection into the *Buildings Exit Code,* adopted and published in 1927. During the next 37 years, 18 revisions of this code were published, greatly expanding its content. In 1963, the document was reorganized and renamed the *Code for Safety to Life from Fire in Buildings and Structures,* or simply, the *Life Safety Code.* To date an additional thirteen editions have been published—the 2006 edition being the latest at the time this handbook was published.

NFPA *101* provides minimum requirements for the design, operation, and maintenance of buildings and other structures for safety to life from fire and similar emergencies. The code requires new and existing buildings to allow for "prompt escape" or to provide people with a reasonable degree of safety through other means.

The code meets its objectives by following two parallel approaches. First, it defines hazards, along with general requirements for the means of egress (a path of travel to a public way outside the building), fire protection features (such as fire doors), and building service and fire protection equipment (such as heating, ventilating, and air conditioning systems, sprinkler systems, and fire detection systems). Next, the code prescribes life safety requirements that vary with a building's use. Buildings used as one- and two-family dwellings, for example, have different life safety needs than hospitals and schools. Unique among fire safety codes, the provisions of the *Life Safety Code* depend on the type of occupancy and whether the occupancy is new or existing. The code can be used in conjunction with a building code or by itself in jurisdictions that have not adopted a building code.

NFPA *101* in particular and building codes in general are the predominant overall guides to life safety from fire in buildings in the United States. NFPA *101* identifies the following 10 fundamental requirements that are the basis for most of the specific provisions in the code. More information on these principles is found in Section 4, Chapter 3, "Concepts of Egress Design."

Multiple Safeguards. The design of every building or structure intended for human occupancy must be such that reliance for safety to life does not depend solely on any single safeguard. An additional safeguard(s) must be provided for life safety in case any single safeguard is ineffective due to inappropriate human actions or system failure.

Appropriateness of Safeguards. Every building or structure must be provided with means of egress and other safeguards of the kinds, numbers, locations, and capacities appropriate to the individual building or structure, with due regard to character of the occupancy, capabilities of the occupants, number of persons exposed, fire protection available, height and type of construction of the building or structure, and other factors necessary to provide occupants with a reasonable degree of safety.

Number of Means of Egress. Two means of egress, as a minimum, must be provided in every building or structure, section, and area where size, occupancy, and arrangement endanger occupants attempting to use a single means of egress that is blocked by fire or smoke. The two means of egress must be arranged to minimize the possibility that both might be rendered impassable by the same emergency condition.

Unobstructed Egress. In every occupied building or structure, means of egress from all parts of the building must be maintained free and unobstructed. No lock or fastening is permitted that prevents free escape from the inside of any building other than in health care occupancies and detention and correctional occupancies where staff are continually on duty and effective provisions are made to remove occupants in case of fire or other emergency. Means of egress must be accessible to the extent necessary to ensure reasonable safety for occupants having impaired mobility.

Awareness of Egress System. Every exit must be clearly visible, or the route to reach every exit must be conspicuously indicated. Each means of egress, in its entirety, must be arranged or marked so that the way to a place of safety is indicated in a clear manner.

Lighting. Where artificial illumination is needed in a building or structure, egress facilities must be included in the lighting design.

Occupant Notification. In every building or structure of such size, arrangement, or occupancy that a fire itself might not provide adequate occupant warning, fire alarm facilities must be provided where necessary to warn occupants of the existence of fire.

Vertical Openings. Every vertical opening between the floors of a building must be suitably enclosed or protected, as necessary, to afford reasonable safety to occupants while using the means of egress and to prevent spread of fire, smoke, or fumes through vertical openings from floor to floor before occupants have entered exits.

System Design/Installation. Any fire protection system, building service equipment, feature of protection, or safeguard provided for life safety must be designed, installed, and approved in accordance with applicable NFPA standards.

Maintenance. Whenever or wherever any device, equipment, system, condition, arrangement, level of protection, or any other feature is required for compliance with the provisions of the code, such device, equipment, system, condition, arrangement, level of protection, or other feature must thereafter be maintained unless the code exempts such maintenance.

Egress Analysis

Egress analysis is an important component of a life safety evaluation, as well as a tool for other forms of life safety assessment. The analysis uses anthropometric and biokinetic data on occupants, together with hydraulic flow analogies or other models, to calculate the time required to evacuate a building or space. The result can be compared to a calculated time for deterioration of the environment. Some basic engineering approaches to egress analysis have been developed and are presented in the *SFPE Handbook of Fire Protection Engineering*.[5,6] It is critical that results of egress analysis calculations, whether manual or computer, be examined with respect to the vagaries of human behavior that accompany an emergency.

Emergency egress systems should be assessed in terms of adequacy and reliability. Adequacy refers to structural components that determine the capacity to evacuate part or all of a building within a safe egress time span. Reliability considers how efficiently the egress capacity will be utilized. Factors of reliability include alerting messages and instructions, signage and emergency lighting, and protection of egress routes from fire, smoke, and toxic gases. Figure 20.1.6, a logic diagram, enumerates some features of egress adequacy and reliability.

Fire Safety Evaluation Systems (FSES)

NFPA 101A addresses fire safety evaluation systems (FSES). FSES is a fire risk indexing approach to determining equivalencies to NFPA *101* for certain occupancies. The FSES originally was created to provide a uniform method of evaluating health care facilities and to identify measures that would provide a level of fire safety equivalent to NFPA *101*.

Occupant Risk. Unlike NFPA *101,* the FSES for health care occupancies begins with a determination of relative risk derived from occupant characteristics. Variations of selected characteristics are assigned relative weights. Values were determined from the experienced judgment of a panel of fire safety professionals. Occupancy risk is then calculated as the

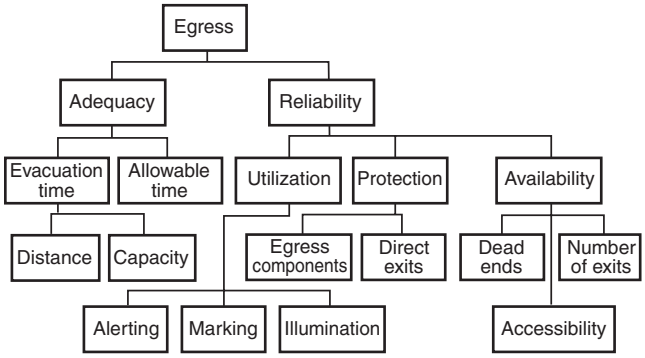

FIGURE 20.1.6 Logic Diagram of Egress Features

product of the risk factor values appropriate for the particular occupancy.

Safety Parameters. Safety features must offset this calculated risk. Thirteen possible safety parameters are considered. These parameters and their respective ranges of values for health care occupancies are based on opinions of the same expert panel.

Safety Strategies. An important concept of the FSES is reliability through redundancy by the simultaneous use of alternative safety strategies. Fire safety strategies considered in the FSES are containment, extinguishment, and people movement. Figure 20.1.7 indicates the expert panel's opinion of which safety parameters apply to each strategy. Values for a particular

occupancy are entered in the appropriate places on Figure 20.1.7 and then added for each column. The resulting sums are compared to predetermined minimum values and to the occupancy risk previously calculated.

A method of minimizing the cost of retrofitting for compliance with the FSES for health care occupancies has been adapted for personal computers.[7] This approach is of practical interest to persons with fiscal responsibilities for health care facilities. The software includes the integrated code compliance optimizer, full-screen data editor, and file manager. ALARM 1.0 is available from the National Fire Protection Association (http://www.nfpa.org) through the One-Stop-Data-Shop. NFPA 101A includes FSESs for health care occupancies, correctional facilities, board and care facilities, business occupancies, and educational occupancies. One of the most widely used of these is Fire Safety Evaluation System for Business Occupancies. A PC-based computerized version has been developed. Fire risk indexing (FRI) models, such as the FSES, are powerful tools for assessing fire safety, especially in existing buildings. Designers can use FRI to determine the attributes needed to bring a building up to an acceptable level of fire safety. See the *SFPE Handbook of Fire Protection Engineering* for more information on this concept.

Fire Scenarios

In the theater, a scenario outlines the action of a play. Used in forecasting and political analysis, scenarios are sequences of events that lead to some specified circumstances. Scenarios are particularly suited to examining related conditions (such as building occupancy) and events (such as ignition). A fire scenario is a generalized, detailed description of an actual or hypothetical, but credible, fire incident. Such a scenario identifies a chain of events leading to deaths and other fire losses.

Each fire scenario includes all details relevant to a fire's development and the subsequent behavior of people and protection mechanisms. A properly developed fire scenario describes all essential elements of a fire incident. Scenario development is one of the most useful devices for anticipating a largely uncertain future. Fire protection engineering evaluation of a building or facility involves creating and analyzing fire scenarios. In the simplest form, a fire protection engineer hypothesizes plausible fire scenarios using professional experience and scientific principles of fire dynamics. A more sophisticated form uses computer models to predict fire scenario events.

Fire scenarios are particularly useful in assessing life safety in buildings. By considering various fire scenarios, it often is possible to identify and evaluate the potential for life loss. Plausible fire scenarios are an essential component of some other techniques of life safety assessment, such as the performance-based approach.

Evacuation Models

Computer models for the assessment of life safety in buildings are developing rapidly, concurrent with technical knowledge and hardware capability. These advances occur internationally in acknowledgment of their potential effect on reducing loss of life from fire.

Computer simulation is the process of representing item by item and step by step a system's essential features and then predicting what is likely to happen by running the model case by case. A great advantage of computer simulation is that by using computer-generated random numbers, the model can represent with desired precision processes for which satisfactory analytical approximations do not exist. A system that is not well enough understood to permit mathematical relations between variables to be formalized may often be modeled as a simulation. In studying behavioral systems, the need for simulation becomes acute. When objective data are very difficult to obtain, most predictions must be derived from vague, tentative, and intuitive conjectures. Such ill-defined structures and laborious analyses make computers indispensable tools.

The flexibility of simulation modeling and the complexity of the evacuation problem have resulted in numerous applications. These models differ in complexity, input requirements, underlying assumptions, specific application areas, and validation. Computer simulations of emergency egress range from simple travel time models to detailed representations of human decision making.

Performance-Based Approach

Most building codes maintain only an assumed, implicit relationship between fire safety requirements and fire safety objectives. For example, the number of exits has an intuitively positive correlation with life safety but no explicit relationship and no functional association for determining costs or benefits.

Performance-based evaluation focuses on fire safety objectives. This implies an examination of how all materials, products, components, and assemblies in a building work together as a system to meet fire safety objectives. For example, in determining adequacy of egress routes, it is desirable to consider the overall effect of number, size, length, and reliability of use, as well as the interdependencies among fire growth, fire resistance, and fire suppression.

The performance-based approach establishes fire safety objectives and leaves means for achieving objectives to the design professional. Carrying out this significant departure from traditional code practice requires the capability to determine whether fire safety objectives are being met.

NFPA *101* provides requirements for the evaluation of a performance-based life safety design. The evaluation process is summarized in Figure 20.1.8. On the left-hand side of Figure 20.1.8 is input from the code, life safety goals, the objectives necessary to achieve these goals, and the measures that are to be used to determine whether the objectives have been met.

At the top of Figure 20.1.8 is the input necessary to evaluate a life safety design. The design specifications are to include certain retained prescriptive requirements as specified in the code. All assumptions about the life safety design and the response of the building and its occupants to a fire need to be clearly stated. Fire scenarios are used to assess the adequacy of the design.

Appropriate methods for assessing performance are to be used and safety factors are to be applied to account for uncertainties in the assessment. If the resulting predicted outcome of the scenarios is bounded by the performance criteria, then the

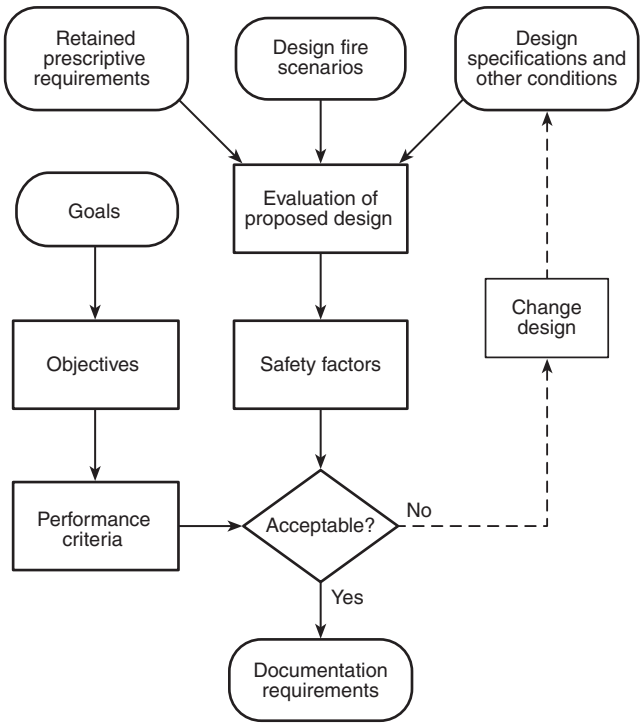

FIGURE 20.1.8 Performance-Based Life Safety Evaluation Process

objectives have been met and the life safety design is considered to be in compliance with the code. A design that fails to comply can be changed and reassessed as indicated on the right-hand side of Figure 20.1.8.

Although the performance option of this code contains goals, objectives, and performance criteria necessary to provide an acceptable level of risk to occupants, it does not describe how to meet the goals, objectives, and performance criteria. Professional design and engineering are needed to develop solutions that meet the performance provisions. Additional information on performance-based fire codes and standards is found in Section 3, Chapter 10, "Performance-Based Codes and Standards for Fire Safety," and the *SFPE Engineering Guide to Performance-Based Fire Protection Analysis and Design of Buildings.*[8]

SUMMARY

The main goals of life safety are to prevent fire, control fire if it happens, and to evacuate occupants. Many factors need to be evaluated when assessing life safety in buildings. The qualified evaluator must, therefore, have a good understanding of a range of concepts, including ignition potential, fire hazards, fire detection, fire suppression, emergency notification, building construction, occupant behavior, exit systems, and emergency management. Tools that can be used in the assessment process include fire code requirements, egress analysis, fire safety evaluation systems, fire scenarios, computer evacuation models, and the performance-based approach.

Fire Protection Strategies

Key Terms

egress, evacuation capability, fuel control, ignition control, occupant characteristics, personal care, residential board and care occupancy, special hazards

Although it has been with us for more than a century, the residential board and care home has been a phenomenon in the United States since the 1970s. Reasons for the growth of this type of occupancy are numerous. The population of state hospitals was reduced sharply in the 10-year period from 1969 to 1979. Social, judicial, economic, and therapeutic pressures to remove patients from the restrictive environments of psychiatric hospitals, nursing homes, state schools, and other institutional settings helped create a need for board and care facilities. This occupancy provides the deinstitutionalized person with a more normal setting to live in and furnishes the support services the resident needs to cope with life's daily requirements.

Today's older adults often live alone, even after they are unable to care for all their own needs. They might need to be in a setting where someone can look after their nutrition, personal hygiene, and so on. In recent decades, the rapid growth of assisted living facilities has driven the overall growth in board and care facilities, a trend that will continue to accelerate due to the aging baby boom population.

Alcohol and drug rehabilitation programs often use the halfway house concept, in which the individual is somewhat sheltered from the pressures of returning too quickly to society for independent living. Shelters for battered persons, unwed mothers, and homeless children have also become more common.

The fire experience in what NFPA statistical analysts call board and care homes was striking during 1979–1983 and remains a concern today (Table 20.2.1). Many of the multiple-death fires reported in Table 20.2.1 killed over half the residents, and it is not unusual for the largest fires to totally destroy facilities. At the same time, these fires are becoming less frequent. Fires involving 10 or more fatalities in particular are declining, and this is a hopeful development.

This chapter examines what makes board and care facilities so susceptible to fire and loss of life and what must be done to improve the fire record.

See also Section 5, Chapter 5, "Reaching High-Risk Groups"; and Section 20, Chapter 1, "Assessing Life Safety in Buildings."

DEFINITION

A residential board and care occupancy is defined in NFPA *101*®, *Life Safety Code*®, and *NFPA 5000*®, *Building Construction and Safety Code*®, as a building or portion thereof that is used for lodging and boarding of four or more residents, not related by blood or marriage to the owners or operators, for the purpose of providing personal care services. The characteristic of providing personal care services distinguishes a board and care facility from a rooming house or dormitory.

In fire incident databases, a board and care facility is defined by its occupants' needs. It is important to keep the distinction between the code and database definitions in mind, because there is no guarantee that the occupants' needs match the care the facility provides. In particular, the care needs of occupants that qualify a property as a board and care facility for fire-reporting purposes will often be greater than the care delivered by a facility legitimately classified as a board and care facility under NFPA *101* and *NFPA 5000.* Therefore, Table 20.2.1 might not properly describe

Philip R. Jose, P.E., CSP, is a private consulting fire protection engineer. He chairs the Life Safety Code and Building Code Technical Committee on Board and Care Facilities and is a Life Safety Code seminar instructor for NFPA.

*The classification as a board and care home is based on the needs of the occupants, specifically the presence of tenants who were over age 65 or had chronic mental illness. The classification is not based on the level of care the facility offered or the level of care it claimed to offer.

Source: NFPA Fire Incident Data Organization.

the fire experience of facilities that NFPA *101* and *NFPA 5000* would have classified as board and care homes or that claimed to be board and care homes.

The NFPA *101* and *NFPA 5000* definition could easily describe a hospital or a nursing home. The primary difference is in the definition of personal care. The care given in a hospital or a nursing home is certainly personal, but its primary purpose is to meet the medical needs of patients. In the board and care facility, the care provided is not medical in nature, nor does it require the services of doctors and nurses. It is generally a kind of assistance that can be rendered by laypersons who help residents cope with the rigors of daily living. This care might include looking after residents' personal hygiene, cleaning their living quarters, helping those who are physically handicapped to move around, preparing meals, looking after residents' financial matters, seeing that appointments are kept, reminding residents to take their medications, and numerous other tasks.

As this discussion implies, NFPA *101* and *NFPA 5000* seek to identify distinct populations in terms of needed levels of care and then define distinct categories of facilities that are established to provide the level of care required by a group of potential residents. A separate problem must be solved; making sure that residents are not put in facilities that are unable to or will not serve all their needs. This problem, implicit in most of the fires in Table 20.2.1, is one for enforcement authorities and probably the most important key to fire safety for all populations needing care.

Few board and care facilities call themselves by that name. Some facilities that fit into the definition of this occupancy include the following:

- Assisted living facilities
- Group homes for mentally retarded persons
- Group homes for released psychiatric patients
- Rest homes for older adults
- Foster care homes
- Orphanages
- Shelters for battered persons
- Shelters for unwed mothers
- Halfway houses for rehabilitated alcoholics
- Halfway houses for rehabilitated drug abusers
- Halfway houses for prison parolees
- Shelters for runaways
- Rescue missions with overnight accommodations

Whatever their names, a common thread ties these facilities together. They provide residents with more than just food and shelter. The residents usually are furnished some form of assistance, support, or care that is not of a medical nature.

The technical committee responsible for developing the board and care chapters of NFPA *101* and *NFPA 5000* has worked very hard to balance the need for a high level of fire safety with the financial constraints imposed on the owners and operators of the facilities. Many new small board and care facilities are existing residential structures that have been converted to this new occupancy. The owners and operators of these facilities are filling a significant need for this type of housing. The cost of upgrading these homes to meet board and care requirements is a major issue. The committee has allowed for certain code modifications to meet this concern. One such, often controversial, modification is the sprinkler exemption for conversions of existing buildings with a prompt evacuation capability and eight or fewer residents. It is important to note that by definition, a facility with a prompt rating houses a group of people with "the ability to move reliably to a point of safety in a timely manner that is equivalent to the capacity of a household in the general population." The committee feels with that restriction and the many other fire safety features required for this occupancy, a reasonable level of fire safety is provided.

CODE REQUIREMENTS FOR NEW BOARD AND CARE FACILITIES

Starting with the 2003 editions of NFPA *101* and *NFPA 5000,* the requirements for new board and care facilities are not dependent on the evacuation capability of the residents. For new facilities, one set of requirements applies, regardless of the evacuation capability. This new approach provides one level of safety for all

new facilities. Not only does this simplify the application of code requirements for new facilities, it resolves the ongoing compliance problem presented by an aging resident population.

The code has always required that facilities upgrade to meet the requirements for new construction whenever the evacuation capability of the residents changed to a slower classification. This routinely occurs as residents grow older and less able to evacuate at the same rate. Owners can be faced with costly modifications, which might include the installation of automatic sprinklers. Possible alternatives are moving selected residents to other facilities or hiring additional staff. Now that new facilities are governed by one set of requirements, this issue needs to be addressed only in existing facilities.

This same approach is not realistically viable for existing board and care facilities, as nearly all structures would require significant costly modifications to meet the code requirements to provide a level of safety appropriate for all evacuation-capability classifications. The existing approach of providing increased levels of protection, dependent on the evacuation capability of the residents as a group, continues to be valid and reasonable for existing facilities.

CLASSIFYING BOARD AND CARE FACILITIES

Classifying a board and care facility is an extremely important first task when conducting an inspection or evaluating a facility for compliance with NFPA *101* or *NFPA 5000.* If a mistake is made here, most of the inspection or evaluation that follows will be invalid. Answers to three questions determine building requirements for board and care facilities:

- Is the facility new or existing?
- Is the facility large or small?
- If existing, what is the facility's evacuation capability?

New or Existing

If the structure is built new or if it is a conversion from another occupancy type other than health care, the requirements for new board and care facilities in NFPA *101* must be met. If not, the requirements for existing facilities apply.

Large or Small

Simply counting the number of available beds for residents determines the size of the facility. Staff or family members are not counted when making this determination. By definition, a resident is a person who is receiving personal care and resides in the board and care facility. It is only the total number of residents in the facility that determines if it is large or small. Small facilities are those that provide sleeping accommodations for not more than 16 residents. Large facilities are those that provide sleeping accommodations for 17 or more residents.

Evacuation Capability in Existing Facilities

All *occupants* of the building, as a group, are evaluated when determining the evacuation capability. *Everyone* in the structure is included when making this determination, not just the residents. Assistance by staff, if provided, is a key part of the evaluation. A group of residents who might otherwise be classified slow could be considered prompt when well-trained staff assist in the evacuation process. Remember, however, if staff assistance is used to enhance the rating, they must always be present in the facility to provide that assistance when needed.

There are three classifications of evacuation capability: prompt, slow, and impractical. The rating may be arrived at in one of three ways—using the definitions to come up with a subjective determination; using NFPA 101A, *Guide on Alternative Approaches to Life Safety;* or using a program of timed exit drills.

NFPA *101* requires that facility management furnish to the authority having jurisdiction (AHJ), on request, an evacuation capability determination using a procedure acceptable to the AHJ. If such documentation is not furnished, the evacuation capability is classified as impractical.

If timed drills are used to determine evacuation capability, NFPA *101* recommends that evacuation times of 3 minutes or less be used for classifying a facility as prompt, 3 minutes to 13 minutes slow, and greater than 13 minutes impractical. The slowest time should be used for classification. Evacuation time is measured from the time of alarm to the time the last occupant arrives at a *point of safety* as defined in NFPA *101.*

NFPA *101* requires that six fire drills be performed each year in all board and care facilities, with a minimum of two drills conducted at night when residents are sleeping. It is at this point in the evaluation process that judgment becomes critical. Common sense and experience must be used to look at the residents and staff as a group and determine if the recorded times for drills performed during the last year are realistic. To aid in the determination of evacuation capability, the AHJ might ask the facility owner to conduct a fire drill while he or she is present. Occupants' performance during the day can be observed and compared against the recorded times for night drills when residents are sleeping. Clearly, if the group is unable to evacuate the home within the previously recorded time frames during waking hours, night drills indicating equal or faster times may have been falsified.

Construction and egress arrangement requirements become more strict as evacuation capability decreases. For instance, windows may not be used for the secondary means of escape in a small facility with a slow evacuation rating. Classification of a board and care facility is the most important step in the evaluation process. Taking the necessary time to get it right is critical to the safety of the residents.

OCCUPANCY CHARACTERISTICS

Characteristics of Buildings

The contents of a board and care facility typically fall into the ordinary hazard category by the methods of evaluation under NFPA *101.* There are rarely any large concentrations of combustible materials and usually no use of flammable liquids or gases. No processes pose "special hazards." Ignition sources are typical of those found in residential occupancies, and fuel loads

are generally light. The most significant fire threat in this occupancy is the enormous potential for loss of life.

Structural characteristics of buildings that house residential board and care facilities vary significantly. They range from single-family dwellings, in which a family takes in a few boarders, to high-rise, reinforced-concrete apartment buildings for the elderly operated by religious organizations, to commercial rest homes built for the purpose. Construction can be practically any type.

Characteristics of Residents

A description of the characteristics of the "typical" resident of a board and care facility is just as elusive as a description of a "typical" construction type. Residents of board and care facilities do not fit a stereotype—they may be children or elderly, physically impaired or physically sound, mentally handicapped or fully functioning. They may be capable of self-preservation or totally dependent on others to provide for their safety. No one description fits the residents of all board and care facilities. Variations that exist in the buildings and the range of residents' capabilities in these facilities pose the most significant challenge to fire protection professionals.

FIRE PROBLEMS

Problems of board and care facilities generally fall into two categories: structural and behavioral.

Structural Problems

Many board and care facilities are single-family dwellings or single-family dwellings to which space has been added to accommodate a number of boarders. Consequently, it is probable that many facilities are in structures built to standards intended for housing a "typical" family with normal abilities to detect, respond to, and escape from a fire. What follows are some of the specific fire safety characteristics for those kinds of facilities.

Building Construction. Board and care facilities that are converted dwellings reflect construction preferences for dwellings. Hence, many facilities are housed in one-, two-, and three-story wood-frame structures. In older buildings, balloon construction and unprotected wood structural members are common structural hazards. Under the best circumstances, wood-frame construction can offer some measure of protection, but fire endurance is limited and the combustible structure will eventually contribute fuel to a fire.

Egress Facilities. In converted dwellings, there is generally only a single route that occupants can use from any given room to get to safety outdoors. In converted two-story dwellings, this escape route typically includes an unenclosed stairway that might take escaping residents through the area of the house that is on fire. Often, the only alternate escape route is through a window, which in the case of a three-story building, may be more than 20 ft (6 m) above the ground. Typical of single-family dwellings, exit doors often are equipped with locking devices that impede egress, particularly for those unfamiliar with the locks or incapable of operating them.

Compartmentation. Separation of rooms from corridors and rooms from each other is sometimes nonexistent or of construction that provides little or no resistance to the passage of fire and smoke. If so, a fire in any room can quickly fill the entire building with smoke and toxic combustion products, limiting visibility and making the environment intolerable for human survival.

Vertical Openings. As with many multistory dwellings, the stairway, which also serves as the primary means of escape, normally is not enclosed. Stairs are usually open to the corridor on the upper floors and living spaces on the first floor. The spread of fire and smoke from one floor to the next can occur rapidly.

Interior Finishes. Walls and ceilings may be finished with paneling and acoustical ceiling tiles, without any thought to the combustibility of these materials. The facility owner, trying to improve the environment in which the residents live by providing attractive decor, may be placing them in jeopardy without knowing it. Highly combustible wall paneling and ceiling tiles can contribute to rapid horizontal and vertical fire spread and can be a major factor contributing to flashover. They can also contribute to the speed with which egress pathways become untenable.

Electrical Wiring and Appliances. Wiring is generally typical of the converted building's original use, which as noted is often that of a single-family dwelling. In older buildings, circuits may be inadequate in number and capacity, insulation may be old and deteriorating, fuses may be the wrong size for the circuits they protect, and wiring modifications, if any, may have been made by unqualified people. Use of extension cords, space heaters, and other residential-type electrical appliances may be common and contribute to the risk of fire.

Furnishings. The fire hazard posed by furniture and furnishings varies widely. Often, residents are permitted to bring an unlimited quantity of personal furnishings into the facility. Practically all such products can contribute fuel to a fire, with some, of course, being worse than others. Furniture that burns fiercely or gives off inordinately large quantities of smoke or toxic combustion products is a major hazard.

Behavioral Problems

Much concern over life safety in board and care facilities arises from the fact that they house a number of people who, in many cases, have diminished physical and/or mental capacity. Although this is not true of all facilities, or all residents of a given facility, the very fact that impaired people are residents of a facility that assists them in coping with daily life suggests that they may have problems fending for themselves in an emergency.

The impact that behavioral problems create generally falls into two categories: evacuation capability and safety consciousness.

Evacuation Capability. Because populations housed in board and care facilities differ widely, a broad statement describing evacuation capability in all such facilities cannot be made.

In the case of homes for older adults, some residents may be slow and unsteady, and unable to manage stairs, to see well, or to remember procedures to be followed in a fire. Some may be so incapacitated that they cannot be evacuated without a great deal of assistance. Residents of some facilities may be physically handicapped to such an extent that self-evacuation is not possible.

Evacuation capability can be affected by the facility's staff. In a facility housing deaf residents, for example, the presence of one staff member who can awaken and alert the residents to the emergency might be sufficient to normalize the evacuation capability of the group. In facilities housing more debilitated handicapped persons, a large staff might still be incapable of effecting a prompt evacuation.

Safety Consciousness. One risk factor that this occupancy has to a greater degree than other residential occupancies is that more of the residents tend to be unaware of or unconcerned with the dangers of their actions. This heightened risk applies to all the behaviors where errors lead to fires in ordinary homes, including smoking, use of space heaters, cooking, supervision of children who might play with fire, handling of appliances and electrical equipment, and even deliberate fire-setting.

FIRE PROTECTION STRATEGIES

With respect to life safety, the fire problems in board and care facilities can be addressed by ignition control, fuel control, occupant protection, detection and suppression equipment, and planning and training operations. The systems approach to fire safety in correctional facilities can be modified to apply to board and care facilities as well. (See Section 20, Chapter 14, "Detention and Correctional Occupancies.")

Ignition Control

Smoking materials start many fatal fires in board and care facilities. Every facility must have a smoking policy to address such issues as where smoking is permitted and the proper disposal of smoking materials. Clearly, the policy should attempt to prevent ignitions that occupants cause by falling asleep while smoking or improperly disposing of smoking materials. Noncombustible safety-type ashtrays should be provided in areas where smoking is permitted. In those facilities that permit smoking, designated smoking areas that are supervised or in which an occupant is rarely alone can work well.

Other ignition sources, such as space heaters, cooking and other heat-producing appliances, and electrical equipment must be controlled and maintained properly. The use of such equipment should be limited to those who are capable of operating the appliance properly or to those who are being trained under supervision. Sufficient numbers of electrical outlets should be provided to eliminate the use of extension cords.

Fuel Control

In many board and care facilities, residents are permitted to bring their own furnishings into their sleeping rooms. Most of these furnishings have not been subjected to any type of test to indicate their ease of ignition or heat release rates. New drapes, curtains, upholstered furniture, and mattresses must meet specific NFPA test criteria. An exception is made for upholstered furniture and mattresses belonging to residents when placed in their sleeping room, provided a smoke alarm is installed in the room.

In facilities with existing furnishings that do not meet the referenced NFPA flammability criteria, other protection features, such as early detection, suppression, and compartmentation, should be evaluated to ensure that an acceptable level of protection is provided. Other fuel sources, such as interior finish materials, should also be evaluated with respect to their potential to spread fire.

Occupant Protection

Setting minimum criteria for the protection of life from fire in board and care occupancies is not simple. As indicated, this is not a homogeneous occupancy. Minimum protection in one facility may be overprotection or inadequate protection in another. In few, if any, other types of occupancies is it so difficult to ensure over time that there is a proper match between the care residents need and the care provided to them by the facility.

Evacuation capability is the most significant factor in determining the fire protection features needed to achieve an acceptable level of life safety. A facility that houses a group with a normal ability to respond may need little protection beyond that of other residential occupancies. In buildings housing people who respond slowly, a protection system that provides extra time to react and evacuate may be adequate. Groups that cannot be expected to evacuate to safety unaided may need a defend-in-place protection system.

One might suspect that, over a period of time, all facilities may house residents who are incapable of evacuation, so that protection for the worst situation should be provided. This approach is valid in the instance of homes for the aged, where deteriorating physical and mental conditions are predictable. However, many types of board and care facilities, because of their size and the nature of the services they provide, never deal with people incapable of self-preservation.

For a population with a relatively normal evacuation capability, the most basic system of protection consists of the following:

- Controls to prevent ignition
- Prompt detection
- Means to alert the residents
- Possibly a means of automatically suppressing the fire
- At least two routes of escape
- Prohibiting highly combustible interior finish materials (limiting the rate of fire spread and minimizing the risk of flashover)
- Enclosing vertical openings (limiting the vertical spread of fire and smoke)

For a population that is able to evacuate, but does so slowly or with difficulty, a reasonable system of protection would include all the items listed above, plus the following:

- Stricter controls to prevent ignition
- Early detection and alarm
- A greater need for automatically suppressing the fire
- Exits that are easier to use than those that might be adequate for a more capable population
- Stricter controls on the combustibility of interior finishes
- A greater degree of fire endurance to maintain building integrity during a longer evacuation period
- Compartmentation to confine fire and smoke, thus keeping egress pathways usable during the longer evacuation period
- Greater resistance to the vertical spread of fire and smoke

For a population that is not capable of evacuation, a defend-in-place protection concept would include all the features listed previously, plus the following:

- Sufficient structural fire endurance to allow the building and the internal compartmentation to outlast the fire
- A means of automatically suppressing the fire before it seriously threatens the structure and the compartmentation
- Strict control on furnishings

Note that the code requirements for new board and care facilities are predicated on the assumption that a facility's evacuation capability is impractical.

Fire Detection and Suppression

The means by which ignition and fuel controls are implemented, as well as the occupants' evacuation capability, are critical factors in determining the appropriate level of detection and suppression necessary. Residential sprinklers are the most effective means of increasing life safety. In accordance with NFPA *101* and *NFPA 5000,* a sprinkler system in accordance with one of the following standards may be used in board and care facilities, depending on the size of the facility and, for existing facilities, the evacuation capability of the occupants:

- NFPA 13, *Standard for the Installation of Sprinkler Systems*
- NFPA 13D, *Standard for the Installation of Sprinkler Systems in One- and Two-Family Dwellings and Manufactured Homes*
- NFPA 13R, *Standard for the Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height*

With respect to NFPA 13D, it should be recognized that the water supply duration depends on the evacuation capability rating of the facility and that domestic water demand is not necessarily included. Other exceptions permit sprinklers to be omitted from certain areas such as small closets, bathrooms, attics, and other areas in which fire loss data indicates that fatal fires are less likely to originate. NFPA 13 now mandates the use of either quick response or residential sprinklers for these and all other light-hazard occupancies.

Insurance carriers and applicable codes should be consulted before selecting detection and suppression systems. Preventive maintenance requirements for each type of system should also be considered during the selection and design process. Once installed, inspection, and testing and maintenance of these systems in accordance with applicable NFPA standards is mandatory.

Planning and Training Operations

The facility management must develop an emergency plan that addresses various emergencies or disasters, including fires. The plan should be realistic and capable of being implemented with the minimum resources that may be available, typically during the night. The plan should be coordinated with the local fire department to ensure that their expectations and those of the facility are consistent. The emergency plan must be amended or revised whenever a resident with special needs is admitted to the facility. All staff must understand their responsibilities in the plan and should formally review those responsibilities at least every 2 months.

Capable residents must participate in the training and drills. As discussed above, residents need to be familiar and comfortable with various egress paths available to them. Escape routes used by residents should be routinely alternated during drills so they become familiar with all ways out of the building. Residents should demonstrate the ability to use all egress routes. If windows are used as a secondary means of escape, residents must demonstrate the ability to open them unless staff or other residents are specifically assigned to assist. If assistance is needed, those so assigned must always be present when those needing assistance are present in the building. Local fire departments, fire training schools, and fire marshals' offices may have personnel and audiovisual materials that can assist in staff and resident training. It is important that the training be specific to the facility. This is one area in which board and care facilities have an advantage over other residential occupancies. There can be significantly better control over occupants in these facilities. When properly trained, board and care residents can perform above average during fire drills.

SUMMARY

The number of residential board and care facilities is steadily increasing. The move during the last half century toward reducing populations in psychiatric hospitals, nursing homes, and other types of institutional environments has created a greater need for board and care facilities. Hazards typical of board and care occupancies include structural problems, such as building construction and egress facilities, as well as behavioral problems. Fire protection strategies used in these facilities include ignition control, fuel control, occupant protection, detection and suppression activities, and planning and training operations.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on board and care facilities discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 13, *Standard for the Installation of Sprinkler Systems*
NFPA 13D, *Standard for the Installation of Sprinkler Systems in One- and Two-Family Dwellings and Manufactured Homes*
NFPA 13R, *Standard for the Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height*
NFPA *101®*, *Life Safety Code®*
NFPA 101A, *Guide on Alternative Approaches to Life Safety*
NFPA 5000®, *Building Construction and Safety Code®*

Chapter 3

Hotels and University Housing

Revised by
April Berkol ❑ Byron Briese ❑ Ed Comeau

Chapter Contents

Fire Safety in Hotels
Active Fire Protection Systems and Equipment in Hotels
Fire Safety in University Housing
Fire Prevention Issues in University Housing
Fire Detection Issues in University Housing
Fire Containment and Suppression Issues in University Housing
Institutions and Organizations Involved in University Housing Fire Safety

Key Terms

active fire protection systems, automatic sprinkler system, dormitory, false alarm, fire containment, fire-safe cigarette, Greek housing, hotel, Hotel and Motel Safety Act, lodging occupancy, nuisance alarm, occupancy characteristics, occupant characteristics, residence hall, smoke control system, university housing, unwanted alarm

In NFPA *101*®, *Life Safety Code*®, and *NFPA 5000*®, *Building Construction and Safety Code*®, requirements for hotels and dormitories are located in the same chapters. NFPA *101* and *NFPA 5000* definitions for hotel and dormitory are as follows:

Hotel—A building or groups of buildings under the same management in which there are sleeping accommodations for more than 16 persons and primarily used by transients for lodging with or without meals

The definition of *hotel* is further refined in NFPA *101* and *NFPA 5000* to include hotel, inn, club, motel, bed-and-breakfast, or any other structure meeting the foregoing definition of hotel.

Dormitory—A building or a space in a building in which group sleeping accommodations are provided for more than 16 persons who are not members of the same family in one room or a series of closely associated rooms under joint occupancy and single management, with or without meals, but without individual cooking facilities.

It is important to note that the definition for dormitory that is used by the National Fire Incident Reporting System (NFIRS) includes occupancies other than just the typical dormitory found on campuses across the country. It includes military barracks, monasteries, and nursing quarters. For this reason, the statistics generated since 2000 for "dormitories" are no longer only applicable to university housing.

As used in this chapter, *university housing* includes dormitories or residence halls and Greek housing (whether on or off campus) in addition to apartments and houses.

See also Section 20, Chapter 1, "Assessing Life Safety in Buildings"; and Section 20, Chapter 4, "Apartment Buildings."

FIRE SAFETY IN HOTELS

Hotel Fire Record

The May 1981 issue of *Fire Journal,* NFPA's membership publication now titled *NFPA Journal,* provided a bleak summary of multiple-fatality hotel fires in the United States reported to NFPA since 1934. The article also contained an analysis of the fire scenarios involved in 170 fatal hotel fires experienced in the previous decade.

April Berkol is director of environmental health, fire, and life safety at Starwood Hotels and Resorts Worldwide, Inc., headquartered in White Plains, New York, and is a member of the NFPA Board of Directors.

Byron Briese is a vice-president with Rolf Jensen and Associates in Fairfax, Virginia. He earned a bachelor of science degree in fire protection engineering at the University of Maryland and is a member of NFPA's Residential Occupancy Committee.

Ed Comeau is publisher of *Campus Firewatch,* a monthly electronic newsletter focusing on campus fire safety issues. He is the founder and former director of the Center for Campus Fire Safety and the former chief fire investigator for NFPA.

The *Fire Journal* article followed these four landmark hotel fire incidents in North America that occurred between November 1980 and February 1981:

- MGM Grand Hotel (Las Vegas, Nevada, November 1980)
- Stouffers Inn (Harrison, New York, December 1980)
- Inn on the Park (North York, Ontario, Canada, January 1981)
- Hilton Hotel (Las Vegas, Nevada, February 1981)

These four hotel fires resulted in 125 civilian deaths as well as injuries to hundreds of civilians and scores of fire fighters.

As shown in Table 20.3.1, fire deaths of this magnitude, within such a short period of time, had not occurred in North American hotels in almost four decades. Previously, between June 1946 and December 1946, nearly 200 fatalities were recorded in three notorious fatal hotel fires, including the LaSalle Hotel in Chicago and the Winecoff Hotel in Atlanta.

The large scale of the fire incidents in the early 1980s shook public confidence in the lodging industry and prompted industry experts and regulatory authorities to reconsider the life safety strategies used for hotel occupancies.

The review of fire scenarios clearly showed the need to emphasize protection of the sleeping-room areas of hotels. Smoking materials and intentionally set fires were the leading ignition factors in the data set of fires reviewed.

Unlike the period following the 1946 incidents, fire suppression and detection technology had evolved by the early 1980s to provide tools to effectively protect building occupants in the incipient stages of a fire. These technologies, complemented by cooperative fire safety research into industry-specific solutions, coupled with public expectations regarding fire safety, resulted in significant changes to building and fire safety codes in the United States, as applied to hotels.

Evolution of Life Safety Strategies for Hotels

Prior to the landmark fires of the early 1980s, little emphasis was placed on the use of automatic sprinklers in hotels. Reliable, commercially viable, early-warning fire detection technology did not exist until the latter part of the twentieth century. Further, although fire research had been ongoing for decades, application to residential settings was limited.

TABLE 20.3.1 Summary of Fire Incidents, Hotel Fires in the United States, as Reported to NFPA, with Ten or More Fatalities, 1934–2005

City	*Hotel*	*Date*	*Deaths*
Lansing, MI	Kerns Hotel	December 1934	32
Atlanta, GA	Terminal Hotel	May 1938	35
Minneapolis, MN	Marlborough Hotel	January 1940	19
Houston, TX	Gulf Motel	September 1943	54
Chicago, IL	LaSalle Hotel	June 1946	61
Dubuque, IA	Canfield Hotel	June 1946	19
Atlanta, GA	Winecoff Hotel	December 1946	119
Chicago, IL	Barton Hotel	February 1955	29
Atlantic City, NJ	Surfside Hotel	November 1963	25
Jacksonville, FL	Hotel Roosevelt	December 1963	22
St. Paul, MN	Hotel Carlton	January 1966	11
Boston, MA	Paramount Hotel	January 1966	11
Anchorage, AK	Lane Hotel	September 1966	14
Seattle, WA	Ozark Hotel	March 1970	20
Los Angeles, CA	Ponet Square Hotel	September 1970	19
Tucson, AZ	Pioneer International	December 1970	28
Tyrone, PA	Pennsylvania House Hotel	January 1972	12
Berkely Springs, WV	Washington House	August 1974	12
Portland, OR	Pomona Hotel	July 1975	11
Fremont, NE	Pathfinder Hotel	January 1976	20
Breckenridge, MN	Stratford Hotel	January 1977	17
Bay City, MI	Wenonah Park Hotel	December 1977	10
Kansas City, MO	Coates House Hotel	January 1978	20
Honesdale, PA	Allen Motor Inn	November 1978	12
Greece, NY	Holiday Inn	November 1978	10
Cambridge, OH	Holiday Inn	July 1979	10
Las Vegas, NV	MGM Grand Hotel	November 1980	85
Harrison, NY	Stouffers Inn	December 1980	26
Houston, TX	Hilton Hotel	March 1982	12
San Juan, PR	Dupont Plaza	December 1986	97

Source: NFPA's archive files, *The1984 Fire Almanac,* and NFPA's Fire Incident Data Organization database.

The January 1930 issue of *NFPA Quarterly* provided a summary of numerous hotel fires experienced within the United States during the prior 30-year period. Based on this experience, several hotel fire safety requisites were summarized by the *Quarterly,* including the need for fire-resistive construction, the provision of proper exits, the protection of vertical openings, the use of fire walls, and the provision of fire alarm facilities.

The article summarized nearly 100 hotel fire incidents that occurred between 1910 and 1928 where automatic sprinklers were present. Despite a significant success rate for control and suppression of fires (72 of 76 incidents where sprinklers activated were extinguished with not more than four sprinklers), sprinkler installation was listed below construction features in the summary of hotel fire safety requisites.

Automatic sprinklers were recommended for the entire building "where possible," but otherwise, complete coverage was only considered mandatory for buildings of combustible construction or in limited hazardous areas such as kitchens and basements.

By the mid-1980s the effectiveness of automatic sprinkler protection was recognized. In testimony provided to a science subcommittee of the U.S. House of Representatives in 1988, Rolf Jensen, in his capacity as president of the Society of Fire Protection Engineers, observed that the twentieth-century history of fatal fire incidents in hotels involved "fast fires," killing "large numbers of people in a single incident." Mr. Jensen's testimony detailed the progress that had been made to develop sprinkler technology that could be effectively applied to hotels as well as other residential structures.

Code and Legislative Developments Related to Sprinkler Systems in Hotels

The 1976 edition of NFPA *101* reflected the decades-old protective philosophy discussed previously and contained no specific requirement for automatic sprinklers in hotels. Requirements for smoke detection systems were limited to corridors in new facilities.

NFPA *101* was amended in 1988 to require the installation of automatic sprinklers in new and existing high-rise hotels. By 1990, each of the United States model building codes also required this level of protection, with the Uniform Building Code requiring new hotels with 20 or more sleeping rooms, regardless of height, to be protected with automatic sprinklers.

Three decades following the publication of the 1976 edition of NFPA *101*, the 2006 edition emphasizes the use of active fire protection systems, notably automatic sprinklers, in hotels. With limited exceptions for smaller properties or those hotels with guest-room entrances leading directly to the exterior, NFPA *101* and *NFPA 5000* require full sprinkler protection for new hotels.

Several states, including large tourism states such as Nevada and Florida, legislated retroactive fire protection requirements for certain existing lodging establishments, generally high-rise hotels. In the 1980s, the states of Alaska, California, and New Jersey exempted fire protection system installations from taxation by virtue of either a tax credit (Alaska) or a property tax exemption (California and New Jersey), thus easing the financial cost of such improvements in existing buildings including hotels.

In 1989, NFPA issued a new sprinkler standard, NFPA 13R, *Standard for the Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height,* aimed at making sprinkler protection more affordable for low-rise, residential-use buildings. NFPA 13R, combined with the development and listing of chlorinated polyvinyl chloride (CPVC) and polybutylene (PB) sprinkler pipe, reduced the cost of sprinkler installation, especially in existing hotels.

In 1990, Congress enacted the Hotel and Motel Fire Safety Act of 1990 (Public Law 101-391). This statute brought the power of the federal government's purse to bear on the lodging fire safety issue by limiting meetings in lodging establishments by federal agencies to hotels and motels that met the fire safety requirements outlined in the act. Individual federal employees on official travel were also limited, after a phase-in period, to staying only in lodging facilities that also met these requirements.

Industry Response to Hotel Fires

In addition to code and legislative changes, the hotel industry responded to the fire challenge experienced in the early 1980s. In 1987, in cooperation with leading hotel firms, NFPA formed the Lodging Industry Membership Section to provide a forum and focus within the association for the industry's voice and needs.

The automatic sprinkler industry developed equipment specifically devised for life safety protection. As new "quick-response" sprinkler technology and fire detection capability were developed, many hotel owners and operators voluntarily retrofitted new protective systems into existing buildings as well as new construction projects.

By 1988, and noted in the first large-scale study of fire safety in the lodging industry conducted by the American Hotel and Motel Association, now the American Hotel and Lodging Association, almost universal usage of smoke alarms within hotel guest rooms was reported. The study also noted that about half of all hotel rooms were equipped with automatic sprinklers, with the number rising to about two-thirds when only high-rise hotels were considered.[1]

As evidenced by Table 20.3.2 covering the years 1980 to 2002, there was a downward trend in reported lodging industry fire incidents, losses, and most importantly, casualty figures.

The effectiveness of automatic sprinklers in hotels can be seen in Table 20.3.3. For the years 1994 to 1998, estimates show a 100 percent reduction in fatalities per 1000 fires with automatic fire suppression systems present.

Improvements to fire loss statistics have occurred despite an unparalleled building boom in the 1990s when thousands of new hotels were constructed. (See *Lodging Profile.*[1])

Recent Lodging Industry Fire Experience

For the years 1999 to 2002, data developed by NFPA suggest that three factors—cooking equipment, smoking materials, and arson—are today's leading causes of fatal fires in hotels and motels. See Tables 20.3.4 and 20.3.5.

TABLE 20.3.2 Structure Fires in Hotels and Motels, by Year: 1980–2002

Year	Fires	Civilian Deaths	Civilian Injuries	Direct Property Damage (in Millions of Dollars) As Reported	Direct Property Damage (in Millions of Dollars) In 2002 Dollars
1980	12,530	80	752	63.7	139.2
1981	12,880	148	719	69.5	137.3
1982	10,240	52	587	42.2	78.6
1983	9,550	73	562	103.2	186.2
1984	9,670	34	538	65.6	113.4
1985	9,310	85	412	74.0	123.5
1986	8,790	57	416	74.4	122.2
1987	8,210	54	430	70.6	111.7
1988	8,230	35	382	85.1	129.5
1989	7,710	24	333	68.2	99.0
1990	7,090	54	496	70.3	96.9
1991	6,610	22	372	84.8	111.9
1992	6,530	26	395	63.5	81.4
1993	6,140	62	456	63.9	79.5
1994	5,890	28	349	59.3	72.0
1995	5,460	36	299	71.5	84.4
1996	5,610	43	332	110.6	126.9
1997	5,010	21	284	81.6	91.4
1998	4,750	24	257	55.3	61.1
1999	4,610	24	249	124.6	134.4
2000	4,830	11	170	82.8	86.6
2001	4,590	12	217	59.3	60.2
2002	4,180	16	138	77.1	77.1

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest ten; civilian deaths and injuries are rounded to the nearest one; and direct property damage is rounded to the nearest hundred thousand dollars.

Source: NFIRS and NFPA survey. Inflation adjustments were based on U.S. Census Bureau's *Statistical Abstract of the United States: 2006,* "Table 705, Purchasing Power of the Dollar."

TABLE 20.3.3 Automatic Suppression Systems in Hotel and Motel Fires Reported to Public Fire Departments: 1994–1998 Annual Averages

Percentage of fires in buildings with automatic suppression system	34%
Deaths per 1000 fires with automatic suppression system	0.0
Deaths per 1000 fires with no automatic suppression system present	7.7
Reduction in deaths per 1000 fires when automatic suppression systems were present	100%
Average loss per fire when automatic suppression system was present	$7,160
Average loss per fire with no automatic suppression system	$15,320
Reduction in loss per fire when automatic suppression systems were present	53%

Source: National estimates based on NFIRS and NFPA survey. 1998 is the most current data available.

Cooking Equipment. Changes to cooking equipment and oils have led to the development of more effective means to control cooking fires, notably advances in wet chemical fixed extinguishing systems. As with any commercial kitchen, hotel kitchens require the installation of fire suppression equipment effective for the hazard present.

Smoking Materials. For smoking, research[2] authorized by Congress pursuant to the 1990 Fire Safe Cigarette Act and undertaken by the National Institute of Standards and Technology (NIST) concluded that the commercial production of a relatively fire-safe cigarette was feasible. Although regulation at the federal level has not passed legislation, several states have introduced requirements limiting the sale of cigarettes to only those cigarettes that were deemed fire safe effective in January 2003.

Faced with the possibility of having to produce different cigarettes for different states, the nation's largest producer of cigarettes, the Altria Corporation (formerly Philip Morris) took the position that all such cigarettes should be fire safe.[3] With that

TABLE 20.3.4 Leading Causes of Structure Fires in Hotels and Motels: 1999–2002 Annual Averages

Cause	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*	
Cooking equipment fire	1060	(23%)	0	(0%)	37	(19%)	14.0	(16%)
Identified cooking equipment	770	(17%)	0	(0%)	35	(18%)	10.2	(12%)
Confined cooking fire	290	(6%)	0	(0%)	2	(1%)	3.7	(4%)
Smoking materials	710	(16%)	9	(56%)	45	(23%)	7.0	(8%)
Intentional	530	(12%)	6	(37%)	35	(18%)	24.7	(29%)
Heating equipment	440	(10%)	3	(17%)	14	(7%)	4.1	(5%)
Identified heating equipment	380	(8%)	3	(17%)	13	(7%)	4.0	(5%)
Confined chimney or flue fire	30	(1%)	0	(0%)	0	(0%)	0.0	(0%)
Confined fuel burner or boiler malfunction or fire	30	(1%)	0	(0%)	1	(0%)	0.1	(0%)
Clothes dryer or washer	430	(9%)	0	(0%)	21	(11%)	1.9	(2%)
Electrical distribution or lighting equipment	360	(8%)	1	(7%)	15	(8%)	9.3	(11%)
Candle	120	(3%)	0	(0%)	10	(5%)	1.8	(2%)
Torch, burner, or soldering iron	80	(2%)	0	(0%)	6	(3%)	3.0	(3%)
Exposure to other fire	80	(2%)	0	(0%)	0	(0%)	4.7	(6%)
Contained trash fire	100	(2%)	0	(0%)	0	(0%)	0.0	(0%)

Note: These are the leading causes, obtained from the following list: intentional (from the NFIRS field "cause"); playing with fire (from factor contributing to ignition); confined heating (including confined chimney and confined fuel burner or boiler fires), confined cooking, and contained trash or rubbish (from incident type); identified heating, identified cooking, clothes dryer or washer, torch (including burner and soldering iron), electrical distribution and lighting equipment, medical equipment, and electronic, office, or entertainment equipment (from equipment involved in ignition); smoking materials, candles, lightning, and spontaneous combustion or chemical reaction (from heat source); and mobile property involved (from mobile property involved in ignition). Exposure fires include fires with an exposure number greater than zero, as well as fires identified by heat source or factor contributing to ignition when no equipment was involved in ignition that were not intentionally set. The same fire can be listed under multiple causes, based on multiple data elements.

These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest ten; civilian deaths and injuries are rounded to the nearest one; and direct property damage is rounded to the nearest hundred thousand dollars. Property damage has not been adjusted for inflation.

change in position and with additional research by NIST,[4] new legislation[5] was introduced in April 2002 by Senators Richard Durbin (D-Ill.) and Sam Brownback (R-Kan.) and Rep. Edward Markey (D-Mass.) to effect such change. For current information about the changing status of legislation to require fire-safe cigarettes, see http://firesafecigarettes.org.

Arson. As for arson, its traditional rationales include arson for profit, revenge, and emotional disturbance. The 1990s saw a new dimension: arson as a weapon in domestic terrorism. Although yet to strike the hotel industry, arson as a means to express a political philosophy adds a new rationale for ensuring the reliability of fire protection equipment and systems and for a stronger hotel emergency team to ensure the security of lodging occupants and establishments. Arson is a difficult crime to prevent. Typically, the industry steps up its security measures in times of difficult labor relations, political unrest, when controversial individuals or groups meet or stay at a particular hotel, and so forth. Properties will add cameras to their perimeter surveillance systems and increase security patrols during such times.

ACTIVE FIRE PROTECTION SYSTEMS AND EQUIPMENT IN HOTELS

Industry experience, for nearly a century, underscores the need for the installation of adequately designed and maintained active fire protection systems and equipment in hotels. These systems can include fire alarm systems, automatic sprinkler systems, and smoke control systems, as well as smoke alarms and kitchen fire suppression systems. This chapter will briefly discuss fire alarm systems, automatic sprinkler systems, and smoke control systems for use in hotels. For information on smoke alarms, see Section 14. Also see Section 17, Chapter 2, "Chemical Extinguishing Agents and Application Systems."

Selection of the proper system or systems will depend in large measure on the size and configuration of the property.

Fire Alarm Systems

A fundamental design parameter for fire alarm systems in lodging occupancies is that most building occupants are transient

TABLE 20.3.5 Structure Fires in Hotels and Motels by Equipment Involved in Ignition: 1999–2002 Annual Averages

Equipment Involved	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*	
No equipment involved	1780	(39%)	12	(76%)	88	(45%)	49	(58%)
Clothes dryer or washer	430	(9%)	0	(0%)	21	(11%)	2	(2%)
Range or cooking surface	430	(9%)	0	(0%)	16	(8%)	2	(2%)
Confined cooking fire	290	(6%)	0	(0%)	2	(1%)	4	(4%)
Lamp, bulb, or lighting	120	(3%)	0	(0%)	1	(0%)	2	(2%)
Wiring, switch, or outlet	120	(3%)	1	(7%)	3	(2%)	5	(6%)
Fixed area heater	120	(3%)	0	(0%)	4	(2%)	1	(1%)
Unclassified kitchen or cooking equipment	100	(2%)	0	(0%)	5	(3%)	4	(5%)
Contained trash or rubbish fire	100	(2%)	0	(0%)	0	(0%)	0	(0%)
Portable cooking or warming equipment	90	(2%)	0	(0%)	6	(3%)	0	(0%)
Torch, burner, or soldering iron	80	(2%)	0	(0%)	6	(3%)	3	(3%)
Oven or rotisserie	80	(2%)	0	(0%)	5	(2%)	0	(1%)
Unclassified heating, ventilating and air conditioning, other	80	(2%)	0	(0%)	5	(2%)	0	(1%)
Air conditioner	80	(2%)	0	(0%)	3	(1%)	0	(1%)
Unclassified equipment involved in ignition	60	(1%)	0	(0%)	3	(2%)	0	(1%)
Central heat or boiler	60	(1%)	0	(0%)	0	(0%)	0	(1%)
Water heater	60	(1%)	3	(17%)	4	(2%)	1	(1%)
Cord or plug	50	(1%)	0	(0%)	9	(5%)	1	(1%)
Fireplace or chimney	50	(1%)	0	(0%)	0	(0%)	0	(0%)
Confined chimney fire	30	(1%)	0	(0%)	0	(0%)	0	(0%)
Confined fuel burner or boiler fire or malfunction	30	(1%)	0	(0%)	1	(0%)	0	(0%)
Elevator or lift	30	(1%)	0	(0%)	0	(0%)	0	(0%)
Unclassified portable appliance designed to produce heat	20	(1%)	0	(0%)	1	(0%)	0	(0%)
Steam table or warming drawer or table	20	(1%)	0	(0%)	0	(0%)	0	(0%)
Other known equipment	230	(5%)	0	(0%)	14	(7%)	9	(10%)
Other confined fire	10	(0%)	0	(0%)	0	(0%)	0	(0%)
Total	4550	(100%)	16	(100%)	194	(100%)	86	(100%)

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest ten; civilian deaths and injuries are rounded to the nearest one; and direct property damage is rounded to the nearest million dollars. Property damage has not been adjusted for inflation.

Nonconfined fires in which the equipment involved in ignition was unknown or not reported have been allocated proportionally among fires with known equipment involved. Sums may not equal totals due to rounding errors.

users of the buildings. Little detailed knowledge of the building should be assumed, as numerous guests use a given hotel for as little as a single night. In numerous labor markets within the United States, employee turnover rates can be significant, thereby also limiting the number of individuals within a hotel with detailed knowledge of the building.

High-rise hotels and large campus-type properties will require the use of addressable technology and voice technology to efficiently pinpoint fire incidents and effectively notify guests and employees of an emergency.

The installation of fire alarm systems in hotels will typically be subject to the requirements of *NFPA 72®*, *National Fire Alarm Code®*, which is widely referenced by model building codes. Notification devices, both audible and visual, must account for the fact that occupants may need to be alerted to a fire emergency from a deep-sleep condition.

Automatic Sprinkler Protection

With few exceptions, the installation of sprinkler protection throughout all portions of newly constructed hotels, regardless of their height, has become a general requirement in most building codes. Of particular importance for the protection of smaller hotels and dormitories is NFPA 13R, which may provide for more economical design and installation of automatic sprinkler systems in low-rise residential occupancies.

Once installed, automatic sprinkler protection should be inspected, tested, and maintained in strict accordance with NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems.* As automatic sprinkler systems age, it is imperative that piping, valves, and related hardware be maintained in working order, that fire pumps and water supplies remain within design tolerance, and that as modifications are made to the underlying building, sprinkler protection changes reflect these changes.

Smoke Control Systems

For high-rise and atrium hotels, smoke control concepts, including stairway pressurization and smoke exhaust, play an important role in mitigating initial smoke production from fires until sprinklers activate and make any staged evacuation tenable. NFPA *101* and *NFPA 5000* permit atria in hotels and dormitories, provided that they meet certain conditions. Included in these conditions are the requirements for properly designed automatic sprinkler protection and either an engineering analysis to show that the building is designed to keep the smoke layer interface above the highest unprotected opening to adjoining spaces, or 6 ft (183 cm) above the highest floor level of exit access open to the atrium, or that it has an engineered smoke control system that will do the same. The design parameters for smoke control systems and the engineering methods used for the analysis can be found in NFPA 92A, *Standard for Smoke-Control Systems Utilizing Barriers and Pressure Differences,* and NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria, and Large Spaces.*

FIRE SAFETY IN UNIVERSITY HOUSING

Overview of University Housing

As used in this chapter, *university housing* includes dormitories (more accurately known as *residence halls*), university-owned apartments and houses (whether located on or off campus), and on- and off-campus Greek housing (whether owned by the university, fraternity, or sorority). For the purposes of this chapter, colleges and universities are generically referred to as "universities."

On-campus university housing consists of dormitories/residence halls, university-owned apartments, and houses. Some Greek houses are university owned, whereas others are owned by the fraternity or sorority. In some cases, the building may be privately owned and is rented by the local chapter. The capacity of residence halls at these institutions is approximately 15 percent of the 17 million students enrolled.[6]

According to the U.S. Department of Education, there were more than 4000 degree-granting colleges and universities in the United States[6] and it was projected that more than 17 million students enrolled in 2- and 4-year institutions in the fall of 2006.[7] For many of these students, this was their first time living away from home, meeting new friends, and having new experiences.

Fire Deaths in the University Environment

Unfortunately, over the years we have seen that tragedy can strike these students. According to information compiled by Campus Firewatch from January 2000 to April 2007, at least 109 people died in student housing fires. Over 80 percent of the fire deaths occurred in off-campus houses and apartments and the remainder occurred either in residence halls or fraternity houses (i.e., in Greek housing). Clearly, the predominant fire-death risk is in the off-campus environment (Table 20.3.6).

Occupancy and Occupant Characteristics

University years are a period when young adults have a sense of invulnerability. A number of factors come together in campus environments that create a potentially high-risk environment.

Close Quarters. There is a greater density of people living in close proximity to one another, both on and off campus. This creates a situation in which the actions of one person can potentially endanger a greater number of people than would otherwise be expected.

Risky Behavior. Young adults tend to engage in risky behaviors, such as drinking, that contribute to the incidence of fire. Alcohol consumption has long been connected with college campuses. Although the recent trend is toward educating students in more responsible behavior, the problem still exists. The connection between alcohol consumption, student behavior, and the incidence of fires in student housing, both on and off campus, is a serious concern.

Currently, there is no known research that definitively connects impaired judgment from alcohol consumption to fire risk in the student demographic. However, in speaking with fire chiefs across the country in college communities, there is no question that there is a definite correlation between the two. In a number of the incidents identified by Campus Firewatch, alcohol has played a factor. This is further reinforced in a study conducted by *USA TODAY* for an article on campus-related fires.[8]

Level of Scrutiny. Although on-campus housing facilities tend to be more regulated and monitored, off-campus housing facilities are subject to a lower level of scrutiny and a potentially lower level of fire safety.

Dormitories/Residence Halls

Note that in NFIRS, the classification "dormitories" includes school, college, and university dormitories; nurses' quarters;

TABLE 20.3.6 Summary of Fire Deaths in the University Environment

City	*University*	*Date*	*Type of Housing*	*Deaths*
East Orange, NJ	Seton Hall University	1/19/00	Residence hall	3 students
Bloomsburg, PA	Bloomsburg University	3/19/00	Fraternity	3 students
Cambridge, MA	Massachusetts Institute of Technology	4/10/00	Residence hall	1 student

Boston, MA	Boston University	3/16/07	Off-campus	1 student[c]
Cincinnati, OH	Cincinnati State	4/21/07	Off-campus	1 student[d]

[a]The city where the death occurred could not be determined. The student was living in a trailer.
[b]The woman was scheduled to deliver her child three hours after the fire occurred. Since the fetus was full-term, the Lincoln Fire Department classified this as two fire deaths.
[c]The victim was from Bloomsburg University and was visiting two BU students when the fire occurred.
[d]The victim had been enrolled at Cincinnati State until the semester before the fire. He was reportedly taking this semester off and he stayed in Cincinnati, living in off-campus student housing.

convent, monastery, and other religious dormitories; and bunkhouses and workers' barracks. For this reason, statistics are not available specific to the occurrence of fires in university residence halls.

The types of dormitories/residence halls that are found on campuses can range from wood-frame renovated houses to noncombustible high-rise buildings. More schools are building third-party residence halls as a solution to providing housing. Third-party residence halls are buildings that are built and owned by a private developer but function as residence halls. One vendor, who has buildings on 39 campuses, estimates that there are approximately 30 companies building privately run residence halls.

Fires in residence halls pose a special risk because of the higher concentration of people who live in these buildings—one fire can quickly endanger a large number of occupants.

Residence halls tend to be occupied by younger students, such as freshmen and sophomores. Because housing is limited on a number of campuses, and as they get older, students tend to move off campus into Greek housing or rented houses and apartments.

Since residence halls are under the control of the university, it is possible to impose conditions that can dramatically improve the level of fire safety in these buildings as opposed to off-campus residential occupancies. These can include the following:

- Regulating the combustibility of contents such as furniture, wall, and floor finishings
- Regulating appliances such as microwaves, refrigerators, and so on
- Regulating the use of open flames, including candles, incense, and smoking

Many residence halls have staff assigned to them to help the students, often referred to as resident assistants, or RAs. This staff is generally made up of older students who live in the building and have received training in a variety of different areas. RAs can serve a vital role in fire safety since they are living in the

building and can identify any potential hazards and assist in ensuring that students understand the importance of fire safety and the dangers of tampering with fire protection equipment.

The residence hall physical plant can be maintained to a consistent level of fire safety by the university as opposed to off-campus housing in the community. Dangerous conditions can be corrected properly.

Students who live in residence halls are subject to stricter behavior guidelines than off-campus students. When students move into a residence hall, they are often provided with information regarding expected behavior, what comprises a violation, and the penalties that can follow. Because of the presence of university staff in these buildings, it is more likely that violators can be identified and either counseled or penalized as necessary. If a student's actions are serious enough, the student can be removed from the residence hall altogether.

Apartments and Houses

Because of the lack of existing on-campus dormitory space, some institutions are either building or purchasing off-campus apartment complexes to provide student housing. In other cases, the school may be buying private houses to serve the same function. Although these structures may be "off campus," since the institution owns them, they should be provided the same fire protection as dormitories/residence halls.

Greek Housing

In the Greek system, the fire-death problem clearly lies within the fraternity community rather than the sororities. From 1990 to May 2006, there has been only 1 fire fatality in a sorority versus 27 within fraternities, according to information compiled by NFPA and Campus Firewatch.

Because of the recognized problem with fires in Greek occupancies, a number of communities, as well as the state of New Jersey, have passed ordinances and laws requiring that they be equipped with automatic fire sprinklers. Some fraternal organizations are taking it upon themselves to install sprinklers in their properties nationwide, recognizing the importance and value of these systems.

"Circle of Life" Approach to University Fire Safety

A comprehensive approach to fire safety for students living in residence halls and Greek housing is needed. As part of this approach, it is important to remember that the education and training that are provided will also give students the fire safety tools they need to protect them when they move off campus, where almost 80 percent of the fire fatalities do occur.

The solutions to fire safety problems in universities often are not unique. What is unique is the environment in which they must be employed. An approach developed by Campus Firewatch involves the four following components that are collectively known as the "Circle of Life" and includes:

- Prevention
- Detection
- Containment
- Suppression

FIRE PREVENTION ISSUES IN UNIVERSITY HOUSING

For general information on fire prevention, see Section 1, Chapter 5, "Fire Prevention and Code Enforcement."

There is a unique challenge in the campus environment to educate and train the students. People of this age have a sense of invulnerability that can be difficult to overcome and convince them of the risk they face from fire. For this reason and other reasons, it is important to ensure that the environment around them is as fire safe as possible, so if they should involve themselves in risk-taking behavior, or if a fire should occur, the effects of it can be minimized. For example, there should be sufficient exits that are properly marked and illuminated. If there are fire safety design features, such as fire doors that are routinely propped open for convenience, then the university or landlord should evaluate strategies to stop this practice from occurring.

The basic fire prevention strategies in university housing are to do the following:

- Reduce fuel load
- Reduce ignition sources
- Enforce good housekeeping
- Educate students about the fire protection features of their housing

Reducing Fuel Load

The fuel load in a fire comprises the structure, its interior finish materials, and the contents that are placed inside of the structure.

Structure. Many residence halls that are built today are made up of noncombustible materials. This construction helps to reduce the fire load significantly and also helps to compartmentalize the building, limiting fire spread. However, there are many older buildings, either built as residence halls or converted into residence halls, which are constructed of combustible materials. Reduced ignition sources, good housekeeping practices, and student fire safety education are particularly important in these combustible structures.

Interior Finish. For a general discussion of interior finish, see Section 18, Chapter 2, "Interior Finish."

Interior finish can, and has, played a significant role in the spread of fires in university housing. At the Chapel Hill fraternity fire, the wood paneling on the walls was identified as a significant contributing factor to the spread of the fire from the basement to the second floor. Universities and landlords should be cognizant of the materials used inside of the buildings and how they may contribute to the fire spread.

Contents. Furniture represents much of the fuel load in student housing. In an environment where it is possible to control the type of furniture, such as residence halls, appropriate flamma-

bility and combustibility criteria should be followed. Personal contents such as clothes and books that students bring cannot be regulated and should be considered a part of the normal fuel load in any student housing occupancy.

Students may personalize or decorate areas using combustible materials. This situation can especially be a problem during holidays. For example, at the Providence College fire in 1977 where 10 students were killed, the combustible decorations on the corridor walls were identified as a significant factor in the fire spread. A Halloween decorating contest at Seton Hall, months after the fatal fire at that university, was stopped by the fire department because of the accumulation of combustible materials, including hay, in the corridor.

Reducing Ignition Sources

In the university housing environment, control of smoking hazards, electrical hazards, and cooking hazards can be particularly helpful in reducing ignition sources.

Smoking. Many universities have implemented no-smoking policies in their residence halls, often in response to public health concerns. The fire safety professional should be concerned with students attempting to circumvent no-smoking regulations, especially during colder weather when people are more reluctant to go outside to smoke. In order to smoke in their rooms, students sometimes disable smoke detectors or find alternative locations to smoke within the building. This can lead to a fire breaking out in areas that may not normally be inhabited, such as stairwells or utility closets.

Electrical. Electrical equipment represents a significant concern in the university housing environment. Many residence halls and Greek houses were built prior to the advent of computers, microwaves, stereos, televisions, and other electrical equipment that students commonly possess. Two problems arise because of increased electrical needs.

First, a room, house, or facility may not have sufficient electrical capacity to provide the required power, which may cause the electrical system to overload. If circuit breakers continually trip, the occupants may try to circumvent such safety features to ensure that power is not interrupted. For example, occupants may run extension cords from other areas into their living space to power the equipment, leading to problems such as worn or frayed cords or overloaded circuits in another area.

Second, if there are not enough outlets, occupants are likely to use extension cords and power taps (commonly known as "power strips"). The use of such devices creates problems, such as the following:

- Overheated electrical cords that may be coiled or bunched up, creating a potential ignition source
- Physical damage—electrical cords that are run under carpet and around furniture in such a way that they can become damaged or worn, exposing bare conductors
- Overloading—even though occupants may use power strips equipped with individual circuit breakers, the circuit is not necessarily adequately protected

Halogen torchiere lamps have been a concern in residence halls and Greek housing because of the high temperature of the bulb. In recent years, manufacturers have implemented design changes to prevent combustible materials from contacting the bulb, helping to reduce the potential for ignition. Nonetheless, the use of torchiere lamps is discouraged by a number of universities, not only because of the fire hazard but also because of their high power demand.

Cooking. Cooking should be permitted only in specifically designated cooking areas. The use of hotplates and other cooking devices should be restricted or prohibited to minimize the potential for a fire. To regulate the size of microwaves and refrigerators in residence halls, some institutions specify a vendor to provide this equipment to the students and only use of specified equipment is permitted.

Enforcing Good Housekeeping

For general information, see Section 11, Chapter 2, "Housekeeping Practices."

Maintaining an environment that is relatively clean and orderly helps to reduce the amount of combustible fuel load that can potentially be ignited or serve as a fuel load to a fire. The 1996 fire in Chapel Hill was fueled in its initial stages by trash that had not been discarded following a party the evening before.

Recycling has created a challenge to good housekeeping. Recycling containers for paper and cardboard placed in buildings create two concerns. The first is that a container with a concentrated combustible fuel load may either be ignited (accidentally or deliberately) or may serve as a fuel package for an external fire. It is, therefore, important that recycling containers be emptied on a regular basis and that their placement be regulated with consideration given to fire safety.

The second concern is that recycling containers might be placed in a means of egress. The philosophy is that corridors and stairways should be kept clear of any such fuel loads because they may impact the safety and integrity of the escape route if they should become ignited. Also, these containers may serve as an obstruction along the egress route. Placement of these containers should be carefully monitored and controlled.

Educating Students About Fire Protection Features

A key component of any fire safety education program is ensuring that the occupants understand the importance of fire safety and how their actions can have a direct impact on the level of fire safety in their residence hall, fraternity, sorority, apartment, or house.

Students often are not fully aware of the fire protection features in the buildings they occupy and may inadvertently bypass them by, for example, propping open fire doors to facilitate pedestrian traffic flow. Students should understand the importance of fire protection systems, such as sprinkler and fire alarm systems, and the results of tampering with them. During an inspection at one university, audible notification appliances in some

of the rooms were found to have been disabled by the students. In several fatal fires, smoke detectors were found to have been either disabled or removed entirely. The risks and penalties for tampering with fire protection systems should be communicated to every student and enforced.

Fire safety education and training for university students can be difficult to accomplish because of the regular turnover of students. Furthermore, any fire safety education program must compete for the attention of the student audience. The fire safety professional may have to be creative and tailor the message to appeal to the students.

Sample strategies include the following:

- *Audience-appropriate videos.* The U.S. Fire Administration's video "Get Out and Stay Alive" is one such program, among others.
- *Live fire training.* Students and/or staff can be given live fire training, such as fire extinguisher training that includes propane-fueled fires.
- *Fire academies.* The Boulder Fire Department and the University of Colorado, among a number of schools across the nation, hold annual fire academies for the resident assistants and the Greek leadership. Such intensive training programs stress the importance of student actions in fire safety. Training programs also motivate the students to look at their living areas with a more critical eye for fire safety dangers.

FIRE DETECTION ISSUES IN UNIVERSITY HOUSING

For general information on detection technology, see Section 14, "Detection and Alarm."

Unquestionably, smoke detection plays a critical role in any fire safety program. Properly installed, operating smoke detection systems or smoke alarms can literally make the difference between the occupants being able to escape from a fire and being trapped by the smoke and flames.

Unfortunately, in the university environment, smoke alarms are sometimes disabled. In a number of fatal fires, especially off campus, the batteries were removed from smoke alarms. In some cases, smoke alarms could not even be located following the fires. Steps should be taken to ensure that such fire protection features are properly maintained.

False or Unwanted Alarms

False or unwanted alarms are a particular problem in the university setting. Students can activate the fire alarm system as a prank, which causes the residents to become desensitized to the alarms and to not react when needed. The problem with unnecessary activation of the fire alarm system is it creates apathy among the students. The occupants will become "numb" to the sound of the fire alarm system and will begin to ignore it, which could have tragic consequences. For example, there had been a number of false alarms in the weeks leading up to the Seton Hall fire in January 2000. Because of this, several of the occupants of the building did not evacuate when the fire alarm system went into alarm on the night of January 19, 2000. This time, there really was a fire.

A *false alarm* is a situation in which someone has deliberately activated the fire alarm system, knowing that there is no danger. For example, a student activating a manual pull station when there is no fire would be classified as a *malicious false alarm.* An *unwanted alarm* or *nuisance alarm* is one when the fire alarm system is activated but not under conditions where a fire exists. For example, a smoke alarm placed in or near a shower and activated by the shower steam would be considered an unwanted or nuisance alarm.

In addition to creating apathy among the students, false or unwanted alarms place undue stress on the local responders. If they are continually responding to false or unwanted alarms at a building, they may develop a "cry wolf" syndrome. In addition, a false alarm takes these units out of service to respond to other emergencies.

The solution that some schools adopt to avoid overloading the local responders is to have the alarms investigated, often by security, before notifying the local fire department. This is a very dangerous procedure since it may allow a fire to grow to a point where it can be fatal. This was the case at Catawba College where a student was killed in a fire that occurred after a series of other smaller fires and false alarms. A clear distinction must be made between false alarms and unwanted alarms.

Engineering, Education, and Enforcement Strategies

Engineering, enforcement, and education are three strategies that can be employed to help reduce the number of false and unwanted alarms.

Engineering. Maintenance of the smoke detectors is critically important. By having an ongoing program of inspection and maintenance, the number of alarms caused by dirty smoke detectors can be reduced.

Using devices that cover the manual fire alarm boxes (pull stations) is an engineering solution to false alarms. When the device is lifted, a local alarm sounds, alerting people in the area. Such covers do not restrict access to the pull station, which can be activated if necessary.

The use of addressable fire alarm systems is beneficial in helping to identify problem areas. Detectors that are improperly located or are continuing to cause unwanted alarms can be identified and corrected.

Education. Educating the occupants and enforcing proper behavior are also important components when it comes to reducing the number of alarms. At one university, postings were put up in the buildings after every alarm advising students as to the cause of the alarm. If the alarm activation was accidental, they provided information on how to avoid future activations. If the alarm was malicious, then information about the incident as well as a reward was offered.

Enforcement. Universities may impose sanctions on resident students up to and including dismissal for maliciously activating

a fire alarm. One university offers rewards to find offenders and has installed CCTV cameras to record violators in the act.

A particularly vexing problem is that of off-campus houses and apartments where the smoke alarms are not part of a fire alarm system that can monitor the condition of the devices. Disabled or missing smoke alarms can contribute substantially to the risk of fatality in a fire in any residential occupancy. Strategies include the following:

- Severe penalties for students who are caught activating the fire alarm needlessly
- Financial penalties being imposed on the floor or building where there is an ongoing problem of false alarms, leading to peer pressure to help reduce the problem

FIRE CONTAINMENT AND SUPPRESSION ISSUES IN UNIVERSITY HOUSING

Fire Containment

For general information, see Section 18, "Confining Fires."

A common violation of the principle of fire containment in university housing occurs when doors are propped open in corridors and stairwells. Even if they aren't designed to protect openings in a fire or smoke barrier, they will serve to stop the spread of the smoke, reduce the number of people who may be endangered, and also limit the amount of damage that may be caused by fire or smoke. Doors that are supposed to be kept closed to limit the spread of smoke and fire are frequently propped open simply for convenience. Educating the students and maintenance and cleaning staff about the importance of ensuring that barrier doors are kept closed can help to alleviate this problem.

Fire Suppression

Two types of fire suppression can be used: manual (by portable fire extinguishers or the fire department using hoselines) and automatic.

Fire Extinguishers. Fire extinguishers can play a valuable role in ensuring that the fire remains in the incipient stage. However, there are certain considerations, as discussed more extensively in Section 17, Chapter 5, "Fire Extinguisher Use and Maintenance."

First, the fire extinguisher should be matched to the probable hazard that will be encountered. Many of the fires that would be encountered in student housing would probably involve Class A combustibles such as wood, paper, and so on. A water-based fire extinguisher would probably be the best type to use in this environment. However, the occupants must be knowledgeable in the steps to take if a fire should occur. Training and education must be conducted prior to an incident to ensure that the occupants know what actions to take. This can be a time-consuming, yet important, responsibility of the university.

Fire extinguishers, especially those that are water based, can be inappropriately discharged as a "squirt gun" and then placed back on the wall. When such misuse occurs, the extinguisher is no longer operational. Constant vigilance by staff is necessary to ensure that the fire extinguishers are not tampered with and that they are promptly recharged when necessary.

Because of the need for ongoing occupant training and education in the use of fire extinguishers, one university has taken the step of removing them from all residence halls. This was done, however, only in fully sprinklered, noncombustible buildings.

Fire Department Response. When a fire does occur, time is critically important. The sooner the occupants of the building are alerted to the fire, the better their chances are of escape and survival. Also, the sooner that the fire department is notified of the fire, the faster it will be able to respond, suppress the fire, and rescue any trapped occupants. For this reason, it is important that procedures are in place to notify the fire department promptly whenever a fire alarm is sounding.

Automatic Sprinklers

Based on the occupancy and occupant characteristics (particularly in the residence halls and Greek environment), the need for sprinklers is paramount. For this reason, NFPA *101* requires automatic suppression systems for new construction.

Recognizing the importance of automatic fire sprinklers in life safety, a number of schools across the country are voluntarily installing these systems in their residence halls. Fire sprinklers provide a significant level of safety when used in concert with fire alarm systems and student education, especially given the risk presented by student behavior, actions, and lifestyle. In addition to protecting lives, sprinklers will minimize the property damage and the amount of time that students will be displaced. Often, they can re-enter the building almost immediately, except for the areas directly affected by the fire and water discharge.

In the wake of the Seton Hall fatal fire, legislation was introduced across the country calling for the installation of sprinkler systems in residence halls and Greek housing. The most sweeping legislation was enacted in 2000 by the State of New Jersey, which called for sprinkler systems to be installed within 4 years. All of the schools met this deadline, greatly increasing the level of fire safety for students across the state.

INSTITUTIONS AND ORGANIZATIONS INVOLVED IN UNIVERSITY HOUSING FIRE SAFETY

University and Fire Department Interaction

The university should work closely with the local fire department in all areas of fire protection. This effort should include not only the academic and support buildings and residence halls but also the off-campus Greek and private student housing. Especially in off-campus housing, the fire department is a critical component in helping to provide a fire-safe environment for the school's students.

Universities should not completely rely on the fire department for all fire safety needs. For example, fire prevention is ultimately the responsibility of the institution. The fire department

cannot be expected to inspect the residence halls and other buildings for fire hazards as frequently as the university staff.

Depending on whether it is a public or private university, the fire department may or may not be legally required to conduct plan reviews. However, it is a good idea to always involve the fire department in any plan reviews of new construction or renovations. This coordination helps to build a stronger relationship between the university and the fire department; the university can gain valuable information on fire-safe design and the fire department can improve its familiarity with the different occupancies on campus.

Organizations Involved in University Housing Fire Safety

A number of organizations are active in various facets of campus fire safety. They are as follows:

Campus Firewatch
P.O. Box 1046
Belchertown, MA 01007
http://www.campus-firewatch.com

Campus Safety Health and Environmental Management Association
c/o National Safety Council
1121 Spring Lake Drive
Itasca, IL 60143
http://www.cshema.org

Center for Campus Fire Safety
P.O. Box 2358
Amherst, MA 01004

United States Fire Administration (USFA)
16825 S. Seton Avenue
Emmitsburg, MD 21727
http://www.usfa.fema.gov

SUMMARY

Since the late 1980s, building and fire codes have changed to require fire protection systems and equipment for lodging establishments. More recently, similar awareness and action have taken place in the area of university housing.

In both lodging and university housing, occupants have unique characteristics. For example, hotel occupants are in an unfamiliar environment. Students can be very familiar with their housing but engage in risky behavior. Hotels and university housing both feature high population density.

These occupant characteristics lead to the need for an effective emergency organization, automatic sprinklers, compartmentation, effective egress design, and detection and alarm systems. Regular fire drills will enhance survivability. Continued improvements in fire protection technology and related areas, such as fire-safe cigarettes, are expected to contribute to further decline in fires in hotels and university housing.

Chapter 4

Apartment Buildings

Kenneth Bush

Chapter Contents

Occupancy Characteristics
Occupancy Hazards
Life Safety Concepts

Key Terms

apartment building, condominium, hazard classification, means of egress, occupancy characteristic, occupancy hazard, public fire and life safety education, residential occupancy

Apartment buildings are those structures containing three or more living units with independent cooking and bathroom facilities, whether designated as apartment houses, tenements, condominiums, or garden apartments. Apartments differ from multi-unit residential occupancies that are not considered homes, such as hotels and boarding homes, by the provision of individual cooking facilities, the number of sleeping rooms, and the less transient nature of the occupants.

The adequate protection of residential buildings and their occupants from the effects of fire has historically been a major concern of fire protection professionals. The construction of multiple dwelling units makes this job more complex. Such construction not only adds to building size and occupant numbers but also adds major complexity due to building design, construction, and fire protection features.

See also Section 20, Chapter 2, "Board and Care Facilities"; Section 20, Chapter 3, "Hotels and University Housing"; Section 20, Chapter 5, "Lodging or Rooming Houses"; and Section 20, Chapter 6, "One- and Two-Family Dwellings."

OCCUPANCY CHARACTERISTICS

According to statistics compiled from the U.S. Census Bureau, there were an estimated 109,902,090 occupied housing units in the United States in 2004. Of that number, 21,136,883 units, or approximately 21 percent of the total number of such units, consisted of three or more units, meeting the definition of "apartment building" in NFPA *101*®, *Life Safety Code*®, and *NFPA 5000*®, *Building Construction and Safety Code*®. The breakdown of all housing units both occupied and vacant by size was 5,739,277 in structures with 3 or 4 units; 6,088,586 in structures with 5 to 9 units; 5,521,813 in structures with 10 to 19 units; and 9,526,484 in structures with 20 or more units.[1,2]

The U.S. population is aging. In 2000, approximately 12.4 percent of the U.S. population was age 65 or over, with an additional 22.1 percent of the population age 45 to 64. Projections from the U.S. Census Bureau indicate that by the year 2050, these figures will increase to 20.7 percent for the group of persons age 65 or over, including 5 percent age 85 or over, and an additional 22.2 percent of the population from 45 to 64 years of age. Coupled with these statistics comes an increasing need for housing units that are compact, economical, and require less individual maintenance. As land values continue to increase, there is little wonder why the design, construction, and occupancy of multi-unit buildings has become a popular issue with the U.S. public.

During 2004, approximately 1,550,500 fires were attended by public fire departments in the United States. Of that number, 526,000 fires occurred in structures, of which 410,500, a significant 78 percent of all structure fires, occurred in residential properties. Of these residential structure fires, 301,500, or 57.3 percent of all structural fires, occurred in one- and two-family dwellings and another 94,000 occurred in apartment buildings, accounting for 17.8 percent of all structural fires. This figure represents an increase of 2.7 percent of fires reported in apartments compared to 2003. This means that a fire occurred in a structure at the rate of one every 60 seconds, and in particular, a residential fire occurred every 77 seconds.[2]

For the period 1977 to 2004, the number of structure fires was at its peak in 1977 when 1,098,000 structure fires occurred. The number of structure fires then decreased quite steadily,

Kenneth Bush is a senior fire protection engineer with the Office of the Maryland State Fire Marshal. He is a member of five NFPA technical committees and a member of the Life Safety Code and Building Construction and Safety Code Technical Correlating Committees.

particularly in the 1980s, to 688,000 by the end of 1989, for an overall decrease of 37.3 percent from 1977. The number of structure fires continued to decrease at a steady rate following 1989 by an overall figure or 24.7 percent to 517,500 incidents by the end of 1998 and has remained in the vicinity of 526,000 fires per year from 1998 to 2004.

OCCUPANCY HAZARDS

The occupancy hazards of apartment buildings include all risk factors that may arise in particular segments of the population. Preschoolers and older adults, if present, have a higher risk of dying in fires because of the mental or physical limitations associated with their age. Older children and younger adults may be at risk if they are physically or mentally handicapped or as a result of drug or alcohol use. Fatal fires are more common at night when people are asleep.

Another important consideration for the protection of apartment buildings is the difference in causes attributed to fire incidents between this property classification and one- and two-family dwellings (Figure 20.4.1). This difference is most likely due to the centralized design and installation of systems typically found in most apartment buildings. Equipment fires are usually the result of poor maintenance or misuse; such equipment tends to have closer supervision in apartment buildings. The number of fires and related casualties caused by occupants, especially from cooking operations, remains high in all types of residential structures. This demonstrates the need to properly apply all required code provisions to these occupancy types, and it also demonstrates the importance of public education regarding the causes, prevention, and control of home fires.

There were 3900 civilian fire deaths in 2004 with almost 82 percent, or 3225 of these deaths occurring in a residential setting. Of these deaths, 510 occurred in apartment fires, a substantial increase of 24.4 percent from 2003. Home fire deaths were at their peak in 1978 when 6015 fire deaths occurred. These numbers slightly decreased during the period of 1979 to 1982, except for 1981, and further decreased a substantial 20 percent during the period to 4820 by the end of 1982. For the next six years, the number of home fire deaths remained consistent in the area of 4655 to 4955 deaths, except for 1984 when 4075 deaths occurred.

In addition, during 1984 there were 17,785 civilian fire injuries, with 14,175 injuries, or nearly 80 percent occurring in residential occupancies. Of the number of persons injured in residential properties, 3200 such injuries occurred in apartments. For the period from 1977 to 2003, the number of civilian injuries ranged from a high of 31,275 in 1983 to a low of 17,785 in 2004 for an overall decrease of 43 percent. It is recognized that these statistics may not represent the actual number of total injuries, as many such injuries occur at small fires where no fire department response is made, or where the responding fire department may not be aware of injured persons that do not require medical attention or are transported for treatment by private means (Table 20.4.1).

During 2004, fire caused an estimated $9.8 billion in property damage, with $5.9 billion attributed to fires in residential occupancies. The $5.9 billion residential property fire loss in 2004 represented a slight increase of 2.1 percent from 2003. The actual property loss from fires in apartments during 2004 totaled $885 million, a decrease of 1.3 percent from 2003. Fires in structures resulted in $8.3 billion in property damage, a moderate decrease of 5.3 percent. The average loss per structure fire

TABLE 20.4.1 Estimates of 2005 Civilian Fire Deaths and Injuries by Property Use

	Civilian Deaths			Civilian Injuries		
Property Use	*Estimate*	*Percentage Change from 2004*	*Percentage of All Civilian Deaths*	*Estimate*	*Percentage Change from 2004*	*Percentage of All Civilian Injuries*
Residential (total)	3,055	–5.3	83.1	13,825	–2.5	77.1
One- and two-family dwellings[a]	2,570	–4.1	69.9	10,300	–1.9	57.5
Apartments	460	–9.8	12.5	3,000	–6.3	16.7
Other residential[b]	25	–28.6	0.7	525	+10.5	2.9
Nonresidential structures[c]	50	–37.5	1.4	1,500	+11.1	8.4
Highway vehicles	500	–3.8	13.6	1,450	+11.5	8.1
Other vehicles[d]	20	–33.3	0.5	200	0.0	1.1
All other[e]	50	+11.1	1.4	950	+11.8	5.3
Total	3,675	–5.8		17,925	+0.3	

Note: Estimates are based on data reported to the NFPA by fire departments that responded to the 2005 National Fire Experience Survey. Note that most changes were not statistically significant; considerable year-to-year fluctuation is to be expected for many of these totals because of their small size.

[a]This includes manufactured homes.

[b]Includes hotels and motels, college dormitories, boarding houses, etc.

[c]This includes public assembly, educational, institutional, store and office, industry, utility, storage, and special structure properties.

[d]This includes trains, boats, ships, farm vehicles, and construction vehicles.

[e]This includes outside properties with value, as well as brush, rubbish, and other outside locations.

Source: *Fire Loss in the United States During 2005,* Table 3, NFPA, Sept. 2006.

was $15,806, a decrease of 4.2 percent. During the reporting period of 1997 to 2004, the average loss per structure fire ranged from a low of $3757 to a high of $17,016 in 2001 for an overall increase of 353 percent. The increase in the average structure loss between 1977 and 2001 was 56 percent when adjusted for inflation. It should be noted that this overall property loss statistic represented a significant 20.5 percent decrease in the totals from the previous year, much of which was attributed to losses incurred by wildfires in Southern California during 2003 (Table 20.4.2).

Citing the number of fires and fire casualties that continue to dominate fire loss statistics, and considering the increased interest in multiple-unit building design, particularly among a growing elderly U.S. population, a number of fire safety initiatives targeted at the residential fire problem remain key to any reductions in these numbers. Currently, five major strategies exist to further reduce the numbers of fire incidents, contain property losses, and control the number of home fire deaths and injuries. First, more widespread public safety education is needed on how to prevent fires and how to avoid serious injury or death should a fire occur. A primary message of any such education must contain information on the common causes of fatal and significant loss fires.

Second, the use, including proper installation and maintenance, of smoke alarms, and the development and practice of home escape plans play another significant role in the control of overall fire losses. Third, accompanying this use of early warning devices comes a need for the aggressive pursuit of the installation and maintenance of approved residential sprinkler systems.

Fourth, additional means to improve the safety of household products should be sought. Recent regulations on the production of child-resistant lighters and research on self-extinguishing cigarettes are two excellent examples of such safe product initiatives. Acceptance of the manufacture, purchase, and use of upholstered furniture and mattresses that are more resistant to cigarette ignition, and to the use of decorations that have been made, or specially treated, to resist ignition represents another change that has already produced positive results and will continue to influence fire safety trends in the future. Lastly, there has to be special considerations for the fire safety needs of high-risk populations, especially very young children, older adults, and the poor.[3]

Smoke detectors and smoke alarms have been a great success in apartment buildings, as well as in private homes. Use of smoke alarms continues to grow, but more slowly since 1982. In 1995, 93 percent of all homes had at least one smoke alarm, and there was evidence that their use in apartments was higher still, probably because state and local laws requiring smoke alarms often have stronger requirements for apartments. However, NFPA studies indicate that when fire occurs, roughly one-third of apartment smoke alarms are not operational, the same share as for one- and two-family dwellings. These studies also indicate that smoke alarms cut the risk of dying in a home fire by roughly 40 percent. However, the estimated reduction is only 16 percent in apartments, townhouses, and condominiums based on fires that occurred between 1985 and 1994. Although available data do not lead to definite conclusions, it appears that the difference in effectiveness levels may be due to the fewer number or longer distance in apartment building escape routes, more success in early detection to prevent fires from growing large enough to report, or the delayed reaction of apartment dwellers to alarms outside of their unit.

TABLE 20.4.2 Estimates of 2005 Structure Fires and Property Loss by Property Use

	Structure Fires		Property Loss[a]	
Property Use	*Estimate*	*Percentage Change from 2004*	*Estimate*	*Percentage Change from 2004*
Public assembly	13,500	+3.9	$320,000,000	+1.3
Educational	6,000	–14.3	67,000,000	–1.5
Institutional	7,500	+15.4	40,000,000	+60.0**
Residential (total)	396,000	–3.5	6,875,000,000	+15.6**
One- and two-family dwellings[b]	287,000	–4.8*	5,781,000,000	+16.8**
Apartments	94,000	0.0	948,000,000	+7.1
Other residential[c]	15,000	0.0	146,000,000	+27.0*
Stores and offices	23,000	–2.1	687,000,000	+17.2*
Industry, utility, defense[d]	11,500	–4.2	376,000,000	–11.1
Storage in structures	30,000	–6.3	590,000,000	–21.1**
Special structures	23,500	+9.3	238,000,000	+19.0
Total	511,000	–2.9	$9,193,000,000	+10.6**

Note: The estimates are based on data reported to the NFPA by fire departments that responded to the 2005 National Fire Experience Survey.
[a]This includes overall direct property loss to contents, structure, a vehicle, machinery, vegetation, or anything else involved in a fire. It does not include indirect losses, e.g., business interruption or temporary shelter costs. No adjustment was made for inflation in the year-to-year comparison.
[b]This includes manufactured homes.
[c]Includes hotels and motels, college dormitories, boarding houses, etc.
[d]Incidents handled only by private fire brigades or fixed suppression systems are not included in the figures shown here.
*Change was statistically significant at the .05 level.
**Change was statistically significant at the .01 level.
Source: *Fire Loss in the United States During 2005,* Table 4, NFPA, Sept. 2006.

Once a potentially serious fire starts, apartment buildings can pose special problems to fire department suppression forces. The variety of these types of residences, as well as the architectural desire to make buildings aesthetically pleasing yet functional, creates an interesting combination of fire protection demands. Building designs, space considerations, and parking arrangements can create major access problems, particularly for fire-fighting apparatus (Figure 20.4.2). Long hose lays and blocked roadway access can create problems for fire-fighting operations in addition to existing problems, such as weather, personnel deficiencies, and hampered water supplies (Figure 20.4.3). Architectural designs may use false partitioning and veneered construction, giving an unrealistic impression of the type and magnitude of the actual building construction (Figure 20.4.4). Although NFPA *101* makes no special requirements for the construction of these buildings, many such requirements are found and enforced through model building codes, such as *NFPA 5000,* as well as through many local codes and ordinances currently in effect. Sometimes the location and construction of apartment buildings make egress for residents and access by fire fighters very difficult (Figure 20.4.5).

Apartment buildings are typically a collection of more than two self-contained dwelling units with independent living and cooking facilities. Model building codes, such as *NFPA 5000,* establish the criteria for separation between dwelling units in order for them to be classified as other occupancy types, most likely one- and two-family dwellings. These substantial separation requirements are intended to protect dwelling units from a fire in a neighboring unit, even if the fire severity causes collapse of the unit involved in fire. Residents of these buildings are typically less transient in nature and are more familiar with the building construction and arrangement, especially exiting patterns and levels of protection afforded such as the installation of smoke detection, fire alarms, and automatic sprinkler systems.

FIGURE 20.4.2 Apartment Building Designs and Parking Arrangements Creating Major Access Problems and Hindering Fire-Fighting Operations

FIGURE 20.4.3 Location and Lack of Access Routes for Many New Apartment Buildings Creating Major Fire Apparatus Placement and Fire-Fighting Operations Problems

FIGURE 20.4.4 Architectural Designs Using False Partitioning and Veneered Construction

The levels of protection required by most model codes take this level of familiarity into consideration when establishing reasonable levels of protection.

Whenever apartment units are utilized for other purposes, such as day-care homes, residential board and care facilities, or even business offices, the levels of protection and design considerations must be adjusted accordingly. Such modifications may affect only one or a limited number of apartment units, or may involve modification to the entire building. Earlier editions of NFPA *101* made some adjustments to its requirements based upon the advanced ages of building residents; however, that distinction no longer exists in more recent code editions. Many times, local statutes, such as zoning codes or license requirements, restrict the nature of occupancy, and the number and abilities of persons who may reside in an apartment building.

FIGURE 20.4.5 Limited Fire Department Access Due to Proximity of Waterway

Another important consideration to remember is that the term "condominium" refers to ownership, not occupancy. Therefore, the occupancy classification for residential occupancies is not dependent on property lines or ownership arrangements.

An additional problem arises in the location and combination of apartments with other occupancy types, particularly those above and behind mercantile and business occupancies (Figure 20.4.6). Where multiple occupancy classes occur in the same building and are so intermingled that separate safeguards are impractical, means of egress facilities, construction, protection, and other safeguards must comply with the most restrictive code requirements for the occupancies involved.

LIFE SAFETY CONCEPTS

The apartment fire death and injury problem is very complex, and several strategies must be presented to help solve it. The installation and proper maintenance of smoke alarms and quick-response residential sprinklers in sleeping areas provide an effective, low-cost, and widely available method of early warning so that evacuation, containment, and suppression can begin during the incipient stages of a fire.

FIGURE 20.4.6 Combination of Apartments with Other Occupancy Types

Public Education

The general public must be taught to protect themselves and others occupying the residential unit from fire through the safe use and installation of alternative heating devices, the proper storage and handling of flammable liquids, and the identification and correction of home fire hazards. In addition, stringent flammability standards for upholstered furniture, such as those previously issued by the U.S. Consumer Product Safety Commission (CPSC) for children's sleepwear and mattresses, will provide long-term fire safety benefits. Specially designed systems that are effective in terms of life safety should be installed to provide a high level of protection to occupants, particularly where large numbers of persons are present, such as in a high-rise apartment building, or where the occupants' ability to escape is hampered, such as in apartments for the elderly.

Design Considerations

Although such fire safety precautions are not always practical, particularly within an individual dwelling unit, a more concentrated effort must be made to confine the fire and its effects to a well-defined, limited area of the structure. This task is accomplished through the adoption of accepted fire safety and building construction codes, such as NFPA *101* and *NFPA 5000.* Since many current laws and regulations prevent fire inspection authorities from entering individual living units, adequate fire protection features must be designed and constructed during the initial phases of the project. The regulation of interior furnishings provides only a partial solution to the fire safety problem, although such consumer items are generally in use for many years before they are replaced. Futhermore, the individual habits and attitudes of building occupants can never be regulated and are difficult to change.

Additional requirements of *NFPA 5000* address fire safety requirements intended to promote property protection and to enhance the safety of fire fighters and other emergency personnel who must enter the building under varying degrees of fire conditions. Such levels of protection include detailed requirements for building construction and other structural features and the installation of standpipes and alarm and communication systems for fire service use. Although these requirements have been modeled from those recognized by NFPA *101* for occupant protection, *NFPA 5000* is intended to address other issues concerning property protection and emergency operation procedures.

One of the most important, yet sometimes most complicated considerations of adequate protection is the proper classification of occupancy. All residential occupancies, including apartment buildings, require occupancy by persons for more than 24 hours. However, the number and abilities of building occupants, particularly to be able to escape a fire without assistance, play vital roles in the classification of an occupancy, and hence, directly affect the design, construction, and arrangement of the building and associated levels of protection.

All occupants of an apartment building are expected to have the ability to recognize a direct fire threat, or the warning from a building alarm system, and be able to physically exit the building without obstruction, including locked egress doors. Where these criteria are not met, classification of the building as a different occupancy type, such as a health care facility, residential board and care facility, or detention and correctional occupancy, may be warranted. Even though it is recognized that reaction to a fire may be delayed while residents are asleep, it is assumed that they will be able to take appropriate actions for self-preservation when warned of potential danger.

Because apartment buildings are so diverse in size, configuration, and resident population, many regulatory codes pay particular attention to construction designs and fire protection features. NFPA *101* covers the presence of hazards such as cooking and heating equipment, as well as the occupant's degree of familiarity with his or her living space. NFPA *101* and *NFPA 5000* require most new apartment buildings to be protected by automatic sprinklers. However, sprinkler protection is not required where each apartment has a door directly to the outside at ground level, such as in townhouse-style apartments, or is served by an interior stair totally enclosed by fire-rated construction, or where an outside stair serves a maximum of two units located on the same level (Figure 20.4.7). NFPA *101* has a unique method of regulating the construction and design of existing apartment buildings based on the type and extent of automatic fire detection and/or fire suppression equipment provided. Recognizing equivalency provisions found elsewhere in NFPA *101,* the

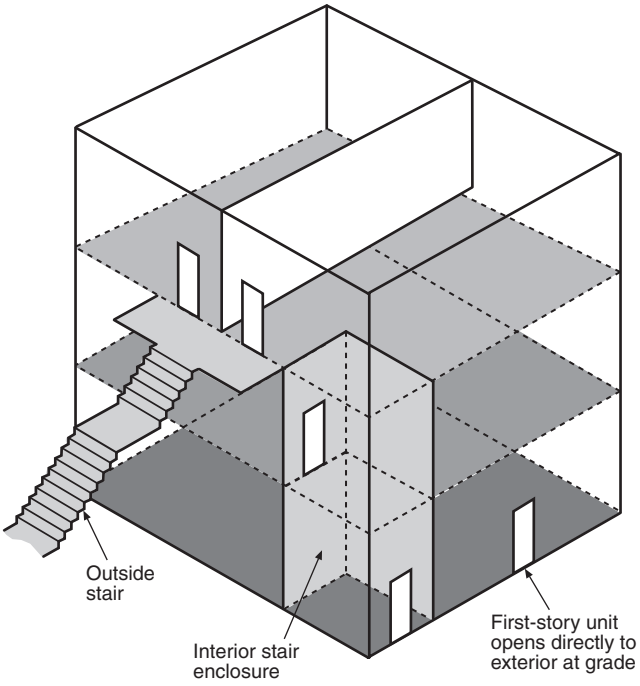

FIGURE 20.4.7 Required Exiting Arrangements for New Apartment Buildings Without Sprinkler Protection

technical committee on residential occupancies established four equivalent schemes to provide a high degree of flexibility. These designs provide a minimum level of life safety for apartments. Some systems have additional protective capability, permitting greater building heights and larger building areas.

This overall approach provides one of the first system design attempts to be codified. Whereas a total system would have many design approaches, this more limited system offers only four different approaches. Yet an evaluator can identify an appropriate method from the four approaches based on the building size, height, and arrangement. This allows the person evaluating the existing building to formulate a safety approach that best fits the building, rather than fitting the building to a single codified design criterion.

The contents of living units in residential occupancies fall into the ordinary-hazard classification as defined by NFPA *101* and *NFPA 5000*. Characteristics of these hazards include moderately rapid burning and considerable smoke generation (Figure 20.4.8). Under normal conditions, no unduly dangerous exposure should develop during the period necessary to escape from the fire area given prompt occupant notification of the fire. Generally, this classification represents conditions found in most buildings. Even with the introduction of plastics, foam materials, and other combustible materials in furnishings, the amount and configuration of such materials present a lower hazard than in other occupancies where they may be sold, stored, or displayed. NFPA 13, *Standard for the Installation of Sprinkler Systems,* classifies the contents of apartment buildings as "light hazard" for the design of extinguishing systems. This classification difference is based on the threat to life safety assumed in

FIGURE 20.4.8 Exits from Apartments Discharging to a Public Way, Protected from Fires in Exposure Occupancies, Particularly Parking Areas

the ordinary classification versus that assumed where the extinguishing capability of the automatic sprinkler system results in the light-hazard classification.

Means of Egress

In designating the number and types of exits required for apartment buildings, NFPA *101* and *NFPA 5000* determine the occupant load on the basis of 1 person/200 ft^2 (18.6 m^2) of gross floor area, or the maximum probable population of any room or section under consideration, whichever is greater. Many buildings, such as dormitories, may produce a greater occupant load. However, even though some portions of these buildings are densely populated, the whole building may not necessarily exceed 1 person/200 ft^2 (18.6 m^2) of gross area, owing to the space taken for toilet facilities, hallways, closets, and living rooms. These requirements do not preclude the need for providing adequate exit capacities from concentrated use and sleeping areas based on the maximum probable population, rather than on the design figure. The capacities of required exits are as specified in NFPA *101* and *NFPA 5000.*

Travel within the individual dwelling unit need not comply with the requirements for means of egress, but must be arranged as means of escape. The differences between means of escape and means of egress have an impact on the size and type of escape components, especially doors and headroom of some occupiable spaces. Most of these requirements apply to the unit only, and not necessarily to the entire building.

Although seemingly contrary to the basic code requirements of two distinct, remote means of egress from all locations, several exceptions to this rule are found within the requirements for apartment occupancies. Whereas the traditional interior exit corridor arrangement commonly found in larger apartment buildings and condominiums requires two remote exits, several other options in apartment building configurations permit other arrangements. The common townhouse arrangement, which provides an exit directly to the street or yard at ground level or

by way of an outside or enclosed stairway serving that apartment only, permits the front door to be the only required exit. Therefore, a rear door, which is often provided, would not be required and could be a sliding door to a porch or patio.

Another exit arrangement unique to apartment buildings permits an exception to the typical requirement for remoteness of exits from nonlooped exit access corridors in apartment buildings that have corridor doors from dwelling units arranged so that exits are located in opposite directions from such doors. In addition, a provision was introduced into the code to limit travel distances from areas of apartment buildings, other than those within living units, to a maximum of 200 ft (61 m) in unsprinklered buildings and a maximum of 250 ft (76 m) in sprinklered buildings.

In apartment buildings, travel distance does not typically include the means of escape within the dwelling unit; only the path of travel in the means of egress is considered. Likewise, common paths of travel are only considered outside the dwelling unit. Travel distance in nonsprinklered buildings is tacitly regulated by limiting any floor level of an individual dwelling unit to no more than one level above or below the entrance floor. In the event of multiple levels within a single dwelling unit, consideration must be given to the limitation of no more than two levels within a dwelling unit to be open to each other. Where a third level exists, it must be separated from the other two levels as required by other code provisions.

Another exception is a basic design approach for garden apartments where the apartment entrances are enclosed around a single protected stairway. This single stairway usually is open to the exterior or is glass enclosed. It must be separated from the building by construction of at least 1-hour fire resistance rating. The doors should be treated similarly. Note that this exception for a single exit is limited to buildings having four or fewer stories with not more than four living units per story and protected throughout by an approved, supervised automatic sprinkler system, and to existing buildings of three stories or less. Interestingly, the basic design of a typical garden-style apartment has influenced other chapters of NFPA *101*. Previous editions of NFPA *101* required that all exit stairways continuing beyond the floor of discharge be interrupted at that level by partitions, doors, or other effective means to make clear the direction of egress to the street. However, an exception to this requirement allows these stairways to continue one-half story beyond the level of discharge without such physical interruption. This exit arrangement is typically found in garden-style apartments that have apartments or service areas on the ground floor or terrace level. Based on this exception, stairways serving these levels need not be interrupted at the floor of exit discharge for fire safety reasons. Recently, fire escape ladders and alternating tread devices have been added as recognized means of egress components from apartment buildings. It must be recognized, however, that these types of means of egress components are acceptable in a very limited number of circumstances, such as from areas having low occupant loads of persons physically capable of using such devices.

In addition to the number and types of required exits, the arrangement and travel distance to these exits are regulated by the general requirements of NFPA *101* and *NFPA 5000,* with due consideration to the levels of fire protection features within the building. As in other occupancies, all exits must terminate directly at a public way or at an approved exit discharge (see Figure 20.4.8), unless certain additional protection features, such as automatic sprinkler protection and vestibule separation and/or enclosures, are provided to permit 50 percent of the required exit capacity to discharge through areas on the level of discharge. NFPA *101* and *NFPA 5000* also recognize the use of areas of refuge, particularly for spaces accessible to persons with severe mobility impairments. Because of the high level of satisfactory performance and response to fire conditions by supervised automatic sprinkler systems, any story of an apartment building equipped with this level of protection may be considered an area of refuge even if an occupant does not have access to any of the apartment units. Because locked apartment unit doors create inaccessibility to spaces other than the corridor, the corridor maintains its tenability due to the effectiveness of the automatic sprinklers and serves as the area of refuge. This does not preclude the demonstration of the corridor to maintain tenable conditions, especially if the aggregate area of the corrider is less than 1000 ft^2.

Minimum levels of illumination must be provided for public spaces, hallways, stairways, and other means of egress. Emergency lighting is required for apartment buildings that have more than 12 living units or are more than three stories high, except in buildings where every living unit has a direct exit to the outside at grade, such as in townhouses. Approved exit signs are required in all apartment buildings with more than one required exit. However, discretion should be used in placing such signs where exits are obvious or where all occupants are familiar with the building.

Because a higher degree of transient occupancy in some apartments is a definite possibility, special exiting considerations are made within the individual living units, in addition to those found in the public access spaces. All individual living units with two or more rooms must comply with the minimum provisions for operable exterior openings to be used as a secondary means of escape or with the specialized separation or protection requirements of NFPA *101* and *NFPA 5000*. Not only must these openings be of a minimum size, but they also must be accessible and easy to operate. In addition, every dwelling unit greater than 2000 ft^2 (180 m^2) or having a travel distance to the primary means of escape greater than 75 ft (22.5 m) must have two primary means of escape remote from each other, or it must be protected by an approved supervised automatic sprinkler system. Special multilevel units, such as penthouses, are permitted to have regular, curved, or spiral stairways that connect to one level above or below the entrance to the apartment.

Additional requirements prohibit any door in an apartment building, including individual unit doors, from being locked against egress while the building is occupied. This means that a door may be locked so that it can be opened from within the building but not from the outside. Ordinarily, dead bolts, double-cylinder locks, and chain locks would not meet these provisions. Multiple-death fires may occur if a key cannot be found to unlock the door or the chain is not removed. A concept that sets apartment buildings apart from other residential occupancies is a unique arrangement where a nontransient population

is required to escape the building utilizing a common corridor egress system. In recognition of heightened security concerns, one additional operation is permitted to operate locks installed on doors between public spaces and individual dwelling units. This operation may include a sliding chain and catch or bolt, or any similar device such that no key or special knowledge or effort is necessary. Additional locks or latches may be installed provided that no more than two operations are required to open the door. In that case, one action must operate more than one locking or latching device. Note that in existing residential occupancies, NFPA *101* permits two additional releasing operations, for a total of three. The use of delayed egress locks, however, is permitted in apartment buildings protected throughout by automatic sprinkler systems or fire detection systems. The limitation of one such locking device in any one egress path and the 15- or 30-second delayed release provides the security needed for infrequently used doors but at the same time ensures that the door remains available for emergency use.

Another feature unique to apartment buildings permits stairway doors to be locked to prohibit building re-entry when such stairs are arranged as smokeproof enclosures. This requirement differs slightly from other occupancy types for which a number of restrictions exist to permit locking of doors from the exit stair to prevent re-entry onto a floor of the building (Figure 20.4.9).

In apartment buildings, the protection of vertical openings, such as stairways, elevator shafts, and atria, follows the requirements found in NFPA *101* and *NFPA 5000*. Smokeproof enclosures are required in existing high-rise apartment buildings except those that are totally sprinklered. This limits the possibility of smoke contamination of exits and ensures a safe, protected means of egress. The protection from hazards, as well as the classification of interior finishes, is also based on the levels of fire detection and/or protection within the building.

The recognition of the limited fire hazard and fuel loading in apartment buildings permits a unique reduction for the fire resistance requirements for vertical openings. In apartment buildings protected throughout by automatic sprinklers, vertical openings are permitted to be enclosed by construction having a fire resistance rating of 1 hour regardless of the number of stories connected by the opening unless the building is a high-rise.

A relatively new provision of the model codes prohibits unenclosed vertical openings of any kind within new buildings or fire sections of new buildings served by a single exit. In addition, any new building with unprotected vertical openings is required to be protected throughout by an approved supervised automatic sprinkler system. However, convenience openings, which meet the special requirements found in other chapters of NFPA *101* and *NFPA 5000* are permitted without exception in apartment buildings.

A highly effective form of fire protection in a residential occupancy is early warning. All living units in an apartment building must be equipped with approved smoke alarms. These smoke alarms are usually located in hallways that have access to the sleeping areas although new unsprinklered apartment buildings must also be equipped with smoke alarms in every sleeping room. In multiple-level units, a smoke alarm also should be located at the tops of stairways. Detection systems must be

FIGURE 20.4.9 Locked Stairway Doors Served by Smokeproof Enclosure

installed in accordance with basic engineering practices. Special consideration should be given to room configuration, air movement, and stagnant air pockets that would reduce detector efficiency, and to cooking areas, fireplaces, or other normally smoke-producing appliances that cause an excess of nuisance alarms. All smoke alarms required for installation in multiple-dwelling units must be powered by the building's electrical system. In order to reduce the possibilities of unnecessary alarms due to ambient conditions, or where incipient incidents can be controlled without total building evacuation, smoke alarms within individual units are not required to sound the building fire alarm. This permits rapid notification of those persons most intimate with the fire without unnecessary evacuation of areas of the building not immediately affected by the incident. Secondary power sources are not required for single-station smoke alarms in existing buildings only. In addition, where a single apartment needs more than one smoke alarm, there is no requirement to interconnect multiple smoke alarms within a single unit. However, the audibility requirements of *NFPA 72®*, *National Fire Alarm Code®*, almost always require multiple smoke alarms within a single dwelling unit to be electrically interconnected

such that when one detects smoke, all smoke alarms within the dwelling unit sound their audible (and visible, where applicable) alarms. Note that this type of detection system is required in addition to the requirements for any other detection or suppression system.

Manual fire alarm systems are required in apartment buildings according to the building's size and height. As building designs become higher and more complex, additional special features are required, such as annunciator panels, visible alarm signals, voice communications systems, and automatic transmission of building fire alarms to the fire department. Voice communications systems are often used as part of a multifaceted system that allows the fire department to provide verbal instructions to building occupants during a fire. Where levels of protection, such as automatic sprinkler protection or exit access directly to the exterior of the building, particularly at ground level, are suitable to maintain a safe egress system for a longer period of time, other fire protection features, such as fire alarm systems, are not required to be installed. This is in recognition of the benefits associated with a properly designed, installed, and maintained automatic sprinkler system in a type of occupancy in which fire casualties remain at a high level.

As mentioned before, NFPA *101* and *NFPA 5000* require almost all new apartment buildings to be protected by automatic sprinklers. In existing apartment buildings, the extent of automatic sprinkler protection is again governed by the building's size and height, as well as by the four protection options discussed in NFPA *101*. To the extent permitted by the applicable sprinkler system installation standard, the use of residential or quick-response sprinklers is required for new installations of sprinkler systems in dwelling units, apartments, and hotel guest rooms. The increased technology, cost-effectiveness, and appearance of these systems have provided numerous additional incentives for mandating this protection option. An exception permits the elimination of the draftstops and closely spaced sprinklers as required by NFPA 13 for convenience openings within dwelling units.

Continuing efforts have been made by the technical committees of the model building codes, NFPA *101,* and the sprinkler standards to coordinate the requirements for automatic sprinkler protection in buildings housing residential occupancies. Two examples are the levels of protection necessary for closets within individual dwelling units and for open parking structures in buildings protected by systems designed in accordance with NFPA 13.

Caution should be exercised when designing automatic sprinkler protection in buildings where residential and other occupancies are located. Often mercantile or business uses occupy the lower floors of a building, with residential units located on upper floors. These nonresidential spaces might pose an additional threat of a fire during nonbusiness hours, having the potential of affecting the tenability of egress routes from residential areas above. These buildings might be classified as mixed-use buildings, and do not fall within the scope of NFPA 13R, *Standard for* the *Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height,* for the design and installation of automatic sprinkler protection. Therefore, the sprinkler design for these types of structures must conform to the requirements of NFPA 13.

Designers of sprinkler systems for apartment buildings must pay particular attention to details, because residential and quick-response sprinklers cannot always be installed in a system that could normally be designed with standard sprinklers. There may also be other situations, such as vaulted ceilings or areas with special ambient temperature considerations, where residential sprinklers or quick-response sprinklers might not be listed for use. In all cases, the intent to obtain the quick response afforded by these types of sprinklers, as well as the high spray provided by residential sprinklers, serves to maintain tenability within the room of fire origin.

NFPA *101* requires portable fire extinguishers to be located in hazardous areas only, not throughout the entire building. Many building owners place these extinguishers in individual living units, under the direct responsibility of the occupant. In addition, a provision of NFPA *101* eliminates the need for portable fire extinguishers in buildings protected throughout by an approved supervised automatic sprinkler system. The possible ineffective use of such devices by persons not routinely trained in their operation, as well as the expense and effort to install and maintain portable extinguishers, especially in unsecured areas, is addressed by using early warning and suppression operations of smoke alarms and automatic sprinklers, especially those systems utilizing fast-response or residential sprinklers, to adequately notify building occupants and to control fires without the need for occupant intervention. It should be noted, however, that some fire prevention codes, including NFPA 1, *Uniform Fire Code*™, require the installation of portable fire extinguishers throughout apartment buildings. The requirements of NFPA 1 and NFPA *101* differ because the two codes have differing scopes, goals, and objectives.

The design, installation, and maintenance of all such fire detection and protection systems are based on referenced fire protection standards, as well as on sound engineering judgment. For residential occupancies of four or fewer stories, see NFPA 13R.

When fires cannot be confined to the area of origin, the means of egress must be sufficiently protected to allow all building occupants enough time for safe evacuation. This basic concern for providing safety for the occupant in a room during a fire led to a minimum corridor wall construction to keep fire in a corridor from entering a room or to keep fire in a room from entering the corridor. Doors protecting openings in these enclosures must provide a level of protection commensurate with the expected fuel load in the room and with the fire resistance of the corridor wall construction. Contrary to the general rule for door assembly considerations, the requirements for doors in residential occupancies apply to the leaf only, with a 1¾ in. (45 mm) solid, bonded, wood-core door considered equivalent to a door with a 20-minute fire protection rating. The door rating requirement establishes a minimum quality of construction and does not require a complete listed fire door assembly. However, the requirement that doors between apartments and corridors be self-closing reduces the risk of fire fatalities. Fire spread can occur mainly due to the door being left open as the occupant flees the fire. People may die after opening the door to a fully involved room, or after causing a room to become fully involved by opening a door and introducing oxygen to the fire. Under

both circumstances, a door equipped with spring-loaded hinges or a door closer would prevent smoke or fire from spreading down the corridor and exposing other occupants. Since a fire and its effects can be adequately and quickly contained in spaces that are protected by residential or quick-response sprinklers, the installation of those styles of sprinklers now permits the elimination of corridor walls and doors separating exit access corridors from spaces not used as dwelling units or hazardous areas. Such spaces may include meeting rooms, lobbies, gift shops, offices, and other ancillary spaces found in a number of apartment buildings. Spaces where a higher fuel load, or where sources of ignition may exist, such as workshops, storage rooms, and laundries, are not permitted to use this corridor wall exception.

During a fire, the evacuation of all residents from a large apartment building is at best a time-consuming process. This problem is compounded by the introduction of larger and taller structures, complex and intricate building designs, and a larger population of residents who are incapable of rapid evacuation, especially by stairways. For these reasons, the most expedient movement of a sizable number of residents may be horizontally. The introduction of required areas of refuge serves three purposes fundamental to the protection of building occupants by (1) limiting the spread of fire and fire-produced contaminants, (2) limiting the number of occupants exposed to a single fire, and (3) providing for horizontal evacuation by creating safe and tenable space on the same level.

Accessible means of egress and associated areas of refuge are required in new apartment buildings based on the evacuation capabilities of the building's occupants and on the construction and design characteristics of the building and levels of fire protection features. Since the majority of apartment residents are assumed to be capable of vertical evacuation using stairways, the location of stairways provides both the required area of refuge as well as the required means of egress. Where travel time to stairways increases due to excessive horizontal distances and/or where a majority of residents have reduced mobility, specialized areas are required on the same floor level.

Typically, all building service equipment and utilities in apartment buildings are required to be designed and installed in accordance with sound engineering practices and all applicable NFPA standards. The use of a public corridor as part of the supply, return, or exhaust air system is not permitted in accordance with NFPA 90A, *Standard for the Installation of Air-Conditioning and Ventilating Systems.* In fact, in certain apartment building designs, these corridors must be pressurized against smoke movement. The standard requirements for the reliability of the means of egress and fire retardancy for interior furnishings and decorations, as well as the proper maintenance and testing of fire protection equipment also apply equally to apartment occupancies. With the advent of new innovations in gas heater technology and design, including automatic fuel shutoffs and oxygen-depletion alarms, the use of approved gas space heaters is now permitted under certain conditions commensurate with the listing of the heater.

Occupants of each living unit must be given emergency instructions on a yearly basis, indicating the location of alarms, exiting paths, and actions to be taken in response to a fire in the living unit and in response to the sounding of an alarm. However, other operating features, such as specialized fire safety training and fire exit drills, have been deleted due to the nontransient nature of most building occupants.

SUMMARY

The statistical data previously cited provide clear evidence that the fire problem in apartment buildings and in residential occupancies as a whole is complex, significant, and not easily solved. The increasing demand for adequate, yet low-cost, functional and aesthetically pleasing housing has led to an increasing demand for adequate, safe, and economical fire protection. The problem intensifies with the demand for higher and larger buildings with a higher density of occupants and with the demand for more personal services for building occupants. Although the solution to these fire problems undoubtedly requires much future study, the obvious short-term solution of effective code formulation, adoption, and enforcement is the immediate responsibility of every fire safety professional.

Chapter Contents

Occupant and Occupancy Characteristics
Fire Safety
Means of Escape
Passive Fire Protection
Active Fire Protection Systems and Equipment

Key Terms

bed-and-breakfast, occupancy characteristic, occupant characteristic, rooming house, self-preservation, university housing

Lodging or rooming houses are defined by NFPA *101®, Life Safety Code®,* and *NFPA 5000®, Building Construction and Safety Code®,* as those buildings in which separate sleeping rooms are rented and sleeping accommodations are provided for 16 or fewer persons on either a transient or a permanent basis, with or without meals, but without separate cooking facilities for individual occupants.

Facilities with sleeping accommodations for more than 16 persons are classified as hotels and dormitories, and those with individual cooking facilities are classified as apartment buildings. Occupants must be capable of self-preservation. The presence of four or more occupants who are incapable of self-preservation reclassifies the facility as a health care, or possibly, a board and care facility. Based on these restrictions, the classification "lodging or rooming house" is effectively limited to facilities providing sleeping accommodations without separate cooking facilities for up to 16 persons who are capable of self-preservation.

Lodging or rooming houses can be in buildings of any construction type permitted by local building codes. NFPA *101* does not identify any minimum construction requirements for occupant life safety purposes. Because most lodging or rooming houses are located in converted dwellings or share space with mercantile operations, construction is generally found to be Type III or V, as defined by NFPA 220, *Standard on Types of Building Construction,* and *NFPA 5000*. The hazard of the contents is considered "ordinary," a trait consistent with most residential occupancies.

For related topics, see the following chapters in Section 20: Chapter 1, "Assessing Life Safety in Buildings"; Chapter 2, "Board and Care Facilities"; Chapter 3, "Hotels and University Housing"; Chapter 4, "Apartment Buildings"; and Chapter 6, "One- and Two-Family Dwellings."

OCCUPANT AND OCCUPANCY CHARACTERISTICS

How familiar occupants of lodging and rooming houses are with the layout of the houses they live in varies considerably. Permanent occupants of a rooming house have the advantage of being familiar with the layout of the building. Occupants of a campus lodging house, better known as a fraternity or sorority house, are not permanent; however, over the course of a semester they can become increasingly familiar with the layout of the building. Bed-and-breakfast guests, like hotel guests, are typically transient in nature.

Mixed occupancies generally are not encountered in lodging and rooming houses, except in cases in which mercantile-use spaces are located on the lower floor or floors and sleeping rooms are located above. Neither NFPA *101* nor *NFPA 5000* permits such an arrangement without specific protection requirements.

Rooming Houses

In the 1970s and 1980s, several new markets spurred a growth in the number and nature of lodging and rooming houses, which were once considered budget-conscious alternatives to expensive hotels. Landmark court decisions required that psychiatric patients capable of living in less

Richard R. Anderson, CFPS, is vice-president of Anderson Risk Consultants and chair of NFPA's Lodging Industry Section Executive Committee.

restrictive environments than psychiatric hospitals be released to live in the general population. Although many deinstitutionalized people do not require the assistance of support staff, such as might be found in residential board and care facilities, they prefer not to assume all the responsibilities of independent living, meal preparation, and the like and choose to live in rooming houses.

Due to the limited number of sleeping accommodations and the lack of separate cooking facilities for individual occupants, lodging or rooming houses are viewed, from a life safety standpoint, as falling above one- and two-family dwellings and below dormitories, hotels, and apartment buildings.

NFPA *101* and *NFPA 5000* requirements for lodging and rooming houses center on four key elements essential to life safety: means of escape, detection and alarm systems, separation of sleeping rooms, and automatic sprinkler protection. These four elements are covered in the sections that follow.

Bed-and-Breakfast Properties

Bed-and-breakfast properties are typically distinctly different from rooming houses, dormitories, or fraternity and sorority houses. They are typically owner-occupied, well kept, and often upscale accommodations. Bed-and-breakfasts and country inns have become increasingly popular in the United States as alternative travel accommodations to hotels. Many facilities known as bed-and-breakfasts meet the definition of hotel because they provide sleeping accommodations for more than 16 guests.

Fraternity/Sorority or University Housing

Fraternity houses, sorority houses, and university housing in converted dwellings are found on and around university campuses. These properties pose many of the same life safety hazards posed by rooming houses. In most cases, these properties are occupied by young adults who might be prone to risky behavior—for example, smoking, consuming alcohol, and using controlled substances—which can serve to increase the life safety hazard.

FIRE SAFETY

Because most fires involve behaviors and transitory hazards that may not be identified in an annual inspection, the property owner should be well versed in understanding fire hazards.

Inherent Hazards

The leading causes of fires in lodging and rooming houses during the 4-year period from 1999 to 2002 were cooking equipment (42%), smoking materials (16%), and arson (10%). Whereas cooking equipment was involved in 42 percent of all fires in rooming and boarding houses, 25 percent were confined to the cooking equipment.[1] Smoking in the guest rooms and common areas of bed-and-breakfast properties can be prohibited, and enforcement of a no-smoking policy can eliminate one of the leading causes of fires in these occupancies. However, smoking is typically allowed in rooming, fraternity, and sorority houses. Fire-retardant textiles, furniture, and mattresses can help slow the spread of fires caused by smoking materials.

Electrical Equipment

The original design of the electrical systems for homes converted to or used as bed-and-breakfast occupancies did not consider the use of modern-day appliances, such as 2000 watt hair dryers, 900 watt space heaters, coffee makers, and the like. If a property has undergone renovations to facilitate its use as a bed-and-breakfast, the electrical system might have been updated. However, if there were no renovations, electrical systems may be prone to improper use of extension cords and outlet strips due to the lack of sufficient receptacles. The use of extension cords and outlet strips should be limited due to the potential of overloading circuits. Where used, such devices should be listed, approved, and used according to the manufacturer's recommendations. From 1992 to 2002, electrical equipment represented the cause of 5 percent of structural fires in lodging and boarding houses.[1]

Building Systems

Due to the limited size of lodging or rooming house occupancies, building systems are typically not very sophisticated; however, it is not uncommon for them to have a central air and heating system. These systems might be required to be equipped with smoke dampers to isolate the air-handling equipment from the remainder of the system or smoke detectors in the ducts arranged to automatically shut down the system upon detection of smoke. See NFPA 90A, *Standard for the Installation of Air-Conditioning and Ventilating Systems,* for detailed requirements for such systems.

Heating and cooling systems should be installed by qualified installers and maintained in accordance with the manufacturer's recommendations. Inadequate heating can lead to the use of supplemental heating devices, such as portable electric, kerosene, or fixed-space heaters. Each represents a specific hazard and has its own accompanying set of requirements.

Appliances

Appliances in a lodging or rooming house occupancy include appliances similar to those found in a residence. However, the frequent use of clothes dryers to do laundry for up to 16 guests can lead to a dangerous buildup of lint that could result in a fire. In rooming houses some tenants may be permanent and are, therefore, likely to accumulate more electrical appliances than transient tenants, such as those in a bed-and-breakfast facility.

Open Flames

Sources of open flames in lodging or rooming houses include candles and fireplaces. The National Candle Association recommends that candles never be left unattended. Many bed-and-breakfast owners have instituted policies that prohibit the use of candles in the guest rooms or have replaced them with battery-operated candles. Battery-operated candles can actually flicker and appear very realistic, thus providing the desired ambiance without the danger.

Cooking Equipment

The presence of individual cooking facilities changes the type of occupancy, typically to an apartment building. However, a central kitchen is sometimes found in lodging or rooming house occupancies. The leading cause of fire incidents in U.S. lodging and room houses from 1999 to 2002 was cooking equipment, which resulted in 16 civilian injuries and $0.9 million in direct property damage.[1] Central kitchens are typically only accessible to staff. Cooking equipment in such central kitchens should be protected in accordance with NFPA 96, *Standard for Ventilation Control and Fire Protection of Commercial Cooking Operations.*

Fireplaces

Wood-burning fireplaces are common in bed-and-breakfast properties and are typically used more often than in private residences. Annual cleaning and inspection of the flue can prevent the buildup of flammable creosote and reveal defects in the flue or blockage, such as a nest.

Occupancy Conversion or Remodeling

Fire hazards may be inadvertently created during conversion or remodeling. Existing wall and ceiling finishes might be removed, exposing combustible structural components. Concealed combustible spaces may be created by installing drop ceilings and new wall finishes. Concealed combustible spaces can permit rapid fire development and spread and limit accessibility for fire fighting. The wall and ceiling finishes in new facilities are limited to Class A, B, or C as defined in NFPA *101* and *NFPA 5000*; however, wall and ceiling finish materials can exceed these limitations and significantly increase fire spread and smoke generation in existing buildings.

MEANS OF ESCAPE

In lodging or rooming houses, the egress system consists of means of escape, which, by definition, is a way out of a building or structure that does not conform to the strict definition of means of egress but does provide a safe way out.

Sleeping rooms and living areas above and below grade are required to have a primary and secondary means of escape, one of which must be either an enclosed interior stairway, an exterior stairway, a horizontal exit, or an existing fire escape. The primary means of escape must provide a safe path of travel from the building, one that does not expose occupants to an unprotected vertical opening, except in completely sprinklered buildings of three stories or fewer (Figures 20.5.1, 20.5.2, and 20.5.3). In buildings protected throughout by automatic sprinklers, secondary means of escape are not required.

The example in Figure 20.5.1 shows an enclosed interior stairway that discharges directly outside. Access to the interior stairway is by an interior corridor that is not exposed to an unprotected vertical opening. The secondary means of escape could be through windows of sufficient size to provide egress. The bottom of the stairway can be enclosed several ways; this is only one example. In the example of means of escape shown

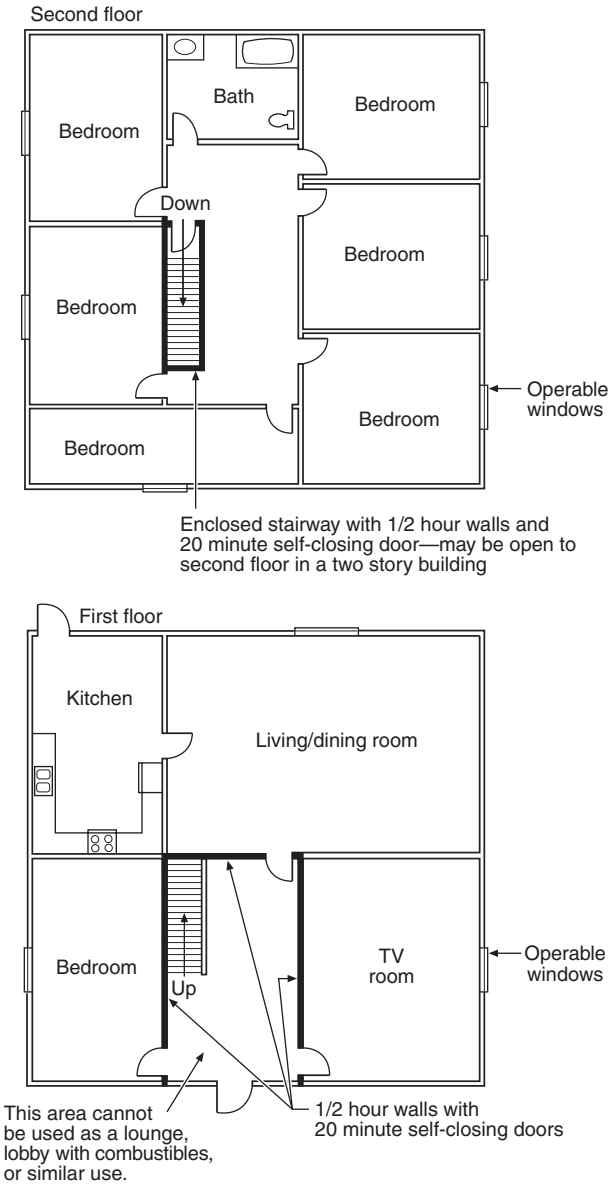

FIGURE 20.5.1 Means of Escape from a Lodging or Rooming House Using an Interior Stairway

in Figure 20.5.2, the tenants reach the exterior stairway via an interior corridor that is not exposed to an unprotected vertical opening. The secondary means of escape is through windows.

In the example shown in Figure 20.5.3, access is not through an interior corridor, and the secondary means of escape is through the open interior stairway.

The specified means of escape should meet the requirements of NFPA *101* and *NFPA 5000*. Detailed requirements for secondary means of escape are provided in NFPA *101* and *NFPA 5000*; they include either a door or stairway that provides unobstructed travel to the outside of the building at street or ground level or an outside operable window located not more than 20 ft (6.1 m) above the ground. Note that a secondary means of escape is not required where the room has a door leading directly

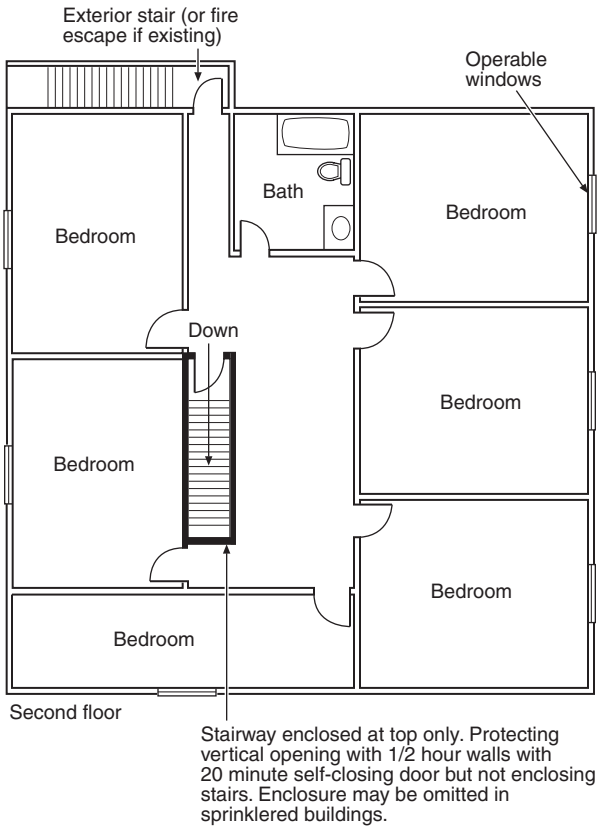

FIGURE 20.5.2 Means of Escape from a Lodging or Rooming House Using an Exterior Stairway

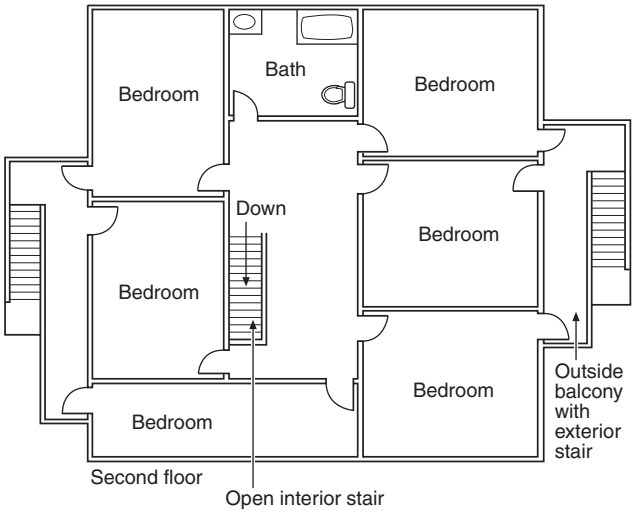

FIGURE 20.5.3 Means of Escape from a Lodging or Rooming House Using an Outside Stairway with Exterior Exit Access

outside at grade level or to an approved outside stair. No required means of escape may be routed through an area that is not under the control of the occupant who is leaving the building or be routed through a door that may be locked.

PASSIVE FIRE PROTECTION

Fire Doors

The installation of automatic or self-closing doors is an effective, relatively low-cost, and easy-to-maintain life safety feature. Fire-rated doors can help to confine a fire to the room of origin. Fire doors must not be blocked or otherwise secured in the open position, and they must positively latch when closed. See NFPA 80, *Standard for Fire Doors and Other Opening Protectives,* for details on the installation of fire doors.

Lack of Fire Blocking

Many older buildings lack fire blocking in walls and ceilings due to the lack of a building code or its enforcement at the time of construction. Such a lack of fire blocking, sometimes referred to as "balloon construction," can accommodate rapid, undetected spread of fire and smoke.

Separation of Sleeping Rooms

Sleeping rooms should be separated from corridors by smoke-resistant walls and self-closing doors. This feature helps prevent smoke from compromising the egress corridors in case of a fire in a room. In addition, if the corridor becomes smoke-logged before all occupants can escape, the smoke-resistant separation will allow occupants to remain within the room for a limited period of time.

Vertical Openings

Vertical openings, or "holes" in the floor that connect two or more contiguous stories, are not limited to stairs. They include shafts, floor penetrations for air ducts, heat grates, and other old floor openings that were never covered. Each represents a path for vertical fire and smoke spread. Unprotected vertical openings have been identified as significant contributing factors in many fatal fires.

CASE STUDY: Small Inn Fire. The fire that broke out on July 17, 2001, in a small inn in Allentown, New Hampshire, demonstrates how the lack of some of the passive fire protection measures mentioned in this section can result in tragedy. A three-alarm fire killed the innkeeper and destroyed the historic building that dated from 1760. Of the six guests who were occupying the premises, all survived, three by climbing to the roof of a portico. The NFPA fire investigation and analysis[2] revealed that the following played a significant role in the incident:

- There was only a single path of escape from the attic bedroom.

- No fire alarms or smoke detectors were functioning.
- There were unprotected vertical openings.

ACTIVE FIRE PROTECTION SYSTEMS AND EQUIPMENT

Detection and Alarm Systems

Detection and alarm systems in lodging or rooming houses play a critical role in the early warning and evacuation of occupants. A manual fire alarm system should be installed in accordance with *NFPA 72®, National Fire Alarm Code®*.

Smoke alarms installed in accordance with *NFPA 72* and powered by the building electrical service are required on each floor, including basements, but excluding crawl spaces and unfinished attics. When activated, the smoke alarms should be audible in all areas. This requirement can be satisfied by interconnecting smoke alarms with the manual fire alarm system. In addition to smoke alarms in the corridors on each level, a single-station smoke alarm powered by the building electrical system is required in each sleeping room to alert the occupant to a fire or smoke in the room. It is critical that the fire alarm system be audible in all sleeping rooms.

Automatic Sprinkler Protection

Automatic sprinkler systems are designed to operate during the early stages of fire development and minimize the fire's overall impact. If the room of fire origin is provided with a sprinkler system, flashover should be prevented, thus improving the opportunity to escape or be rescued and minimizing property damage. NFPA *101* and *NFPA 5000* require most new lodging or rooming houses to be protected by automatic sprinklers. Modifications to other requirements are permitted where sprinklers have been installed. In existing buildings, where automatic sprinkler protection is provided, the following code modifications are permitted:

- The lodging or rooming house is permitted to be located above another occupancy type.
- No secondary means of escape is required.
- It may be permissible for the primary escape stairway to remain unenclosed if each bedroom and living area has a secondary means of escape.

NFPA *101* and *NFPA 5000* recognize three standards for the installation of automatic sprinkler systems in lodging or rooming houses. For small, one- and two-family residences in which boarders are housed and rooming houses that are not part of a mixed occupancy, NFPA 13D, *Standard for the Installation of Sprinkler Systems in One- and Two-Family Dwellings and Manufactured Homes,* permits a simple, lower-cost system. For larger buildings of up to four stories in height, NFPA 13R, *Standard for the Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height,* may be used. For large buildings, especially those housing multiple occupancies, NFPA 13, *Standard for the Installation of Sprinkler Systems,* is the appropriate installation standard. Successful testing of water mist suppression systems in residential properties may offer a desirable protection strategy to owners of historic bed-and-breakfast occupancies containing irreplaceable antique contents and furnishings.

Staff Emergency Training

By combining the recognition of individual responsibilities to report fire-related hazards and how to initiate the appropriate actions should a fire occur, the risks to employees and the workplace can be reduced. Staff should be familiar with their responsibilities in the event of a fire including guiding guests or tenants in proper evacuation. NFPA *101* fire drill requirements for dormitories call for them to take place often enough so that the occupants are familiar with the emergency procedures, evacuation routes, alarm operation, and tone. In hotels, where guests are transient and may only be there for one night, the staff must be trained and prepared to assist the guests in the event of an incident. Although these code requirements do not directly apply to lodging or rooming house occupancies, the concepts can be readily applied to them to enhance a facility's life safety program.

SUMMARY

Lodging or rooming houses are defined as facilities providing sleeping accommodations without separate cooking facilities for up to 16 persons who are capable of self-preservation. Fire spread in these occupancies can be rapid due to lack of firestopping, unprotected vertical openings, storage of combustible materials, and the lack of automatic sprinkler protection. Primary fire hazards include electrical and other building service equipment, supplemental heating devices, smoking, and cooking.

Fire and life safety protection involves providing adequate means of escape, detection and alarm systems, bedrooms that are separated from corridors by smoke-resistant walls and self-closing doors, and automatic sprinkler systems.

Chapter 6

One- and Two-Family Dwellings

James K. Lathrop

Chapter Contents

Importance of Evacuation
Fire and Life Safety Hazards
Prevention of Fire Ignition

Key Terms

dwelling, evacuation, fire prevention, heating equipment, residential sprinkler system, smoking materials

One- and two-family dwellings are defined as residential structures in which not more than two families reside. These dwelling units may be attached to or detached from one another, and typical styles include detached single-family dwellings, townhouses, and duplexes. There are many different designs, such as the one-story ranch, two-story colonial, split-level, and three-level townhouse. Wood frame and masonry are the most common construction types.

In 2003, 70 percent of all housing units occupied year-round were single-family detached or attached units, and another 6 percent were manufactured housing. The figures for seasonal housing were comparable at 63 percent and 23 percent. Two-family houses were not tabulated separately, but housing units in buildings with two to four housing units accounted for another 8 percent of the total year-round housing and 3 percent of the total seasonal housing. Therefore, one- and two-family housing accounts for 75 to 84 percent of all housing in the United States. This total has not changed since the last edition of the *Fire Protection Handbook.*

Each year, the majority of all U.S. fire deaths occur in one- and two-family dwellings. During 1999–2002, 94 percent of the civilian structure fire deaths occurred in the home and 83 percent of those occurred in one- and two-family dwellings, a share comparable to their share of all housing units. Thus, it is important to consider every element of fire safety for its potential value in this setting. Unless otherwise indicated, all data contained in this chapter come from *Selections from U.S. Fires in Selected Occupancies—Homes,* by Marty Ahrens, NFPA Fire Analysis and Research Division, NFPA, March 2006.

NFPA *101*®, *Life Safety Code*®, and *NFPA 5000*®, *Building Construction and Safety Code*®, include requirements for one- and two-family dwellings. In particular, NFPA *101* addresses the need for two means of escape from every room for occupant evacuation; the selection of interior finish materials to prevent rapid early fire growth and spread and to protect occupant evacuation routes; and smoke alarms to provide early warning. Beginning with the 2006 edition of NFPA *101,* all new one- and two-family dwellings require sprinkler protection.

See also Section 4, Chapter 5, "Strategies for Occupant Evacuation during Emergencies"; Section 14, Chapter 6, "Household Fire Warning Equipment"; and Section 16, Chapter 6, "Residential Sprinkler Systems."

IMPORTANCE OF EVACUATION

The philosophy of life safety and fire protection for one- and two-family dwellings is based on evacuation of the building in the event of a fire. The defend-in-place concept used in other types of occupancies, which relies on fixed fire protection systems and fire-resistant construction, does not lend itself to one- and two-family dwellings. To allow residents time to evacuate, they must be alerted to a fire that has been detected at the incipient stage, they must know what action to take, and they must have adequate means of escape. Even with residential sprinkler systems, ocupants need to evacuate. NFPA 13D, *Standard for the Installation of Sprinkler Systems in One- and Two-Family*

James K. Lathrop is vice-president of Koffel Associates, Inc., and a fellow of the Society of Fire Protection Engineers. He is also assistant chief of the Niantic, Connecticut, fire department.

Dwellings and Manufactured Homes, permits a limited water supply, so defending in place is not an option in most cases.

Proper installation and use of smoke alarms can accomplish early warning. *NFPA 72®, National Fire Alarm Code®*, recommends smoke alarms be installed in all sleeping rooms, outside of each separate sleeping area, in the immediate vicinity of the sleeping rooms, and on each additional story of the dwelling including basements. Additional information on smoke alarms can be found in Section 14, Chapter 6, "Household Fire Warning Equipment."

Means of Escape

After the occupants have been alerted, they must promptly evacuate. A written fire escape plan should be made for each dwelling, showing two means of escape from every habitable room, especially the bedrooms, and this plan should be practiced by the entire family. Programs such as NFPA's Exit Drills in The Home (EDITH) explain how to write and practice a home fire escape plan.

Adequate means of escape from each room should be provided in accordance with the requirements of NFPA *101* and *NFPA 5000.* Two means of escape are required from each room. One must be a door or stairway, and the second way can be an operable window. Figure 20.6.1 illustrates means of escape from a three-bedroom single-family home. The bedroom in the upper left has no window, but it has a door directly to the outside. The alternate means of escape from the other bedroom is through windows and must comply with the requirements of NFPA *101* and *NFPA 5000.* Figure 20.6.2 shows the minimum

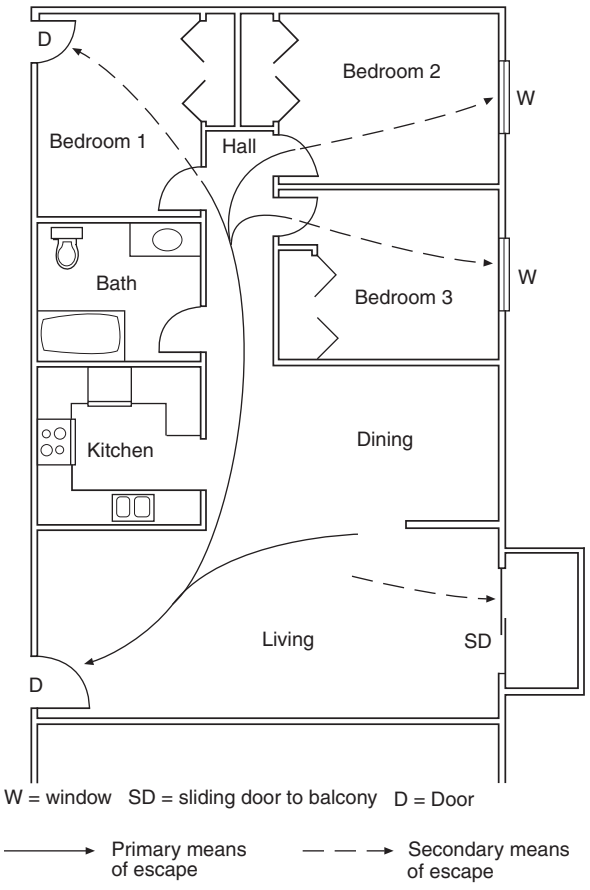

FIGURE 20.6.1 Means of Escape from Single-Family Home

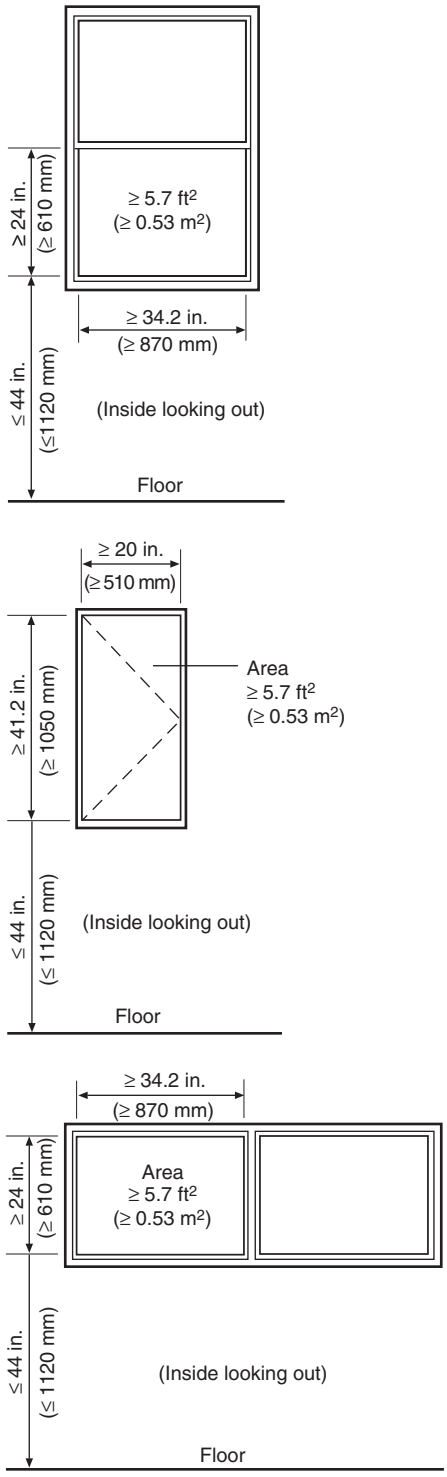

FIGURE 20.6.2 Escape Window Minimum Opening Dimensions

size and dimensions of outside windows used as a second means of escape.

Adequate means of escape also involves eliminating obstacles created by some security provisions. Escape may be slowed—possibly more than safe escape allows—by security measures like double-cylinder locks, which require a key to open from inside. Escape may be totally obstructed by security measures, either designed (such as burglar bars) or makeshift (such as nailing windows shut).

Residential Sprinklers

Residential-type automatic sprinkler systems provide a high degree of protection for one- and two-family dwellings. A growing number of communities require sprinklers in all new dwellings, as does the 2006 edition of the *Life Safety Code*. Even where they are not required, sprinklers are a valuable and effective fire safety choice. In any property, sprinklers reduce the chances of dying if fire occurs and the average property loss per fire by one-half to two-thirds. From 1994 through 1998 automatic suppression systems, usually sprinklers, were present in 1 percent of one- and two-family dwelling fires, 7 percent of the apartment fires, and in 2 percent of reported home fires overall. The fire death rate per 1000 fires was 77 percent lower and the average loss per fire was 85 percent lower in fires in which this equipment was present. Additional information on sprinkler systems in one- and two-family dwellings can be found in Section 16, Chapter 6, "Residential Sprinkler Systems."

FIRE AND LIFE SAFETY HAZARDS

Many other fire protection strategies are under discussion, but they have not yet been reduced to codes or regulations. These address the contribution of various types of contents, furnishings, and construction elements to fire growth, smoke and gas generation, and confinement after a fire begins.

Most fire fatalities in one- and two-family dwellings are a result of smoke inhalation, not burns, and most victims die in a room that is not the room of fire origin. In other words, they die as a result of a fire that has produced enough smoke to spread beyond the room in which the fire began. Prevention and early action are needed to control the development of these lethal conditions.

When studying fire data in one- and two-family dwellings, it is very important to understand that the statistics are significantly different between numbers of fires and numbers of fatal fires. For example the leading cause of fires in one- and two-family dwellings is cooking equipment, but by far the leading cause of fatal fires in dwellings is smoking materials. Table 20.6.1 demonstrates these differences.

TABLE 20.6.1 Leading Causes of Structure Fires in One- and Two-Family Dwellings, 1999–2002 Annual Averages

Cause	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*	
Cooking equipment fire	63,400	(23%)	220	(9%)	2570	(24%)	357	(8%)
Identified cooking equipment	45,800	(16%)	220	(9%)	2300	(22%)	350	(8%)
Confined cooking fire	17,600	(6%)	0	(0%)	280	(3%)	7	(0%)
Heating equipment	48,900	(17%)	300	(12%)	1090	(10%)	571	(13%)
Identified heating equipment	36,100	(13%)	300	(12%)	1060	(10%)	563	(13%)
Confined chimney or flue fire	10,400	(4%)	0	(0%)	10	(0%)	7	(0%)
Confined fuel burner or boiler malfunction or fire	2,500	(1%)	0	(0%)	10	(0%)	1	(0%)
Electrical distribution or lighting equipment	27,900	(10%)	200	(8%)	770	(7%)	577	(14%)
Intentional	25,500	(9%)	410	(17%)	850	(8%)	515	(12%)
Smoking material	16,400	(6%)	640	(26%)	1150	(11%)	307	(7%)
Candle	14,400	(5%)	130	(5%)	1230	(12%)	304	(7%)
Exposure to other fire	11,800	(4%)	20	(1%)	70	(1%)	161	(4%)
Clothes dryer or washer	11,200	(4%)	10	(1%)	240	(2%)	90	(2%)
Playing with heat source	10,200	(4%)	180	(7%)	940	(9%)	175	(4%)

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest hundred, civilian deaths and injuries are rounded to the nearest ten, and direct property damage is rounded to the nearest million dollars. Property damage has not been adjusted for inflation.

PREVENTION OF FIRE IGNITION

Leading Causes of Fire Fatalities

The leading cause of fire deaths in one- and two-family dwellings is smoking materials or lighted tobacco products (Tables 20.6.2 and 20.6.3). Fatal smoking material fires most often involve the ignition of upholstered furniture, mattresses, or bedding, which also rank highest as combustible items first ignited in all kinds of fatal fires. Because it is not unusual for a fire to smolder for hours before it progresses to open burning, many of these fatal fires occur at night when everyone is asleep. Although smoking material is the leading cause of fatal one- and two-family dwelling fires, it is fifth in list of causes of the total number of fires in one- and two-family dwellings.

A major change from the last edition of the *Fire Protection Handbook* is that intentional fires have moved to the second leading cause of fatal fires in one- and two-family dwellings. These fires previously ranked third. Intentional fires rank fourth as the cause of all fires in one- and two-family dwellings.

The third-ranking cause of fire deaths in one- and two-family homes is heating equipment. Heating equipment was also the second leading cause of fires. Heating equipment includes fixed or portable space heaters, chimneys, central heating units, fireplaces, and water heaters. Each type of heating appliance has its own rules for safe installation, maintenance, and use. NFPA 211, *Standard for Chimneys, Fireplaces, Vents, and Solid Fuel-Burning Appliances,* in particular, covers solid-fueled appliances. Maintaining adequate clearance to combustibles, whether fixed (e.g., walls and structural members) or moveable (e.g., furniture, bedding, and clothing), is a common problem for all types of portable and area heating equipment. Safe fueling practices are especially important for liquid-fueled units, as is adequate venting for gas-fueled units and regular inspection and cleaning for solid-fueled units.

Electrical distribution equipment ranked a very close fifth as a cause of fire deaths. Many people mistakenly believe that electrical system fires represent a larger share of fires, but the widespread and long-term use of NFPA 70, *National Electrical Code®*, has reduced them to a lower-order problem, usually involving some kind of failure to observe the code. Electrical distribution equipment fires can take many forms. Damaged components, such as frayed cords, broken switches, or plugs; bypassed protection systems, such as oversized fuses or pennies in place of fuses; overloaded cords, circuits, or outlets; and cords run through traffic areas or pinned by furniture, are all potential problems. Knowledgeable, experienced people should always perform repairs and modifications in strict accordance with applicable codes.

Cooking equipment ranked fifth as a cause of fire deaths but first in fires and fire injuries. Such equipment also accounts for a majority of unreported fires, which injure tens of thousands. Unattended cooking is a principal cause. Others include combustibles, such as rags, pot holders, or bags, placed too close to heat; failure to clean stove tops and ovens; and overhanging curtains, drapes, or clothing.

The sixth leading cause of fire deaths in one- and two-family dwellings was "playing with heat source, usually matches or

TABLE 20.6.2 Leading Causes of Structure Fires Resulting in Civilian Fire Deaths in One- and Two-Family Dwellings, 1999–2002 Annual Averages

Cause	*Fires*		*Civilian Deaths*	
Smoking material	16,400	(6%)	640	(26%)
Intentional	25,500	(9%)	410	(17%)

TABLE 20.6.4 Structure Fires in One- and Two-Family Dwellings by Area of Origin, 1999–2002 Annual Averages

Area of Origin	*Civilian Deaths*		*Fires*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*	
Common room, living room, family room, lounge, or den	730	(30%)	18,900	(7%)	1,340	(13%)	481	(11%)
Bedroom	590	(24%)	34,800	(12%)	2,700	(25%)	702	(16%)
Kitchen or cooking area	390	(16%)	59,200	(21%)	2,850	(27%)	561	(13%)
Unclassified function area	100	(4%)	3,600	(1%)	240	(2%)	87	(2%)
Unclassified structural area	70	(3%)	4,600	(2%)	140	(1%)	106	(2%)
Garage or vehicle storage area	40	(2%)	9,600	(3%)	330	(3%)	304	(7%)
Crawl space or substructure space	40	(2%)	7,800	(3%)	240	(2%)	186	(4%)
Unclassified	40	(2%)	4,000	(1%)	110	(1%)	125	(3%)
Dining room, bar, or beverage area	40	(2%)	2,000	(1%)	120	(1%)	48	(1%)
Other known area	410	(15%)	137,100	(49%)	2,530	(25%)	1667	(41%)
Total	2450	(100%)	281,600	(100%)	10,600	(100%)	4267	(100%)

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest hundred, civilian deaths and injuries are rounded to the nearest ten, and direct property damage is rounded to the nearest million dollars. Property damage has not been adjusted for inflation. Nonconfined and noncontained structure fires in which the area of origin was unknown or not reported have been allocated proportionally among fires with known area of origin. Totals may not equal sums due to rounding errors.

Source: NFIRS and NFPA survey.

lighters." Children playing with fire also is the leading cause of fire deaths for children under age 6. Children must be monitored closely and taught at an early age that matches and lighters are tools for adults, not toys. These fire deaths have dropped sharply since the Consumer Product Safety Commission adopted regulations requiring butane lighters manufactured in the United States to be child-resistant in mid-1994. Matches and lighters must be kept out of the reach and sight of young children.

Location of Fire Fatalities

Nearly three-fourths of all fatal fires in one- and two-family dwellings begin in living rooms, family rooms, or dens; bedrooms; or kitchens (Table 20.6.4). These areas are also the leading areas for fires, injuries, and direct property damage. The number of one- and two-family dwelling fires has decreased over the last couple of decades as has the number of civilian deaths. This is seen in Table 20.6.5. However, the decrease appears to be leveling off, which indicates that we cannot sit back, but must be aggressive in attacking this problem

SUMMARY

The majority of U.S. fire deaths occur in one- and two-family dwellings, the most common form of housing in the United

States. Fatalities are most often the result of smoke inhalation rather than burns. The requirements for one- and two-family dwellings are covered by NFPA *101* and *NFPA 5000*, which address the need for two means of escape from every room for occupant evacuation; the selection of interior finish materials to prevent rapid early fire growth and spread and to protect occupant evacuation routes; and smoke alarms to provide early warning. In new construction sprinkler protection must be installed, and it is also encouraged in existing homes. A written evacuation plan, adequate means of escape, and properly installed and functioning smoke alarms are critical to life safety. In recent years, residential-type automatic sprinkler systems have proved an effective means of fire suppression. Fire prevention measures should be taken to avoid ignition in the home. The most common sources of ignition of fatal fires in one- and two-family dwellings are smoking material, arson, heating equipment, cooking equipment, electrical equipment, children playing with heat sources, and candles.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on one- and two-family dwellings discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 13D, *Standard for the Installation of Sprinkler Systems in One- and Two-Family Dwellings and Manufactured Homes*

NFPA 13R, *Standard for the Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height*

NFPA 70, *National Electrical Code®*

NFPA 72®, National Fire Alarm Code®

NFPA *101®, Life Safety Code®*

NFPA 211, *Standard for Chimneys, Fireplaces, Vents, and Solid Fuel-Burning Appliances*

NFPA 5000®, Building Construction and Safety Code®

Background on Manufactured Housing
Manufactured Housing Standards
HUD Code Requirements
NFPA Requirements

Key Terms

HUD *Manufactured Home Construction and Safety Standards,* manufactured home, manufactured home construction, manufactured home safety, manufactured home site, manufactured housing, oil-burning equipment, residential fire sprinkler systems, smoke alarms

Manufactured homes represent an important and affordable housing option for over 22 million people in the United States. By 2000 an estimated 10.5 million units made up the manufactured housing inventory, including those used year-round, either occupied or vacant, and used seasonally.[1] (The U.S. Census Bureau reported a lower figure of 8.9 million total units and a lower population served, apparently because of differences in definitions and labeling rules.[2]) During 2000, newly placed manufactured homes accounted for almost 23 percent (280,900 units) of the combined total of new privately owned (site-built) one-family houses completed and manufactured homes placed for residential use (1,242,000 total combined units). This share for manufactured homes represented an increase of over 17 percent in 1990, a recent low point in manufactured home placements, and roughly the same as 20 percent in 1980.[3]

Manufactured homes are getting larger. In 2000, some 70 percent of the 250,419 manufactured homes shipped were multisection units, and the remaining 30 percent were smaller single-section homes. The share of multisection units was just under 50 percent in 1991. Further, on an average square foot basis, multisection manufactured homes are becoming comparable in size to site-built homes. For example, in 2001 the average square footage of a multisection home was 1695 ft^2 (157.5 m^2), which was 74 percent of the average site-built home at 2282 ft^2 (212.0 m^2).[1,4]

Most new manufactured homes (68 percent) are located on private property with the remainder located in manufactured home communities. Manufactured homes are predominantly located in rural areas with a concentration in the southern regions of the United States. In 1997, 44 percent of manufactured homes were located in rural areas compared to 20 percent of detached single-family dwellings. Also, during 1997, over one-half of all occupied manufactured homes were located in the South compared to 37 percent of occupied single-family dwellings. During 1993, the five states receiving the greatest percentage of new manufactured homes were North Carolina, Texas, Florida, Georgia, and South Carolina.[5–8]

This chapter covers manufactured homes and their construction, fire safety features, installation, and associated utilities. The development of the HUD *Manufactured Home Construction and Safety Standards, 24 CFR, Part 3280* (HUD Code), which governs manufactured home construction in the United States, is discussed. The recent developments of NFPA standards, such as NFPA 501, *Standard on Manufactured Housing,* and NFPA 225, *Model Manufactured Home Installation Standard,* are addressed. Related manufactured home fire experience is also addressed.

See also Section 20, Chapter 6, "One- and Two-Family Dwellings."

BACKGROUND ON MANUFACTURED HOUSING

Manufactured Home Defined

Amendments made in 1980 to the National Manufactured Housing Construction and Safety Standards Act of 1974 changed the definition of manufactured homes from "mobile" to "manufactured." Manufactured homes in the United States are built in accordance with the federal HUD Code,

Kirsten M. Paoletti is a fire protection and code consultant with Robson Woese, Inc., in Albany, New York. She is a former instructor for NFPA's Life Safety Code seminar and served as NFPA staff liaison for the Technical Committee on Fire Safety for Manufactured Housing.

which preempts state and local building codes. Manufactured homes are factory-assembled structures that can be transported in one or more sections. Sections are typically 8 ft (2.5 m) or more wide and 40 to 80 ft (12.2 to 24.4 m) long, each built on a permanent chassis. When assembled on site for occupancy as a dwelling, manufactured homes are connected to required utilities and placed on stabilizing devices, which may be piers and footings, or a permanent foundation. Manufactured homes are constructed in sections. A single-wide home is one that is made up of a single, transportable section. A multiwide home is one that is made up of two or more transportable sections, typically referred to as double-wide and triple-wide (Figure 20.7.1). The length of a manufactured home is the home's largest overall dimension in the traveling mode including cabinets and other projections that contain interior space. The final length, in terms of the outside dimensions of the living space, is typically 4 ft less than the traveling mode length. Although predominantly single-story structures, the single most important advancement since the late 1990s has been the development of two-story models. With recent innovations in chassis and transportation systems as well as improved architectural compatibility with existing homes in urban/suburban surroundings, multistory models, although still a small percentage of the overall housing market, have gained tremendous consumer interest and will likely translate into increased availability by manufacturers.[9] Figure 20.7.2 illustrates a multistory manufactured home.

HUD Code manufactured homes are not to be confused with modular homes. A modular home is built in a factory in units and transported to a site where the units are joined together on a permanent foundation. It is designed and constructed in accordance with a building code that has been adopted, administered, and enforced by a state or local regulatory agency. Further, some non–HUD Code factory-built, commercial modular units are used as temporary classrooms, construction site offices, or for business uses such as banks or fast-food restaurants. Depending on the application and local authorities having jurisdiction (AHJs), such structures typically must comply with state or local building codes.

FIGURE 20.7.1 Installed Double-Section Manufactured Home

FIGURE 20.7.2 Installed Multistory Manufactured Home (Source: Manufactured Housing Institute)

Manufactured Home Construction

HUD Code manufactured homes consist of four major components or subassemblies: the chassis, floor system, wall system, and roof system.

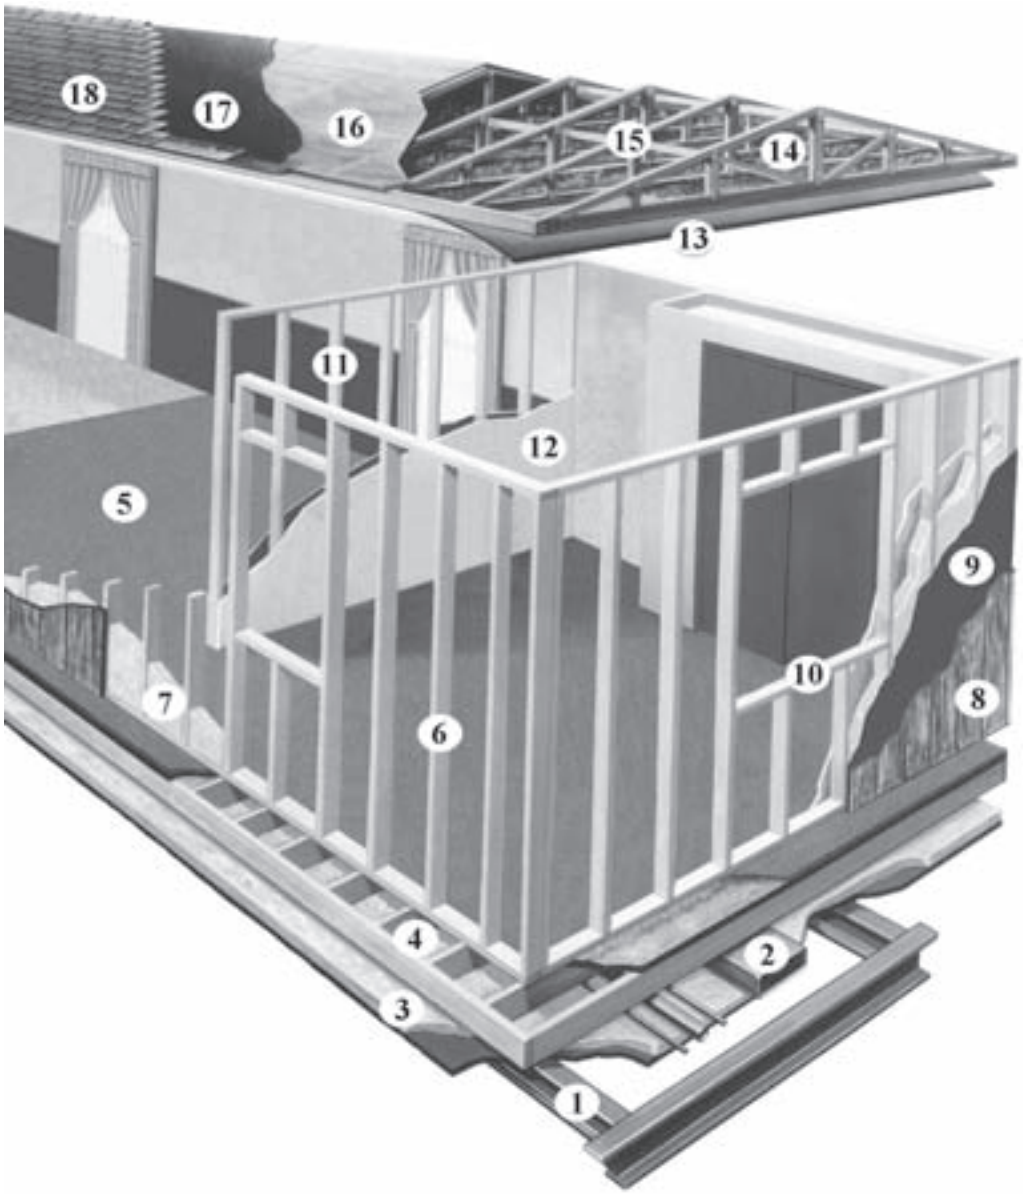
Chassis System. The chassis is the structural base of the manufactured home, which receives all of the vertical loads from the walls, roof, and floor and transfers them to stability devices, which may be piers, footings, or a permanent foundation. The chassis generally consists of two longitudinal steel beams braced by steel cross members. Steel outriggers extending from the outsides of the main beams bring the width of the chassis to the approximate overall width of the superstructure.

Floor System. The floor system consists of its framing members with sheet decking of particleboard, oriented strand board (OSB), or plywood, glued and nailed to the joists; glass fiber insulation blankets or cellulose insulation installed between the joists; and a bottom board material sealing the bottom of the floor. Trunk ducts and piping are often installed longitudinally within the floor system. The floor finish is generally carpeting, resilient flooring, linoleum, or tile.

Wall System. The exterior wall system consists of vinyl, wood, cement board, hardboard, or sometimes metal on wood studs applied over laminated fiberboard, insulative fiberboard, or OSB sheathing. The interior surfaces of exterior walls are most often constructed of gypsum wallboard, and fiberglass insulation blankets provide exterior wall insulation. Interior partitions are most often constructed of gypsum wallboard attached to wood studs.

Roof System. The roof system consists of either the framed wood roof rafter and ceiling joist system or a wood truss system. This roof decking generally consists of oriented strand

board (OSB) or plywood attached to the top of the roof rafters or trusses. The finished roofing is most often composition shingles and infrequently metal without decking. Blown rockwool or cellulose insulation or fiberglass insulation blankets provide the roof insulation. The interior ceiling finish, which consists of gypsum wallboard, is attached directly to the bottom chords of trusses or joists. Steel strapping or brackets are used to reinforce connections between the walls and floor systems and between the walls and roof to make a complete transportable section (Figure 20.7.3).



1. Steel chassis.
2. Heating ducts in floor cavities, normally sized for central air conditioning.
3. Fiberglass or cellulose insulation under the entire floor covered by a bottom board material that acts like a vapor barrier.
4. 2 in. × 6 in. (51 mm × 152 mm) wood floor joists spaced every 16 in. to 24 in. (406 mm to 610 mm). Joists are normally positioned and secured transverse to steel I-beams.
5. Decking of particleboard, oriented strand board (OSB), or plywood, under carpeting or vinyl rolled goods.
6. 2 in. × 6 in. (51 mm × 152 mm) or 2 in. × 4 in. (51 mm × 102 mm) wood studs spaced every 16 in. or 24 in. (406 mm or 610 mm) in exterior walls.
7. Fiberglass insulation in all exterior walls, plus a vapor barrier.
8. Vinyl, wood, hardboard, cement board, or metal exterior siding.
9. Laminated Kraft fiberboard, insulative fiberboard, or OSB.
10. Glass windows with screens. At least one egress window in each bedroom.
11. 2 in. × 4 in. (51 mm × 102 mm) or 2 in. × 3 in. (51 mm × 76 mm) wood studs in the interior walls.
12. Gypsum wallboard for interior wall paneling. Flame spread index shall not exceed 200, except for walls enclosing a furnace or water heater shall not exceed 25.
13. Gypsum wallboard on either cathedral or flat ceilings, flame spread index shall not exceed 75.
14. Fiberglass or cellulose roof insulation, plus a ceiling-area vapor barrier.
15. Load-tested, wood roof-rafter system normally 2 in. × 3 in. (51 mm × 76 mm) chords, for structural strength against wind and snow loads.
16. Plywood or OSB roof decking.
17. Roofing underlayment between shingles and roof decking.
18. Shingled pitched roof.

FIGURE 20.7.3 Typical Manufactured Home Construction Systems and Materials (Source: Champion Home Builders Co.)

HUD Code Manufactured Home Fire Experience

Post–HUD Code homes have much lower fire losses per fire incident compared to pre–HUD Code homes.* From 1989 to 1998, manufactured homes built after 1976 averaged 1.2 civilian fire deaths per 100 fires compared to 2.6 civilian fire deaths per 100 fires for manufactured homes built before 1976. The 54 percent lower fire death rate per 100 fires in post-1976 units was also strengthened by a significantly lower rate of reported fires per 1000 units, although precise calculations are not possible because the census reporting on year of manufacture breaks at 1974–1975 and not at 1976. Manufactured homes built after 1976 also averaged 4.3 civilian fire injuries per 100 fires, 22 percent lower than the 5.5 civilian fire injuries per 100 fires for manufactured homes built before 1976.[10]

Post–HUD Code manufactured home fire incident, death, and injury rates are roughly the same as rates for other one- and two-family, stick-built dwellings relative to the number of occupied units.† Annual average statistics for the 1999–2002 period show that the fire death rate per 100 fires in HUD Code homes was 1.7 compared to 0.8 for one- and two-family dwellings. The fire injury rate was 3.9 per 100 fires in HUD Code homes and 3.8 in one- and two-family dwellings. There were 2.0 fires per 1000 housing units in HUD Code units, lower than the 3.2–3.5 fires per 1000 units in one- and two-family dwellings. HUD Code homes had 3.3 deaths per 100,000 housing units, a slightly higher rate, compared to 2.7–3.0 deaths for one- and two-family stick-built homes. The statistics for deaths and injury rates in pre–HUD Code manufactured homes are significantly higher than one- and two-family dwellings, 2.6 deaths per 100 fires and 5.5 injuries per 100 fires, respectively.[11]

Table 20.7.1, which compares pre– and post–HUD Code fire causes from 1999 to 2002, shows a continued downward shift in the share of electrical distribution and heating system fires in post–HUD Code manufactured homes when compared with statistics from 1989 to 1998. Electrical and heating systems must meet the installation and testing requirements of the HUD Code. Further, furnace and water heater compartments must meet the flame spread and combustibility construction requirements. In both pre– and post–HUD Code homes, occupant-related fire causes comprise a significant share of the total fire causes. These include incendiary or suspicious fires, caused by cooking, smoking materials, children playing, and open flame.

The dramatic difference in the injury and death rates is directly attributable to HUD's uniformly applying and enforcing the fire safety provisions of the HUD Code. Both the mandatory smoke alarm provision and the restrictions on flame spread ratings, throughout the unit and especially around heating and cooking equipment, are major contributors to the effects of the HUD Code. From 1999 to 2002, 45 percent of post-standard manufactured home fires were reported as having no smoke alarms present, a higher percentage than in 1997 and 1998. As noted in the NFPA report *Manufactured Home Fires in the U.S.,* "Because all post-standard manufactured homes are required to be sold with smoke alarms installed, this implies a disturbingly high rate of smoke alarm removal by occupants."[12]

When smoke alarms are not present in post–HUD Code homes, the fire death rate is significantly higher than in HUD Code homes where smoke alarms were recorded as present (1.3 deaths per 100 fires compared to 0.9 deaths per 100 fires). Every HUD Code home must have installed and tested smoke alarms, which are verified at the plant by approved quality control procedures. One study of manufactured home smoke alarm installation and testing practices found that nearly 100 percent of smoke alarms were installed, tested, and left in place at the factory. In a few cases, for special transportation-related reasons, smoke alarms were removed after testing, and reinstallation instructions were provided for those responsible for the setup of the home. In fire incident reports, a home recorded as not having smoke alarms most likely involves the removal of them by some party following the manufacturing process, or the devices were possibly not

TABLE 20.7.1 Structure Fires Reported to U.S. Fire Departments: Pre-Standard and Post-Standard Manufactured Home Fires, by Cause, 1999–2002

Cause	*Pre-Standard Percentage (Pre-1976)*	*Post-Standard Percentage (Post-1976)*
Electrical distribution	17	10
Heating	16	8
Intentional	13	10
Exposure (to other hostile fire)	10	16
Other equipment	9	21
Cooking	9	9
Open flame, candle, or torch	7	7
Appliance, tool, or air conditioning	7	5
Smoking material (i.e., lighted tobacco product)	4	5
Child playing	4	4
Other heat source	3	4
Natural causes	1	1
Total	100	100

Note: These are percentages of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. Only percentages are shown because so few fires have unitage coded after 1998. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Totals may not equal sums because of rounding.

Changes in coding and analysis rules produced some shifts in shares by major cause, beginning in 1999 and growing thereafter. Major changes include (1) movement of unknown-equipment fires from "other equipment" to "unknown," where they are then statistically allocated; and (2) movement of playing fires where firestarter age is not recorded from "child playing" to the category for the heat source, primarily "open flame."

Source: NFIRS and NFPA survey.

*For statistical purposes, post–HUD Code homes refer to manufactured homes built after the year 1976. Pre–HUD Code refers to homes built before 1976.

†For statistical reasons in this data set only, post–HUD Code homes are those built in 1975 and later, and pre–HUD Code homes are those built before 1975.

found during a fire investigation. Nonworking smoke alarms are a concern in manufactured homes and other dwellings. The issue of nonworking smoke alarms was addressed in the Consumer Product Safety Commission's (CPSC) National Smoke Detector Project, which found that power supplies (batteries or ac power) were too often disconnected. The project found that the leading reason for nonoperability of home smoke alarms, when it occurs, is frustration over nuisance alarms, leading to occupants disabling the offending smoke alarms. Home manufacturers typically provide homeowners with the smoke alarm manufacturer's literature, which includes instructions for the inspection and testing of smoke alarms. Some manufacturers also provide additional fire safety information in their homeowner's manuals.[13–16]

The installation of smoke alarms alone is not enough. To ensure reasonable fire safety, homeowners need to practice fire prevention, periodically test and maintain smoke alarms, and develop and practice home escape plans. Clearly, with working smoke alarms and these fire safety practices, the manufactured home fire experience could be further improved.

MANUFACTURED HOUSING STANDARDS

HUD Code Development

Manufactured housing in the United States is built in accordance with the preemptive federal standard, *Manufactured Housing Construction and Safety Standards, 24 CFR, Part 3280* (HUD Code), which is administered by the U.S. Department of Housing and Urban Development (HUD). Effective mid-1976, the HUD Code was based on NFPA 501B, *Standard for Mobile Homes* (ANSI No. A119.1), which was the result of a cooperative NFPA and industry committee project developed under the NFPA consensus codes and standards-making process. In 1979, NFPA 501B was withdrawn following the federal legislation that established the HUD Code. Unique among built structures, the federal preemptive status sets a single construction and performance specification for all manufactured homes that are built in the United States. Neither state nor local jurisdictions can reduce or increase on the federal standards without a great deal of effort to amend the requirements.

In 1997, NFPA reinstituted the standard for manufactured housing as NFPA 501, based in part on the 1977 edition of NFPA 501B and the HUD Code, and it was updated to include current technology. The 1999 edition of NFPA 501 contained significant revisions to the smoke alarm requirements, and it was developed through the NFPA Manufactured Housing project consisting of the Technical Correlating Committee on Manufactured Housing and the six technical committees involved with specific areas of responsibility including administration, electrical, fire safety, mechanical, plumbing, and structural. The current edition of NFPA 501 incorporates significant revisions concerning the installation of smoke alarms; residential sprinkler installation requirements; updated electrical provisions; new heating, cooling, and fuel-burning system requirements; updated plumbing provisions; revised load testing for trusses; and updated referenced standards.

In 1998 HUD selected NFPA to develop proposals for revisions to the HUD Code, and NFPA submitted a proposal to HUD for the revision of smoke alarm requirements to reflect current state-of-the-art smoke alarm technology and installation practices. A notice of the proposed rulemaking, for HUD Code smoke alarm revisions, was published in the May 2000 *Federal Register* and the final rule was published in the March 2002 *Federal Register.* In addition, NFPA has submitted recommendations to HUD for changes to the HUD Code based on the 1997, 1999, 2000, and 2003 editions of NFPA 501.[17]

NFPA 501A, *Standard for Fire Safety Criteria for Manufactured Home Installations, Sites, and Communities,* was prepared by the same technical committees involved with the NFPA Manufactured Housing project. NFPA 501A provides state and local AHJs with the requirements for fire safety at manufactured home sites, including accessory buildings, structures, and communities.

NCSBCS/ANSI A225.1, *American National Standard, Manufactured Home Installations,* was published by the National Conference of States on Building Codes and Standards, Inc. (NCSBCS). In 2001, an agreement was reached between NCSBCS and NFPA that allowed transfer of the ANSI A225.1 standard to NFPA. The 1994 edition of NCSBCS/ANSI A225.1 formed the basis for the first edition of NFPA 225, *Model Manufactured Home Installation Standard*. This document was not only developed to pick up where the previous NCSBCS document left off, but it also became an integral part of providing another option, along with other state-sponsored installation standards, that could potentially be considered by HUD, the ultimate overseer of manufactured homes. NFPA 225, *Model Manufactured Home Installation Standard,* covers the installation of manufactured homes at sites or communities whenever the manufacturer's installation instructions are not available. This document is applicable to new installations of single-section and multisection homes, regardless of whether they are at new or existing manufactured housing sites. The criteria in NFPA 225 are intended to be adopted and enforced by the authority having jurisdiction when an alternative state standard does not exist. In addition to covering the basic administrative criteria, provisions are included for site preparation work, foundations, and procedures during on-site installation/erection, as well as management of appliances and utility connections. Requirements reflecting current design loads and practices associated with seismic, wind, and flood events have been included.

HUD Code and Regulatory Enforcement Program

NFPA standards activity regarding manufactured homes began in 1937 with publication of the first standard in 1940, and the documents have evolved over the years. The 1969 edition of NFPA 501B, ANSI A119.1 and its revisions through 1977, had become the guiding industry construction standard for manufactured homes. For example, the Mobile Home Manufacturers Association (MHMA), which became the Manufactured Housing Institute (MHI), required that its members meet NFPA 501B before the HUD Code became effective in June 1976. NFPA 501B was the basis for the HUD Code. It addressed the unique construction characteristics, or the body and frame design; plumbing systems; heating, cooling, and fuel-burning systems; and electrical systems of transportable homes. By the early 1970s, almost all states adopted the NFPA 501B standard for manufactured homes, and concerned federal agencies, such as

the Federal Housing Administration and the Veterans Administration, used it in connection with home purchases under loan programs they administered.

However, both the manufactured housing industry and the federal government were concerned about the lack of enforcement by states, counties, and cities. To ensure a safe, low-cost form of housing of uniform quality throughout the United States, Congress passed the National Manufactured Housing (formerly Mobile Home) Construction and Safety Standards Act of 1974 (Title VI of the Housing and Community Development Act of 1974). This act established HUD as the sole source of standards governing the construction of these homes in the United States. It gave HUD the authority to establish procedural and enforcement regulations necessary to ensure that makers of manufactured homes uniformly met the construction standards.

HUD fully implemented the act in June 1976, substantially adopting NFPA 501B as the construction standard and naming the NCSBCS as the contract agent for ensuring uniform enforcement. The HUD manufactured housing program requires that manufacturers participate in a system of design approvals and inspections to ensure that a home complies with the HUD Code. The enforcement system includes preproduction design approval, production inspections, and postproduction consumer complaint handling. An independent, third-party design approval primary inspection agency (DAPIA) reviews and approves home designs and the manufacturer's quality assurance manuals. An independent, third-party production inspection primary inspection agency (IPIA) ensures that homes in the plant comply with the design, quality assurance manuals, and the HUD Code. Before production begins, the IPIA conducts a plant certification inspection, and during production, each home is inspected in at least one stage of its construction. During a plant visit, to assure quality control, the IPIA inspects each visible part of each home on the production line. A state with an approved state administrative agency (SAA) may act as the DAPIA or IPIA in that state.[18]

All transportable sections of each manufactured home sold in the United States must bear a HUD certification label, which certifies that the home has been inspected, has passed all of the quality assurance checks, and is in compliance with the HUD Code. These metal labels are attached to the exterior siding of the transportable sections of each home and bear a unique IPIA identification number for each section.

In 1984, some of the HUD Code fire safety provisions were revised following research on means of egress and fire growth and spread issues, conducted by the Center for Fire Research, National Bureau of Standards (NBS), now the National Institute of Standards and Technology (NIST). However, the HUD Code has not kept up with developing fire safety technology. In December 2000, the Manufactured Housing Improvement Act was passed, which provides for a more timely process of establishing new standards, updating the existing standards, and providing comments to HUD on related programs for consumer protection, regulatory enforcement, and similar programs that affect the industry. The act established a federal advisory committee that mostly conducts its business in accordance with ANSI procedures. Since its inception, the advisory committee, generally referred to as the Manufactured Housing Consensus Committee (MHCC), has made numerous recommendations to HUD on ways to keep the HUD Code up-to-date. The act provides a mechanism for HUD adoption and adaptation of requirements from private-sector, consensus standards such as NFPA 501. Also under the act, each state will be required to establish an installation program and a dispute resolution program. The MHCC has provided base guidelines to HUD that can be adopted by each state. Conversely, a state can establish its own program but the criteria must be at least as stringent as the federal criteria.[19]

Approximately 6.6 million manufactured homes have been built under the act. The infusion of safer new manufactured homes into the U.S. housing stock has dramatically affected life safety and fire incidents in manufactured homes built after June 1976.[20]

HUD CODE REQUIREMENTS

HUD Code Fire Safety Provisions

Since 1976, the HUD Code has required that the interior finish be regulated for flame spread characteristics and, in certain areas of the home, for combustibility. Fire blocking is required in concealed wall and partition spaces. At least two exterior doors are required, and they must be arranged to provide a means of unobstructed travel to the outside. The minimum width of doors is specified, as is the ability to operate locking mechanisms without a key from inside to facilitate egress. Each room designed expressly for sleeping, unless it has a door to the outside, must have at least one outside window large enough to permit emergency egress. The window must meet size and location specifications and must be able to be opened without the use of special tools or special knowledge.

In 1979 the Center for Fire Research, National Bureau of Standards (NBS), now NIST, issued a report following four years of fire tests in manufactured homes. The purpose was to provide experimental data on the potential growth and spread of fire in manufactured homes and recommend upgrades in the level of fire protection for kitchen areas and flame spread ratings for interior finishes.* The Center for Fire Research also conducted research and issued reports on emergency egress from manufactured homes. Following these reports, HUD issued the first update to its standard in 1984. HUD lowered the maximum height above the floor of the egress window latch from 60 to 54 in. (1.5 to 1.4 m). More importantly, HUD issued a stricter limit on ceiling interior finish flame spread—to a flame spread index of 75 from 200—and expanded its criteria on kitchen cabinet protection. Other minor changes included further clarification of fire-blocking construction techniques in concealed wall, ceiling, and floor construction; recognition of $^{5}/_{16}$-in. (8-mm) thick gypsum wallboard as fire-blocking material; and clarification of smoke alarm placement instructions.[21–24]

The HUD Code also specifies the minimum construction requirement, thickness, and gauge of the metal ventilating hood

*These NBS (NIST) fire tests of over 25 years ago focused on major fire growth factors understood during the 1970s such as room geometry and combustible interior finish. Based on further NIST research during the 1980s, the role of combustible contents, including heat release rates, was also identified as having a significant influence on the rate of compartment fire growth leading to flashover.

to be installed over a kitchen range. In addition, the HUD Code limits the flame spread of the wall and cabinet finishes in the immediate vicinity of the kitchen range. This combination of requirements effectively negates or minimizes the direct exposure of the wall and cabinet surfaces nearest the kitchen range in the event of a cooking surface fire. Fire experience statistics show that these provisions produce smaller cooking and heating fires in post-1976 manufactured homes and that a much smaller share of such fires spread beyond the room of origin than in pre-1976 units.

HUD Code Utility Provisions

Manufactured homes requiring fuel-gas are required to be equipped with a natural gas piping system that is acceptable for LP-gas. The gas piping system must be designed for a pressure no more than 14 in. (3.4 kPa) water column and no less than 7 in. (1.7 kPa), and manufacturers are required to provide written instructions regarding the design pressure limitations for safe and effective operation. The HUD Code regulates piping materials, routing, sizing, joints, and anchoring. Tubing for gas piping systems cannot be run inside walls, floors, partitions, or roofs, and listed appliance connectors, when used, cannot run through walls, floors, ceilings, or partitions except cabinetry. Shutoff valves must be installed in the gas piping at appliances upstream of unions or connectors. Piping systems are to be tested at specified pressures before and after connection of gas appliances. Gas supply connections cannot be located beneath an exit door. Manufacturers are required to affix a permanent label on the outside of the home at the gas supply connection, providing supply requirements and precautions for installers. For fuel-gas systems the HUD Code references ANSI Z223.1/NFPA 54, *National Fuel Gas Code,* and NFPA 58, *Liquefied Petroleum Gas Code.*

Where oil is used as the heating fuel, there are specific requirements for oil tanks, fill and vent pipes, liquid level gauges, and shutoff valves. Materials for oil piping systems are specified as to size, type of joints, couplings, grading, hangers, and leakage tests. For oil-burning equipment the HUD Code references NFPA 31, *Standard for the Installation of Oil-Burning Equipment.*

A unique feature of the HUD Code concerns the installation of heat-producing appliances. Especially noteworthy is the requirement that all fuel-burning appliances except ranges, ovens, illuminating appliances, clothes dryers, solid fuel-burning fireplaces, and solid fuel-burning fireplace stoves be installed so that the combustion system is completely separate from the home's interior. Combustion air inlets and flue gas outlets must be listed or certified components of the appliance. The required separation may be obtained by installing direct vent systems (sealed combustion systems) or by installing the appliance within an enclosure so its appliance combustion and venting systems are separated from the manufactured home's interior.

No forced-air appliance, or its air return system, can allow the creation of a negative pressure that will affect either its combustion air supply or that of any other appliance, nor can the systems act to mix products of combustion with circulating air. Other requirements for heat-producing appliances include special provisions relating to solid fuel-burning fireplaces or fireplace stoves. The size and air tightness of circulating air duct materials are specified, and the design and combustibility of duct materials are regulated. Special provisions are included for registers and grills and ducts in expandable or multiple transportable section connections.

The HUD Code includes specific requirements for electrical installations. It concentrates on those provisions that differ from provisions applicable to all buildings under NFPA 70, *National Electrical Code®*. Some special features relate to the fact that manufactured homes are factory assembled, to the underchassis wiring requirements, to the wiring of expandable units with multiple transportable sections, to the need to bond metal parts, and to the grounding of services and appliances. For example, regarding electrical hookups at the site, manufacturer's installation instructions typically require a four-conductor service entrance (two hot conductors, a neutral, and a ground conductor); a grounding conductor must also be run from the electrical distribution panel to a grounding rod, and on the distribution side of the electrical system, the neutral bus in the electrical panel must be isolated from the grounding system. The HUD Code and approved quality control procedures require that at the factory the manufactured home electrical system be subjected to a continuity test to ensure metallic parts are properly bonded, an operational test to ensure that appliances are connected and working, and a polarity check to determine if connections have been properly made. Also, a dielectric strength test is conducted at 900 to 1079 V for 1 minute or alternatively at 1080 to 1250 V for 1 second to detect and correct electrical current leakage or short circuits.[25]

NFPA REQUIREMENTS

NFPA 501 Fire Safety Provisions

As discussed previously, NFPA 501 contains provisions impacting fire safety and reflecting state-of-the-art concepts and technology. Of particular note are the sections addressing the installation of smoke alarms and residential sprinklers. The Technical Committee on Fire Safety for Manufactured Housing had previously updated the smoke alarm requirements based on a 1998 research report, *Smoke Alarms in Manufactured Housing,* from the NIST Building and Fire Research Laboratory. These requirements are in harmony with other NFPA codes and standards, including *NFPA 72®, National Fire Alarm Code®,* and NFPA 13D, *Standard for the Installation of Sprinkler Systems in One- and Two-Family Dwellings and Manufactured Homes.*[26]

Smoke Alarms. Smoke alarms must be ac powered or powered by a nonreplaceable, 10 year battery, and they are permitted to be installed on flat ceilings, sloping ceilings, or walls, with specific requirements for each arrangement. Regarding location, smoke alarms are required in all sleeping rooms, outside each sleeping area, and on each additional story of the home. If installed within a 20 ft (6.1 m) horizontal path of a cooking appliance, they must have an alarm-silencing means or be of a photoelectric type. If stairs lead to other occupied levels, smoke alarms must be installed near the top of each stair. Smoke alarms are required to be interconnected so that the operation of one will sound all of the smoke alarms in the home. There are additional requirements for visual notification appliances if they are provided.

Following their installation at the manufactured home factory, smoke alarms must be functionally tested. Recognizing that smoke alarm testing is also a critical responsibility of others after the home leaves the factory, NFPA 501 requires that the home manufacturer provide testing instructions for the setup crews or other installers to use at the site and for the homeowner for periodic testing and maintenance. Further, the home manufacturer is to provide the homeowner with instructions to replace alarms if they fail to respond during tests and to replace smoke alarms after 10 years of service.

Residential Fire Sprinkler Systems. NFPA 501 contains minimum requirements for residential fire sprinkler systems if installed by the home manufacturer. The requirements are voluntary unless the AHJ requires fire sprinklers in all detached one- and two-family dwellings. When fire sprinkler systems are to be provided in the manufactured home, they are to be designed, installed, and tested in accordance with NFPA 13D, and the home manufacturer must affix a certificate adjacent to the home data plate. The certificate is to include information on the residential sprinkler system, such as sprinkler specifications, minimum water supply required, and control valves. The home manufacturer is required to provide setup crews or other installers with instructions for inspection and testing of the system. Further, when the system is connected at the home site, the water supply must be verified and tested, and those data added to the system certificate. The home manufacturer is also required to provide the homeowner with information about the automatic fire sprinkler system's operation, testing, and maintenance.

There are several other important fire safety provisions in NFPA 501, including definitions on interior finish and limited-combustible materials and requirements on the application of foam plastics. Means of egress provisions include design requirements for exterior doors, egress windows from sleeping rooms, and interior passage and room requirements.

NFPA 501 Utility Provisions

NFPA 501 addresses heating, cooling, and fuel-burning equipment installed within or external to a manufactured home and contains specific requirements for the various systems. The following NFPA codes and standards are referenced: ANSI Z223.1/NFPA 54, NFPA 58, NFPA 90B, *Standard for the Installation of Warm Air Heating and Air-Conditioning Systems,* and NFPA 31. Additionally, NFPA 501 contains requirements for electrical conductors and equipment installed within the home and service entrance equipment that connect the home to an electrical supply. In addition to NFPA 501 requirements, NFPA 70 applies to manufactured home electrical systems. It further states that service entrance equipment must be installed in accordance with NFPA 70 and that bonding and grounding of the service must meet NFPA 70 requirements.

NFPA 501A Provisions for Manufactured Home Installations, Sites, and Communities

NFPA 501A covers fire safety requirements for manufactured home installation, home sites, accessory buildings, structures, and communities. A manufactured home site is a parcel of land for one home and its supplemental structures. A manufactured home accessory building or structure is a supplemental structure such as an awning, cabana, garage, carport, or storage building. A community building is a nonresidential building used for manufactured home community purposes.

Fuel storage and supply systems for manufactured home sites and communities must meet the requirements of the referenced NFPA or federal standards, including ANSI Z223.1/NFPA 54, NFPA 58, and NFPA 31. The same requirements also apply to manufactured home community buildings. Electrical service equipment and installations must meet the applicable provisions of NFPA 70.

NFPA 501A includes manufactured home separation requirements for fire safety and requires that fire separation distances comply with local regulations. However, the fire separation distances mandated by *NFPA 5000®*, *Building Construction and Safety Code®*, must be used where local rules or regulations do not exist. Manufactured home installations must follow the printed instructions provided by home manufacturers, including the installation of the support system and utility connections.

NFPA 501A includes fire safety requirements for manufactured home community buildings, including construction, control of outdoor hazards, fire detection and alarm systems, and water supplies for fire protection. The posting of emergency information in conspicuous places is required for manufactured home communities. The standard also contains setback requirements for accessory buildings and exit requirements as well. The appendices of NFPA 501A provide manufactured home community management and manufactured home residents advisory material on fire safety responsibilities and procedures.

SUMMARY

In the United States, manufactured homes, which are factory-assembled structures that can be transported in one or more sections, are built in accordance with the federal HUD Code and NFPA codes and standards. These codes and standards cover many aspects of design, construction, and installations, including body and frame design; plumbing systems; heating, cooling, and fuel-burning systems; electrical systems; and smoke alarms. NFPA 501, *Standard on Manufactured Housing,* contains provisions impacting fire safety and reflecting state-of-the-art concepts and technology.

NFPA 225, *Model Manufactured Home Installation Standard,* addresses provisions for the installation of manufactured homes used as dwelling units. The criteria established by NFPA 225 govern single-section as well as multisection homes and provide requirements for everything from interconnection criteria for multisection homes to anchor provisions to restrict movement from wind loads, seismic events, and floods.

NFPA 501A, *Standard for Fire Safety Criteria for Manufactured Home Installations, Sites, and Communities,* covers fire safety requirements for manufactured home installation, home sites, accessory buildings, structures, and communities. To ensure fire safety, occupants must also practice fire preven-

tion, periodically test and maintain smoke alarms, and develop and practice home escape plans.

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on manufactured housing discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 13D, *Standard for the Installation of Sprinkler Systems in One- and Two-Family Dwellings and Manufactured Homes*
NFPA 31, *Standard for the Installation of Oil-Burning Equipment*
NFPA 54, *National Fuel Gas Code*
NFPA 58, *Liquefied Petroleum Gas Code*
NFPA 70, *National Electrical Code®*
NFPA 90B, *Standard for the Installation of Warm Air Heating and Air Conditioning Systems*
NFPA 225, *Model Manufactured Home Installation Standard*
NFPA 501, *Standard on Manufactured Housing*
NFPA 501A, *Standard for Fire Safety Criteria for Manufactured Home Installations, Sites, and Communities*
NFPA 5000®, Building Construction and Safety Code®

Definition and Background
Fire Loss History
High-Rise Fire Risk
Unique Features of a High-Rise
Code Required Features
High-Rise Issues to Consider

Key Terms

egress, fire department access, fire resistance, high-rise building, National Institute of Standards and Technology (NIST), NFPA High-Rise Building Safety Advisory Committee, performance-based codes, smoke movement, stack effect, World Trade Center

The high-rise building has garnered significant attention in the fire safety world over the years, but perhaps never more so than since 2001. The public; the code bodies; the local, regional and federal governments; and the design, build, and ownership communities are all reviewing high-rise building safety and developing positions regarding the need (or lack of need) for additional protection in those buildings. This chapter describes some of the code provisions and special features of the high-rise building, as well as presenting historical data on high-rise building fires.

See also Section 1, Chapter 7, "Protecting Against Extreme Events"; Section 20, Chapter 1, "Assessing Life Safety in Buildings"; and Section 20, Chapter 3, "Hotels and University Housing."

DEFINITION AND BACKGROUND

High-Rise Building Defined

NFPA *101*®, *Life Safety Code*®, and *NFPA 5000*®, *Building Construction and Safety Code*®, define a high-rise building as a building where the floor of an occupiable story is greater than 75 ft (23 m) above the lowest level of fire department vehicle access. This definition is consistent with most U.S.-based model building codes but is not consistent around the world. Many local authorities having jurisdiction also use varying heights and measurement criteria to determine whether a building is a high-rise, with heights ranging from 40 ft (12 m) to as high as 150 ft (45 m). When evaluating whether a code requires a building to be treated as a high-rise, it is important to review the code, as well as any local amendments, to determine the method of measuring building height and what height threshold is used to define a high-rise.

Code application to high-rise buildings is also inconsistent. For many years, most of the U.S. model building codes limited high-rise provisions to business and residential buildings. NFPA *101* contained provisions for high-rise buildings that varied by occupancy. In 2006, most U.S. codes for high-rise apply to all high-rise buildings except open parking garages and some special use structures. Open parking garages are excluded because of the minimal risk imposed by the open structure.

Background

The original intent of the high-rise building provisions was to provide greater protection in buildings where rescue of occupants via ladders was no longer practicable. The 75 ft (23 m) threshold and the measurement of level of fire department vehicle access to the top occupied floor were intended to track with the maximum height that fire department ladders could reach. Many of the jurisdictions that lowered the threshold did so because their equipment was incapable of reaching such heights.

Extensive high-rise provisions first appeared in U.S. codes in the early 1970s. These provisions contained an option to either sprinkler the building or to separate each floor into 2-hour compartments. If the sprinkler option was chosen, several "construction modifications" were permitted.

James R. Quiter, P.E., FSFPE, leads the consulting practice for Arup in the Americas from the firm's San Francisco office. Arup is a global firm of designers and business consultants with over 7000 employees in over 30 countries. He is also chair of NFPA's Safety to Life Committee and the High Rise Building Safety Advisory Committee.

Over time, most codes have been changed to require automatic sprinklers, yet still allow some of the original "modifications" that were originally permitted.

Many codes outside the United States also address high-rise buildings, and many apply high-rise provisions at a building height of about 75 ft (23 m). Provisions similar to those found in U.S. codes apply in other countries. Codes from outside the United States may include more restrictive criteria, including the number and location of fire fighter lifts (elevators); the number, width, and travel distance to escape stairs; compartmentation requirements; and structural fire resistance. In parts of Asia, buildings over a certain height (often in the 15- to 30-story range) also require one or more open-air refuge floors.

In recent years in the United States, two problematic areas have gradually begun to be addressed. The first is that building codes typically apply to new buildings, yet there is a huge stock of existing buildings, particularly in older cities, to which building code requirements do not apply. Retrofit sprinkler ordinances have been passed in many U.S. cities, often after a local disaster. These retrofit laws are not consistent in the level of protection they require, in the types of buildings to which they apply (that is, office, hotel, apartment, condominium), or in the time allowed to complete the retrofit. NFPA *101* has gradually added to the types of existing high-rise buildings required to have automatic sprinklers, but it is not necessarily applied to all existing buildings. Therefore, the public has no easy way of knowing the level of protection they will be afforded in a high-rise building, particularly as they travel from city to city.

Another series of code changes has occurred more recently. Some codes require additional protection measures in some buildings as they get higher. Few people, when they walk into a 7- to 10-story building, picture that building as a high-rise. Yet the level of protection traditionally required is the same as that required in a 50- or 100-story building down the street. Similarities between two such buildings are that exterior rescue above 75 ft (23 m) is difficult if not impossible (depending on local fire department apparatus and access to the building). However, the dynamics of air movement (and therefore smoke movement), the viability of total evacuation versus staged evacuation, and the level of information needed by occupants and the fire service are clearly different in a very tall building compared to a mid-level (but still "high-rise" building). These ideas are beginning to be addressed in a piecemeal fashion in the codes but often with little technical analysis or evaluation of risk. NFPA has established a High-Rise Building Safety Advisory Committee to try to coordinate and guide the NFPA codes as they adapt to the new high-rise performance expectations of society.

FIRE LOSS HISTORY

The NFPA Fire Analysis and Research Division publishes an annual statistical report on high-rise fire incidents.[1] Table 20.8.1 is shown in five parts and is taken from the 2005 edition of the annual survey, with statistics through 2002. It shows, by year, the number of fires, deaths and injuries, property damage, and percentage of high-rise fires to total fires. Separate parts of Table 20.8.1 show results for apartment buildings, hotels, health care occupancies, offices, and all structures. The tables seem to show that there has been a general trend of improvement in all categories.

Table 20.8.1 reflects fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. Fires are rounded to the nearest hundred, civilian injuries are rounded to the nearest ten, and direct property damage is rounded to the nearest million dollars; civilian deaths are not rounded. Property damage has been adjusted for inflation, using the Consumer Price Index, to 2002 dollars.

Significant High-Rise Fires

Throughout history, there have been many significant high-rise fires. Table 20.8.2 contains a summary of fires occurring from 1911 to 2004 that have resulted in 10 or more deaths. These fire incident reports include only those submitted to and documented by NFPA. Since not all fires are reported to NFPA, the information should not be considered complete.

Since 2000, several events have caused the fire protection community to refocus on whether we are adequately addressing high-rise protection, through mechanisms such as the NFPA High-Rise Building Safety Advisory Committee. Similar committees have been formed by government entities and professional associations around the world.

One of the recent events that has inspired this rethinking was the World Trade Center disaster of September 11, 2001. However, several other significant fires have also occurred.

Recent Events

Cook County Office Building. Chicago had two significant fires in existing high-rise buildings in the early 2000s. The first occurred at 69 West Washington Street in the Cook County office building on October 17, 2003. In this incident, the fire started in a storage room on the 12th floor of a nonsprinklered building. It was able to spread through the suite of origin, and because corridor walls were not full height, it also spread hot smoke and gases into the corridor system. A stair enclosure with a vestibule was located almost directly across the corridor from the area of fire origin. When the fire department responded and opened the doors from the corridor into the stairs, hot smoke and gases flowed into the stairwell. In this building, stairwell doors were locked from the stair side for security purposes, and no automatic or remote unlocking capability was provided. Six occupants, all who were trapped above the 12th floor, died in the stairwell. Those were the only fatalities in this event. The postfire analysis concluded that, if the stair doors had not been locked from the stair side, there would likely have been no fatalities. Similarly, if the building had been sprinklered, it is unlikely that the smoke and gases would have been as hot, as buoyant, or in the same quantities. Therefore, the fatalities (and much of the damage) could have been avoided by the presence of sprinklers. Perhaps the only lesson learned from this fire is that we ought to apply the knowledge that we already know. Sprinklers greatly increase the safety of buildings, and locked stairwells, even from the stair side, create a hazard.

TABLE 20.8.1 High-Rise Building Fire Experience for Selected Property Classes, by Year, 1985–2002 Structure Fires

Year	*Fires*	*Civilian Deaths*	*Civilian Injuries*	Direct Property Damage (in Millions of Dollars) *Current Dollars*	Direct Property Damage (in Millions of Dollars) *2002 Dollars*	*What Percentage of All Apartment Fires Were High-Rise?*

2000	11,300	85	560	34	35
2001	12,300	32	360	64	65
2002	10,900	26	410	31	31

Note: Property damage figures for office buildings are underestimated in several years due to problems in handling some large-loss fires, such as the $325 million One Meridian Plaza fire in Pennsylvania in 1991 and the $230 million World Trade Center incident in 1993, whose more than 1000 injuries also are not properly reflected in national estimates. The events of September 11, 2001, are not reflected in these figures.

[a]Property damage figures for apartments in 1991 are inflated by problems in handling the Oakland wildfire in the estimates.

[b]The "Adjusted Estimates" are calculated using only NFIRS Version 4.1 data to estimate the percent of fires (and losses) that occurred in high-rise buildings. Use Adjusted Estimates for trend analysis, as they are more comparable in approach to pre-1999 data, but for any single year, use the main estimates, which are considered more accurate.

[c]Based on high-rise share of fires in 1995 and 1996, because all deaths were in buildings with unknown height.

Source: *High-Rise Building Fires,* NFPA Fire Analysis and Research Division, p. 5, August 2005. Original data from NFIRS and NFPA survey.

For a discussion of the evacuation from the Cook County office building, see Section 4, Chapter 1, "Human Behavior and Fire."

La Salle Bank Building. The second Chicago fire, on December 6, 2004, occurred at the La Salle Bank Building and had better results. Again it was a fire in a nonsprinklered high-rise building. This building had operable windows, and several occupants went to windows for fresh air. There were no fatalities in this fire although there were 37 injuries. The fire was notable nationally because it closely followed the 69 West Washington Street fire, making it the second significant high-rise fire in the same city in a short period of time. As with 69 West Washington, sprinklers in the building would have greatly reduced the amount of smoke and heat generated and therefore would probably not have required occupants to rely on operable windows for fresh air.

Chicago has since passed a retroactive high-rise sprinkler ordinance and has also outlawed door locks on stairwells, unless there is automatic and remote release.

Parque Central Building. In October 2004, a fire began on the 34th floor of the Parque Central Building in Caracas, Venezuela. This building was a 56-story government office building. The fire did more than $250 million (U.S.) in damage, burning the structure's contents from the 34th to the 50th floor. The building was fully sprinklered; however, the sprinkler system was inoperable. Postfire analysis indicated that had the sprinkler system been active, the fire would have been limited to the floor of

origin. The lesson learned from this fire is that the systems that are provided in buildings should be maintained.

Madrid Office Building. On February 12, 2005, a nighttime fire in a Madrid office building resulted in significant fire and structural damage to the building, but no fatalities. Again, the fire was in a nonsprinklered building, and the results would likely have been very different in a sprinklered building. Therefore, although we may learn from the structural response to this fire, from a life safety point of view, sprinkler protection was likely the first and best protective measure that could have been provided.

Lessons Learned. The lessons learned from these fires are simple. The satisfactory protection of the structure, maintaining the integrity of the egress systems, and the compartmentation of high-rise buildings must be ensured. That is not enough, however. All high-rise buildings should be protected by automatic sprinklers; if they were, they would be significantly safer. It is recognized that there is no simple means of sprinklering existing high-rise buildings. Therefore, means to encourage sprinkler protection in those buildings, such as tax incentives on capital improvements and extended times for installation, need to be factored into the process of requiring automatic sprinklers. However, until such sprinklers are required, there is the risk of significant fire and risk to life safety in our stock of nonsprinklered high-rise buildings.

The World Trade Center

Much has been written and discussed about the World Trade Center (WTC) events of September 11, 2001. This chapter can-

not address the event in any level of depth, given that the National Institute of Standards and Technology (NIST) has written reports totaling over 10,000 pages for WTC 1 and 2 and will have more to say about WTC 7. Neither of the NIST reports addresses all the fire protection design issues that must be considered. Before discussing the NIST recommendations, there are a couple of thoughts or concepts that bear serious consideration.

The first question is whether the incident involving WTC 1 and 2 is an event that should be considered in high-rise building design. Other questions include whether all buildings, or a subset of landmark buildings, are going to be designed to defend against terrorist threats and hostile acts. If so, which threats? What will this design cost, and can society afford it? Also, if buildings are designed to protect against these extreme events, will day-to-day life become more difficult, or will our reaction to more typical or equally severe but unusual threats become more hazardous? For instance, if we decide to fully evacuate all high-rise buildings for all events, will we end up with more injuries and deaths than we save?

For example, one common recommendation that has been heard coming out of the event is the need to harden stairwells. What does this mean? How hard should they be made? If they are hardened, what are the results? For instance, if a bomb were detonated in a hardened stairwell, is it better or worse than the traditional stairwell? The bottom line is we cannot react to a single event without understanding that there may be negative implications in the building's response to other events—the theory of unintended consequences. It is a difficult task to apply rigor to our thinking as we respond to events such as security threats that may be very unlikely, impossible to predict, and subject to emotion. If we do not, however, the overall performance of a building may be worsened rather than improved.

A second big question coming out of the WTC disaster is whether we, as a society, are comfortable with the performance of the rest of the WTC complex. There was significant damage to several of the buildings, including the collapse of WTC 7, a 47 story building. Although the ignition was due to the attacks on WTC 1 and 2 and the lack of water for both automatic sprinkler systems and manual fire-fighting efforts was also due to that event, the fuel and fire causing the collapse were all within the WTC 7 building. There may well be lessons to be learned from this event that can extend to typical high-rise buildings.

The NIST Recommendations

In 2005, NIST issued a series of recommendations on the collapse of the World Trade Center Towers.[2] The report included 30 recommendations in eight general groups. This paper does not attempt to address each of those recommendations. However, to gain a feel for the recommendations, the groupings are described as follows:

Group I: Increase Structural Integrity
Group II: Enhanced Fire Resistance of Structures
Group III: New Methods for Fire Resistance Design of Structures
Group IV: Improved Active Fire Protection
Group V: Improved Building Evacuation
Group VI: Improved Emergency Response
Group VII: Improved Procedure and Practices
Group VIII: Education and Training

These recommendations were issued in draft form and many organizations have responded with comments. Many of the recommendations were logical outgrowths of the event, but some others could lead to substantial changes in building design. NIST has offered to work with model code groups in developing code language to respond to these recommendations. Some of the far-reaching recommendations are considered controversial because they may not necessarily spring from the World Trade Center events or because the recommendation seems to stem from an event that occurred only because of the method of attack. Others will lead to long-term improvements in buildings or building operations, or perhaps will spur industry to develop new products. Still other recommendations can be accomplished quite easily with changes in operations or methods.

The NIST reports can be found on the NIST website (http://www.nist.gov or http://wtc.nist.gov). This includes all of the research reports that have led up to the recommendations, as well as the recommendations themselves.

HIGH-RISE FIRE RISK

Why do high-rise buildings require more protection than other buildings? Simply put, the risk of a significant hazardous event is greater than that associated with a non–high-rise building. This is because the number of people exposed is likely greater than normal; the building's floor area is likely greater than normal; the impact of an event is more likely to impact other floors and more people than an event in a large low-rise building; evacuation via building systems will take longer; the dynamics of smoke spread will encourage spread to upper floors; external evacuation is not practical; and a localized structural collapse could impact other portions of the building or of adjacent buildings. While codes do not explicitly define these risks, many of the code provisions do address them. For the designer, it is important that these risks be considered, rather than just assuming that the code has adequately covered them for any specific building.

UNIQUE FEATURES OF A HIGH-RISE

Some of the major issues that make high-rise buildings different from other buildings include fire department access, egress, smoke movement, and fire control.

Fire Department Access

Fire department accessibility, a major issue, takes several forms:

- The limitations of present-day fire apparatus in reaching upper floors from the exterior of the building
- The height of the fire and the number of personnel required to deliver adequate types and amounts of equipment to the fire area. (Due to the possible height of the fire area, equipment transport and force deployment efforts

could exact an exhaustive toll on fire-fighting forces before they can even mount a fire attack. This has a significant impact when available fire fighters and equipment are limited. This condition can also occur in a large low-rise building with the same distance problems as a high-rise, although the elevation difference in a high-rise exaggerates the problem.)

- Inherent delays in deploying equipment. (Delays in deploying equipment and fire fighters can indirectly affect fire growth, thereby resulting in a fire of greater magnitude by the time manual forces are in place to attack.)
- The height and location of a building. (The height and location of a building can further restrict the fire department's ability to approach the area of origin from more advantageous directions. As a result, the fire department may only be able to approach a fire area from below. In many cases where the area of origin has no automatic suppression and compartmentalization, the area of origin may not be approachable at all, resulting in a defensive approach that depends on fuel consumption for control and extinguishment. This approach typically results in a large or unacceptable loss.)
- Communication issues. (Fire department as well as other first responder radio transmitters struggle to work or do not work at all in the confines of a high-rise building. Delays in reporting real-time fire conditions, summoning more help to upper floors, or learning of imminent threats can jeopardize the fireground safety parameters.)

Egress

Egress and people movement systems within a high-rise building also make the building unique. In a low-rise building, it is typical to assume that total evacuation of the building can occur in a relatively short time. In a high-rise, however, full evacuation may take more than an hour. Also, because all occupants are using the same stairs, full evacuation in many circumstances may lead to slower evacuation of those most affected by the event. In addition, competition for stair use by first responders can further slow evacuation travel times. Because of these differences, a high-rise requires a well-conceived and delivered evacuation system which revolves around education and information. Therefore, written emergency plans, fire drills, and training are important factors regarding safety in a high-rise. Notification to occupants is typically provided by zone via voice communication, which allows those most directly affected to evacuate or relocate first and gives emergency responders the opportunity to communicate with others in the building, perhaps to initiate a full and orderly evacuation.

In tall buildings, relocation to other areas is often the first mode of evacuation. This may be by horizontal exit or relocation to other floors. Most events do not necessitate full evacuation of a building, and initial relocation to nearby areas may prevent slips and falls or exhaustion-related injuries. From the area of relocation, the authorities can decide whether evacuees should remain in place, use the elevators, or continue down the stairs in an organized manner.

Smoke Movement

The high-rise building often has natural forces affecting fire and smoke movement that are not normally significant in lower buildings. Stack effect and the impact of exterior winds can be very significant, and very different, in high-rise buildings.

Stack Effect. Stack effect results from the temperature differences between two areas, usually the inside and outside temperatures, which create a pressure difference that results in natural air movements within a building. In a high-rise building, this effect is increased due to the height of the building. Many high-rise buildings have a significant stack effect, capable of moving large volumes of heat and smoke through the building.

No manual fire-fighting techniques are known to counter stack effect or to mitigate its effect during a fire. Stack effect cannot be eliminated because of the temperature differences and building height. As a result, potential stack effect will exist and may vary with climatic conditions. The only way to mitigate the potential of stack effect is to design and construct the building to minimize the effect. A thorough review of available resources on the subject will enhance design and construction. Basic concepts include the following:

- Compartmentalization from floor to floor and wall to wall, which involves sealing penetrations and exterior building tightness
- Limiting continuous shaft heights or constructing vestibules on stairs, elevators, and other vertical shafts
- Use of vestibules and gasketing on exterior doors at both the bottom and top of a building
- Eliminating naturally ventilated shafts and floors that could contribute to stack effect during a fire (elevator shafts with normally open vents, which are commonly utilized, can significantly enhance stack effect)
- Zoning, compartmentalization, and control of mechanical systems, which could contribute to, or be affected by, stack effect

Winds. Winds can profoundly affect fire and smoke movement within a building. Wind patterns around high-rise buildings have been the subject of study due to their effect on structural issues, but very little has been studied with regard to fire protection. In high-rise buildings, winds can vary radically in intensity and direction at different floor levels or sections. It is known that wind velocity and direction can be very different at the street level than at upper sections of the structure, and there is no known method of predicting or preliminarily measuring their effects.

The primary design approach to mitigate the effect of wind on smoke movement is to make the exterior walls of a building as airtight as possible. This approach is highly dependent on the design criteria, materials chosen, and integrity of workmanship. The result should be that wind direction and velocity will have a reduced impact on air movement within the structure, thereby allowing conventional smoke management systems to overcome the effects of wind to some degree. It is noted that the degree of the smoke management system's ability to overcome the wind effect is based on many variables, including system

design, system power, tightness of the building, wind velocity, and wind direction.

It is reasonable to assume that, if wind is not taken into consideration in the design and construction of the high-rise building and the exterior of the building is not reasonably tight, any fire may be significantly affected by wind velocity and direction. Wind direction can complicate the accessibility and preferred direction of fire attack and can increase fire and smoke impingement on areas of refuge, possibly exceeding their design criteria.

Even when heating, ventilating, and air conditioning (HVAC) systems are zoned and compartmentalized, they can share common exhaust shafts and fresh-air intake shafts. Such shafts and duct runs often penetrate multiple fire zones, requiring special attention to design and protection. Many high-rise buildings integrate smoke management systems with conventional HVAC systems. Although this is acceptable, and in many cases preferred, it requires special design considerations, including fail-safe devices and adequate controls, acceptance testing, and ongoing maintenance. See NFPA 92A, *Standard for Smoke-Control Systems Utilizing Barriers and Pressure Differences*, and NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria, and Large Spaces*, for additional information on the design of smoke management systems.

Fire Control

Of special importance in a high-rise building is the ability to control a fire. With large numbers of people in a building, many of whom may be above the fire location, fire control is both a life safety and property protection issue. Fire control affects many of the features of the building including its overall fire resistance, compartmentation, automatic and manual suppression, and control of contents.

Most new high-rise buildings around the world are now required to have automatic sprinklers. This is a significant first step in fire control but may not be enough by itself. Codes require manual suppression capabilities in the form of standpipes and portable extinguishers. All of this may be inadequate, however, if the contents in the building become significantly more hazardous than were originally assumed for the building.

CODE REQUIRED FEATURES

NFPA *101* and *NFPA 5000* contain general high-rise building protection criteria in Chapters 11 and 33, respectively. The occupancy chapters use these as base criteria and add or subtract as deemed necessary for the particular occupancy. In Chapter 33 of *NFPA 5000,* the following criteria are addressed:

- Construction types and construction modifications
- Voice communication for fire alarm
- Two-way fire department communication systems
- Automatic sprinkler protection
- Smoke-proof exit enclosures
- Emergency lighting
- Standby power
- Emergency command center

These features are intended to address many of the unique features of a high-rise building. Over the past several years, code requirements such as these have caused the active protection of existing high-rise buildings to gradually improve. Tables 20.8.3 and 20.8.4 show the levels of automatic sprinkler, fire detection, and fire-resistive construction in hotel and office buildings from 1985 to 1998.

HIGH-RISE ISSUES TO CONSIDER

Areas to which the design and code community should give serious consideration with respect to high-rise buildings include risk evaluations, thresholds, and structural fire resistance.

Risk Evaluations

Very large buildings should not be designed using a "cookbook" approach. Rather, an integrated, holistic, and rational engineering approach should be used. Although there are not enough events in high-rise buildings to do statistical analysis of the risks, there are many ways to look at risk in relation to high-rise buildings. As a building gets taller, the number of occupants increases, and the potential for disaster increases. Engineering decisions should be based on such factors as potential occupant load; whether a building may be a target; potential contents and businesses within the building; the capability and effectiveness of built-in systems such as automatic sprinklers, emergency power, and other systems to protect the occupants and the structure; and supplemental, unique features in the building. Without such analysis, the rigor that the building demands and the public deserves will not be included in the design process. This rigor should lead to an informed, well-documented design, so that the thought process on which the design is based can be followed in the future. Only then will high-rise buildings be engineered rather than pieced together. Application of current codes to very or extremely tall buildings is worthy of scrutiny and discussion. Criteria that are virtually identical for a 10 story building and a 100 story building should be adjusted for the taller structures; the only question is how. Such an approach exists today in the form of performance-based codes, but their use in high-rise buildings has been limited, particularly in the United States.

Thresholds

Although codes are gradually grappling with the concept that not all high-rise buildings are the same, it may make sense to develop some thresholds of protection. For instance, high-rise requirements may start at 75 ft (23 m), or 7 or 8 stories, based on the reach of fire department apparatus. The next threshold may occur at about 20 stories, where full-building evacuation becomes unwieldy, and where stack effect can significantly affect smoke movement. Subsequent thresholds may be at 40, 60, or 100 stories, where the time to evacuate may exceed the fire resistance of a structure, where elevators may need to be considered in building evacuation, where special provisions for fire fighter access may be needed, where mechanical systems alone may not be able to overcome stack effect, and where people

movement and psychology may have to be factored into how messages are transmitted and received. At one of these thresholds, it may well be that prescriptive codes no longer apply and that a performance-based approach using engineered systems is the only allowed alternative. Once this analysis is done, it may also be that requirements can be relaxed somewhat in the 7- to 20-story building range. As an example, in China, buildings over 820 ft (250 m) are considered as super-high-rise buildings, and approval involves the central government authorities.

Structural Fire Resistance

Although the current code methods of evaluating structural fire resistance are archaic, they still provide a very accurate and con-

sistent model of expected performance. Simulation techniques are available that can reveal much more about a building's potential behavior than a 1-, 2-, or 3-hour rating. In the automotive industry, physical crashes and crash simulations are used on new car models to determine how a vehicle will respond to a series of events. Those same models can be used (and are starting to be used) in the building industry to judge structural and fire performance.

Another aspect of structural fire resistance in tall buildings is the need for a building to withstand an event for long periods of time. In a medium-height building, the current building codes reasonably match full evacuation time with structural fire resistance. As we get into very tall buildings, however, should we consider a change in fire resistance? If so, how much (given that fires will only burn a finite amount of time)? A balance on

this item that has not yet emerged and needs to be found. Costs and acceptable end-points if sprinklers fail also need to be discussed. Surely, total building collapse is unacceptable, but is localized collapse or deflection over small areas acceptable in the rare event of a fire and sprinkler failure? With more stringent provisions come more costs.

SUMMARY

The high-rise building presents several challenges not found in traditional low-rise buildings. Those involved with the design and construction of high-rise buildings should recognize those challenges and address them accordingly. Although codes provide a basis for dealing with a high-rise, each building should be considered individually. Items to consider include height, occupancy, occupant load, unusual uses, availability of fire service, and the expectations of society.

Chapter 9

Assembly Occupancies

Revised by
Gregory Miller ■ Edward Roether

Chapter Contents

Occupancy Characteristics
Special Considerations
Occupancy Hazards
Life Safety Concepts for Assembly Occupancies
Main Entrance/Exit Criteria
Life Safety Evaluation

Key Terms

aisle accessway, assembly occupancies, continental seating, crowd management, dead-end aisles, festival seating, fire exit hardware, fixed seating, legitimate stage, life safety evaluation, normal seating, panic hardware, Station Nightclub fire

Assembly occupancies generally can be defined as rooms, spaces, or structures in which groups of people gather for a purpose, such as deliberation, worship, entertainment, or to await transportation. Examples of assembly occupancies are large meeting rooms, restaurants, nightclubs, dance halls, bars, cocktail lounges, auditoriums with fixed or loose chair seating, libraries, concert halls, theaters, cinemas, multipurpose rooms, exhibition halls, convention centers, sports facilities, field houses, places of worship, and passenger terminals for air or surface transportation.

Because the safety and hazards of large numbers of people gathered in one place are a specific concern with this type of occupancy, a minimum number of occupants must be reached to establish whether a room, space, or structure constitutes an assembly occupancy. Although this minimum number of occupants can vary between codes, NFPA *5000*®, *Building Construction and Safety Code*® and NFPA *101*®, *Life Safety Code*®, set the threshold at 50 persons. Occupancies with similar uses but having occupant loads less than 50 would be incidental within other occupancy classifications. An example might be a small meeting room in an office building (incidental assembly use in a business occupancy). NFPA *101* and *NFPA 5000* recommend, via annex notes, classifying small restaurants and drinking establishments with occupant loads of less than 50 as mercantile occupancies.

See also Section 4, Chapter 2, "Calculation Methods for Egress Prediction"; Section 4, Chapter 4, "Techniques of Crowd Management"; Section 4, Chapter 5, "Strategies for Occupant Evacuation During Emergencies"; and Section 20, Chapter 1, "Assessing Life Safety in Buildings."

OCCUPANCY CHARACTERISTICS

The density of the occupant population presents a unique concern for safety in assembly occupancies. No other occupancy experiences occupant loads of such density. The occupant load is dependent upon how the space is being used. Typically, one person per 15 ft^2 (1.4 m^2) of net area would be expected in less concentrated spaces, 7 ft^2 (0.65 m^2) of net area in concentrated spaces, and 5 ft^2 (0.46 m^2) of net area in very concentrated spaces.

Assembly occupancies are usually inhabited by persons who do not use the building frequently and, therefore, might not be familiar with exit locations, egress paths, or other safeguards present. In addition, many assembly occupancies, such as theaters, concert halls, nightclubs, lounges, and some restaurants, are used in conditions of low lighting levels. Such high occupant densities under these conditions impact physical movement and the behavior of people. The capacity and maintenance of the means of egress elements, fire resistance of building construction and interior finish materials, fire suppression systems, crowd management, and the method of alerting occupants of an emergency require proper attention.

All of these factors—high occupant density, unfamiliarity with the building, and low lighting levels—are common to the many and varied forms of assembly occupancies. Provisions must be made to deal with all of these factors to avoid panic and facilitate orderly egress when an emergency occurs. Despite these factors, sprinklered assembly occupancies have had a remarkably good fire

record. A fire on February 20, 2003, at the nonsprinklered Station Nightclub in West Warwick, Rhode Island, resulted in the loss of 100 lives (Figure 20.9.1).

Tables 20.9.1 and 20.9.2 provide data on structure fires in assembly occupancies.[1]

SPECIAL CONSIDERATIONS

Restaurants and Nightclubs

Both restaurants and nightclubs share common concerns, such as aisles that do not provide adequate access to exits. Adding tables in an effort to increase the number of occupants may simply be uncomfortable under normal conditions but can be disastrous in an emergency. Although nightclubs share this concern with restaurants, it is more acute with nightclubs due to increased consumption of alcohol.

Proper aisle access and aisles must be maintained to facilitate egress. Aisles should be wide enough to accommodate the movement of people, taking into consideration the position of chairs during normal use and during emergencies. Proper aisle access and aisle widths also provide more comfort and make table service easier and more efficient in restaurants. Nightclubs differ from restaurants in that there can be less focus on ease and efficiency in table service and the occupant load is more concentrated. Certain techniques, such as using small, round tables rather than larger, square tables, help achieve maximum patron capacity.

In both restaurants and nightclubs, the decor can be elaborate and thematic. Care and attention are required to assure that decor does not obstruct or obscure exits, exit markings, emergency lighting, automatic sprinkler systems, and other safety features. Absence of effective, well-understood procedures for alerting patrons to an emergency and notifying the fire department can have disastrous outcomes in these occupancies. Delayed notification shortens the available evacuation time in case of an emergency and delays fire department response. Reluctance to notify patrons and the fire department of an emergency before the last possible minute significantly reduces the likelihood of safe egress.

Fixed Seating

Occupancies that use fixed seating present the usual challenges, such as exit marking, emergency illumination, and occupant notification; however, there are some added unique considerations. Fixed seating arrangements have very concentrated occupant densities in a confined environment where there is limited ability to move. People exiting from their seats must move through the space between the rows of seats (called an *aisle accessway* in *NFPA 5000* and NFPA *101*) to reach an aisle, and then tra-

TABLE 20.9.2 Structure Fires in Public Assembly Properties, Excluding Eating and Drinking Establishments and Religious and Funeral Properties, 1999–2002 Annual Averages

Occupancy	*Fires*	*Civilian Deaths*	*Civilian Injuries*	*Direct Property Damage (in Millions of Dollars)*
Fixed use amusement or recreation	710	0	6	15.2
Variable use amusement or recreation	930	1	6	11.9
Club	950	1	17	31.4
Library, museum, or courtroom	450	0	5	11.2
Passenger terminal	220	0	2	0.7
Theater or studio	270	0	6	3.2
Unclassified or unknown-type public assembly property	360	0	2	8.2
Total	3890	2	43	81.8

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest ten, civilian deaths and injuries are rounded to the nearest one, and direct property damage is rounded to the nearest hundred thousand dollars.

Source: National estimates based on NFIRS and NFPA survey.

verse the aisle to a cross-aisle, vomitory, vestibule, concourse, or corridor, and continue to an exit. Proper design of each exit access component for the fixed seating area is critical for safe egress of all occupants during an emergency.

Prior to the 1988 edition, NFPA *101* classified fixed seating into two types: (1) normal and (2) continental (Figures 20.9.2 and 20.9.3).

Normal seating is characterized by a limited number of seats, with cross-aisles limiting dead-end aisles. Continental seating is characterized by long rows of chairs discharging into side aisles, which, in turn, connect directly to exits from the room. In 1988, NFPA *101* was the first model code to adopt concepts for all seating in new assembly occupancies rather than dividing seating into two categories. These concepts can now be found in other model codes. This approach recognizes the advantages of continental seating, such as reduced egress time, and applies those principles comprehensively to all seating. Since the inception of this new approach, the requirements for

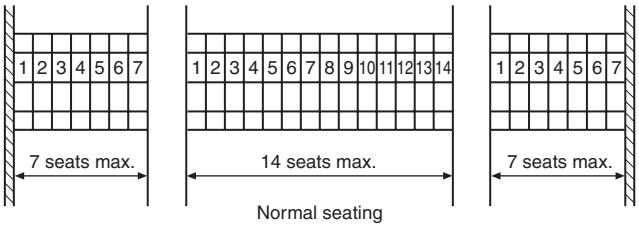

FIGURE 20.9.2 Arrangement of Seats and Aisles in an Assembly Occupancy with Normal Seating

assembly seating have been refined through the code development process.

NFPA 5000 and NFPA *101* utilize one approach for all assembly seating arrangements. Egress capacity factors are used to calculate minimum required clearances. Alternative factors

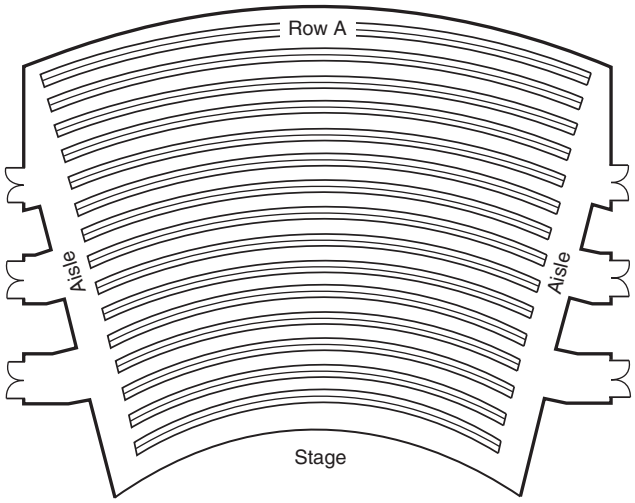

FIGURE 20.9.3 Arrangement of Seats and Aisles with Continental Seating

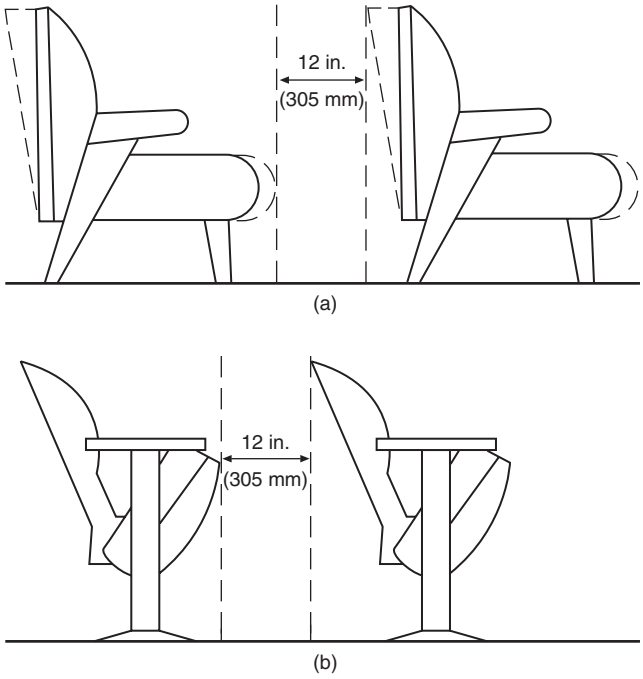

FIGURE 20.9.4 Correct Measurement of Minimum Spacing Between Rows of Seats (Aisle Accessway Width) (a) Without Self-Rising Seats and (b) With Self-Rising Seats

are utilized where the assembly seating is protected from smoke since more time to egress would be provided by such protection. However, an overall evaluation of life safety is necessary to support such modifications. Assembly seating requirements are summarized as follows:

1. Rows of seats are permitted to extend to 100 seats between aisles provided there is sufficient clearance between rows. However, rows would typically have fewer seats between aisles due to practical considerations.

2. The minimum clear width between rows of seats, called the *aisle accessway,* is determined by starting with 12 in. (355 mm) for an allocated number of seats, which is then increased proportionately for the number of additional seats up to a maximum width of 22 in. (560 mm) (Figure 20.9.4).

3. The length of *dead-end aisles,* an aisle exiting in only one direction, is limited unless the assembly seating is protected from smoke. However, the length of dead-end aisles in a smoke-protected assembly would be limited by the number of seats served by the aisle and the width of the aisle along with practical considerations.

4. The minimum width of aisles is determined by the greater of either a specified minimum width or a formula based on egress capacity factors, which take into account the riser height of the steps in a stepped aisle, the slope of a ramped aisle, and the locations of handrails.

5. The travel distance to an exit from assembly seating areas is limited to 200 ft (61 m) or 250 ft (76 m) if the occupancy is protected by an approved, supervised automatic sprinkler system. Greater distances are permitted where the occupancy is protected from smoke; it is permitted to be unlimited where the occupancy is smoke protected, the seating facility is of Type I or Type II construction as defined in *NFPA 5000,* and all portions of the means of egress are open to the outside.

Smoke-protected assembly seating is defined by NFPA *101* and *NFPA 5000* as seating served by a means of egress that is not subject to smoke accumulation within or under the structure. Smoke-protected assembly seating is typically achieved in indoor venues by providing an engineered smoke control system. NFPA *101* establishes conditions that must be assessed as part of a life safety evaluation when considering provisions for smoke-protected assembly seating. See the end of this chapter for a brief discussion of life safety evaluation. Where loose chairs are used in lieu of fixed seating, care must be taken to keep the chairs from being moved into a haphazard arrangement that could impair exit access. Generally, loose chairs must be arranged in a manner similar to fixed seating to maintain required aisle accessway and aisle widths. To prevent chair movement during use, most codes require loose chairs to be fastened together in groups to make them difficult to reposition in order to maintain egress paths. Many chair manufacturers produce chairs with interlocking features to meet this requirement. These features usually require no tools to join or separate the chairs, which can also be stacked for storage.

Festival Seating

A concept called *festival seating* is popular for certain entertainment events, particularly concerts. Festival seating is an audience or spectator accommodation in which no seating, other than the floor or ground surface, is provided for the audience gathered to observe a performance. This type of seating has the potential to result in overcrowding and high audience density that may compromise occupant safety. Also notable is the po-

tential for injury prior to the actual event as patrons rush into the venue seeking the best locations. Festival seating should be used with caution. NFPA *101* requires the completion of a life safety evaluation for festival seating for more than 250 occupants; in addition, trained crowd managers are required for all assembly occupancies. See the end of this chapter for a discussion of a life safety evaluation.

Multipurpose Rooms

Ballrooms, meeting rooms, cafeterias, and gymnasiums are usually multipurpose rooms and may be used for dining, dancing, sporting events, exhibits, meetings, receptions, or other uses. In general, local codes contain requirements for each use. Overall, the key to occupant safety is adequate exiting. If movable walls or partitions subdivide large areas, each subdivision must have proper exit access and exits. Care must be taken to ensure that proper means of egress is designed into the arrangement.

Exhibit Halls

Exhibit halls are large assembly areas that are multipurpose in nature. Special diligence regarding control of display and chair arrangement must be exercised to ensure unimpeded egress and to maintain the proper travel distances to exits. Therefore, a permit process for the authority having jurisdiction's approval of display and seating layouts is recommended prior to each trade show or exhibition.

Exhibit halls might have excessive quantities of combustible materials unless provisions are made for remotely storing the packing materials needed to transport the displays and for surplus quantities of literature. The importance of this cannot be overemphasized, since failure to remove this heavy fuel load to proper storage areas, remote from the exhibit hall, can result in large, rapidly spreading fires. The McCormick Place fire of January 1967, in Chicago, Illinois, is an example of the fire potential of this type of occupancy.[2] Special attention must be paid to the travel distance within a larger exhibit booth or display to the aisle; this distance should be limited to 50 ft (15 m). Multilevel exhibit booths present problems with regard to both egress and fire protection. This type of booth, as well as large exhibit booths with ceilings, can shield the booth's contents from the building's automatic sprinkler system. In these cases, consideration should be given to providing sprinkler protection for the booth itself. In all cases, booths should be constructed of noncombustible, limited combustible, or fire-retardant-treated materials. NFPA *101* and *NFPA 5000* contain special requirements for exhibit halls. Because of the fuel load and the large number of occupants, moderate and larger size exhibit halls should be provided with automatic sprinkler systems in accordance with NFPA 13, *Standard for the Installation of Sprinkler Systems.*

Sports Facilities

Sports arenas, stadiums, ballparks, and field houses usually have fixed seating for large numbers of spectators, as well as large areas. It is not uncommon for such occupancies to hold more than 10,000 people. Smoke development during a fire can present a major threat to life safety when large numbers of people are evacuating a sports facility. Proper clearances between rows of seats, aisle width, and travel distances require proper care during the planning stage. Protecting the assembly seating and exit path from smoke provides more time for people to evacuate, thereby allowing adjustment in clearances and travel distances where smoke protected.

On the positive side, these occupancies usually include very large open areas, permitting smoke to be diluted or held above exiting occupants' heads in the early stages of a fire, keeping them reasonably safe for egress. Engineered smoke control systems can be designed to keep enclosed facilities protected from smoke similar to outdoor facilities. If they are used for exhibitions, the special considerations for exhibit halls must also be followed. Requirements for the design of smoke-control systems are provided in NFPA 92A, *Standard for Smoke-Control Systems Utilizing Barriers and Pressure Differences,* and NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria, and Large Spaces.*

Care must be taken to prevent the accumulation of combustible waste under seating areas; such trash accumulation, along with combustible construction, contributed to the Bradford, England, soccer stadium fire of 1985, in which 56 spectators died.

Passenger Terminals

Passenger terminals require special consideration for fire safety because only general rules can be written for their regulation. Dense populations are localized, especially at departure and arrival gates. NFPA *101* and *NFPA 5000,* via annex notes, recommend special occupant load factors for airport terminals. As in most assembly occupancies, the occupants of passenger terminals are generally unfamiliar with the building, its egress routes, and its protection features. Proper marking of exits and egress routes and limiting travel distances to exits are particularly important.

The potential for significant loss of life from fire in passenger terminals that are not sprinklered has been tragically realized in recent years. On November 18, 1987, a fire originated within an escalator at the King's Cross Station—a subway station in London, England—leading to the deaths of 30 occupants and one fire fighter.[3] On April 11, 1996, workers using cutting torches inadvertently started a fire in a combustible concealed space in the ceiling of a terminal building at the airport in Düsseldorf, Germany. The ensuing fire spread rapidly and undetected in the void space. By the time it was noticed, a significant portion of the ceiling void was involved in fire. Delays in occupant notification resulted in numerous people trapped in spaces adjoining the main terminal area, such as airline clubrooms and lounges. Because these mezzanine areas were only provided with means of egress back through the main terminal area, and inadequate occupant notification was provided, 17 occupants lost their lives and 62 were injured.[4]

Passenger terminals must have their projected occupant loads carefully analyzed based on projected passenger operations; capacity of aircraft, vehicles, and trains utilized; and peak scheduling and possible delays, which involve embarking and disembarking passengers. A study of embarking and

disembarking passengers with safety factors for delays should be performed. In addition certain sterile or secure areas and the people who must use these areas in a given time frame need to be analyzed. Unlike most other assembly facilities, the projected occupant load does not increase proportionally with increased floor area.

Special Amusement Buildings

Special amusement buildings are temporary, permanent, or mobile structures that contain a device or system conveying passengers, space for viewing a display, a walkway course in any direction, or any combination for the purposes of amusement. These structures are of particular concern because the egress path might not be readily apparent due to low lighting levels, visual or audio distractions, and intentionally confounded paths of travel. In addition, amusement displays can involve a large amount of combustibles. The Haunted Castle fire at the Great Adventure Amusement Park in Jackson Township, New Jersey, on May 11, 1984, is an example of all of these concerns that was not equipped with an automatic sprinkler system. Eight teenagers, ranging in age from 15 to 19 years, died in that fire.[5] Special amusement buildings require unique protection provisions. Consideration should be given to automatic sprinkler protection, special controls to increase lighting levels and turn off confusing or confounding sounds and visual displays when smoke is detected, the strategic placement of exit signs, and control of interior finish materials. NFPA *101* and *NFPA 5000* contain provisions for special amusement buildings that address all the above considerations.

Requirements for special amusement buildings in NFPA *101* and *NFPA 5000* include multilevel play structures, such as those found in children's play areas in fast-food restaurants. It is important to note that NFPA *101* and *NFPA 5000* classify special amusement buildings as assembly occupancies even when the occupant load is less than 50 persons; other assembly uses must meet the 50-occupant load threshold before they are classified as assembly occupancies.

OCCUPANCY HAZARDS

Cooking and Open Flames

Cooking is often associated with the use of assembly occupancies (Tables 20.9.3 and 20.9.4).[1] The hazards associated with cooking in traditional kitchens can be handled by automatic extinguishing systems and proper vapor removal, as outlined in NFPA 96, *Standard for Ventilation Control and Fire Protection of Commercial Cooking Operations.* The widespread use

TABLE 20.9.3 Leading Causes of Structure Fires in Eating and Drinking Establishments, 1999–2002 Annual Averages

Cause	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*	
Cooking equipment fires	4500	(45%)	1	(27%)	68	(51%)	30	(14%)
Identified cooking equipment	3300	(33%)	1	(27%)	56	(42%)	28	(13%)
Confined cooking fire	1210	(12%)	0	(0%)	12	(9%)	2	(1%)
Electrical distribution and lighting equipment	1050	(11%)	0	(0%)	5	(4%)	42	(20%)
Heating equipment fires	790	(8%)	0	(11%)	8	(6%)	12	(6%)
Identified heating equipment fire	510	(5%)	0	(11%)	7	(5%)	12	(5%)
Confined heating equipment	280	(3%)	0	(0%)	2	(1%)	0	(0%)
Smoking materials	820	(8%)	4	(82%)	8	(6%)	19	(9%)
Intentional	760	(8%)	2	(54%)	12	(9%)	42	(20%)
Exposure to other fire	150	(2%)	0	(0%)	0	(0%)	6	(3%)
Contained trash or rubbish fire	180	(2%)	0	(0%)	1	(1%)	0	(0%)

Note: These are the leading causes, obtained from the following list: intentional (from the NFIRS field "cause"); playing with fire (from factor contributing to ignition); confined heating (including confined chimney and confined fuel burner or boiler fires), confined cooking, and contained trash or rubbish (from incident type); identified heating, identified cooking, clothes dryer or washer, torch (including burner and soldering iron), electrical distribution and lighting equipment, medical equipment, and electronic, office, or entertainment equipment (from equipment involved in ignition); smoking materials, candles, lightning, and spontaneous combustion or chemical reaction (from heat source); and mobile property involved (from mobile property involved in ignition). Exposure fires include fires with an exposure number greater than zero, as well as fires identified by heat source or factor contributing to ignition when no equipment was involved in ignition that were not intentionally set. The same fire can be listed under multiple causes, based on multiple data elements.

These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest ten, civilian deaths and injuries are rounded to the nearest one, and direct property damage is rounded to the nearest million. Property damage has not been adjusted for inflation.

Other known assembly or sales area	90	(1%)	0	(0%)	0	(0%)	3	(1%)

of "display cooking" presents new problems in vapor removal and in protecting the cooking surfaces and humans in case of fire. However, display cooking on properly designed and fixed equipment can be made reasonably safe with fixed systems, proper means of egress, and trained staff.

The use of portable cooking equipment must be carefully evaluated before it is permitted. Cooking equipment that uses LP-gas is common; however, large LP-gas cylinders, such as those commonly found on outdoor gas grills, must never be used indoors. A failure of the valve or connecting hose or other event could result in propane leakage and potentially result in a vapor cloud explosion. Such an event in an indoor assembly occupancy would obviously be catastrophic. Small LP-gas cylinders, similar in appearance to aerosol spray cans, can be used safely indoors with properly listed equipment. Details on the use of such equipment are found in NFPA 58, *Liquefied Petroleum Gas Code.*

The use of open-flame devices in tableside and flambé cooking should be carefully reviewed before it is permitted. Specially designed equipment and properly trained staff are necessary to ensure safety. The use of candles and other open flames requires the same degree of awareness as tableside

cooking. Several commercial devices are available that make open-flame lighting safe, even in the event of a tip-over. Coordination between facility operators and the fire department can help maintain an acceptable level of safety.

Theatrical Stages

The distinctive fire hazards of theaters tend to revolve around the stage area. The 1903 Iroquois Theater fire in Chicago, Illinois, is probably the most vivid example of a stage fire and its tragic consequences.[6] The Iroquois Theater was not protected with automatic sprinklers and did not have many of today's code-required safeguards.

Traditional proscenium stages have scenery and lighting "flown" above the stage and scenery on the back and sides of the stage; shops along the back and sides of the stage; and storage, props, trap doors, and stage lifts under the stage floor. The potential for maximum fire severity is great with this combination of fuel and potential ignition sources. Since the Iroquois Theater fire, many safeguards have been required to control these hazards, including the following:

- Automatic sprinklers at the ceiling level, below the gridiron, in usable spaces under the stage, and in all auxiliary spaces surrounding the stage
- Ventilation over the stage, operable manually or automatically by fusible links
- An automatically closing fire-resistant curtain to cut off the stage from the audience chamber

All of these features are necessary with a full theatrical stage, defined in NFPA *101* and *NFPA 5000* as a *legitimate stage.*

Modern stages are generally modified versions of the classic theatrical stage. More scenery is now moved horizontally, eliminating the need for the high scene loft or fly space. Modern stages also tend to be variations of the traditional proscenium stage, thrusting the stage farther out into the audience or having it open to the audience on three sides, as in an arena theater—often called "theater in the round."

Whatever the arrangement of scenery on the stage, scenery handling equipment and allied shops need to be protected to prevent a large stage fire from threatening the audience, either directly or indirectly during evacuation.

Projection Booths

Projection booths refer to any booth housing equipment for the transmission of light onto a screen, curtain, or stage. The hazard is not with the projection of motion pictures or slides made on flammable film, as is commonly assumed, but with the mechanism used to project light. Electric arc, zenon, and other light sources generate hazardous gases, dust, or radiation and can fail with explosive force under certain circumstances. Where these light sources are used, a booth around the projection equipment is required to protect the audience. Proper ventilation also is required. Incandescent light sources do not produce the same hazard and, therefore, need not have the same enclosure. The enclosure of projection rooms in modern motion picture theaters is for sound control, not fire protection purposes.

Modern motion pictures and slides use safety film, which does not introduce the hazards of nitrocellulose found in early movies. Therefore, modern projection rooms are not designed for, and cannot safely project, non–safety film.

Storage

Improper storage practices present a hazard for fire and life safety in assembly occupancies, as in many other occupancies. Storage of tables and chairs, scenery, or supplies in aisles, exit access paths, or exits compromises not only life safety of a large number of occupants trying to evacuate but also fire department response. It is essential that space be allocated for proper storage of materials, supplies, props, tables, chairs, and other items associated with assembly occupancies to avoid the creation of unnecessary hazards.

LIFE SAFETY CONCEPTS FOR ASSEMBLY OCCUPANCIES

Many life safety features contribute to the protection of assembly occupancies, including construction, fire suppression, alarm systems, interior finish, and employee training (Tables 20.9.5 and 20.9.6).[1]

Construction

Assembly occupancies have a high occupant density under variable conditions, which, to one degree or another, makes alerting and evacuating the occupants more difficult than in other occupancies. Because of this, building construction is an important element in the life safety system.

In general, the building should be constructed to allow the structure to remain intact under fire conditions and not contribute significantly to the fire development for at least the time necessary for evacuation. Obviously, for a one-story building, this is relatively easy to accomplish when occupant loads are moderate in size (under 1000). But even a one-story building with proper exits may require structural protection and/or fire-resistant finish materials to ensure everyone's safety. The roof height and the required evacuation time, type of construction, finish materials, fire suppression, and means of egress need to be analyzed and considered specifically to the type of assembly occupancy.

As building heights increase, the level of construction and protection must increase accordingly to permit large assembly occupancies on higher stories. NFPA *101* and *NFPA 5000* specify sizes of assembly occupancies permitted in buildings based on construction, height of the assembly occupancy above the level of exit discharge, and fire protection provided (such as the presence of automatic sprinkler systems). Whereas *NFPA 5000* is generally limited to new construction, NFPA *101* applies to both new and existing assembly occupancies.

Alarm Systems

Prompt notification of occupants of an emergency cannot be overemphasized. However, the sounding of a fire alarm without

TABLE 20.9.5 Automatic Suppression Systems in Public Assembly Property Structure Fires Reported to Public Fire Departments Excluding Fires in Eating and Drinking Establishments and in Religious and Funeral Properties, 1994–1998 Annual Averages

Percentage of fires in buildings with automatic suppression system	26%
Deaths per 1000 fires with automatic suppression system present	0.0
Deaths per 1000 fires with no automatic suppression system present	1.1
Reduction in deaths per 1000 fires when automatic suppression systems were present	100%
Average loss per fire when automatic suppression system was present	$6,320
Average loss per fire with no automatic suppression system	$30,490
Reduction in loss per fire when automatic suppression systems were present	79%

TABLE 20.9.6 Automatic Suppression Systems in Fires in Eating and Drinking Establishments Reported to Public Fire Departments, 1994–1998 Annual Averages

Percentage of fires in buildings with automatic suppression system	29%
Average loss per fire when automatic suppression system was present	$6,500
Average loss per fire with no automatic suppression system	$18,800
Reduction in loss per fire when automatic suppression systems were present	65%

Source: National estimates based on NFIRS and NFPA survey.

accompanying verbal instructions might introduce the threat of panic, or alternatively, delay in occupant response. To overcome these possibilities, an appropriate alarm system—perhaps one using prerecorded or electronically synthesized voice messages—can be installed. Such voice-evacuation systems are required by NFPA *101* and *NFPA 5000* in assembly occupancies that have occupant loads greater than 300 persons.

Panic Hardware or Fire Exit Hardware

Because of the threat of a large group of occupants rushing to an exit, leaning together on the door, and making use of traditional knob-activated latching devices difficult or impossible, assembly occupancies usually require panic hardware or fire exit hardware. Panic hardware and fire exit hardware consist of a door-latching assembly incorporating a wide barlike or push padlike device that releases the latch on application of force in the direction of egress travel. Security-conscious owners in the past have objected to panic hardware or fire exit hardware because of the potential for slipping the latch from the outside for purposes of gaining unauthorized entry. However, modern panic and fire exit hardware designs provide for both life safety and security.

There is no excuse for chained or padlocked doors, given the availability of secure exit hardware. Outdoor facilities using gates offer different challenges. Although panic devices or fire exit hardware can be installed on gates, they cannot be made secure due to practical considerations without potentially compromising the hardware's ability to reliably open under crowd pressures. Therefore, other means to secure gates are often taken regardless of whether gates are provided with secure exit hardware or not. Any measures to secure exit gates must be removed prior to occupancy when such outdoor facilities are opened to the public so that such gates will open on contact.

Interior Finish

Interior finish is a key element in providing fire control and life safety. Materials used in assembly occupancies must limit the rate of flame spread and smoke production. Generally, materials are limited to flame spreads of 75 or less (Class A or B), when tested in accordance with NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials,* for all but the smallest assembly uses. Drapes, hangings, tapestries, and other decorative materials must be fire retardant when tested in accordance with NFPA 701, *Standard Methods of Fire Tests for Flame Propagation of Textiles and Films,* if they constitute a significant part of the decor or if they would provide a continuous path for fire travel. Ignition of such materials without fire retardant can lead to very rapid fire growth and spread, with the potential for a high death toll in densely occupied spaces, such as the 1942 Cocoanut Grove nightclub fire in Boston, Massachusetts, in which 492 people perished. Proper treatment to make materials fire retardant is necessary to avoid disaster.[7] For additional information on interior finish, see Section 18, Chapter 2, "Interior Finish."

The fire at the Station Nightclub in West Warwick, Rhode Island, on February 20, 2003, was ignited by the improper use of indoor pyrotechnics. It is believed that foam sound insulation surrounding the stage area that did not limit the rate of flame spread and smoke production contributed to the rapid spread of this deadly fire.

Employee Training

Employees of assembly occupancies are critically important to the life safety of patrons. If staff members are trained properly, they can prevent serious injury or death to many patrons. The Beverly Hills Supper Club fire in 1977 at Southgate, Kentucky, showed the importance of staff assistance in fire survival.[8] Although the building lacked proper exits and had no automatic fire sprinkler protection, staff members saved hundreds of lives by leading patrons to means of escape unknown to the patrons.

The management of every assembly occupancy should devise an emergency plan in conjunction with the local fire department, deal with the many contingencies associated with fires, and properly train staff members in safe emergency procedures.

Assembly occupancies can be safely occupied when the following conditions are avoided:

- Overcrowding
- Blocked or impaired exits or means of exit access
- Chained or locked exits
- Storage of combustibles in improper locations
- Improper use or insufficient control of open flames
- Disregard for fire characteristics of materials and decorations

Crowd Management

The 2006 edition of NFPA *101* requires "trained crowd managers" for all assembly occupancies regardless of occupant load. This is a significant revision compared to the prior (2003) edition of the code, which set the occupant load threshold at 1000 occupants before crowd managers were required. Where the occupant load exceeds 250, an additional trained crowd manager or supervisor is required for every 250 occupants. Assembly occupancies used exclusively for religious worship with an occupant load not exceeding 2000 are exempt from the requirement for crowd managers. For additional information, see Section 4, Chapter 4, "Techniques of Crowd Management."

Sprinkler Protection

In response to the tragic Station Nightclub fire, the 2006 editions of NFPA *101* and *NFPA 5000* require automatic sprinkler protection for all of the following new assembly occupancies regardless of occupant load:

- Bars with live entertainment
- Dance halls
- Discotheques
- Nightclubs
- Assembly occupancies with festival seating

In addition, NFPA *101* now requires those same existing assembly occupancies with an occupant load of greater than 100 to be protected with a supervised automatic sprinkler system. This new provision requires retrofitting such existing assembly occupancies with automatic sprinkler protection.

Other new assembly occupancies are required by NFPA *101* and *NFPA 5000* to be protected by automatic sprinklers where the occupant load is 300 or greater or where necessary based on the building's construction type.

MAIN ENTRANCE/EXIT CRITERIA

The 2006 edition of NFPA *101* requires the following new assembly occupancies main entrance/exit on each level to accommodate two-thirds of the occupant load of such levels:

- Bars with live entertainment
- Dance halls
- Discotheques
- Nightclubs
- Assembly occupancies with festival seating

As in the requirement for automatic sprinkler protection, the increase of accommodating two-thirds of the occupants from the previous one-half the occupant load at the main entrance was in reaction to the Station Nightclub fire in Warwick, Rhode Island, in 2003.

LIFE SAFETY EVALUATION

A *life safety evaluation* is a comprehensive report on the planned safety measures considering such things as the nature of the assembly event and participants, crowd management, medical emergencies, fire hazards, structural systems (e.g., temporary stages, rigging, etc.), severe weather, earthquakes, civil disturbances, and hazardous materials. It also considers the relationships between facility management, event participants, emergency responders, and others. When required, a life safety evaluation must be prepared by persons having experience with the conditions described and must be approved by the authority having jurisdiction.

A life safety evaluation is an ongoing exercise that requires periodic confirmation at appropriate times depending on the facility and/or events being held. A change in the type of events, operational practices, or the built environment would warrant an evaluation of life safety. Operational practices may not be fully known when an application for a building permit is submitted. Therefore, consideration should be given to those contingent items needing confirmation prior to issuance of a certificate of occupancy.

Detailed guidance on the development of life safety evaluations is included in NFPA *101*.

SUMMARY

Assembly occupancies, by their nature, pose unique life safety challenges. Typical characteristics include large numbers of people with a high occupant density and an emotional or raucous environment (such as during a sporting event or rock concert). Because of the large number of occupants, evacuation of the building can take longer when compared to other occupancies. To ensure rapid evacuation, sufficient means of egress systems must be provided and maintained. Prompt notification must be made to the occupants and clear directions provided. This requires a well-documented emergency plan, trained staff, and facility management who must not hesitate in implementing the emergency plan. Fire-resistive construction, automatic fire suppression systems, adequate means of egress, alarm and communications systems, and trained staff all contribute to the safety of assembly occupants.

Lessons learned from the tragedies described in this chapter have been incorporated into codes, such as NFPA *101*®, *Life Safety Code*®, and *NFPA 5000*®, *Building Construction and Safety Code*®. Codes alone, however, are not the entire solution—they must be enforced. In other words, incorporation of lessons learned into the codes and even code adoption do not ensure occupant safety. Codes must be enforced for the entire life of the facility. Facility management must commit to life safety by maintaining fire protection systems and conducting

frequent staff training. An open line of communications with the local fire department and other emergency response agencies (police, emergency medical services, etc.) will help to keep assembly events safe. Every assembly event poses unique hazards and each should be evaluated carefully and mitigated.

NFPA members can download at no cost a number of investigation reports on public assembly fires from NFPA's website at http://www.nfpa.org. Nonmembers may order investigation reports through the NFPA library.

Chapter 10

Mercantile Occupancies

Ed Schultz

Chapter Contents

Mercantile Occupancy Classifications
Occupant and Fire Loads
Mall Buildings
General Life Safety Factors Applying to Mercantile Occupancies

Key Terms

accessory occupancy, exit, mall building, means of egress, mercantile occupancy, occupant load factor, smoke management, sprinkler system

This chapter addresses mercantile occupancies, from small stores operated by families to large shopping malls and multiuse projects. It also describes changes in building codes in response to the increased complexities of megaprojects.

Because in many instances a mercantile use may be an ancillary or accessory use in a building with a different occupancy classification, this chapter covers only those facilities whose primary occupancy classification is mercantile.

See also Section 20, Chapter 1, "Assessing Life Safety in Buildings."

MERCANTILE OCCUPANCY CLASSIFICATIONS

Mercantile occupancies are facilities in which a wide variety of goods and services are displayed and sold. Examples of such goods and services include clothing and footwear; jewelry; beauty, health, and fitness products; home furnishings; luggage, books, cards, and stationery; music, electronic equipment, and photography supplies; sport specialties; toys, hobbies, and pets; drugs, varieties, and tobacco; food and food specialties; and hardware.

Many items displayed in mercantile occupancies are combustible and spread over the available floor where customers circulate to view and purchase the items. Many mercantile occupants are in an unfamiliar environment that may be conducive to rapid fire development after a fire begins. This condition raises various levels of concern because the size of the mercantile occupancy and the number of occupants vary greatly. Therefore, it is important to categorize mercantile stores by size.

Small Mercantile Occupancies

In the past, smaller shops were constructed principally in cities and towns, along business thoroughfares, next to each other, often with basements for stock, and sometimes with an office or dwelling unit immediately above them. Many such stores still exist today, especially in older business sections of cities; they are sometimes called "ma and pa" stores because their proprietors often live in the dwelling units directly above them. However, this type of store is slowly fading out of existence.

Because of more restrictive zoning regulations, larger stores are now constructed without other occupancies above them, unless the mercantile occupancy serves an ancillary or accessory use such as a retail shop in a hotel lobby. In addition, basement space, even for stock space, is being phased out because stock space on the same level as the sales area is more efficient and functional. Also the retail merchandising concepts have changed to that of displaying as much of the available merchandise on the sales floor as possible. This decreases the amount of inventory held in stockrooms.

Originally, these stores were constructed primarily of wood- or masonry-bearing walls with wood joists, floors, and roofs. Subsequent establishment of fire districts in urban areas, plus the adoption of more stringent building code requirements, led to construction with noncombustible materials, such as masonry walls, load bearing or nonload bearing; steel joists; concrete floors; and metal roof decks.

Ed Schultz is founder and principal of Code Consultants, Inc., in St. Louis, Missouri.

Until recently, these small stores were seldom sprinklered. NFPA *101*®, *Life Safety Code*®, and *NFPA 5000*®, *Building Construction and Safety Code*®, currently require sprinkler protection based on height and area and, in certain instances, whether the stores are located below the level of exit discharge.

Medium Mercantile Occupancies

Medium-size mercantile occupancy stores, such as supermarkets and discount drugstores, did not become numerous until the mid- to late 1940s. In many areas, they replaced the neighborhood grocer and the corner druggist, who could not compete with high-volume chains.

Medium mercantile occupancy stores generally range in size from 10,000 to 40,000 ft^2 (2800 to 3700 m^2), are usually one story with mezzanine management offices, and are usually constructed of noncombustible unprotected construction. Until the mid-1970s sprinklers were not required in these stores.

These stores are generally freestanding buildings, unless they are part of a shopping center complex, and they may have relatively large contiguous parking areas surrounding them.

Medium-size mercantile occupancy stores usually have at least two principal areas: (1) the stock space or "back of the house" employee area and (2) the sales space or customer area. Approximately one-tenth to one-third of the total area is apportioned to stock and the remainder to sales. These stores typically include nonmercantile accessory uses, such as management offices, that occupy a small area in relation to sales and stock space. From a retailer's viewpoint, the distinction between retail stock space and storage space is important. Employees enter the retail stock areas frequently during the day to bring merchandise onto the sales floor. Storage areas, on the other hand, are less frequently accessed because goods are set aside in these areas for extended time periods. Today, if one corporation operates many stores, its storage areas are generally in a separate location, essentially a distribution warehouse. Again the new retail marketing concepts are reducing the amount of area used for stock and storage areas in favor of enlarging the sales area to display more merchandise.

Large Mercantile Occupancies

The multiple-category merchandise store, such as a department store and bulk merchandising retail buildings, is as common as other types of mercantile occupancies. Generally from one to three stories high, their area normally exceeds 40,000 ft^2 (3700 m^2).

Earlier department stores were constructed exclusively in business and retail districts in cities. Stores were typically either of exterior masonry-bearing wall construction with protected wood joists and floors or of reinforced concrete. Many had no sprinkler protection. Today, most newly or recently constructed department stores are of protected and unprotected noncombustible construction and are protected by complete automatic sprinkler systems.

As their name implies, department stores are divided into departments or sections for different kinds of merchandise, with or without partition walls. Departments are laid out in a particular way to influence customer movement patterns vertically and horizontally through the store according to a preconceived merchandising plan. Vertical movement in multistory stores is most effectively accomplished using escalators and stairs in open wells in highly visible and accessible areas.

At one time basements were quite commonly used as either sales or stock areas. This practice generally is no longer followed because basement space is not as desirable as the same area constructed at or above ground level.

Unlike the vast majority of small and medium mercantile occupancies where stock space is located in the rear of the store, stock space in large mercantile occupancies is often distributed throughout the store in many small stockrooms. These stockrooms often represent 10 to 15 percent of the total floor area, with the remaining area used for retail sales.

Another example of a large mercantile store is the discount store, which grew out of the well-known "five-and-dime" variety store. It is usually one story high and laid out like a retail food supermarket, with shopping carts, self-service, and checkout counters. However, the same sectioning of merchandise occurs as in a department store.

Over the last 20 years, bulk merchandising retail stores have come into existence. These facilities are a blend of warehouse operation and retail sales store. Typically, pallet or rack storage is used in a large portion of the building with other areas of the building designed in the more traditional retail display using fixtures and low-level racks or shelves to display merchandise. A large portion of the facility typically has shelving and rack storage that can extend to a height of 20 ft (6 m) or more. The retail merchandise is displayed on the lower portion of the rack and the stock is located directly above. This arrangement eliminates the separate stock areas that are typical to retail department stores.

Bulk merchandising retail stores generally have very limited interior finishes and are typically constructed as warehouse facilities with exposed concrete floors, masonry exterior walls, and unprotected steel columns and roof structures. These stores function as self-service facilities with shopping carts and they have checkout counters near the main entry of the facility.

Since this type of retail operation displays and sells a variety of commodities, many of the design standards that must be used are those used for storage (warehouse) facilities. See the chapters on new and existing mercantile occupancies that are listed in NFPA *101* for a listing of some of these design standards. These properties are sufficiently challenging in size and fuel load that they may require a specific engineering analysis to design, and confirm the adequacy of, built-in fire protection. See, for example, several research reports from the Fire Protection Research Foundation dealing with flammable and combustible liquid storage in wholesale/retail occupancies.

Accessory Occupancies

To round out the full range of goods and services a customer needs and expects, mercantile occupancies sometimes include accessory or ancillary occupancies, in addition to administrative office areas. Examples are restaurants, beauty shops, travel agencies, banks, and optometry services.

OCCUPANT AND FIRE LOADS

Occupant Load

Actual occupant load varies with the seasons, generally being higher before school begins, around holidays, and during occasional clearance sales. NFPA *101* and *NFPA 5000* take these primary merchandising seasons into account in establishing the occupant load factor for calculating egress requirements. The model construction codes, including NFPA *101* and *NFPA 5000,* require that occupant load for mercantile occupancies be calculated on the basis of a factor of one occupant per 30 ft^2 (2.8 m^2) of street floor or basement sales areas, and a factor of one occupant per 60 ft^2 (5.6 m^2) of other upper sales floors. These factors for occupant load vary based on the expected flow of customers into and out of these large stores. An increase in occupant load is also created by the retailer merchandising concepts of placing the higher-volume sales items on the main level to accommodate and benefit from the higher customer flow.

These factors have been recognized by some of the codes by addressing building designs that have main entrances on more than one floor level. In these design concepts, the customer flow (occupant load) is projected to be less than a single main floor design but more than a second-level sales floor. Therefore, the occupant load factor assumed for this type of design concept is one occupant per 40 ft^2 (3.7 m^2) for both of the floor levels having main entrances. The occupant load for stock or storage space that is not open to the public and other accessory occupancies is calculated using different factors, depending on the particular use.

Fire Load

As in most other occupancies, contents represent the major potential hazard. Sprinklers have proven effective as a means of combating fires in mercantile occupancies. In terms of life safety, NFPA *101* reflects cost-benefit considerations in the use of sprinklers. Its requirements for sprinklers, based on height and area limits, let many small shops be unsprinklered (unless they are accessory uses to an occupancy requiring sprinklers), while requiring medium and large mercantile occupancies to be protected with automatic sprinklers. In recent years, recognition has been given to the variety of contents of mercantile occupancies. The building and fire codes have now addressed the amounts of select contents that could be classified as hazardous that may be stored or displayed in areas of a mercantile occupancy. The maximum quantities permitted are generally limited to control area; this provides for separation of materials that are considered as presenting a physical hazard such that a single fire or other type of condition would only affect the materials in one control area.

MALL BUILDINGS

A mall is commonly defined as a covered or roofed interior area used as a pedestrian way, which connects buildings or portions of a building housing single and/or multiple tenants. Mall buildings became very popular in a relatively short time period, and today most large shopping centers either planned or under construction are of this type. In addition, many mall buildings are now being built in urban areas as multiuse projects in conjunction with parking decks, office buildings, hotels, recreational facilities, and public or private transit systems.

The mall may be considered as either (1) a way of exit access from the connected buildings or (2) a pedestrian way permitting an increase in the distance of travel from each of the tenant stores to a mall exit.

The first instance treats the entire complex as one building or one compartmented retail facility; the mall is simply an extension of the sales space. In terms of exit access, the mall is an aisle common to the various tenant stores that extends (continues) exit access aisles of tenant stores to mall exits. This treatment, in terms of NFPA *101* and *NFPA 5000,* leads to the strict application of all design factors as though the shopping center were a large single mercantile occupancy or department store.

The second instance employs a systems approach. The mall is considered to offer a higher degree of safety than a typical aisle serving as an exit access if certain minimum conditions and systems are provided. The mall should be of at least sufficient clear width to accommodate egress requirements for all mercantile tenants, but in no case less than 20 ft (6 m) wide at its narrowest dimension. The minimum width dimension of 20 ft (6 m) is particularly significant in terms of protecting occupants from direct exposure to a fire within a tenant store while those occupants utilize the exit access paths within the mall. Newly constructed malls with floor openings connecting more than two levels must be provided with an engineered smoke control system.

Design

The mall building is generally designed as one building connecting several sizable department stores and composed of numerous smaller specialty stores (mall tenant shops), all interconnected by a covered, climate-controlled, pedestrian way. The complex may also include ancillary occupancies, such as movie theaters, bowling lanes, ice arenas, food courts, project management offices, and other customer service areas accessed from the mall. Some even contain enclosed amusement parks.

The mall building may be designed as a single- or multilevel structure, depending on such factors as topography, size of the land parcel, and number and size of department stores and retail shops.

When a mall has two levels, the parking areas surrounding it usually are shaped to provide grade access to each level of the department stores and the small shops. This permits each level to serve as an entrance/exit, thus providing stores on all levels increased and equalized customer traffic as customers enter and leave the building (Figure 20.10.1). The two-level shopping center differs from the two-story shopping center in this important respect. When department stores are part of a two-level mall building, they are designed and merchandised in a similar manner.

Building codes have recognized that the construction of mall buildings up to a maximum of three stories high with floor openings within the pedestrian way (the mall) complying with the code mall provisions should not be considered atriums based on the special code provisions that address mall buildings.

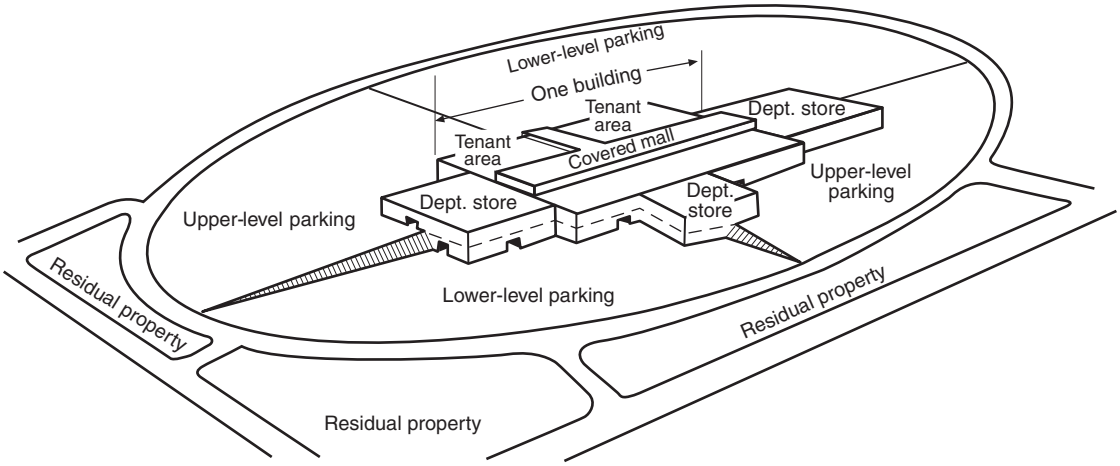

FIGURE 20.10.1 Two-Level Mall Building with Equal Distribution of Customer Traffic on All Levels

Exiting Concept. The mall proper is designed primarily to meet requirements for occupant flow and egress. Storefronts along the pedestrian way (the mall) must be designed to encourage unrestricted customer flow and traffic control from the mall to individual shops and to any connected department stores. This system of customer traffic flow and traffic control reflects the merchandising concept of mall buildings and the exiting concept of the codes. The exit concept is that the mall is an inherently safe space with controlled uses, adequate width, large volume, and high ceiling space that may also have smoke venting, and is protected with automatic sprinklers. This then allows egress capacity design to be based on the assumption that 100 percent of the occupants in the mall building will exit via the mall proper. This allows the back exit system for tenant shops to be sized for the most restrictive of the following:

1. The code-stated minimum dimension
2. The exit width required for the largest single tenant occupant flow exiting into the back exit system
3. The exit width required for occupants exiting from the mall, if the exit passageway also serves as a mall exit

This is the case even if the mall uses the same exit passageway that is used for a second exit by several mall tenant shops. Again this concept is based on the fact that occupants tend to exit the way they entered a store, via the mall itself. Therefore, the back exit system is truly a secondary exit system, and the mall is the primary egress path for mall building occupants.

Open storefronts between the mall and tenant mall shops are critical because swinging doors, whether glass or solid, not only make exiting more difficult but also promote what the retail industry calls "threshold resistance"—that is, customers' reluctance to push, pull, or slide doors to enter. The storefront closures ideally suited for maintaining after hours security are those that can be fully recessed, such as rolling overhead grilles, side-coiling grilles, and horizontal sliding doors. Because the ambient temperature in the mall and the tenant space is the same, the storefront closure only needs to satisfy a security requirement when the store is unoccupied.

Occupant Allowance Requirements. Mall buildings are constructed before tenants are known. When construction begins, the ultimate ratio of sales space to storage space for tenant stores and what changes may occur in the life of the building are also unknown. The use of each tenant space—for example, retail or assembly—is also typically unknown at the time of construction. Hence, occupant load must be projected to determine the required egress width well before negotiations with prospective tenants.

Egress width from the mall need only satisfy the calculated occupant load based on all connected tenant occupancies. It is not necessary to provide egress width from the mall commensurate with the minimum mall width. Doing so would unnecessarily result in wall-to-wall doors.

The occupant load factor used to determine egress width for the mall proper varies with the aggregate area of the connected stores. This sliding scale of occupant load factors reflects the relationship between an increase in a shopping center's size and an increase in its occupant load, which is not linear but parabolic, as Figure 20.10.2 shows. Once determined, the occupant load factor is applied to the gross leasable area (GLA) to calculate the covered mall building total occupant load for egress design. Again, this factor is not applied to gross building area. However, in mall buildings with large seating areas within the mall concourse that are part of a food court concept, the number of occupants for whom seating is provided is normally added to the occupant load that is calculated using the GLA of the mall building to establish the required egress width. Other types of assembly tenant spaces, such as restaurants with seating included within the tenant space, are considered as typical tenant spaces that are a portion of building's GLA.

Systems Approach

In most cases, two- or three-level covered malls are designed for visual communication among levels through openings in the floor of the upper level(s). Wherever practicable, visual com-

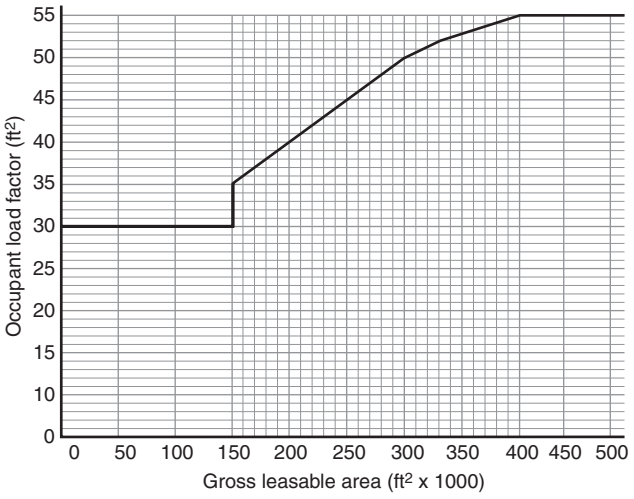

FIGURE 20.10.2 Relationship of an Increase in the Size of a Covered Mall to an Increase in the Occupant Load

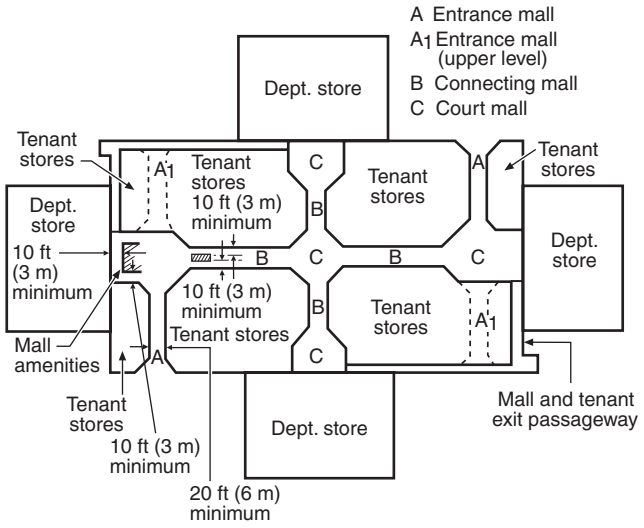

FIGURE 20.10.3 Typical Two-Level Shopping Center (Lower Level)

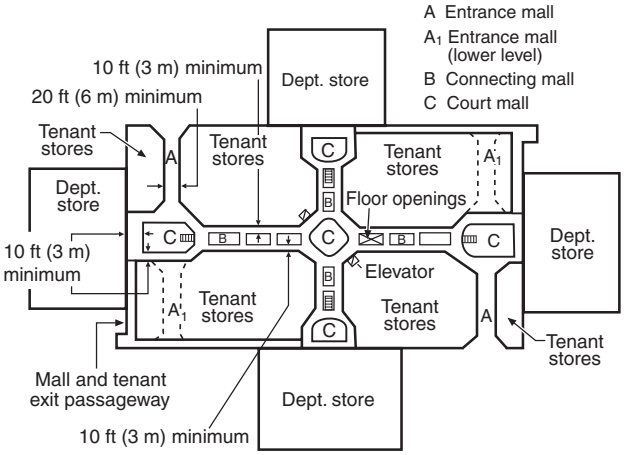

FIGURE 20.10.4 Typical Two-Level Shopping Center (Upper Level)

munication between levels is important in maximizing exposure of storefronts and merchandise to customer traffic. The floor areas between openings in the upper level(s) serve as bridges that promote cross-mall shopping convenience for the customer (Figures 20.10.3 and 20.10.4).

When construction starts, not everything about the shopping center is known, even to the developer. Mechanical, electrical, and fire protection systems are designed for main distribution only in the tenant store areas, with branch distribution added to the construction documents as lease agreements define tenant space.

The mall proper may contain other amenities for sales promotion, customer service, and convenience, such as seating areas, art objects, planting areas, food court seating areas, pools, specialty retail kiosks, directories, openings in upper levels of multilevel structures, and areas designed for promotional activities. Care must be exercised in locating these amenities so they do not interfere with, or encroach upon, required exit access. However, the width of the covered mall connecting courts at entrances to department stores generally is found well in excess of the 20 ft (6 m) minimum to provide for these amenities and at the same time provide for an aggregate of 20 ft (6 m) of exit access width (see Figure 20.10.3).

Stores located on either side of entrance malls and not along the direct path to department stores (commonly called "anchor stores" or "magnet stores" because of their greater customer attraction) do not enjoy as much customer exposure as those located along connecting malls. To compensate and maximize convenient cross-mall customer shopping, stores on opposite sides of the entrance mall are brought closer together by eliminating mall amenities that by themselves are not likely to generate traffic. The minimum mall width of 20 ft (6 m) is entirely compatible with this merchandising concept and does not impose an unreasonable burden on developers or merchants. This minimum width requirement has been applied successfully in shopping centers throughout the United States.

The mall should have an unobstructed exit access of not less than 10 ft (3 m) clear width on each side of the mall floor area, parallel and adjacent to the mall storefronts. The exit access should lead to an exit having a minimum of 66 in. (168 cm) of width. The purpose of requiring 10 ft (3 m) of clear exit access is to provide a higher degree of safety in the covered mall commensurate with its use as a continuation of exit access from the tenant stores. Safe, continuous, and unobstructed exit access from each tenant store is provided, while the owners' merchandising and operational requirements for mall amenities are recognized.

The minimum requirement of 10 ft (3 m) of clear exit access parallel and adjacent to the mall storefronts relates directly to the minimum mall width of 20 ft (6 m). None of the mall amenities mentioned earlier should encroach on this minimum

dimension of 10 ft (3 m). In effect, this requirement precludes the installation of mall amenities in areas of the covered mall that are the minimum 20 ft (6 m) width. In life safety terms, this requirement has proven reasonable and workable and has the added advantage of not being unduly restrictive or burdensome to developers.

Sprinkler Protection

The mall and all its connected buildings must be provided with an electrically supervised automatic sprinkler system throughout. This has proven the most effective way to protect life and property from fire. Sprinklers allow the replacement of many passive long-standing code requirements by active systems in combination with specified design requirements. See NFPA 13, *Standard for the Installation of Sprinkler Systems,* for details on the design and installation of sprinkler systems.

Separation of Mall Tenant Stores

Walls dividing mall building stores from each other can extend from the floor to the underside of the roof deck or floor deck above or to the underside of a noncombustible ceiling. The purpose of this requirement is to help limit fire and smoke spread to its area of origin. No separation is required between a store and the covered mall. The engineering of a smoke-control system may require deletion of the tenant partitions above the ceilings so the system operates effectively to prevent smoke accumulation. Tenant separation walls are usually constructed of metal studs and gypsum board.

Any requirement for separation at the storefront would defeat the merchandising purpose of the mall: to optimize unrestricted customer flow between the mall and the tenant store. This form of compartmentation, in concert with an electrically supervised automatic sprinkler system, eliminates the need for any fire separation wall requirements at the mall storefronts. In shopping centers, additional fire separation is unnecessary and, in fact, burdensome from an operational standpoint. In the leasing and subsequent re-leasing of shopping centers, maximum flexibility to rearrange space is important to continued success.

Smoke Management

Smoke management has been evaluated over the 30 years that mall buildings have existed and several approaches to smoke management are used in these buildings. One approach is a method to remove smoke from the mall when smoke migrates into it, since the mall is a primary component of the means of egress system.

Another approach is to design an engineered smoke management system for both the mall and the tenant spaces. This approach reacts to smoke that develops in a tenant space to limit smoke migration to the mall.

A third approach is to use the expansive volume of the mall building space, including the volume of the mall proper, to act as a reservoir for the accumulation of combustion products. With this method, even if smoke develops and migrates into the mall area, it will represent little threat to life safety since the building is sprinklered throughout, and the smoke and combustion gases entering a large-volume space, such as an atrium or mall, can be expected to be maintained at the higher elevations of the mall, which are typically well above the occupants who are evacuating. Since the mall is typically a large open space, people can see the smoke developing from a distance and use one of the multiple egress paths available to evacuate the mall building, while moving away from the developing fire condition.

Construction codes recognize that active smoke removal or venting may not be necessary in one- or two-level mall buildings. Thus, the type of smoke management system used can vary depending on project design from active mechanical systems to that of a passive design concept. See NFPA 92A, *Standard for Smoke-Control Systems Utilizing Barriers and Pressure Differences,* and NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria, and Large Spaces,* for details on smoke control system design.

General Requirements

In addition to the special code provisions, certain means of egress conditions should be present in all mall buildings:

1. Every floor and every store of a mall building, except those less than 100 ft (30 m) deep, should have at least two exits remotely located from each other. The two required exits may both be through the mall concourse if the exits from the tenant space are remotely located as required by the code.
2. Every mall should have unobstructed 10-ft (3-m) wide exit access parallel and adjacent to the connected tenant spaces. The exit access should extend to the mall exits.
3. Exits from the mall should be arranged so that travel distance from any mall storefront entrance to an exit is no more than 200 ft (61 m).

GENERAL LIFE SAFETY FACTORS APPLYING TO MERCANTILE OCCUPANCIES

A number of factors related to life safety are common to all types of mercantile facilities.

Prompt discovery is one of the most important factors associated with minimizing loss due to fire. This is especially important during nonbusiness hours, from late night to very early morning. Many fires occur in stock areas, as opposed to sales areas. Poor housekeeping and smoking are two significant concerns in stock areas. For example, workers may remove merchandise from cartons for display on the sales floor and not properly dispose of the cartons and packaging, thus increasing the hazard.

Properly engineered sprinkler systems can be expected to respond to a fire to control its development, if not extinguish it entirely. The exit concepts for all large mercantile occupancies, including bulk merchandising stores, require careful design to achieve the operational needs of the facility while ensuring safe evacuation of the occupants in the event of a fire or other emergency.

Some items to consider follow:

1. If the main entrances are in one wall of the store, the code may require 50 percent or more of the required egress capacity to be provided in the same exterior wall. If high racks or fixtures are used, occupants must be able to readily identify the direction to this main exit wall.
2. Do egress paths of travel conflict with merchandise and stock movement? Such could be the case if exit access passes through shipping and receiving areas without defined egress paths identified by floor markings or physical barriers.
3. Does exit access require travel through other use areas in which the egress path is not clear and direct? Exit access through stockrooms, back-of-house or employee areas, or exterior garden departments can be used effectively if a clear and defined egress path is available.

The need to renovate existing facilities as a result of new trends in fashion or store design may arise in mercantile facilities as may the need to reconstruct existing facilities when releasing space, especially in shopping centers. Extra care should be taken to mitigate the potential problem of fire during these times, since reconstruction and renovation are very likely to increase the hazard. See NFPA 241, *Standard for Safeguarding Construction, Alteration, and Demolition Operations,* for more information.

Certain accessory uses, such as food preparation areas in restaurants, often found in mercantile facilities and more particularly in department stores and shopping centers, warrant special attention. Such areas should be segregated with appropriate construction, if not sprinklered, and appropriate fire suppression systems should be installed in food preparation equipment. See NFPA 96, *Standard for Ventilation Control and Fire Protection of Commercial Cooking Operations,* for more information.

SUMMARY

An important purpose of this chapter on the nature of mercantile occupancy is to form a basis for considering or reconsidering code requirements that let the mercantile trade function optimally and yet provide the necessary degree of life safety for the facilities' occupants.

All requirement-related items discussed in this chapter have been practically applied in many stores and mall buildings throughout the United States. They have answered the need for life safety without imposing burdensome or unreasonable restrictions on either the developers or the merchandising needs of the mall buildings.

In addition to NFPA *101* and *NFPA 5000,* other model codes address the issues presented in this chapter in an effort to achieve codification of requirements for mall buildings. This effort's success will depend on how successfully the life safety concern is addressed in harmony with the retail merchandising purpose of the mall building.

Overreaction in the formulation of code requirements is possible if the fire record is not reviewed and used as a guide to the need for additional requirements. This is especially important when operational needs of the building type being considered are not fully understood. Therefore, code revisions should be tested to see if they are unreasonably restrictive or unfounded in terms of any real threat to life safety, compared to practicability in application and in terms of costs and benefits.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on mercantile occupancies discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

Chapter Contents

Building Construction
Occupancy Characteristics
Potential Fire Scenarios
Means of Egress
Exit Lighting
Automatic Sprinklers
Existing Buildings

Key Terms

defend in place, Fire Safety Evaluation System, fire scenario, means of egress, occupancy characteristic, relocation, staged evacuation, total evacuation

As the service side of the economy continues to grow, more and more of us have become part of the many industries that deal in information. For example, based on U.S. Census statistics, the seasonally adjusted annual rate of the value of construction put in place for "Offices" grew 4.2 percent from January 2005 to January 2006. This indicates a continued growth in the development and construction of office space. Record keeping, data processing, and information management are central to businesses that are physically located in office buildings, and office buildings are the prototype for the class of properties defined as business occupancies in NFPA *101®*, *Life Safety Code®*, and *NFPA 5000®*, *Building Construction and Safety Code®*.

Most of the fires each year in business occupancies occur specifically in general business offices (Tables 20.11.1 and 20.11.2). Large numbers of business occupancy fire problems also occur in college classroom and administrative buildings, medical offices, and bank buildings. Other examples of this occupancy class include city or town halls, courthouses, laboratories not involving hazardous chemicals, and some ambulatory outpatient clinics. In each of these properties, information storage has dominated the building's distinctive fuel load. However, in recent decades the increased use of desktop computers and peripheral equipment has added to the overall fuel load.

The business occupancy has long been considered a low-hazard occupancy and, therefore, not worthy of serious protection consideration. However, this is not the case, as this chapter will show. It examines building construction, occupancy characteristics, potential fire scenarios, means of egress, effects of sprinklers, effects of detection systems, and special cases of existing buildings.

Rather than recite requirements available for reference in codes and standards, this chapter approaches the subject of protecting life in a business occupancy from a more philosophical standpoint. It challenges the reader to look beyond the codes and to observe, measure, and understand the impact that building and occupancy conditions actually have on persons in them.

During the 1999–2002 period, the 4900 fires in office properties accounted for 0.9 percent of the 517,130 structure fires, 0.1 percent of the 3140 civilian structure fire deaths, 0.3 percent of the 17,730 civilian structure fire injuries, and 1.6 percent of the $8.6 billion in direct property loss. (The events of September 11, 2001, are excluded from these statistics.)[1]

In addition, fires in office properties fell 60 percent from 10,570 in 1980 to 4200 in 2002 (see Table 20.11.2). From 2001 to 2002, structure fires in these occupancies fell 14 percent. In comparison, structure fires of all types declined 51 percent from 1980 to 1999.[1]

What's driving the reduction in fires? Most industry experts attribute the loss reduction to a combination of improved application of safety codes and standards, increased public fire prevention and awareness, and increased effectiveness of life safety measures.

Office buildings have been terrorist targets in recent years. On February 23, 1993, a terrorist attack at the World Trade Center in New York City claimed six lives. On April 19, 1995, an explosion at a federal office building in Oklahoma City killed 168 people. On September 11, 2001, terrorist attacks on the twin towers of the World Trade Center in New York City and at the Pentagon in Virginia caused thousands of deaths.

NFPA members can download a number of investigation reports on office building fires, including the 1995 attack in Oklahoma City, the first World Trade Center attack in 1993, Philadelphia's One Meridien Plaza, Boston's Prudential Office Building, New York City's Rockefeller Center, and

TABLE 20.11.1 Structure Fires in Office Properties, 1999–2002 Annual Averages*

Occupancy	*Fires*	*Civilian Deaths*	*Civilian Injuries*	*Direct Property Damage (in Millions of Dollars)*
Business office	4060	4	42	114
Research or veterinary office	420	0	4	10
Bank	320	0	3	14
Post office or mailing firm	100	0	1	3
Total	4900	4	51	141

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest ten, civilian deaths and injuries are rounded to the nearest one, and direct property damage is rounded to the nearest million dollars. Property damage has not been adjusted for inflation.

*Excluding the events of September 11, 2001.

A discussion of the terrorist threat to office buildings is provided here only as a point of reference to the changing landscape of risks in America. This chapter does not address the specific risks associated with terrorism.

To be aware of the concept of risk is to begin to understand the fire problem. The business occupancy is certainly of a lower hazard class than many industrial or hazardous materials handling operations. But when more people occupy a single building than reside in a small town, as is often the case in the modern high-rise, the magnitude of the challenge faced in protecting the building, its contents, and, most importantly, its occupants, is realized.

This chapter examines how the contents and the building itself affect fire growth and severity, how growth and severity affect notification and egress time of occupants, and how the conditions of occupants affect their abilities to escape. A format and issues for analysis are presented.

Additional information on determining necessary levels of protection can be found in Section 3, "Information and Analysis for Fire Protection." More information on fire-safe building design can be found in Section 1, Chapter 9, "Systems Approach to Fire-Safe Building Design." Information on interior finish can be found in Section 18, Chapter 2, "Interior Finish." Other relevant information can be found in Section 4, Chapter 5, "Strategies for Occupant Evacuation During Emergencies."

BUILDING CONSTRUCTION

Construction Type

Business occupancies can be found in a variety of building types. Although a two- or three-story noncombustible structure or a fire-resistant high-rise may be most familiar, many business occupancies are housed in ordinary wood frame, joisted masonry, and even heavy timber buildings.

Each construction type affects the business occupancy differently because fires behave differently in each. This discussion and its examples are confined to noncombustible and fire-resistive construction because it is most prevalent. The reader must understand that, in other construction types, the availability of fuel from the structure itself can increase fire severity, thereby decreasing potential structural integrity much more quickly.

Noncombustible Construction. In noncombustible construction, construction materials do not burn, thereby providing a measure of increased occupant safety. In reviewing the life safety needs of a business occupancy in a building of noncombustible construction, the designer or reviewing official can be primarily concerned with fuel load from the contents, furnishings, and interior finish, and with the means of egress. Although the potential fire's effect on the structure also must be assessed, this is usually simpler to do than it is in the case of combustible construction materials.

Fire-Resistive Construction. Fire-resistive structures are similar to noncombustible structures except that the material or combinations of materials used inherently resist failure due to fire or to the spread of fire. These characteristics help ensure sufficient time for persons to egress and/or receive other forms of assistance.

Interior Finish

Interior finish comprises the various aesthetic treatments to the structure that make it more comfortable to work in and more pleasing to the eye. Interior finish includes the materials used to cover walls, ceilings, and floors, such as paint, wallpaper, vinyl and textile wallcoverings, paneling, acoustic panels, hardwood floors, vinyl tile, terrazzo, and carpet.

The main fire performance measure of an interior wall or ceiling finish material is flame spread. This is the ability of the material to propagate a flame front across its surface. Wall and ceiling materials are ranked by relative ratings based on a value of 100 given for a specially prepared sample of red oak. Floor finishes are rated by the amount of heat energy imparted to the surface from an external source that is necessary to sustain combustion; this is called critical radiant flux. The better the flame-spread characteristics—that is, the lower the rating for wall and ceiling material, and the higher critical radiant flux for floor coverings—the more occupant protection can be assumed.

It is important to note that flame-spread ratings are based on tests of materials under controlled conditions and with specific backing materials. A wallcovering mounted on gypsum wallboard would be expected to perform differently than a wallcovering installed over brick or concrete block.

A most important but often overlooked point is that interior finish materials are also fuels. When materials are relatively thin—two coats of paint or one layer of vinyl wallcovering, for example—the additional fuel may be insignificant. In general, wallcovering materials with a thickness of 1/28 in. (0.91 mm) or less are typically exempt from testing on the actual substrate material. If they achieve a Class A rating when tested using fiber cement board as the substrate, they are not subject to the interior finish requirements of NFPA *101* and *NFPA 5000*. But when several layers of wallcovering, carpet, floor coverings, or other materials are present, the hazard and risk change dramatically. It should not be assumed that a low flame-spread rating alone results in a significant risk reduction. It is important to understand the impact this additional fuel has on the entire environment.

Furnishings and Contents

Furnishings and contents make up the bulk of the potential fuel load in a business occupancy. Furnishings, for the purpose of this discussion, include desks, chairs, sofas, and files.

Over the past decades, there have been many changes in the furnishings put into buildings. At one time, desks and chairs were routinely wood. Then metal became popular. Now, any combination of wood, metal, thermoplastics, and foamed plastics can be found. In addition, the increased use of computers has added to the fuel load.

Business occupancies are considered lower hazard than industrial or other occupancies handling hazardous materials. However, this perception sometimes confuses familiarity with safety. The quantity of combustible fuel in business occupancies can be a source of significant hazard, even if hazardous materials

are not involved. In addition, some relatively benign materials may have burning characteristics—such as peak intensity of heat when fully involved in fire—comparable to some hazardous materials.

The designer and code official must be aware of the characteristics of the materials in a building, such as construction materials, interior finish materials, and furnishings. Each provides a degree of protection and a degree of hazard; their combined effect influences risk. Without understanding the potential fire behavior in a business occupancy, one cannot begin to understand its potential effect on people.

OCCUPANCY CHARACTERISTICS

Business occupants are generally characterized as awake, alert, and familiar with their surroundings. Although this is true of most offices, designers and code officials must assess the actual characteristics of a particular business occupancy, such as a doctor's office or an outpatient clinic, in which a minority of the occupants are familiar with the surroundings. In business occupancies, generalities do not always apply. The following three examples of different occupancy conditions emphasize the need for designers and code officials to evaluate the actual occupant conditions.

Support Services

Support services often are found within business occupancies. Each provides a challenge in the analysis of potential fire impact because these service areas present their own special hazards (Table 20.11.3). Examples include cafeterias, auditoriums, print shops, storage areas, parking facilities, small retail outlets,

TABLE 20.11.3 Structure Fires in Office Properties, by Area of Origin, 1999–2002 Annual Averages*

Area of Origin	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*	
Office	750	(15%)	3	(68%)	17	(33%)	43	(30%)
Kitchen or cooking area	290	(6%)	1	(21%)	2	(4%)	1	(1%)
Exterior wall surface	260	(5%)	0	(0%)	0	(0%)	4	(2%)
Attic or ceiling/roof assembly or concealed space	220	(4%)	0	(0%)	1	(1%)	15	(10%)
Exterior roof surface	210	(4%)	0	(0%)	1	(1%)	3	(2%)
Lavatory, bathroom, locker room, or check room	190	(4%)	0	(0%)	0	(0%)	2	(1%)
Confined cooking fire	190	(4%)	0	(0%)	0	(0%)	0	(0%)
Heating equipment room	190	(4%)	0	(0%)	6	(11%)	3	(2%)
Machinery room or area or elevator machinery room	170	(3%)	0	(0%)	0	(0%)	9	(6%)
Storage of supplies or tools or dead storage	130	(3%)	0	(0%)	0	(0%)	6	(4%)
Computer room, control room, or center	110	(2%)	0	(0%)	1	(2%)	1	(1%)
Lobby or entrance way	110	(2%)	0	(0%)	1	(2%)	4	(3%)
Hallway, corridor, or mall	110	(2%)	0	(0%)	2	(5%)	1	(0%)
Wall assembly or concealed space	100	(2%)	0	(0%)	0	(0%)	2	(1%)
Crawl space or substructure space	80	(2%)	0	(0%)	2	(3%)	5	(4%)
Ceiling/floor assembly or concealed space	80	(2%)	0	(0%)	1	(1%)	3	(2%)
Trash or rubbish chute, area, or container	80	(2%)	0	(0%)	1	(2%)	1	(1%)
Switchgear area or transformer vault	70	(1%)	0	(0%)	3	(6%)	3	(2%)
Dining room, bar or beverage area, cafeteria	70	(1%)	0	(0%)	1	(1%)	0	(0%)
Unclassified	60	(1%)	0	(0%)	1	(1%)	5	(3%)
Unclassified equipment or service area	60	(1%)	0	(0%)	0	(0%)	1	(1%)
Unclassified structural area	60	(1%)	0	(0%)	0	(0%)	3	(2%)
Duct for HVAC, cable, exhaust, heating, or air conditioning	60	(1%)	0	(0%)	2	(5%)	0	(0%)
Common room, living room, family room, lounge, or den	60	(1%)	0	(0%)	1	(1%)	2	(1%)
Closet	50	(1%)	0	(0%)	1	(1%)	0	(0%)
Confined fuel burner or boiler fire	50	(1%)	0	(0%)	0	(0%)	0	(0%)
Records storage room or vault	50	(1%)	0	(0%)	1	(2%)	1	(1%)
Unclassified storage area	50	(1%)	0	(0%)	0	(0%)	2	(2%)
Storage room, area, tank, or bin	50	(1%)	0	(0%)	2	(4%)	4	(3%)

*Excluding the events of September 11, 2001.

Source: NFIRS and NFPA survey.

and banks or credit unions. People usually gather in these areas during certain times, often in large concentrations relative to the general occupant load for the entire building. Many service areas increase the potential for fire ignition because of their operation; one example is a cafeteria kitchen.

Child-Care Center

Another growing service area in business occupancies is the child-care center. With more families having both parents, or the only parent, working, employer-provided child care or contract day care is becoming more common. This poses special concerns: the occupants' ages, their lack of familiarity with their surroundings, mobility, and the fact that they sleep in the space from time to time. Special protection must be considered for child-care centers, including smoke detection, sprinkler protection, fire-resistive enclosures, location at grade level with direct access to the outside, and sufficient adult supervision.

Disabilities

Another high-risk segment of the population in business occupancies are people with disabilities. There are special requirements for access and acommodations for disabled people, as well as increasing awareness of the large number of people with ability limitations of some kind to some degree that could affect their response to fire. Disabilities cover a wide range, including sight, hearing, and mobility impairments. A disability also can be temporary or transient, such as a broken leg. Disabilities can increase the time needed to alert individuals or the time necessary to safely egress an area or the building. Designers and code officials must consider the presence of persons with known or hidden disabilities when evaluating a life safety system for a business occupancy.

POTENTIAL FIRE SCENARIOS

Fire safety design for a particular property must begin with a consideration of characteristics of most likely fires and the most serious fire the occupancy might encounter (Table 20.11.4). This may be done by defining potential fire scenarios to use as a basis for analysis.

Ignition Sources

Leading sources of heat for unintentional ignition include electrical distribution systems, portable and fixed space heating

TABLE 20.11.4 Leading Causes of Structure Fires in Office Properties, 1999–2002 Annual Averages*

Cause	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*	
Electrical distribution and lighting equipment	930	(19%)	0	(0%)	22	(44%)	23	(16%)
Intentional	650	(13%)	0	(0%)	6	(12%)	41	(29%)
Heating equipment fires	520	(11%)	1	(33%)	5	(10%)	6	(4%)
Identified heating equipment	460	(9%)	1	(33%)	5	(10%)	6	(4%)
Confined heating equipment fire	60	(1%)	0	(0%)	0	(0%)	0	(0%)
Cooking equipment fires	500	(10%)	1	(33%)	4	(7%)	2	(1%)
Identified cooking equipment	310	(6%)	1	(33%)	4	(7%)	2	(1%)
Confined cooking fire	190	(4%)	0	(0%)	0	(0%)	0	(0%)
Smoking materials	490	(10%)	1	(25%)	1	(3%)	13	(9%)
Exposure to other fire	250	(5%)	0	(0%)	1	(1%)	10	(7%)
Torch (including burner or soldering iron)	240	(5%)	0	(0%)	4	(9%)	5	(3%)
Candle	120	(2%)	0	(0%)	1	(1%)	3	(2%)
Contained trash or rubbish fire	130	(3%)	0	(0%)	0	(0%)	0	(0%)

Note: These are the leading causes, obtained from the following list: intentional (from the NFIRS field "cause"); playing with fire (from factor contributing to ignition); confined heating (including confined chimney and confined fuel burner or boiler fires), confined cooking, and contained trash or rubbish (from incident type); identified heating, identified cooking, clothes dryer or washer, torch (including burner and soldering iron), electrical distribution and lighting equipment, medical equipment, and electronic, office, or entertainment equipment (from equipment involved in ignition); smoking materials, candles, lightning, and spontaneous combustion or chemical reaction (from heat source); and mobile property involved (from mobile property involved in ignition). Exposure fires include fires with an exposure number greater than zero, as well as fires identified by heat source or factor contributing to ignition when no equipment was involved in ignition that were not intentionally set. The same fire can be listed under multiple causes, based on multiple data elements.

These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest ten, civilian deaths and injuries are rounded to the nearest one, and direct property damage is rounded to the nearest million dollars. Property damage has not been adjusted for inflation.

*Excluding the events of September 11, 2001.

equipment, other appliances, torch and other maintenance operations, matches and lighters, and smoking materials. The design professional and code official must know where potential ignition sources are and where they expose potential fuels.

Arson

One of the leading causes of fire in business occupancies is not unintentional, however; it is arson. Arson prevention is partly a matter of understanding the business and those who might wish to harm it, such as competitors, disgruntled employees, angry customers, or economically strapped owners. But arson more often occurs as a result of less direct motives, such as emotional disturbance, so it is important to emphasize security controls and arrangements, such as housekeeping, that will reduce the range of attractive and easy targets for potential arsonists. Also, the importance of arson underscores the limits of fire prevention as a strategy, so postignition fire protection provisions are needed, too.

The value at risk from a fire in a business occupancy can easily be underestimated, with the increase in regular use of computers, facsimile machines, copy machines, printers, and similar equipment, and the purchase of telephone systems for offices and buildings. The value of loss of business and other interruption costs, including the occupancy of temporary space and reduced employee productivity during space restoration, also must be considered.

The designer and code official must look carefully at the business occupancy for available fuels and potential ignition sources. The impact of fire on the occupancy and occupants can then be predicted. Computer models and other engineering tools can translate the occupancy's physical and occupant characteristics into a timeline of fire development and its effects on people and property.

MEANS OF EGRESS

In analyzing the potential fire scenario and choosing strategies to deal with the results of the analysis, it is useful to think in terms of major groups of fire protection provisions. Means of egress will be the first discussed here. Before the means of egress needs can be assessed, however, an objective must first be established: every occupant should be able to reach a safe location from anywhere in the building without incurring serious harm from fire, smoke, or other products of combustion along the way.

For a long time, this objective was fulfilled by evacuating building occupants when fire was discovered. As buildings get larger and taller, this came to be less practical. Some high-rise building populations are the size of a small town; total evacuation may take hours. Nor does it make sense to move people from the 40th floor of a building in response to a small trash fire on the 60th floor, especially if the fire is being controlled or extinguished by an automatic sprinkler system. Persons with severe mobility impairments may not have this option available without assistance.

One method of establishing an acceptable level of protection for persons from fire is the application of NFPA *101* or *NFPA 5000*. They provide requirements for determining occupant loads, arrangement of means of egress, capacity of means of egress, and exit travel distances, as well as requirements for the design of doors, stairs, and interior finish materials. NFPA *101* recognizes differences in existing buildings and new construction, and it provides different requirements for each. In fact, all codes and standards have equivalency clauses so as not to exclude sound engineering approaches that accomplish the same or similar results. The code official must be aware of the application of these equivalency clauses.

Total Evacuation

In a total evacuation, persons should be able to leave the building before conditions become untenable. Fire growth, temperature rise, and the production of toxic combustion products must be estimated. Then the time needed to evacuate the building must be estimated. The difference between the evacuation time and the time to untenable conditions is the time allowed for fire detection, notification of occupants, and occupant reaction.

The alarm system, either manual or automatic, must be chosen based on the time available to notify occupants. In most business occupancies, a manual alarm system is sufficient, but the designer and code official must be aware of conditions that warrant the use of an automatic detection and alarm system. If automatic sprinkler protection is provided, the designer should take advantage of its presence and use it as an alarm-initiating device.

Alternatives to Total Evacuation

If total evacuation is not practical, it is still necessary to ensure that occupants can get to an area of relative safety before conditions become untenable. This is commonly accomplished by a combination of four approaches.

Relocation. Fire conditions and necessary egress time must be estimated. The area of relative safety must then be chosen. This may be a trial-and-error design process because estimated fire conditions and the structure's ability to resist fire affect where the safer areas will most likely be. Furthermore, persons must be able to reach those areas in a reasonable time.

Other egress or occupant protection strategies are similar to relocation and include defend in place, staged evacuation, and use of horizontal exits.

Defend in Place. Defend-in-place strategies are generally used in health care occupancies where patients cannot be readily moved. Although not preferred for business occupancies, the existence of such strategies should be noted and understood.

Staged Evacuation. Staged evacuation can take several forms. One is staged total evacuation where the fire floor occupants are notified, and, after a determined time period, other occupants are notified. This allows those on the fire floor the first opportunity to escape. Persons in areas farther from the fire start to evacuate a bit later.

Another method of staged evacuation is the use of "hardened" areas, or areas of refuge, where persons may seek tem-

porary refuge until they are able to egress. These staging areas pose several questions:

1. How should the area be hardened? Fire resistance is not enough. Ventilation and pressurization are critical to maintaining a tenable environment when the area is exposed to postflashover conditions or smoke migration.
2. How many people will use the area? These areas have been suggested for use by people with disabilities. With the population of mobility-impaired occupants growing in many business occupancies, a minimum number of such occupants must be able to be safely protected in such areas. NFPA *101* and *NFPA 5000* provide guidance on this topic.
3. How will people use these areas? Practice is the only answer. If provided, these areas must be addressed in the fire evacuation plan for the building. This fact would suggest that these staging areas have only limited impact on persons who are not familiar with the building.
4. How will persons eventually leave the building? These areas must not be considered as a place to wait until the fire is extinguished. Persons generally must leave the fire floor. These areas, if provided, should be adjacent to stairs or elevators so that fire department personnel or building fire wardens can assist persons in these areas to other areas of relative safety.

The use of this type of staging area takes much planning, practice, maintenance, and coordination. Unfortunately, it is of little benefit to persons unfamiliar with the building and its features. Therefore, a preferred method would be to establish a way to protect the occupants with little or no special instructions.

In potential impact and effectiveness of staging areas for occupants with disabilities, complete automatic sprinkler protection (properly designed, installed, and maintained) afforded occupants sufficient safety without actually needing to egress the floor (Table 20.11.5). If the sprinkler system uses quick-response sprinklers, there will likely be no perception of risk on the part of building occupants.

Horizontal Exit. Another method of staged evacuation is through horizontal exits. Horizontal exits can be provided by subdividing a building with specially designed fire barriers. Persons passing through doors in these walls move to an area of relative safety. In some cases, the horizontal exit alone may provide enough egress protection. In others, the horizontal exit may be used to provide enough protection to stage occupants, thereby allowing more time for total evacuation or assisted evacuation, as in the case of persons with disabilities.

In either relocation or staged evacuation, fire control is important. To ensure the success of the egress or occupant protection strategy, fire growth and combustion products must be held to a minimum. This can be done in several ways. Fuel can be limited, room geometry can be controlled, and ventilation of fire areas can be limited. A proven effective method of controlling fire growth and smoke production is through the use of automatic sprinklers. Therefore, where occupant relocation or staging is an intended strategy, the building should be protected with automatic sprinklers, although individual conditions dictate the actual protection necessary.

TABLE 20.11.5 Fire Protection Features in Office Property Structure Fires Reported to Public Fire Departments, 1994–1998 Annual Averages

Percent of fires in buildings with smoke or other fire alarms present	53.7%
Percent of fires in buildings having smoke or other fire alarms in which devices were operational	74.3%
Percent of fires in buildings with operational smoke or other fire alarms (product of first two statistics)	39.9%
Percent of fires in buildings with automatic suppression system	25.4%
Deaths per 1000 fires with automatic suppression system present	0.0
Deaths per 1000 fires with no automatic suppression system present	0.3
Reduction in deaths per 1000 fires when automatic suppression systems were present	100.0%
Average loss per fire when automatic suppression system was present	$11,311
Average loss per fire with no automatic suppression system	$28,091
Reduction in loss per fire when automatic suppression systems were present	59.7%

EXIT LIGHTING

The means of egress should be continuously illuminated by a reliable lighting system. This usually means spacing lighting fixtures and providing primary and emergency power to ensure a lighting level of at least 1 footcandle (10 lux), measured at the floor level.

Emergency power can be provided in many ways: batteries, inverters, generators, separate building substations with automatic transfer switches, and power distribution system network grids. The concept behind emergency power for egress lighting is to ensure that the exit path is illuminated if a fire in the building disrupts the primary power source. Because a complete power failure at the utility would rarely occur at the same time a fire in the building would, it is sufficient to have only one of the recommended emergency power sources. However, other design arrangements may be necessary, depending on specific local conditions and utility reliability.

AUTOMATIC SPRINKLERS

As discussed, automatic sprinkler protection can increase the level of fire safety in a business occupancy. From the life safety standpoint, sprinklers limit fire growth and the production of smoke, thereby increasing the time available for persons to egress. If designed to do so, automatic sprinklers can even keep conditions in close proximity to the fire in a tenable range.

Another reason sprinklers should be considered is property protection. Fire department suppression capabilities may

be limited by staffing issues, water supplies, or height of the fire above ground level. If fire fighters must rescue occupants, their fire suppression capability decreases. As property values and mission criticality increase, the typical business cannot afford this potential exposure.

The average loss per fire was cut almost in half when automatic suppression systems were present. Automatic suppression systems were present in only 25 percent of these fires from 1994 to 1998. The average estimated direct property damage was almost twice as high when no automatic suppression system was present. Because a code for undetermined system presence was not included in Version 5.0 of NFIRS until 2004, data on number of fires and loss rates cannot be confidently updated (Table 20.11.6).

Sprinkler protection automatically detects a fire and starts suppression actions, providing additional time for occupants to exit. The sprinkler system can even notify occupants of the fire when arranged to activate the fire alarm. Sprinklers also limit fire and water damage, thereby decreasing business interruption. With the expanded use of quick-response sprinklers, these occupant protection factors and property protection features can be expected to increase.

Retrofitting sprinkler systems is becoming easier with the use of special materials such as lightweight steel pipe, copper tube, and plastic pipe. In addition, sprinklers can be safely installed in buildings with sprayed-on asbestos containing fireproofing through a process of local encapsulation and control. See the additional readings for this chapter for more information on this subject.

EXISTING BUILDINGS

Business occupancies in existing buildings pose several concerns from a life safety standpoint. Many do not meet the requirements of codes, standards, or design practices for new construction. The question should not be, "Do they comply?" Rather, we should ask, "Is the occupant protection objective fulfilled?" In this case, occupant protection should be no different than that previously discussed. The objective is to get people to an area of relative safety before conditions become untenable.

TABLE 20.11.6 Automatic Suppression Systems in Office Property Structure Fires Reported to Public Fire Departments, 1994–1998 Annual Averages

Percent of fires in buildings with automatic suppression system	25%
Average loss per fire when automatic suppression system was present	$11,300
Average loss per fire with no automatic suppression system	$28,100
Reduction in loss per fire when automatic suppression systems were present	60%

Source: National estimates based on NFIRS and NFPA survey.

The difference is that an existing building constrains the protection strategy. Several resources can be used to help find solutions to egress problems in existing buildings.

NFPA *101* has a separate chapter for existing business occupancies. Requirements in that chapter are similar to those for new buildings, but they reflect the necessity of accepting those things that cannot be economically changed, provided a reasonable degree of safety is present.

Another good reference is NFPA 101A, *Guide on Alternative Approaches to Life Safety,* which includes a chapter on a Fire Safety Evaluation System (FSES) for business occupancies. FSES is a measuring system. It compares the level of safety provided by an arrangement of safeguards that differs from those specified in NFPA *101* to the level of safety provided in a building that conforms with the details of the code.

Other analytical methods exist that may be beneficial in evaluating the risk to life in an existing business occupancy. These include hand calculations and computer-based predictive fire models. (See Section 3, "Information and Analysis for Fire Protection.") In any event, the process is the same—determine the fire exposure, the time available for safe egress, and the time needed to egress.

A special category of existing buildings must be mentioned: historic or architecturally significant buildings. Society puts additional constraint on these structures as to the way alterations must be done. Here, historic preservation and life safety objectives must be carefully outlined and communicated. These objectives are not necessarily at cross purposes. Innovative design techniques and engineered performance-based solutions, rather than code compliance, are usually called for. A reference on the process and design tips is included in the list of additional readings following this chapter. Also see Section 20, Chapter 17, "Library and Museum Collections."

SUMMARY

Business occupancies comprise a large segment of the communities protected, and they can be found in a variety of building types. Construction type, occupancy characteristics, potential fire scenarios, means of egress, the effect of sprinklers, and existing conditions all affect the ability to protect occupants from the effects of fire. An objective has been set for protecting these occupants by keeping them in a tenable environment or by allowing them to escape to an area of relative safety before untenable conditions are reached. This area may be outside the building, on another floor, or through a horizontal exit.

The designer and code official must look deeper than codes and standards alone to understand actual conditions and measure exposures. They will then be able to recommend ways of fulfilling the objective of protecting occupants.

Chapter Contents

Fire Problem in Educational Occupancies
Occupant Characteristics
Design Considerations
Occupancy Hazards
Life Safety Concepts

Key Terms

educational occupancy, exit hardware, fire exit drills, means of egress, occupant characteristic, occupant load, open plan design, windows

This chapter addresses *educational occupancies,* which are generally defined as new or existing facilities in which six or more persons gather for purposes of formal or structured instruction. This chapter describes the nature of educational occupants as well as the hazards and life safety concepts relevant to this type of occupancy.

Examples of educational occupancies include public, private, and parochial schools, academies, kindergartens, and other facilities whose purpose is primarily educational, even though their students may be of preschool age. Educational occupancies are typically defined as places where students are present for formalized instruction for more than 4 hours per day, or more than 12 hours per week, through the twelfth grade. This is differentiated from day-care occupancies, which are generally defined as those facilities in which four or more clients receive care, maintenance, and supervision by other than their relatives or legal guardian for less than 24 hours per day. Colleges, universities, and postsecondary trade schools are typically excluded from educational occupancies as well. Furthermore, the definition of an educational occupancy excludes facilities in which instruction is incidental to some other occupancy. In such cases, the requirements of the predominant occupancy shall apply. Examples of excluded facilities include the following:

- Rooms located within places of worship used for purposes of religious education while services are being held in the building
- Rooms used for extracurricular purposes such as piano instruction, dance instruction, martial arts classes, or sport activities
- Classrooms and laboratories located within business or industrial occupancies

See also Section 20, Chapter 13, "Day-Care Occupancies."

FIRE PROBLEM IN EDUCATIONAL OCCUPANCIES

The U.S. fire problem in educational occupancies is outlined in Tables 20.12.1 through 20.12.4. As one can see, between 1999 and 2002, there was an annualized average of approximately 7070 structure fires in educational properties. These fires contributed to an average of 113 civilian injuries and $112 million in direct property damage per year during that period. Although educational occupancy fires can start in a variety of locations, the data indicate that the leading areas of origin tend to be in lavatories or locker rooms, with rubbish, trash, magazines, papers, and other waste products often the first items to be ignited. Almost half of the fires in educational occupancies were intentionally set or the result of fireplay. It is for this reason that traditional fire safety education messages should be augmented with juvenile firesetter programs in educational occupancies. It is important to note that these data are derived from the National Fire Incident Reporting System (NFIRS) and from information gleaned from an annual survey conducted by NFPA. As such, this information does contain some imbedded data garnered from day-care occupancies, colleges, universities, and other adult learner properties.

Table 20.12.5 presents the benefits of automatic suppression systems in educational properties. Note that automatic suppression systems were present in only 24 percent of the fires in educational

Alex L. Szachnowicz, P.E., is the director of facilities for Anne Arundel County Public Schools in Annapolis, Maryland. TABLE 20.12.1 Structural Fires in Educational Properties, 1999–2002 Annual Averages

Occupancy	*Fires*	*Civilian Deaths*	*Civilian Injuries*	*Direct Property Damage (in Millions of Dollars)*
Nursery school through high school	5320	0	88	74
Preschool	210	0	1	1
Elementary school, including kindergarten	1380	0	13	27
High school, junior high, or middle school	3020	0	62	33
Unclassified nonadult school	700	0	12	13
Adult education center or college classroom	980	0	17	30
Day care	440	0	4	4
Unclassified educational	330	0	3	5
Total	7070	0	113	112

Note: These are fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. Fires are rounded to the nearest ten, deaths and injuries to the nearest one, and direct property damage to the nearest million dollars. Sums may not equal totals due to rounding errors. Damage has not been adjusted for inflation.

Source: *U.S. Fires in Selected Occupancies,* National Fire Protection Association, March 2006. National estimates based on NFIRS and NFPA survey.

properties, and the average estimated direct property damage was almost five times higher when no automatic suppression system was present.

OCCUPANT CHARACTERISTICS

People in educational occupancies vary in their ability to deal with an emergency condition, depending on their age, mental and physical conditions, as well as the facility's physical characteristics. Generally, regulations concerning educational occupancies are based on the abilities of children in the third through eighth grades, with special provisions made for younger children. High school occupants gain an extra measure of protection because the fire safety design package is based on younger children's capabilities.

Children younger than those in the third grade require special consideration because of their limited ability to traverse

TABLE 20.12.2 Leading Causes of Structure Fires in Educational Occupancies: 1999–2002 Annual Averages

Cause	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*	
Intentional	2650	(38%)	*	(*%)	27	(24%)	51.2	(46%)
Cooking equipment fires	930	(13%)	*	(*%)	8	(7%)	1.7	(2%)
Identified cooking equipment	570	(8%)	*	(*%)	6	(6%)	1.7	(2%)
Confined cooking fire	350	(5%)	*	(*%)	2	(2%)	0.0	(0%)
Electrical	550	(8%)	*	(*%)	23	(20%)	12.0	(11%)
Heating equipment fires	530	(8%)	*	(*%)	4	(3%)	6.6	(6%)
Identified heating equipment	450	(6%)	*	(*%)	4	(3%)	6.5	(6%)
Confined heating equipment fire	80	(1%)	*	(*%)	0	(0%)	0.1	(0%)
Playing with fire	520	(7%)	*	(*%)	0	(0%)	4.0	(4%)
Smoking materials	350	(5%)	*	(*%)	6	(6%)	3.5	(3%)
Torch (including burner or soldering iron)	220	(3%)	*	(*%)	10	(9%)	4.7	(4%)
Clothes dryer or washer	200	(3%)	*	(*%)	3	(3%)	0.5	(0%)
Contained trash or rubbish fire	550	(8%)	*	(*%)	4	(4%)	0.3	(0%)

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest ten, civilian deaths and injuries are rounded to the nearest one, and direct property damage is rounded to the nearest hundred thousand dollars. Property damage has not been adjusted for inflation.

*The cause of all the fatalities during this period was unknown or not reported.

Other known outside area	80	(1%)	0	(0%)	0	(0%)	1	(1%)
Other known technical processing area	60	(1%)	0	(0%)	6	(5%)	1	(1%)
Other known assembly or sales area	60	(1%)	0	(0%)	1	(0%)	5	(5%)
Other known area	140	(2%)	0	(0%)	2	(2%)	2	(2%)
Contained trash fire	550	(8%)	0	(0%)	4	(4%)	0	(0%)
Other confined fire	40	(1%)	0	(0%)	0	(0%)	0	(0%)
Total	7070	(100%)	1	(100%)	113	(100%)	112	(100%)

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest ten, civilian deaths and injuries are rounded to the nearest one, and direct property damage is rounded to the nearest million dollars. Property damage has not been adjusted for inflation. Nonconfined and noncontained structure fires in which the area of origin was unknown or not reported have been allocated proportionally among fires with known area of origin. Totals may not equal sums due to rounding errors.

TABLE 20.12.5 Automatic Suppression Systems in Educational Property Structure Fires Reported to Public Fire Departments: 1994–1998 Annual Averages

Percentage of fires in buildings with automatic suppression system	24%
Average loss per fire when automatic suppression system was present	$2800
Average loss per fire with no automatic suppression system	$12,900
Reduction in loss per fire when automatic suppression systems were present	78%

Note: Because a code for undetermined system presence was not included in Version 5.0 of NFIRS until 2004, data on number of fires and fire loss rates cannot be confidently updated.

Source: National estimates based on NFIRS and NFPA survey.

stairs or evacuate effectively in an emergency. Because there is a potential for younger children to be overrun by older students and adults on stairs, most codes require that preschool, kindergarten, and first-grade students be located on a level of exit discharge to facilitate egress. Second-grade students are usually limited to one level above a level of exit discharge in recognition of their limited movement ability. NFPA *101* and *NFPA 5000* permit students younger than the third grade to use rooms or areas located on floor levels higher than the first or second level where provided with independent means of egress dedicated for use by the younger children. The codes recognize that these younger students, with the help of teachers and staff, can use stairs and ramps effectively if they do not have to compete with older, larger, and faster students.

DESIGN CONSIDERATIONS

Schools of only one story, with each room having a direct exit to the outside, represent the most conservative design for life safety. However, economics, site restrictions, or programmatic requirements often dictate other design considerations that can be accommodated and made safe by adhering to certain design principles noted elsewhere within this chapter, in NFPA *101,* and in *NFPA 5000.*

The need to accommodate physically and mentally challenged students within the general school population also affects school designs. Access and egress must be considered for these students by providing facilities such as elevators, ramps, horizontal exits, and areas of refuge in multiple-story buildings. Provisions must be made for using elevators or other special facilities to shelter and evacuate these students. It is important that local fire departments be aware of any special arrangements for evacuating physically disabled students and preplan for such scenarios, as their approach to rescue efforts might be affected by such arrangements.

Flexible and Open Plan Designs

Flexible and open plan design concepts used in some schools differ from conventional designs in that the walls may be demountable or easily moved without major reconstruction efforts. The ability to easily rearrange walls to suit changing programmatic or educational needs is valuable, but proper consideration to egress requirements and fire safety must be included in the planning process.

Open plan buildings delineate spaces and corridors by using movable fixtures and low-height partitions (usually maximum height of 5 ft [1.5 m]). Although this design provides greater flexibility, it diminishes the building's overall fire safety level by omitting features that could confine fire and smoke to a single, smaller compartment long enough to permit orderly evacuation. The compensating factor is the occupants' ability to observe the entire area over the low-height partitions and presumably detect any fire in its incipient stage. Because occupants are presumably awake and alert, their natural faculties can serve as fire and smoke detectors. Such early detection should make prompt evacuation and emergency forces notification possible.

Flexible and open plan buildings should be evaluated while all folding walls are extended and in use, as well as when they are in the retracted position. Flexible and open plan buildings shall also be permitted to periodically rearrange their walls and partitions if revised plans have been thoroughly reviewed and approved by the authority having jurisdiction.

Day-Care Occupancies

Requirements for educational occupancies are not applicable to most child, adult, or home day-care occupancies. As occupants of day-care facilities may not always be considered as being capable of self-preservation actions, a higher level of active and passive life safety measures is often prescribed for day-care occupancies. For more information on child, adult, and home day-care occupancies, see Section 20, Chapter 13, "Day-Care Occupancies."

College and Universities

Requirements for educational occupancies are not applicable to colleges, universities, postsecondary trade schools, or other forms of education beyond grade 12. Students at these levels are generally presumed to be capable of adult behavior because of their age and maturity levels. For more information on colleges and universities, see Section 20, Chapter 3, "Hotels and University Housing," and Section 20, Chapter 11, "Business Occupancies."

OCCUPANCY HAZARDS

Multiple Occupancies

Often more than one type of occupancy exists within or adjacent to an educational facility. Typical scenarios often include assembly and business occupancies as well as dormitories.

In multiple-occupancy situations where the occupancies are mixed as described in NFPA *101* and *NFPA 5000,* care must be taken to ensure that the fire and life safety provisions for all occupancies are met. It is important to provide sufficient protection to prevent the educational occupancy from being exposed to

any hazards associated with other occupancies located within or adjacent to the educational facility.

Hazardous Areas and Arrangements

Areas such as laboratories, shops, kitchens, storage areas, janitor closets, laundries, mechanical rooms, and stages may often be separated from educational occupancies or otherwise protected. Usually, fire-rated walls and doors provide the necessary degree of protection unless the hazard is severe, in which case, automatic suppression systems may also be required. Kitchens should also be protected in accordance with NFPA 96, *Standard for Ventilation Control and Fire Protection of Commercial Cooking Operations.*

Clothing, personal effects, and other combustible materials should not be stored in corridors. However, if automatic smoke detection or suppression systems protect the corridors, or if metal lockers are used, clothing and personal effects can be stored in corridors. Metal lockers should not, however, reduce the required egress width.

Child-prepared artwork and teaching materials attached directly to walls should not cover more than 20 percent of the wall area in nonsprinklered buildings or more than 50 percent of the wall area in sprinklered buildings. It is advantageous to not only limit the quantity of artwork and teaching materials displayed but also to avoid placing such materials near a room's exit access doors. Because the artwork's combustibility cannot be effectively controlled, the quantity, in terms of the percentage of the overall wall area covered, is regulated to avoid creating a continuous combustible surface that will spread flames across the room. Hanging banners in rooms and corridors should also be avoided unless they meet the requirements for flame resistance as prescribed in NFPA 701, *Standard Methods of Fire Tests for Flame Propagation of Textiles and Films.* Because banners can frequently obstruct exit signs, emergency lights, and sprinklers, consideration should be given to problems associated with hanging such banners before allowing their use.

LIFE SAFETY CONCEPTS

Occupant Load

The occupant load, in terms of the number of persons for whom means of egress provisions are to be provided, is typically determined on the basis of the occupant load factors prescribed by NFPA *101* and *NFPA 5000*. The occupant load factors utilized should take into consideration the characteristics or actual use of the space being analyzed. NFPA *101* and *NFPA 5000* prescribe an occupant load factor of 20 net ft^2 (1.9 net m^2) per person for typical classrooms in educational occupancies. Shops, laboratories, and vocational rooms should utilize an occupant load factor of 50 net ft^2 (4.6 net m^2) per person. Areas for assembly uses and spaces utilized for business, storage, kitchens, and so on should utilize the occupant load factors appropriate to that specific function.

Means of Egress

There are no substitutes for properly designed and protected exit access paths, exits, and exit discharges. The total capacity of the means of egress for any story, level, or occupied area must be sufficient for the occupant load thereof. Travel distance requirements and dead-end restrictions are especially important in educational occupancies because of the age and nature of the occupants. Every room or space larger than 1000 ft^2 (93 m^2), or with an occupant load of more than 50 persons, must be provided with a minimum of two exit access doors. It is also important that no less than two separate and remote exits be provided and made accessible on every story, level, or mezzanine.

Proper exit and vertical opening enclosures are important to prevent smoke and heat contamination. Precautions must also be taken to prevent corridors from becoming untenable. The use of fire-rated corridor construction, generally with a fire resistance rating of 1 hour, is common practice in nonsprinklered educational occupancies. If the corridor ceiling is an assembly that has a 1-hour fire resistance rating (when tested as a wall), the corridor walls are normally permitted to terminate at the corridor ceiling. NFPA *101* and *NFPA 5000* do not require lavatories to be separated from corridors in educational occupancies, provided the building is protected throughout by an approved, supervised automatic sprinkler system, or the lavatories are separated from all other spaces by walls having a fire resistance rating of not less than 1 hour as shown in Figure 20.12.1. Proper door controls are also necessary to protect corridors, exits, and vertical openings. Although many codes require self-closing doors in these locations, operational necessities make them impractical in many schools. Therefore, integrated magnetic door hold-open devices and staff training are necessary to ensure doors are properly closed at the appropriate times, such as during emergency evacuation scenarios.

Additionally, exit access corridors may not be not less than 6 ft (1830 mm) wide, regardless of the required egress capacity. The intent of the 6 ft (1830 mm) corridor is to permit two files of students to move simultaneously with sufficient room for teachers or monitors to supervise. Short corridors serving only one or two rooms might warrant consideration for some reduction in required width. NFPA *101* and *NFPA 5000* are very exacting about limiting projections, such as drinking fountains, furniture, or lockers into these corridors.

Windows for Rescue

NFPA *101* and *NFPA 5000* require the installation of specially sized windows for fire department use for rescue (Figure

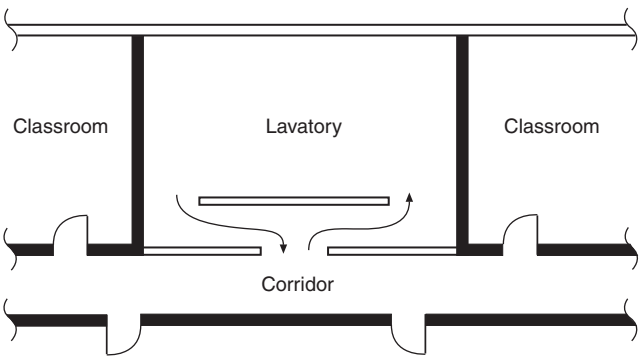

FIGURE 20.12.1 Lavatory Permitted to Be Open to Corridor

20.12.2). One such window is required in any room larger than 250 ft^2 (23.2 m^2) that is normally subject to occupancy by students, unless the building is protected by a supervised automatic sprinkler system. The minimum dimension requirement allows students to escape through the window and fire fighters wearing self-contained breathing apparatus to enter the room for rescue or fire suppression purposes. These windows must be accessible to fire department personnel but are not required on floors above the third story as fire department ground ladders cannot reliably reach these windows. Such taller structures are often protected throughout with automatic sprinklers, which eliminate the need for rescue windows. The requirement for such rescue windows does not apply to any room or space that has a door leading directly to the outside of the building.

Exit Hardware

All exit facilities should be inspected on a daily basis to ensure that they remain unobstructed and function properly. As we become increasingly attuned to safety and security considerations, additional care must be taken with respect to access-control devices and special locking arrangements. Any such locking devices must be approved by the authority having jurisdiction, listed for their intended use, and integrated with the overall life safety and fire protection plan for the building. In no instance are chains or padlocks permitted on exit doors when the building is occupied. If such security devices are used when the building is unoccupied, provisions for their removal must be made to the satisfaction of the local authorities. Any condition likely to interfere with safe egress should be reported to the proper authorities and corrected immediately.

In new educational occupancies, any door in a required means of egress from an area having an occupant load of 100 or more persons is permitted to be provided with a latch or lock only if it is outfitted with approved panic hardware or fire exit hardware. In existing educational occupancies, panic hardware or fire exit hardware is only mandated on required exit doors that are capable of locking or latching if the door's required egress capacity is 100 or more persons.

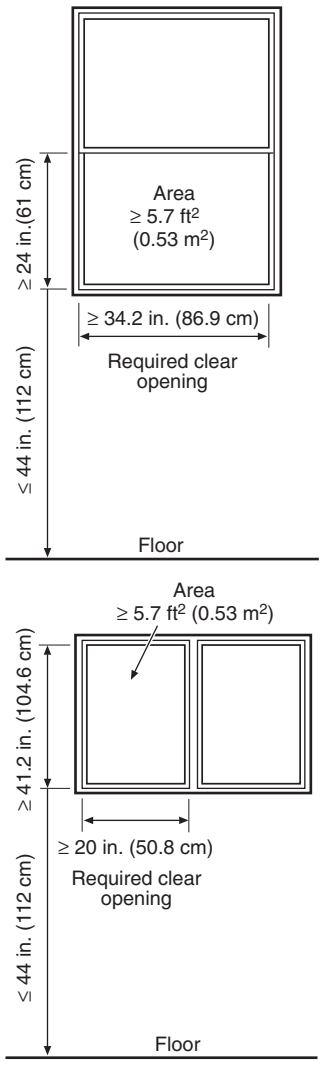

FIGURE 20.12.2 Minimum Dimensional Criteria for Rescue and Ventilation

Means of Egress Illumination and Marking

The means of egress must be properly illuminated any time that the conditions of occupancy require that the means of egress be available for use. Stairways should be provided with a minimum illumination level of 10 ft-candle (108 lux) when measured at the floor. Other walking surfaces along the means of egress route should be provided with a minimum illumination level of 1 ft-candle (10.8 lux) when measured at the floor. Suitable emergency lighting provisions must be provided to automatically illuminate the means of egress system in the event of any interruptions to the normal electrical power supply or building lighting circuitry. Exits should be marked with approved signs that are readily visible from any direction of exit access travel. The access paths leading to the exits should also be marked with approved signage where the route to reach the exit is not readily apparent to the occupants.

Alarm Systems

In general, schools require a manual fire alarm system as a minimum. Because of vandalism, fire alarm systems have sometimes been inappropriately turned off or otherwise disabled in order to prevent malicious or false alarms from disrupting the learning process. Recent changes in some codes permit the deletion of manual fire alarm boxes if the building is protected throughout by an approved automatic fire detection system or supervised automatic sprinkler system, and there is a continuously staffed central location where an evacuation signal can be manually activated. Emergency forces notification must also be provided to alert the fire department of any fire or other hazardous condition.

In school structures not over 1000 ft^2 (93 m^2) and that contain only a single classroom, fire alarm systems are not usually required. As with flexible and open plan design areas, the entire area can be readily observed and, therefore, a fire would likely be easily detected in its incipient state. A minimum separation distance of 30 ft (9.2 m) between the single classroom building and any other structure should be maintained.

Emergency Plans and Fire Exit Drills

Operators of educational occupancies should develop emergency plans in conjunction with the local fire department. The emergency plans should reflect procedures for the reporting of emergencies as well as the occupant and staff response to such emergencies. The local fire department needs to be made aware of the school's plan regarding evacuation of any students with disabilities or staff who might be incapable of self-preservation. Areas of refuge (as required by NFPA *101, NFPA 5000,* or other accessibility laws) should be easily identifiable from the exterior so that fire department personnel can readily access these areas. Emergency plans should be reviewed and updated periodically to reflect any new information or changes in condition.

Frequent fire exit drills are critical in achieving the proper response by occupants during an emergency. Fire exit drills should include the assignment of staff or more mature students to hold doors open in the line of march and to close doors where necessary to prevent the spread of fire or smoke; to search lavatories or other ancillary rooms; to properly account for all occupants; and to achieve a prompt, quiet, and orderly evacuation of the building or relocation to designated areas of refuge. Occupants should not be allowed to retrieve clothing or book bags after the alarm sounds due to the confusion that would result in forming lines, student accountability, and the danger of tripping over dragging apparel.

Fire exit drills should be held not less than once per month when the building is open for occupancy. In climates where winter weather is severe, additional drills should be run before bad weather starts. Everyone within the building should participate in such drills as this ensures that all staff and students understand the fire exit drill procedure. Drills should be unannounced and held at different hours of the day, during changing of classes, when the school is at assembly, and during recess or gym periods. As drills simulate an actual fire or emergency condition, the fire alarm signaling devices should be used so that occupants recognize the signal and respond appropriately. A separate and distinct recall signal should be developed to prevent a premature return to the building. Repetitive training in fire drills will also benefit the student later in life or when he or she is within another occupancy type.

Unfortunately, several high-profile school tragedies have given school officials pause with respect to conducting traditional fire exit drills. Schools should not be dissuaded from conducting these vital drills since delayed egress can lead to tragic consequences. However, some adjustments to previously established emergency evacuation and relocation drills may be advisable. One such alteration may be to involve law enforcement agents to supplement the role traditionally played by the fire service. School-based personnel may also be assigned to scan the school grounds and create a safety perimeter until the proper recall signal is sounded. Where building geometries and fire-resistive design features permit, consideration may also be given to utilizing horizontal exiting strategies and phased emergency evacuation scenarios to relocate students to predetermined safe locations in lieu of evacuating in the traditional sense. It is critical that any such adjustments be documented in the building's emergency plan, practiced frequently, and communicated to the appropriate first responders.

SUMMARY

Because of the nature of their occupants, educational facilities require specific life safety considerations. Educational occupancies can generally be characterized as public, private, and parochial schools for students from kindergarten through grade 12. Examples of educational occupancies include conventional schools, academies, kindergartens, and other facilities whose purpose is primarily educational, even though their students may be of preschool age. Fire protection measures should focus on building design principles, means of egress provisions, exit hardware, fire alarm systems, and emergency planning, staff training, and exit drills. Fire protection strategies must take into consideration the fact that the occupants may vary in their ability to cope with emergency situations. Hazardous areas such as laboratories, shops, kitchens, storage areas, janitor closets, laundries, mechanical rooms, and stages must often be separated from educational occupancies by fire-resistant construction or otherwise protected. In addition, special care must be taken to avoid hazardous arrangements such as the improper storage of clothing and the display of child artwork. In multiple-occupancy situations where the occupancies are mixed, care must be taken to ensure that the fire and life safety provisions for all occupancies are met.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on educational occupancies discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 13, *Standard for the Installation of Sprinkler Systems*
NFPA 45, *Standard on Fire Protection for Laboratories Using Chemicals*
NFPA 54, *National Fuel Gas Code*
NFPA 72®, *National Fire Alarm Code®*
NFPA 96, *Standard for Ventilation Control and Fire Protection of Commercial Cooking Operations*
NFPA *101®*, *Life Safety Code®*
NFPA 101A, *Guide on Alternative Approaches to Life Safety*
NFPA 701, *Standard Methods of Fire Tests for Flame Propagation of Textiles and Films*
NFPA 5000®, *Building Construction and Safety Code®*

Chapter 13

Day-Care Occupancies

Catherine L. Stashak

Chapter Contents

Occupant Characteristics
Construction Requirements
Occupancy Hazards
Life Safety Concepts
Day-Care Homes

Key Terms

capable of self-preservation, day-care home, day-care occupancy, hazardous area, lockup, means of egress, occupant characteristics

This chapter addresses day-care occupancies, which are generally defined as structures in which four or more clients receive care, maintenance, and supervision, by other than their relatives or legal guardians for less than 24 hours per day. This chapter describes the nature of day-care occupants as well as the hazards and life safety concepts pursuant to the occupancy.

Examples of day-care occupancies include adult day-care occupancies, except where part of a health care occupancy; child day-care occupancies; day-care homes; and nursery schools. In areas where local schools offer half-day kindergarten programs only, many child day-care occupancies offer state-approved kindergarten classes for children who need full-day care. As these classes are normally incidental to the day-care occupancy, the requirements applicable to the day-care occupancy should be followed. The definition of day-care occupancy also excludes day-care occupancies that are incidental to some other occupancy. In such cases, the requirements of the predominant occupancy apply. Examples of excluded facilities include the following:

- Rooms located within places of worship used as nurseries or for supervision of children or religious education while services are being held in the building
- Rooms used for temporary child care during short-term recreational activities of the child's relative or guardian, such as within a health club

Table 20.13.1 summarizes structure fire loss in day-care occupancies.

See also Section 5, Chapter 5, "Reaching High-Risk Groups"; and Section 20, Chapter 1, "Assessing Life Safety in Buildings."

OCCUPANT CHARACTERISTICS

Day-care facilities have traditionally been associated with child care and have thus been historically considered as educational occupancies. Changes in society have indicated a need to expand the definition of day-care facilities to include facilities that care for older people. Because physical limitations that apply to children can also apply to older adults, this approach seems logical from fire protection and life safety standpoints. Design criteria for these facilities should focus less on age-group classifications and more on clients' ability to evacuate and staff members' ability to evacuate clients.

Capability of Self-Preservation

NFPA *101*®, *Life Safety Code*®, and *NFPA 5000*®, *Building Construction and Safety Code*®, use the term *capable of self-preservation,* which is defined as the ability of a client to evacuate a day-care occupancy without direct intervention by a staff member, in the chapters that address day-care occupancies. It is the intent of NFPA *101* and *NFPA 5000* to classify children under the age of 24 months as incapable of self-preservation. Children older than 24 months should be capable of navigating stairs without dropping to their knees and will also follow directions. Other examples of incapability of self-preservation for children and adults might be confinement to a wheelchair

Catherine L. Stashak is retired from the Des Plaines, Illinois, Fire Department and works as a fire protection specialist for the Illinois Office of the State Fire Marshal. She is a principal member on the NFPA Technical Committee on Educational and Day-Care Occupancies, which she chaired for 10 years.

TABLE 20.13.1 Structure Fires in Day-Care Occupancies, 1999–2002 Annual Averages

Occupancy	*Fires*	*Civilian Deaths*	*Civilian Injuries*	*Direct Property Damage (in Millions of Dollars)*
Day-care	440	0	4	4

Note: These are fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. Fires are rounded to the nearest ten, deaths and injuries to the nearest one, and direct property damage to the nearest million dollars. Damage has not been adjusted for inflation.

Source: *U.S. Fires in Selected Occupancies,* March 2006. National estimates based on NFIRS and NFPA survey.

or other physical disability and clients who are unable to follow directions or a group to the outside due to mental or behavioral disorders. Examples of direct intervention by staff members include carrying a client, pushing a client in a wheelchair, and guiding a client by direct hand-holding or continued bodily contact. Another common method of evacuation used with infants is to place several infants in one crib and roll the crib out of the facility. If clients are unable to exit the building by themselves, with minimal intervention from staff members, such as verbal orders, classification as incapable of self-preservation should be considered. Client mobility is an important consideration in developing life safety requirements.

It should be recognized that some day-care facilities operate 24 hours per day to care for dependents of people who work at night. These facilities present the greatest hazard because their occupants will most likely be asleep when a fire starts. Therefore, day-care facilities that operate at night require special considerations. No matter what time of day, day-care staff members are required to be awake and alert at all times; however during a nap period it is possible that some staff may be asleep when an emergency occurs.

Lockups

It is possible that a day-care facility might have an area where clients are restrained, and such occupants are considered as incapable of self-preservation because of security measures not under the occupant's control. If this arrangement exists, these areas must comply with the requirements for lockups in NFPA *101* and *NFPA 5000*, which are located in the chapters that address detention and correctional occupancies.

CONSTRUCTION REQUIREMENTS

NFPA *101* prescribes location and construction type limitations for both new and existing day-care occupancies. The types of construction listed in Tables 20.13.2 and 20.13.3 are defined in NFPA 220, *Standard on Types of Building Construction,* and *NFPA 5000*. The types of construction permitted by the code depend on the location of the day-care occupancy in the building relative to the level of exit discharge (LED).

TABLE 20.13.2 Location and Construction Type Limitations for New Day-Care Occupancies

Location of Day-Care Occupancy	*Sprinklered Building*	*Construction Type*
1 story below LED	Yes	I (442), I (332), II (222), II (111), II (000), III (211), IV (2HH), V (111)
	No	NP
Level of exit discharge	Yes	Any type
	No	Any type

OCCUPANCY HAZARDS

Multiple Occupancy

Sometimes more than one type of occupancy exists in conjunction with a day-care facility. Where a day-care facility serves not more than 12 clients in an apartment building, it could be considered a day-care home; a corporate day-care center that serves more than 12 clients could be located within an office building, which is classified as a business occupancy. Where multiple occupancies are mixed, as described in NFPA *101* and *NFPA 5000*, care must be taken to ensure that the fire and life safety provisions for all occupancies are met. It is important to provide sufficient protection to prevent the day-care occupancy from being exposed to hazards of other occupancies in the structure. To be considered separate occupancies, the day-care occupancy must be separated from the other uses by fire barriers, and the occupancies must be provided with independent exit access.

TABLE 20.13.3 Location and Construction Type Limitations for Existing Day-Care Occupancies

Location of Day-Care Occupancy	*Sprinklered Building*	*Construction Type*

Hazardous Areas and Arrangements

Areas such as storage areas and boiler and furnace rooms must be separated from day-care occupancies. Usually, fire-rated walls and doors provide the necessary degree of protection unless the hazard is severe, in which case automatic suppression systems may also be required. In some cases, the fire resistance rating is eliminated if the building is protected throughout with automatic sprinklers.

Clothing, personal effects and other combustible materials should not be stored in corridors. If automatic detection or suppression systems are provided in the corridors, or if metal lockers are used, clothing and personal effects can be stored in corridors. Metal lockers should not, however, reduce the required egress width.

Child-prepared artwork and teaching materials attached directly to walls should not cover more than 20 percent of the wall area in a building that is not protected throughout by an approved, supervised automatic sprinkler system. In a building that is protected throughout by an approved, supervised automatic sprinkler system, child-prepared artwork and teaching materials attached directly to walls should not cover more than 50 percent of the wall. It is advantageous not only to limit the quantity of child-prepared materials displayed but also to avoid placing such materials near a room's exit access doors. Because the artwork's combustibility cannot be effectively controlled, the quantity, in terms of percentage of the overall wall area covered, is regulated to avoid creating a continuous combustible surface that will allow flames to spread across the room.

Draperies, curtains, hanging banners, and other similar furnishings and decorations should meet the requirements for flame resistance when tested per NFPA 701, *Standard Methods of Fire Tests for Flame Propagation of Textiles and Films.* Care should be taken when installing hanging banners so that exit signs and automatic sprinklers are not obstructed.

LIFE SAFETY CONCEPTS

Means of Egress

There are no substitutes for properly designed exit access paths, exits, and exit discharges. Travel distance requirements and dead-end limits are especially important in day-care occupancies because of the nature of the occupants and the slower rate at which evacuation is completed. Proper exit enclosures are important to prevent contamination by smoke and heat. Means of egress requirements for day-care occupancies do not differ much from those for educational occupancies, except that 6 ft (1.8 m) corridors, which are required in educational occupancies, are not required in day-care occupancies.

NFPA *101* and *NFPA 5000* require the installation of specially sized windows for fire department use for rescue as shown in Figure 20.13.1. One such window is required in any room normally subject to client occupancy, other than bathrooms. These windows are not required if the building is protected by a supervised automatic sprinkler system or if the room or space has a door leading directly to the outside of the building or on floors above the third story. The minimum dimension requirement allows clients to escape through the window and fire fighters wearing self-contained breathing apparatus to enter the room for rescue or fire suppression purposes. These windows must be accessible to fire department personnel, so they are not required on floors above the third story as fire department ground ladders do not normally reach such windows.

Although the ability of staff to assist and participate in evacuation is part of the life safety package for day-care occupancies,

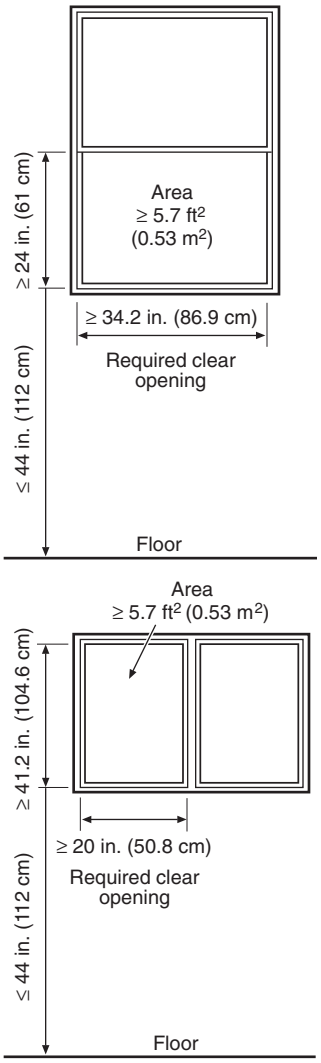

FIGURE 20.13.1 Minimum Dimensional Criteria for Rescue and Ventilation

neither NFPA *101* nor *NFPA 5000* mandates staff-to-client ratios because, from the standpoint of the local authority, ratios are very difficult to enforce. Most state licensing requirements include staff-to-client ratios; additional requirements are considered duplicate effort.

Precautions must be taken to prevent corridors from becoming untenable. The use of fire-rated corridor construction, generally with a rating of one hour, is common practice. If the corridor ceiling is an assembly that also has a 1-hour fire resistance rating (when tested as a wall assembly), the corridor walls are normally permitted to terminate at the corridor ceiling. This requirement is reduced if the building is protected throughout with automatic sprinklers or if rooms occupied by clients have a direct exit to the outside. Neither NFPA *101* nor *NFPA 5000* requires lavatories to be separated from corridors, provided the lavatories are separated from all other spaces by walls having a fire resistance of not less than one hour as shown in Figure 20.13.2.

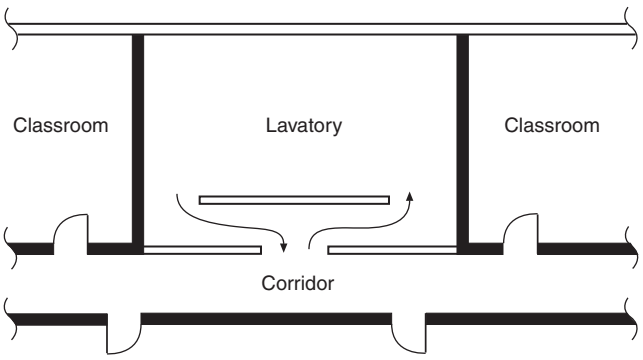

FIGURE 20.13.2 Lavatory Permitted to Be Open to Corridor

Exit Hardware

Any door within a required means of egress from an area having an occupant load of 100 or more should have panic hardware or fire exit hardware if equipped with a lock or latch. It should be noted that the requirement for panic hardware or fire exit hardware is based on the total occupant load of the area served and not the required capacity of the door. In no instance are chains or padlocks permitted on egress doors when the building is occupied.

Closet and Bathroom Doors

Closet Doors. Closet doors should be designed so that clients can open the door from inside the closet. The purpose of this requirement is to prevent arrangements where a client can be trapped in a closet. It is intended that this provision be broadly interpreted to include equipment such as refrigerators and freezers.

Bathroom Doors. Bathroom doors should be designed to allow the door to be unlocked from the outside by an opening device that is readily accessible to the staff. The purpose of this requirement is to permit access to a client in the bathroom should they become injured or sick.

Fire Alarm Systems

Fire alarm requirements for day-care occupancies are more stringent than those for most occupancies because it takes longer for day-care clients to evacuate—they could be asleep or they could be incapable of self-preservation. In day-care centers housed in more than one room, smoke detection is required so as to provide early warning for clients and staff not located in the room of fire origin. This early notification is especially important in centers that have clients incapable of self-preservation or clients that are asleep.

In day-care centers that are housed in one room, fire alarm systems are not usually required. The entire area can be observed; therefore, a fire can be easily detected in its incipient stage. An important part of a day-care occupancy's life safety plan is notification of the local fire department. The sooner fire department personnel arrive on the scene, the sooner they can assist with evacuation of clients.

Staff Training and Emergency Egress and Relocation Drills

Day-care occupancies should develop emergency plans in conjunction with the local fire department. The local fire department needs to be made aware of the day-care facility's plan regarding evacuation of clients who are incapable of self-preservation. Areas of refuge, as required by NFPA *101, NFPA 5000*, or any other accessibility laws, need to be identifiable from the exterior so fire department personnel can readily access these areas.

Frequent fire exit drills are critical in achieving proper response by occupants during an emergency. Fire exit drills should include assignment of staff to close doors where necessary to prevent spread of fire or smoke; to search the lavatories or other rooms; to account for all occupants; and to achieve a prompt, quiet, and orderly evacuation of the building or relocation to areas of refuge. Fire exit drills should be held not less than once per month when the building is open for occupancy. In climates where winter weather is severe, most drills should be run before bad weather starts. This ensures that staff and clients understand fire exit drill procedures.

Drills should be held at expected and unexpected times and at varying times that the day-care center is open, including during outdoor play time and even during nap periods. As drills simulate an actual fire condition, the fire alarm signaling devices should be activated so that occupants recognize the signal and respond appropriately. Repetitive training in fire drills will benefit the client when he or she is within another occupancy type. When a fire alarm is activated within the other occupancy, the day-care client should recognize the signal and respond appropriately.

DAY-CARE HOMES

Day-Care Home Defined

NFPA *101* and *NFPA 5000* provide requirements for smaller day-care occupancies. A *day-care home* is defined as a day-care occupancy that has not more than 12 clients. Day-care homes are further subdivided into family day-care homes that have 4 to 6 clients and group day-care homes that have 7 to 12 clients. NFPA *101* and *NFPA 5000* specify that the caregiver's own children or relatives under the age of six are to be included in the specified staff-to-client ratios for these day-care occupancies. The provisions found in NFPA *101* and *NFPA 5000* recognize that a typical day-care home is usually located in a residential setting. Because of this, it is difficult to mandate fire protection features that are as stringent as in a "full-size" day-care occupancy, such as one serving more than 12 clients.

Means of Escape in Day-Care Homes

In day-care homes, means of escape are permitted as the egress system. The concept of means of escape is well developed in the chapters that address one- and two-family dwellings in NFPA *101* and *NFPA 5000*. However NFPA *101* and *NFPA 5000* require that every room used for sleeping, living, or dining meet the following provisions:

- At least two means of escape must be provided, one of which needs to be a door or stairway providing travel to the outside of the building at street or ground level.
- The second means of escape is permitted to be a window under certain circumstances.
- No room or space that is accessible only by a ladder, folding stair, or through a trapdoor is permitted to be occupied for living or sleeping purposes.
- In group day-care homes, spaces used by clients on any story above the level of exit discharge must have access to at least one means of escape that discharges directly to the outside; the second means of escape can be a window under certain circumstances.
- Spaces used by clients below the level of exit discharge must be provided with not less than one means of escape that discharges directly to the outside, with vertical travel not more than 96 inches to the ground level; the second means of escape can be a window under certain circumstances (Figure 20.13.3).

Staff-to-Client Ratio

It is important that the staff-to-client ratios mandated by NFPA *101* and *NFPA 5000* for day-care homes be followed. Table 20.13.4 addresses the staff-to-client ratios mandated by NFPA *101* and *NFPA 5000* for day-care homes.

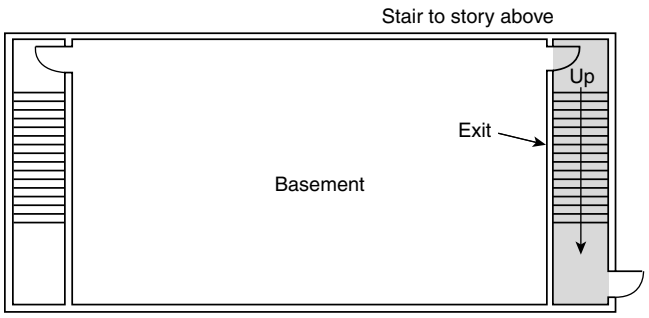

FIGURE 20.13.3 Egress Requirements from Group Day-Care Home Occupying Basement (Source: *Life Safety Code® Handbook,* NFPA, 2006 edition)

TABLE 20.13.4 Required Staff-to-Client Ratios in Day-Care Homes

Day-Care Home Type	*Staff-to-Client Ratios (Including Caregivers' Children)*	*Maximum Number of Clients Incapable of Self-Preservation*
Family day-care homes	1 staff for up to 6 clients	2
Group day-care homes	2 staff for up to 12 clients*	3

*Staff-to-client ratio is permitted to be modified by the authority having jurisdiction (AHJ) where safeguards in addition to those specified by code are provided.

Local authorities may not have knowledge of the full number of day-care homes within their jurisdictions. Parents who wish to earn money while staying home with their own children may simply advertise by word of mouth that they are willing to watch children. No notification may be given to the fire department, which will have to deal with multiple young children when the home is involved in fire. Local authorities may only find out about the day-care home if the owner obtains a license from the state.

SUMMARY

Because of the nature of their occupants, day-care facilities require specific life safety considerations. Day-care occupancies include both child and adult day-care occupancies, day-care homes, and nursery schools. Fire protection measures should focus on building design, means of egress, exit hardware, fire alarm systems, staff training, and emergency egress and relocation drills. The fact that the occupants, whether children, infants, the elderly, or disabled, vary in their abilities to cope with emergency situations should be taken into consideration. Hazardous areas such as janitor's closets, kitchens, storage areas, and furnace rooms should be separated from day-care occupancies or protected with automatic sprinklers. In addition, special care must be taken to avoid hazardous arrangements such as the improper storage of clothing or excessive display of child-prepared artwork.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on day-care occupancies discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

Chapter 14

Detention and Correctional Occupancies

Thomas W. Jaeger

Chapter Contents

Occupancy Characteristics
The Fire Problem in Detention and Correctional Facilities
Systems Approach to Fire Safety in Detention and Correctional Facilities
Lockups

Key Terms

area of refuge, defend-in-place, detection, drills, emergency procedures, evacuation, fire emergency plan, fuel control, ignition control, lockup, occupant protection, suppression

Detention and correctional occupancies include buildings and facilities in which persons are restrained by locks they do not control. Such occupancies include adult correctional institutions, adult local detention facilities, adult community residential centers, juvenile detention facilities, juvenile training schools, juvenile community residential centers, adult and juvenile work camps, and adult and juvenile substance abuse centers. Some psychiatric and acute care hospitals may have similar security provisions, but this chapter addresses only facilities where controlled movements are not based entirely on health care considerations. Security is a major operational consideration in these facilities and must be included in the fire protection design process.

Lockups facilities in occupancies other than detention and correctional facilities are areas where building occupants are restrained for less then 24 hours and occupants are incapable of self preservation because of security measures not under their control. Lockups can be found in courthouses, police stations, international airports, sports arenas and stadiums, shopping malls, and other occupancies where it might be necessary to detain occupants for security purposes. Lockups are now specifically addressed in provisions that are new to the 2006 editions of NFPA *101*®, *Life Safety Code*®, and *NFPA 5000*®, *Building Construction and Safety Code*®.

Large correctional facilities may contain other occupancies, including industrial occupancies such as vocational shops; business occupancies such as classrooms and offices; assembly occupancies such as dining halls, auditoriums, and gymnasiums; and storage occupancies such as warehouses. The principal concern of Chapters 22 and 23 of NFPA *101* and Chapter 21 of *NFPA 5000* is the residential portion of correctional facilities. Except for the locking of doors, other uses within the detention and correctional occupancy must comply with the appropriate occupancy chapters of NFPA *101* and *NFPA 5000*. If locking of doors in these occupancies is required, Chapters 22 and 23 of NFPA *101* or Chapter 21 of *NFPA 5000* should be reviewed for guidance. These chapters of NFPA *101* do permit locking of doors in other use areas if staff is available to unlock the egress doors.

Additional information relevant to fire safety in correctional institutions can be found in Section 18, Chapter 2, "Interior Finish"; Section 18, Chapter 3, "Smoke Movement in Buildings"; and the discussion on portable fire extinguishers in Section 17, Chapter 5, "Fire Extinguisher Use and Maintenance."

OCCUPANCY CHARACTERISTICS

The major difference between detention and correctional occupancies and other residential occupancies is that the occupants are not capable of significant self-preservation actions until staff unlocks the doors. However, the occupants are capable of such actions when the doors are unlocked.

The degree of locking can have a significant impact on the risk to the occupants. For example, a facility with only two locks that can be remotely released to allow the occupants out of the building into a controlled exercise yard generally would present less risk to the occupants than

Thomas W. Jaeger, P.E., is president of Jaeger & Associates, LLC, a consulting fire protection engineering firm. He is chair of the NFPA Technical Committee on Detention and Correctional Occupancies.

one that required 15 locks to be unlocked manually with 10 different keys. Although the number of locks and the method of unlocking have an impact on the level of risk to the occupants, operations have even a greater impact. Because of the nature of the occupancy, there is a natural reluctance for staff to quickly unlock doors until adequate staff and security are present. This operational feature results in a delay in initiating the unlocking of doors and initiating evacuation or relocation.

Five types of restraint or locking systems are generally found in detention and correctional occupancies. These different locking conditions, referred to as "Use Conditions" by NFPA *101* and *NFPA 5000,* are illustrated in Figure 20.14.1 and defined below.

Use Condition I—Free Egress

In Use Condition I, free movement is allowed from sleeping areas and other spaces where access or occupancy is permitted to the exterior through means of egress meeting the requirements of NFPA *101* and *NFPA 5000.* For example, a work release center, where the doors are not locked, would be considered Use Condition I. Use Condition I facilities are permitted to comply with the requirements for Use Condition II facilities or with the requirements for the appropriate residential occupancy in NFPA *101* or *NFPA 5000.* Since a Use Condition I facility has no locks on doors in the means of egress, this type of facility can be treated as a residential occupancy.

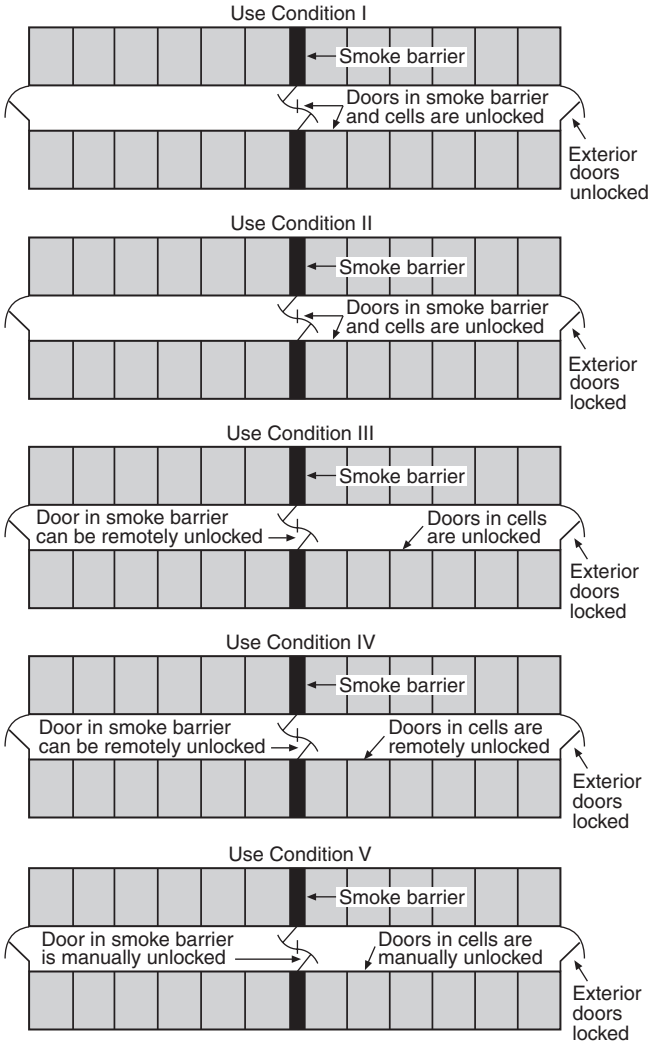

FIGURE 20.14.1 Classes of Restraint: Use Conditions I, II, III, IV, and V

Use Condition II—Zoned Egress

In Use Condition II, free movement is allowed from sleeping areas and any other occupied smoke compartments to other smoke compartments, but the exterior doors are locked.

The individual cell door may be locked from the inside by the occupant and can be unlocked by the occupant. Also, the individual cell door may be locked by the occupant when leaving the cell. This is sometimes done to provide security for the occupants' property while occupants are out of their cells.

Use Condition III—Zoned Impeded Egress

In Use Condition III, free movement is allowed within individual smoke compartments—for example, within a residential unit composed of individual sleeping rooms and within group activity space—with egress from that smoke compartment to another smoke compartment provided by the remote-control unlocking of doors. The exterior doors may be manually locked. Again, the individual cell doors may be locked by the occupant as noted in the Use Condition II section.

Use Condition IV—Impeded Egress

In Use Condition IV, free movement is restricted from an occupied space. Remote-control release is provided to permit movement from all sleeping rooms, activity spaces, and other occupied areas within the smoke compartment to other smoke compartment(s). Exterior doors may be manually locked. NFPA *101* and *NFPA 5000* allow up to a maximum of 10 manual release locks to be unlocked to relocate all occupants from one smoke compartment to an area of refuge for Use Condition IV. Unlocking of the manual release locks cannot require more than two separate keys, and the unlocking must occur as promptly as would occur if remote-control unlocking was used.

Use Condition V—Contained

In Use Condition V, free movement is restricted from an occupied space. Staff-controlled manual release at each door is provided to permit movement from all sleeping rooms, activity spaces, and other occupied areas within the smoke compartment to other smoke compartments.

When evaluating the degree of locking for determination of Use Condition, any operable locks, even those not normally used, need to be considered lockable.

The higher level of security provided, the more demanding the code requirements are for life safety because higher levels

of security result in longer evacuation times, a more difficult population to evacuate, or a combination thereof.

THE FIRE PROBLEM IN DETENTION AND CORRECTIONAL FACILITIES

Each year NFPA statistically analyzes the fire problem in detention and correctional facilities.[1] The expanded version of this analysis, which appears in Tables 20.14.1, 20.14.2, and 20.14.3, identifies the significant common characteristics of correctional facility fires and groups them into several categories.

Most fires in detention and correctional facilities are incendiary or suspicious in nature. Motives can include the following:

- Increased chances of escape
- Malicious damage as a protest against conditions
- Show of force during a riot
- Suicide attempt
- Divert attention from other activities
- Weapon

In nearly all intentionally set fires for which the ignition source could be identified, the source was a match, smoking materials, or a cigarette lighter. These are the ignition sources most readily available to inmates. The typical correctional facility fire is incendiary in origin, starts in a cell, and involves bedding, trash, or papers.

Reported prison and jail fires fell 79 percent from 4180 in 1980 to 860 in 2002. It is encouraging to see that the fire data show both a reduction in the number of fires and the number of civilian deaths in detention and correctional occupancies in recent years even though the population of this occupancy has significantly increased during this same period. It should be pointed out that various detention and correctional agencies

TABLE 20.14.1 Structure Fires in Prisons and Jails by Year, 1980–2004, Structure Fires Reported to U.S. Municipal Fire Departments

Year	*Fires*	*Civilian Deaths*	*Civilian Injuries*	Direct Property Damage (in Millions of Dollars)	
				As Reported	*In 2004 Dollars*
1980	4200	0	190	4.6	10.6
1981	3900	5	420	14.9	30.8
1982	3600	8	210	4.4	8.6

Exterior wall surface	10	(1%)	0	(NA)	0	(0%)	0.0	(0%)
Entrance way or lobby	10	(1%)	0	(NA)	0	(0%)	0.0	(0%)
Other known area of origin	120	(14%)	0	(NA)	2	(7%)	0.2	(7%)
Total	860	(100%)	0	(NA)	27	(100%)	3.6	(100%)

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest ten, direct property damage is rounded to the nearest hundred thousand dollars, and civilian deaths and injuries are rounded to the nearest one. Prison and jail fires with area of origin unknown are proportionally allocated.

*Based on only fires reported in NFIRS Version 5.0, excluding fires reported as confined fires.

NA = Not applicable because total is zero.

Source: NFIRS and NFPA survey.

indicate "off-the-record" that a significant number of fires, up to 75 percent, in prisons and jails are small fires that go unreported to local fire departments due to security concerns.

SYSTEMS APPROACH TO FIRE SAFETY IN DETENTION AND CORRECTIONAL FACILITIES

To deal with the fire safety problem in correctional facilities, two concerns need to be addressed continually: security for the public and safety from fire for the inmates. Fire safety and security are not contradictory concepts, and there need not be an imbalance of emphasis for either in detention and correctional facilities. Neither absolute fire safety nor absolute security is attainable when considered independently, let alone when considered together. The systems approach seeks to guide the analysis and planning of correction toward achieving an economically feasible program that will attain an acceptable level of protection within the intent of the applicable codes and standards and good engineering practices and that is commensurate with the level of security provided.

The systems approach to fire safety helps to achieve these two objectives through a systematic analysis of each problem area and application of available technologies. Fire safety should be an integrated subsystem of building design, construction, and operation. This method of designing fire safety is known as the systems approach or systems concept of fire-safe building design. A system organizes interacting components in such a way that, working together, they perform a predetermined function or reach a specified objective. The use of the systems approach first requires that fire safety goals be clearly identified. These goals should describe the amount of protection a building should provide its occupants, contents, and operations. These goals should be quantified wherever possible. Once these fire safety goals are established, the methods used to achieve them should work collectively to achieve and maintain the prescribed level of fire safety.

TABLE 20.14.3 Structure Fires in Prisons and Jails, by Leading Major Cause, Annual Average of 2000–2004 U.S. Structure Fires Reported to Municipal Fire Departments*

Major Cause	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*	
Intentional	350	(36%)	0	(NA)	22	(80%)	1.7	(48%)
Clothes dryer or washer	170	(17%)	0	(NA)	5	(19%)	0.2	(5%)
Cooking equipment fire	100	(10%)	0	(NA)	1	(3%)	0.0	(1%)
Identified cooking equipment	30	(3%)	0	(NA)	0	(0%)	0.0	(1%)
Confined cooking fire	70	(7%)	0	(NA)	1	(3%)	0.0	(0%)
Electrical distribution or lighting equipment	50	(5%)	0	(NA)	1	(4%)	0.1	(3%)
Smoking materials	50	(5%)	0	(NA)	0	(0%)	0.1	(3%)
Heating equipment	40	(4%)	0	(NA)	0	(0%)	0.2	(5%)
Identified heating equipment	20	(2%)	0	(NA)	0	(0%)	0.2	(5%)
Confined chimney or flue fire	0	(0%)	0	(NA)	0	(0%)	0.0	(0%)
Confined fuel burner or boiler fire	10	(1%)	0	(NA)	0	(0%)	0.0	(0%)
Playing with fire	40	(4%)	0	(NA)	0	(0%)	0.2	(5%)
Air conditioning or fan	20	(2%)	0	(NA)	0	(0%)	0.0	(0%)
Contained trash fire	40	(4%)	0	(NA)	0	(0%)	0.0	(0%)

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest ten, direct property damage is rounded to the nearest hundred thousand dollars, and civilian deaths and injuries are rounded to the nearest one. Candidate causes are examined separately; confined fires are analyzed separately. Major causes are defined by groupings from the data elements of cause, factor contributing to ignition, heat source, and equipment involved in ignition. Major causes are shown only if they accounted for at least 2 percent of fires.

*Based on only fires reported in NFIRS Version 5.0.

NA = Not applicable because total is zero.

Goals of a Simplified Fire Safety System

The systems approach can be illustrated by the simplified fire safety system for correctional facilities. The box at the top of Figure 20.14.2 shows the four goals of the simplified fire safety system.

Life Safety. The protection of life is paramount in any fire. Occupants can be protected by providing a safe area of refuge from the fire within the building or by providing a safe and readily available path of travel to an outside secured area.

Property Protection. The protection of property is also of concern, particularly with today's higher replacement costs. Some areas may be considered more important than others—for example, a control room versus a storage room—and therefore require more protection.

Continuity of Operations. This involves providing protection to limit fire damage so an area can be returned to use quickly. This is a critical issue since there are generally no adequate alternative facilities available to house and provide services to displaced occupants.

Security. The primary function of a detention and correctional facility is to maintain a secure perimeter and protect the public from the occupants. Fire safety must be compatible with this function.

Objectives of a Simplified Fire Safety System

These goals are achieved through a series of objectives:

- Ignition control
- Fuel control
- Occupant protection
- Detection and suppression
- Planning and training

Success in meeting the overall goals depends on the degree of success in meeting these five objectives, and the relationships between goal success and objective success may be mathematically complex. In practical terms, however, no one objective is likely to be sufficient by itself to meet the goals, so it is safest to assume that all five objectives must be addressed. Some methods to attain each objective are listed beneath the objectives shown in Figure 20.14.2. For the objective of ignition control, for example, the methods available to reduce ignitions include the following:

- Controlling smoking materials
- Controlling electrical ignition sources
- Controlling occupant population mix to reduce intentionally set fires

When certain methods for achieving the objective are not practical or not particularly effective, other parts of the system may have to be enhanced to compensate. For example, when ignition sources cannot be effectively reduced, fuel control

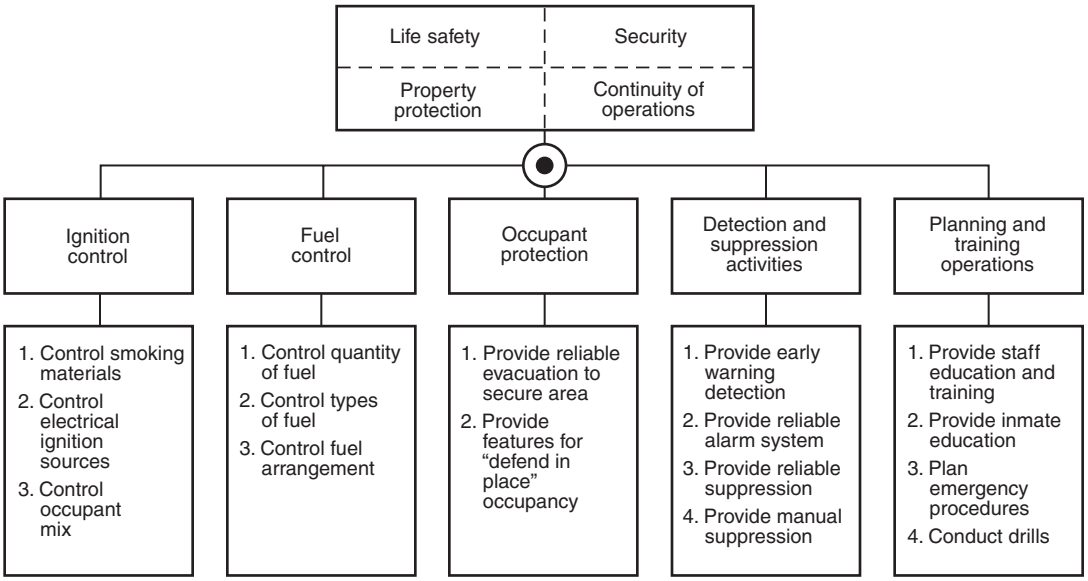

FIGURE 20.14.2 Simplified Fire Safety System for Detention and Correctional Facilities

becomes more important, or when the quantity of combustible materials cannot be effectively controlled, sprinklers may offset the hazard.

Because different objectives do not have an equal impact on the ultimate level of fire protection, the concept of equivalent protection, also known as tradeoffs, may be necessary. For example, under certain conditions, NFPA *101* and *NFPA 5000* permit the use of higher flame spread materials as interior finish if automatic sprinklers are provided. The systems approach provides for analysis of the interacting components of the fire safety system so that alternate means of protection can be evaluated. This evaluation may include initial costs, operational and maintenance costs, and impact on operations.

Ignition Control

Ignition control means greater and more dependable protection of heat sources and separation from fuel sources. In a property where most fires are deliberately set, this primarily means eliminating unnecessary heat sources. Unfortunately, total ignition control is nearly impossible to maintain and may therefore be the least effective fire defense measure. Sources of ignition are nearly always available because cigarettes and matches are, in most cases, available to inmates, and electrical appliances are generally allowed in cells. However, an effort must be made to control unwanted or unnecessary ignition sources. Some jails and prisons prohibit smoking for health reasons. This, of course, will also reduce smoking materials as an ignition source. If smoking is permitted, the types of lighters or matches can be specified. The overall use of electrical power must be carefully supervised. The number and type of heat-producing appliances, such as toasters, hot plates, and space heaters, must be controlled by the facility administrator to prevent overloading circuits. If electrical devices are allowed in cells, adequate electrical outlets should be provided to discourage the use of extension cords.

Fuel Control

Fuel control means controlling the type, arrangement, and burning characteristics of potential fuels. These fuels may include the building structural system, interior finish materials, and combustible contents, such as furnishings and inmates' personal property. Assuming that heat sources will be available, the likelihood of fire and the rate of fire growth can be controlled by limiting the type, quantity, and arrangement of the fuels available. Limiting the speed at which fire develops and spreads reduces its impact on life safety.

Achieving the goal of fuel control means keeping fuel quantity at a minimum, controlling the type of fuel, eliminating those fuels that are easy to ignite or result in fast fires, and separating fuels from readily available ignition sources. One part of fuel control is to eliminate highly combustible furnishings. Since mattresses and bedding are the fuel sources most readily available to inmates, they are most frequently involved in fires. Certain types of polyurethane foam mattresses can be a significant fuel source in prison fires because they can support fast fire development, high heat release, and heavy smoke production.

Mattresses can be made to resist ignition from cigarettes, which are a low-heat ignition source. The federal *Flammability Standard for Mattresses*[2] requires that mattresses resist ignition by cigarettes placed at 18 specified locations. This test does not include sheets or blankets on the mattress and does not indicate the resistance to ignition from open flames or the intensity of the resulting fire. A series of tests of mattresses by the U.S. Department of Agriculture[3] concluded that "the data show that mattresses containing polyurethane foam easily comply with the federal standard[2] where cigarettes are the igniting source; however, such mattresses present a significant hazard where the igniting source is an open flame. Mattresses containing 100 percent polyurethane foam usually burn vigorously until little char

remains. Burning in such cases is accompanied by the release of copious amounts of black smoke."

In 1977, the National Bureau of Standards (now the National Institute of Standards and Technology) conducted fire tests of mattresses and issued a report,[4] which categorized mattresses into four groups in order of safety (Table 20.14.4).

These tests indicate that the best mattresses for use in correctional facilities are those with padding material of cotton treated with boric acid. Mattresses of cotton treated with boric acid pass the federal standard[2] and perform well when exposed to open-flame ignition sources. Such mattresses will burn but at a much slower rate than urethane foam mattresses.[5] Some other materials are entering the market for mattress padding, including treated neoprene. Because occupants of detention and correctional facilities frequently intentionally damage mattresses, operators of these facilities are reluctant to purchase expensive mattresses. Therefore, the most common mattresses found are fire-retardant-covered foam or cotton-treated mattresses.

Inmate possessions and furnishings in the cell must be controlled in order to limit the size of fire that can be expected. Books, clothing, and other combustible personal property allowed in cells should be stored in closable metal lockers or fire-resistant containers. Combustible decorations should be prohibited unless they have been treated with flame retardants. Although rarely used, draperies, curtains, or other decorative and acoustical materials should be noncombustible or rendered and maintained flame resistant according to NFPA 701, *Standard Methods of Fire Tests for Flame Propagation of Textiles and Films.* There is no maximum limit of combustibles permitted in NFPA *101* or *NFPA 5000.* The codes do, however, provide a cautionary statement for management to control the combustibles.

TABLE 20.14.4 Mattress Safety Categories

Group	*Safety Criteria*
A	Mattresses that did not exceed any of the tenability criteria for the duration of the 30 minute test. This group included two treated, cotton-batting mattresses.
B	Mattresses that only exceeded the smoke obscuration criterion. Two neoprene mattresses were in this category.
C	Mattresses that exceeded all tenability criteria, but did not cause full room involvement. This group included three polyurethane foam-core mattresses and one of mixed fiber construction. The best-performing polyurethane mattress was of the type associated with a multiple-life-loss prison fire.
D	Mattresses that exceeded all criteria. Included were one styrene-butadiene latex foam core and one polyurethane foam-core mattress. The latex mattress was of the type associated with a multiple-life-loss fire in a health care institution.

Interior finish materials can contribute fuel to a fire, they may accelerate room flashover, and they can result in rapid fire spread. Materials that have high flame spread rates or produce hazardous concentrations of smoke or noxious gases should not be used. This includes plastic wall finish material, fiberboard, thin paneling, and untreated plywood. Interior finish alternatives with good fire characteristics include paneling treated to provide Class A interior finish rating with a flame spread of 25 or less, painted steel, gypsum board, or masonry block.

Occupant Protection

Occupant protection means providing life safety to building occupants in case of fire. This may be accomplished either by evacuating them to a secure area or by defending them in place. This objective is the most controversial in the fire safety system for correctional facilities because "evacuation" is often interpreted by administrators and staff to mean "escape." Although this assumption is not valid, means of egress does directly affect security.

With reference to the evacuation of inmates, most detention and correctional facilities can be grouped into two general types, based on their physical arrangement. In the first group are larger institutions that have an outdoor secure area such as an outdoor exercise yard or courtyard. It is possible to evacuate inmates rapidly from the fire area to this outside area and still maintain security. In the second category are the inner city high rise facilities and the smaller city or county facilities where there are no separate, secure outdoor areas. In these facilities, which have no enclosed courtyards or other areas to evacuate inmates and still maintain security, it becomes necessary to defend the inmates in place from fire. Evacuating inmates outside the secured perimeter of a facility is as much a safety hazard to the general public as the fire itself.

Defend-in-Place Strategy. The defend-in-place protection strategy is a workable and accepted means of providing fire safety for building occupants and is commonly used to protect persons in hospitals and nursing homes. The technology exists to defend inmates in place so that only a few cells need to be evacuated—possibly only the cell of fire origin. A defend-in-place occupancy, as well as an occupancy using evacuation to a secure area of refuge, needs a reliable means of egress. Unique to detention and correctional facilities, because some occupant populations cannot be mixed with the general population for security reasons, there is often a need for multiple and separate areas of refuge for both inside and outside secured areas. Although means for defending the occupants in place are provided, it is always considered necessary to provide reliable exits. According to NFPA *101* and *NFPA 5000,* this means that two distinct paths of travel must be provided from each cell block or area. The exits should be remote from each other so that a single fire cannot readily block both. In addition, travel distances must not exceed those specified by NFPA *101* and *NFPA 5000.* The travel distance can be increased if the building is sprinklered. The exit access needs to be free and unobstructed, and it should not be circuitous. An exit access that requires travel through a room or an area containing a fire hazard higher than usual for

the occupancy violates the principles of safe egress. Dead-end corridors are not good practice because a fire in a dead end between an exit and an occupant can prevent the occupant from reaching the exit. Means of egress need to be illuminated continuously, and emergency lighting must be provided. Exits and the paths to them should be clearly marked. However, NFPA *101* and *NFPA* 5000 permit the elimination of exit signs in inmate housing areas where no visitors are permitted. The rationale for this is that the inmates cannot leave until someone unlocks the doors and security staff, who are familiar with the locations of exits, direct the evacuation of inmates.

Compartmentation. Compartmentation is an important aspect of occupant protection, whether inmates are evacuated or defended in place. Compartmentation limits the number of persons exposed to a single fire. The walls, ceilings, and floors of fire compartment boundaries must be fire resistant. Openings must be protected with self-closing, fire-rated doors. The degree of fire protection these elements provide depends on the degree of hazard the occupancy presents, or its fuel loading, and the type of building construction—for example, fire resistive versus combustible—and the function served, such as a load-bearing or nonload-bearing wall. For more information on compartmentation, see Section 18, Chapter 1, "Confinement of Fire in Buildings."

Smoke Control. Controlling smoke means controlling the type and quantity of materials used in the building construction and building contents and providing a means of restricting smoke movement within the building. Dilution, which is reducing smoke concentration by introducing massive quantities of uncontaminated air into a building, is not always satisfactory when used alone. Smoke may be generated in such quantities that adequate dilution may not be obtained. Prudent use and placement of automatically opening vents can provide some relief from smoke and combustion products in small, one-story buildings or multitiered cell blocks. However, smoke confinement can best be achieved by providing a physical barrier, such as a wall with self-closing doors and dampers that restrict smoke movement, and by using pressure differences across the physical barrier to prevent smoke from entering the nonfire area. The building's heating, ventilating, and air-conditioning (HVAC) system can be designed to provide this pressurization. Physical barriers alone usually are not effective in controlling smoke movement because they have many penetrations, and the fire, the building HVAC, and/or the weather conditions create uncontrolled pressures. NFPA 92A, *Standard for Smoke-Control Systems Utilizing Barriers and Pressure Differences,* provides requirements for the design and installation of smoke-control systems. For more information on smoke control, see Section 18, Chapter 3, "Smoke Movement in Buildings."

Locking Systems. Since the primary objective of detention and correction facilities is security, reliable locking systems are essential. However, the inability to unlock doors has played a major role in some of the deadliest correctional fire tragedies. Whatever the type of locking system, the system must function reliably in emergencies, whether a facility is designed to evacuate its inmates or to defend them in place. Individual key locks are the most unreliable for several reasons, including the time required to unlock each door, the loss of keys or the breaking of a key in a lock during an emergency, heat and smoke prohibiting entry into the cell block, and confusion due to the number of keys required to release the inmates.

It is important that the number of keys needed to evacuate the occupants to the outside or to an area of refuge be limited to reduce the confusion. Also, all keys needed for evacuation should be marked by sight and touch for quick identification in an emergency.

CASE STUDY: Jail Fires. In two deadly jail fires, a major factor was the loss, early in the incident, of the only set of keys to the fire-involved area, combined with the lack of a secure area of refuge to which prisoners could be evacuated. Both facilities lacked sprinklers; at least one of the two facilities lacked detectors as well. In both facilities, exit problems were cited (in one, the two means of egress were too close together; in the other, the means of egress were blocked and inadequate in number). In one incident, the storage of urethane foam mattresses in an unsecured room was cited as a contributing factor.[6]

Detection and Suppression Activities

Detection and suppression activities deal directly with the fire—detecting its presence, sounding an alarm to alert occupants, and inhibiting fire growth by active fire suppression. To achieve this objective, the following must be provided: an early warning fire detection system, a reliable alarm system, and a reliable fire suppression system. All automatic detection and suppression systems and manual equipment need to be inspected and tested regularly. See NFPA 10, *Standard for Portable Fire Extinguishers*, NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems*, and *NFPA 72®*, *National Fire Alarm Code®*.

There are three separate stages of detection and suppression activities, each of which can be performed automatically or manually (Table 20.14.5). Automatic and manual systems can

TABLE 20.14.5 Stages of Detection and Suppression

Stage	*Manual*	*Automatic*
Detection	Inmate or guard detects fire	Smoke detectors or sprinklers detect fire
Alarm	Guard verbally transmits information to other guards	Fire alarm system activates audible and visible alarms
Suppression	Guards use extinguishers to suppress fire	Sprinklers begin extinguishing immediately

also be combined. For example, detection can be provided by smoke detectors installed throughout the facility with manual fire fighting by fire brigade personnel using a standpipe hose. However, any system needing manual intervention requires that someone make a decision, requires time for human action, and requires trained personnel with the necessary equipment to do the job. The human element is generally the most unreliable part of a fire safety system.

The effectiveness of fire detection and suppression systems depends on the rate of fire growth and the time from ignition until detection and, eventually, suppression activities begin. If the fuel available is capable of producing a fast fire, as it is in padded cells, the extinguishing agent, usually water, must be applied to the fire very quickly after ignition. This is very difficult to do with manual fire suppression even if early warning fire detection, such as automatic smoke detectors, is available. Automatic sprinklers provide reliable fire detection and suppression, and they need no human intervention. With an automatic sprinkler system, the extinguishment phase begins almost simultaneously with detection and alarm, a response difficult to achieve with manual suppression.

Detection and Alarm Activities. NFPA *101* and *NFPA 5000* require smoke detectors in the sleeping areas of detention and correctional occupancies. Smoke detectors may cause needless or nonfire emergency alarms. Therefore, in housing areas, they may alarm at a constantly attended location, such as a control room, and are not required to sound a general evacuation alarm or call the fire department. A manual fire alarm system is also required. NFPA *101* and *NFPA 5000* permit the manual fire alarm boxes to be locked, provided staff has keys. In addition, the alarm systems should be arranged to automatically notify the local fire department. Manual suppression ability should include portable fire extinguishers of the proper type and number, readily accessible fire hose stations for use by correctional officers, and a means to stretch fire hoses through double security gates, or sallyports, so the gates can be closed and security maintained.

Suppression Activities. Sprinklers have been, and are being, installed quite successfully in detention and correctional facilities throughout the United States and Canada. Contrary to some schools of thought, vandalism of sprinklers by inmates, especially in long-term facilities, is very low. It is recommended that institutional type sprinkler heads be used in areas occupied by and within easy reach of inmates. Sprinklers control fire development, thereby reducing the production of heat and smoke. They also give fire service personnel a better opportunity to begin rescue and extinguishment operations. Automatic sprinklers can reduce property loss and limit downtime. In addition, they offer several economic advantages:

- Insurance premiums may be reduced with the installation of sprinkler protection.
- Many building codes offer tradeoffs when sprinklers are used, thereby reducing building costs.
- Sprinklers may also result in fewer persons being evacuated and reduce the burden for manual fire fighting—in effect, increasing security.

NFPA *101* and *NFPA 5000* require the installation of automatic sprinkler systems in all new detention and correctional occupancies, other than those classified as Use Condition I. Prior to the 1997 edition of NFPA *101*, requirements for automatic sprinklers depended on the facility's construction type, number of stories, and use condition.

Planning and Training Operations

Planning and training mean conducting training activities among inmates and staff and planning emergency operating procedures. To achieve this objective, the following methods are used: staff education and training, inmate education, planning emergency procedures, and conducting drills. Planning and training require little capital investment in equipment, but they will make a big difference in reducing the impact of a potentially disastrous fire. In addition, planning and training are important to maintain a high level of security during a fire.

Because fire safety should be everyone's concern, both staff and inmates should be involved in a fire safety program. Each shift should practice the fire emergency plan at least quarterly, and new employees should be briefed routinely on the fire emergency plan. Inmates should be instructed in emergency procedures. Safety information can also be included in an inmate information booklet.

The fire safety program should be designed to meet the needs of the facility. The size and age of the facility and the security classification of the occupants, as well as its proximity to municipal fire departments, should be considered. All training programs should include a short description of the background and evolution of the problem; how to recognize, prevent, and reduce fire hazards; information on the fire protection technology available for application at the facility; hands-on training for staff and inmate fire brigades; emergency operating procedures; and identification of potential problems that affect fire safety.

Fire brigades should be equipped and trained to deal effectively with a fire emergency. Brigade responsibility and functions will vary with the size of the facility and the size and location of the nearest fire department, but they should include calling the fire department, safeguarding lives, providing manual suppression to control the fire until the fire department arrives, and protecting equipment. Fire department access into detention and correctional facilities will usually be delayed because of security.

Each building in a detention or correctional facility should have a written fire emergency response plan detailing staff action during a fire emergency. The plan provides a guide for evaluating the particular problems and coordinating the response of the fire brigade, fire department, staff, and inmates. Emergency response plans should be simple yet comprehensive, specific, flexible, and workable. Preparing the plan can be accomplished in these five steps:

- Define the potential fire protection problems in the particular detention and correctional facility.
- Determine the security needs of the facility.
- Set objectives for what can be accomplished with the plan in an emergency.

- Determine the facility's capability for controlling an emergency.
- Define the roles of the responding agencies, especially the fire department and fire brigade.
- Put the information in written form.

The local fire department should be involved in formulating the fire emergency plan and briefed on building conditions, contents, and fire-fighting equipment within the complex. Fire departments with correctional facilities within their jurisdictions should conduct site surveys and have their own prefire plans for each building.

LOCKUPS

For many years building officials, fire officials, and designers have looked for guidance in codes on how to treat and protect "lockup" areas of buildings. Lockups are holding areas for not more than 50 detainees, where individuals are detained for less than 24 hours. A lockup that has a holding area for more than 50 detainees or detains individuals for 24 hours or more is classified as a detention and correctional occupancy or health care occupancy. Lockups are commonly found in courthouses, international airports, sports arenas and stadiums, shopping malls and police stations. The 2006 editions of NFPA *101* and *NFPA 5000* contain, for the first time, requirements for such lockups.

The only real difference between a lockup area and a detention and correctional facility is that an occupant in a lockup area is detained for less than a 24 hour period and generally sleeping facilities are not provided in lockup areas. Occupants in lockups, like detention and correctional occupancies, are generally prevented from taking actions for self-preservation because of security measures not under the occupants' control.

Because occupants in lockups are generally incapable of self-preservation, the lockup areas require a higher level of life safety than other portions of the same building. Codes require that the lockup areas comply with the requirements of the predominant occupancy plus staff must be present to release locks and/or restraints within two minutes of the onset of a fire or similar emergency or the lockup areas must be provided with a complete smoke detection system and automatically notify the staff and the fire department.

SUMMARY

Providing balanced fire protection and security in detention and correctional facilities can be challenging and has two goals: security for the public and safety from fire for the inmates. The systems approach to fire safety helps to achieve these two goals through meeting a series of objectives, including ignition control, fuel control, occupant protection, detection and suppression, and planning and training. Ignition control involves greater and more dependable protection of heat sources and separation from fuel sources. Fuel control means controlling the type, arrangement, and burning characteristics of potential fuels. Occupant protection can be accomplished either by evacuating inmates to a secure area or by defending them in place. Detection and suppression of fire require an early warning fire detection system, a reliable alarm system, and a reliable fire suppression system. Planning and training include staff education and training, inmate education, emergency procedure planning, and emergency drills. When certain of these objectives cannot be met, other parts of the system may have to be enhanced to compensate. The fire safety program should be designed to meet the particular needs of the facility and should involve the participation of the local fire department.

Fire Safety Evaluation System
Ambulatory Health Care

Key Terms

automatic sprinkler system, disposable equipment and supplies, exit illumination, exit marking, interior finish, means of egress, portable fire extinguisher, smoke control, vertical openings

In today's business environment, health care, medical care, and personal care services have evolved such that there is a wide variety of facilities and business operations delivering health care to the general population. As a result, there are varying levels of risk among the facilities that offer health care and medical services. Within NFPA *101*®, *Life Safety Code*®, and *NFPA 5000*®, *Building Construction and Safety Code*®, there are several types of occupancies where people may receive some form of health care, medical, or personal care service. These include the following:

- Health care occupancies
- Ambulatory health care occupancies
- Residential board and care occupancies
- Business occupancies

The focus of this chapter is on those facilities that pose greater risks due to the impairment of occupants and/or lack of ambulatory capabilities of the occupants. Specifically, this chapter addresses health care occupancies and ambulatory health care occupancies; however, some brief discussion of residential board and care and business occupancies is warranted, as there are important distinctions that should be understood and considered when applying the requirements of NFPA *101* and *NFPA 5000*.

Health care facilities are used for the treatment or care of persons suffering from physical or mental illness, disease, or infirmity, and for the care of infants, convalescents, or aged persons. These facilities provide sleeping accommodations for occupants who may be incapable of self-preservation because of physical or mental disability or age. Some buildings that house health care occupants have security measures that limit freedom of movement.

In recent years, facilities—sometimes called ambulatory health care facilities—have been developed to provide medical treatment on an outpatient basis. Although patients might be placed under general anesthesia or other treatment that would render them incapable of self-preservation, they are not housed overnight. Occupants exhibit some characteristics of people in business occupancies and some characteristics typical of people in health care facilities.

Tremendous growth has occurred in recent years in residential board and care facilities. These facilities are commonly called assisted living facilities, personal care facilities, and so on. Residential board and care facilities provide personal care to occupants in a residential setting. The residents' abilities to respond to a fire threat differ greatly from patients in health care facilities. The safeguards appropriate for health care facilities should be applied only when a facility meets the definition in NFPA *101* and *NFPA 5000* of a health care facility.

In many facilities the presence of doctors providing diagnosis and treatment for patients may suggest that the facility is a health care occupancy. This may not be the case, as most doctor's offices and birthing centers are classified as business occupancies when meeting the definitions and criteria defined in NFPA *101* and *NFPA 5000*. Where doctor's offices solely provide outpatient care and are physically separated from facilities housing inpatient treatment and care areas, such offices can be classified as business occupancies, although associated with the operations and management of a health care occupancy.

Daniel J. O'Connor, P.E., is vice-president of Schirmer Engineering Corporation in Deerfield, Illinois. He is chair of the NFPA Technical Committee on Health Care Occupancies.

Additionally, in recent years there has been a significant growth in facilities known as birth centers. These facilities do not pose the risks associated with health care occupancies as they are intended for low-volume service for healthy, childbearing women and their families, who are capable of evacuating in the event of a fire. Such facilities should meet the definitions for birth center and business occupancy given in NFPA *101* and *NFPA 5000;* otherwise the facility may be a health care occupancy.

This chapter describes the characteristics and fire hazards of health care facilities. It specifically discusses the characteristics of the health care occupant and the fire safety features that all health care facilities should provide.

Additional information relating to health care facilities can be found in Section 8, Chapter 6, "Protection of Electronic Equipment"; Section 18, Chapter 1, "Confinement of Fire in Buildings"; Section 18, Chapter 2, "Interior Finish"; and Section 20, Chapter 2, "Board and Care Facilities."

OCCUPANCY CHARACTERISTICS

Occupants of health care facilities are generally presumed to be incapable of self-preservation. A significant percentage of occupants in hospitals and nursing homes are incapable of self-evacuation or are ambulatory but incapable of perceiving a fire threat and choosing a rational response.

There are three types of care in most modern hospitals: (1) ambulatory, (2) general, and (3) intensive care. Given proper directions, unless smoke or heat is intense, ambulatory patients can make their own way to safety. General care patients may be transported on stretchers or in wheelchairs with some difficulty; horizontal and even some vertical movement is generally possible, although independent evacuation is not. Patients in intensive care are likely to be connected to various life support devices, making movement for even short distances very difficult and evacuation almost impossible without further endangering these patients' lives.

Occupants of nursing homes vary from geriatric residents who are capable of evacuation with limited assistance to residents who are comatose and require close supervision with evacuation being very difficult. Today's nursing home resident is less ambulatory and requires more medical care than a resident of even 10 years ago. The significant increase in the number of assisted living facilities has made the typical intermediate care nursing home resident of yesterday an assisted living resident today.

Because some occupants are incapable of movement or slow to evacuate, a health care facility resembles a ship at sea: it is better to keep the fire from the patient than to remove the patient from the fire. Thus, occupants must be defended in place. As a result, health care facility design and operation must incorporate methods by which a fire can be detected early, contained, and fought rapidly and successfully. Accomplishing this requires careful planning of the health care facility and its day-to-day operation.

NFPA *101,* widely used to establish minimum requirements for life safety from fire within health care facilities, sets forth criteria based on the following general principles:

- Fire-resistive construction
- Subdivision of spaces, known as compartmentation
- Protection of vertical openings
- Provision of adequate means of egress
- Provision of exit marking, exit illumination, and emergency power
- Limits on the use of interior finish materials
- Fire alerting facilities
- Control of smoke movement
- Protection of hazardous areas
- Adequate protection of building service equipment
- Control of fuel loads
- Operational features

Total building fire protection for life safety is more necessary in health care facilities than in other occupancies because of the nature of the occupants. At the same time, exits are slightly less important. The first principle of designing a fire-safe health care facility is that safety must not depend wholly on any single safeguard.

IGNITION SOURCES

In the 1994–1998 period, smoking materials, both lighted tobacco products and implements used to light them, and incendiary and suspicious acts accounted for 75 percent of deaths and 45 percent of injuries in facilities that care for the sick and for 54 percent of deaths and 33 percent of injuries in facilities that care for older adults. These causes totally dominate the ignition side of the life safety problem in these properties, although other causes, notably failures in electrical distribution systems, appliances, and other equipment, are also important in property damage (Tables 20.15.1 through 20.15.4).

More and more health care facilities are establishing smoke-free environment policies. In addition, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) requires facilities to establish a no-smoking policy. As the result of prohibiting or controlling smoking in health care facilities, a new phenomenon has developed: visitors giving smoking materials to patients and residents without the health care staff's knowledge.

Most fatalities in health care fires are so close to the point of origin that their locations are coded as "intimate with ignition" (Table 20.15.5). Most fatalities that occur in the room where a fire begins turn out to have been intimate with ignition. Most intimate-with-ignition fire deaths begin on the victims' clothing or in the mattress, bedding, or upholstered furniture on which they were lying when the fire began.

FIRE LOADS

Studies show relatively low fuel loads within most spaces in health care facilities. Fire duration varies from approximately 20 minutes for patient areas to several hours, depending on the space involved.

A study by the National Bureau of Standards (now the National Institute of Standards and Technology [NIST]) conducted in 1942 involving three hospitals revealed an average fuel load

Lockers, toilets, and barber shops	0.2	1.2	1.4
Approximate average for entire usable floor area of three hospital buildings surveyed			5.7[b]

[a]Combustible floor finish, where present, was ¼ in. (6.35 mm) linoleum; it was assumed to be the equivalent of 1 lb (0.37 kg) of combustible material, such as wood, per ft^2 of floor area (4.88 kg/m^2). Doors, windows, trim, moldings, baseboards, and so on are included.

[b]This approximate average weight was computed from Table 16 on page 25 of the Bureau Report BMS 921. The value is somewhat high because the highest weight in each bracket of combustible contents was used in figuring it, that is, in the bracket "0 to 4.9 lb/ft^2 (23.9 kg/m^2)," the value 4.9 lb (2.22 kg) was applied to the indicated area, and so on.

of 5.7 lb/ft^2 (30 kg/m^2).[1] Fuel loads for typical spaces are indicated in Table 20.15.6. A 1980 study of fuel loads in a U.S. Navy hospital confirms the relatively low fuel loads for general hospital areas but indicates that higher fuel loads may be anticipated in some spaces such as medical libraries, X-ray file rooms, linen storage, and general storage rooms. Further, the increased use of disposables and modern medical record storage practices are likely to result in above average fuel loads. These areas may contain fuel loads sufficient for fires from 1- to 3-hour duration. However, such spaces represent a small percentage of total floor area.

A major portion of the floor area of health care facilities is used for patient sleeping or treatment rooms. Fuel loads for such spaces are low. For example, fuel loads in nursing homes have been estimated at 2.5 to 3 lb/ft^2 (10 to 15 kg/m^2).[2] NIST surveys indicate that fuel loads for hospital patient rooms approximate 4 lb/ft^2 (20 kg/m^2) and that the combustible load in patient sleeping areas ranges from approximately 3 to 4.5 lb/ft^2 (15 to 23 kg/m^2). A study of a Navy hospital indicates fuel loads for sleeping rooms average 1 lb/ft^2 (5 kg/m^2) or less. Assuming standard time/temperature conditions, fire duration for patient areas and a majority of other occupied spaces would be less than 30 minutes.

Disposables

The use of combustible disposable equipment and supplies is common in health care facilities. Disposables include bedding, gowns, gloves, drapes, collection bags, tubing, dishes, glasses, syringes, needles, and many diagnostic and therapeutic instruments. All such items require packaging, which can add to the combustible load both before and after use.

Data Processing and Medical Records

Used to satisfy general business needs as well as to store patient records, data processing centers contain quantities of combustibles. These combustibles could expose high-value equipment, result in loss of vital records, and produce a fire that threatens occupants outside the data processing areas. Special protection should be considered for data processing centers.

Health care facilities generate and store medical files in considerable quantity. Files stored in closed steel cabinets do not represent any significant increase in hazard over that typical of most areas. However, files stored on open shelving create a serious fire hazard. Large quantities of open-file storage should be treated as a severe hazard and should be separated by fire-rated construction and protected by automatic sprinklers.

FIRE SEVERITY

Determining relative fire hazard involves considerations beyond total fuel loads. The arrangement of combustibles, their chemical makeup, and their physical state are all factors to be

evaluated in addition to room geometry, ventilation rates, fire compartment size, and fire protection facilities. Generally, the faster a fire develops, the greater its threat.

Although the total fuel load in patient rooms remains low, the nature of the combustibles is important. Foam plastic decubitus pads, upholstered furniture, and polyurethane foam mattresses may not affect the length of time a fire will burn, but such items have affected the rate of fire growth. These types of products can cause fire to grow to a large size quickly.

Fires that reach flashover produce acutely lethal atmospheres generating thousands of cubic feet of smoke per minute. Such fires threaten fire-rated barriers and produce enough energy to drive smoke to remote areas. A fire that grows to full room size in a health care facility represents an unacceptable level of risk; there is a high likelihood that such a fire will result in injuries or fatalities if its origin is in the patient sleeping area. Therefore, every effort should be made to recognize and eliminate or adequately protect fuel arrangements that might produce such fires.

Fire tests and actual fire experience have shown that certain common arrangements and types of fuels in patient rooms create especially hazardous situations because they are able to produce large fires in short time periods. In January 1976, for example, multiple-death fires in both the Wincrest and Cermak House nursing homes involved wooden wardrobes within patient sleeping rooms.[3,4] Tests show that combustible wardrobe fires can result in acutely hazardous environments in as little as 120 seconds.[5]

A 1989 fire in a Norfolk nursing home resulting in 12 deaths originated in a foam plastic decubitus pad on a mattress in a patient sleeping room. The fire grew to flashover in less than 5 minutes.[6] A 1985 fire in a Michigan hospice initially involved an upholstered chair. The fire caused eight deaths.[7] Analysis of this fire established that flashover could have occurred in the room of origin in under 4 minutes. See Figure 20.15.1 for documentation of the analysis for the hospice fire.

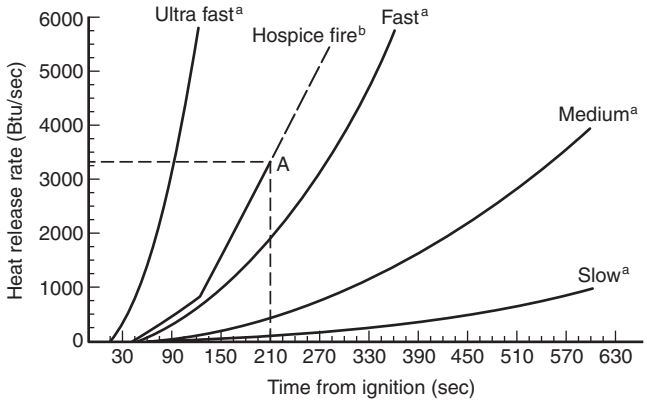

FIGURE 20.15.1 Comparison of the Hospice Fire to *NFPA 72®, National Fire Alarm Code®* Growth Curves. [a]From *NFPA 72®, National Fire Alarm Code®*. [b]From NFPA study of the hospice fire, Southfield, Michigan, December 1985 and CFR/NBS fire model analysis. A = Room flashover

Any combination of finishes, combustible building materials, or contents and furnishings that could result in full room involvement or flashover in 5 minutes or less represents a severe fire hazard in a health care facility. Such spaces should always be protected by automatic sprinklers and separated by fire-rated construction.

Computer fire models developed at NIST have been used to establish the rate of heat release required to produce flashover in a typical patient sleeping room. Under the "worst" circumstances—where the room door is partially open—a 1 MW fire can cause flashover. When the room door is fully open, approximately a 2 MW fire is necessary to cause flashover. NFPA *101* suggests that upholstered furniture, mattresses, and wardrobes be constructed to produce a maximum rate of heat release of 250 kW. It also has been determined that when a fire grows beyond 250 kW in size, hazard thresholds are exceeded, and patients must be removed from sleeping rooms.

Furnishings are frequently major contributors to fire growth. Recent developments make it possible to determine whether furnishings in a given environment can produce sufficient energy to cause full room involvement.

A simplified equation for estimating the rate of heat release required for flashover to occur in a room[8] is given by the expression

$$\dot{Q} \geq 750A\sqrt{h}$$

where

$\dot{Q}$ = Rate of heat release (kW)

A = Ventilation opening area (ft^2 [m^2])

h = The height of the opening (ft [m])

Once the heat release rate required to produce flashover is known for a typical room geometry, such information can be compared to actual heat release rates for typical furnishings, as determined by tests conducted in a calorimeter such as the NIST furniture calorimeter[9] or by Underwriters Laboratories (UL) Subject 1056, "Outline of Investigation for Upholstered Furniture." Figures 20.15.2 and 20.15.3 are idealized curves developed by NIST that illustrate the rate of heat release for typical furnishings as a function of time. Such information can be used to establish the probability of flashover; it also allows estimation of the time required to reach critical fire size.

Interior Finish

A successful fire protection strategy requires fires to remain small. Any large fire in a confined space creates a potentially lethal atmosphere. A fire's initial growth may be affected significantly by the interior finish of walls, ceilings, and floors. Interior finishes, therefore, deserve special attention. Combustible wall and ceiling finishes can act as a fuse, causing a fire to spread to objects remote from the fire origin. Wall and ceiling finishes also provide a large continuous surface over which fire may spread. Thus, an interior finish may, by releasing energy, cause a fire that would otherwise have remained small to become large.

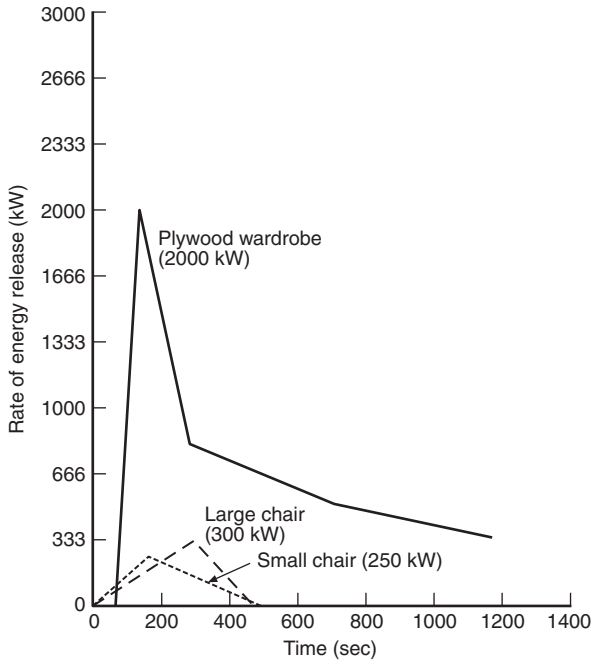

FIGURE 20.15.2 Heat Release Rates for Miscellaneous Furniture

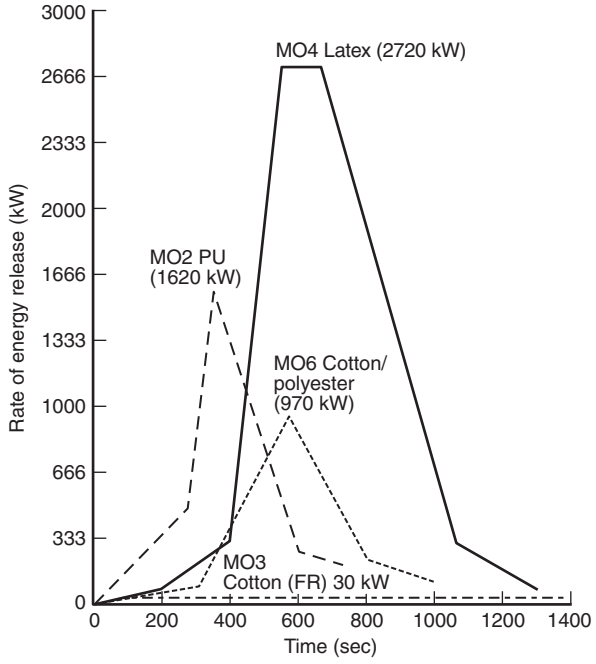

FIGURE 20.15.3 Heat Release Rates for Beds

The relative hazard of an interior finish is usually determined by a test conducted in accordance with NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials,* commonly called the "tunnel test."

Interior finish on walls and ceilings within the means of egress and any room should be limited to Class A materials, which have a flame-spread rating of 25 or less. Class B materials, or those with a flame-spread rating of 25 to 75, are considered tolerable, but they should be limited to small rooms. Full-scale experiments show that automatic sprinklers can limit fire growth in rooms with Class C wall and Class D ceiling finishes.[2,5] Accordingly, in buildings with automatic sprinkler protection, it has been judged acceptable practice to allow the use of materials having higher flame-spread classifications than would otherwise be permitted. For example, Class B materials are sometimes used where Class A is normally specified and Class C materials where Class B is normally required. In new health care facilities, higher flame-spread classifications are permitted based on the mandatory requirement for sprinklers.

Further, it has been shown that the performance of interior finishes also is related to location.[10] Finishes on the upper portions of walls and ceilings contribute more significantly to flame propagation than finishes on the floor or on the lower half of a wall. Therefore, where finishes are limited to the lower half of a wall and are less than 4 ft (1.2 m) above floor level, materials having a higher flame-spread rating than would otherwise be allowed might be used without significantly affecting fire growth. For example, where Class A materials are judged necessary, a Class B material might be allowed on the lower portion of a wall.

In the past, floor finish materials were excluded from requirements for interior finishes, based on favorable experience and the assumption that limited exposure exists at the floor level during an actual fire. However, a fire on January 9, 1970, in the Harmer House Convalescent Home in Marietta, Ohio, significantly changed this attitude.[11] Thirty-two persons died in this fire. Carpeting with foam-rubber backing was judged to have played a significant role.

Interior floor finishes in the corridors of nonsprinklered health care facilities should be limited to Class A materials or those with a minimum critical radiant flux of 0.45 W/cm^2. Where automatic sprinklers are provided, interior floor finishes need not be regulated beyond the federal flammability standard.

BUILDING CONSTRUCTION

Because occupants of health care facilities must be defended in place, construction is an important factor, especially in multistory buildings. Buildings preferably should be constructed of noncombustible materials that resist the effects of fire and maintain structural integrity.

Buildings of two or more stories should be constructed of noncombustible materials with major structural members having at least a 2 hour fire resistance. Materials that either burn or support combustion, although less desirable, are considered acceptable if special precautions are taken. An automatic sprinkler system is an essential part of the total fire defense system for combusitble buildings.

Any evaluation of building materials should include consideration of their smoke-generating capabilities. In addition, plastic construction materials, which are becoming more

common, are sometimes capable of generating large quantities of smoke.

Subdivision of Building Spaces

Mixed and Separated Occupancies. There are basically two ways to handle multiple occupancies in a building that houses a health care facility and other uses. One alternative is to separate the different occupancies. The second alternative is to treat the entire facility as a mixed occupancy and comply with the provisions that are the most stringent of the occupancies involved. When using the mixed occupancy design alternative, there are no specific fire-rated separation requirements. Fire-rated separation requirements, however, do apply in addition to other restrictions when adjacent occupancies are separated from health care occupancies. The health care occupancy chapters and the ambulatory health care occupancy chapters stipulate the fire-resistance separation requirements (2 and 1 hours, respectively) and other provisions when the health care facility is intended to be separated from adjacent occupancies.

Figure 20.15.4 shows health care and other occupancy areas intermingled without fire separations as a mixed occupancy facility. Figure 20.15.5 shows a health care occupancy (hospital) separated from an adjacent business occupancy and ambulatory health care occupancy. In this case, 2 hour fire-resistive separa-

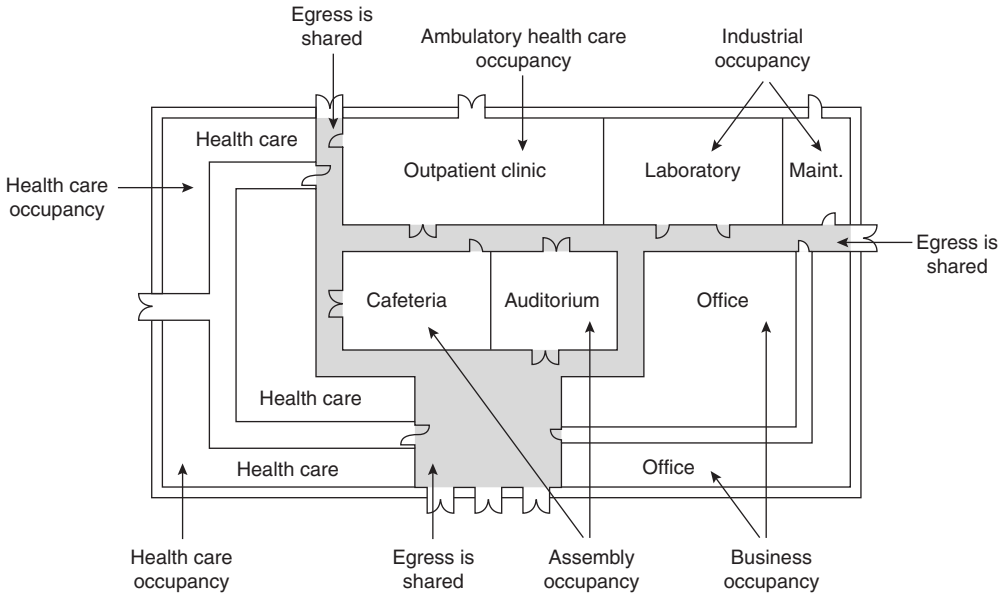

FIGURE 20.15.4 Multiple Occupancy with Mixed Uses

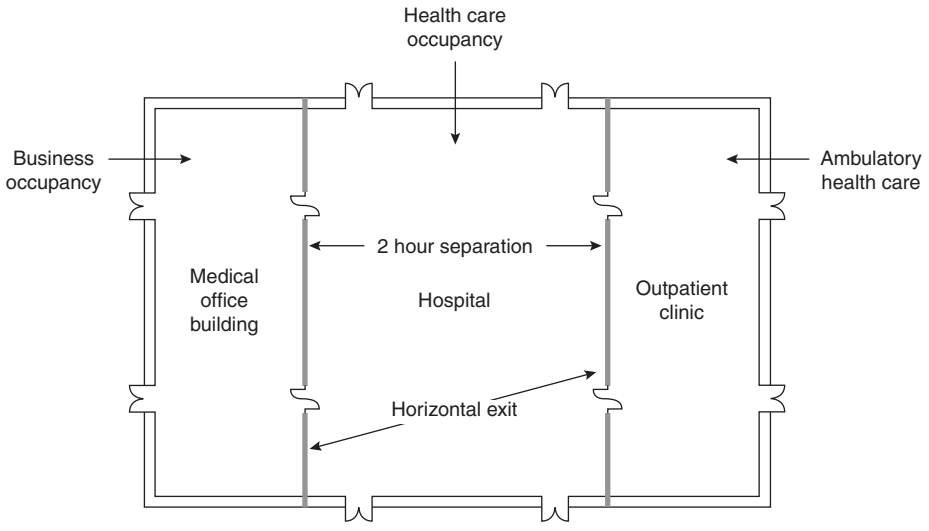

FIGURE 20.15.5 Multiple Occupancy with Separated Uses

tions are used to qualify the hospital, business, and ambulatory health care areas as separate occupancies.

Separation of Patient Sleeping Rooms. Because it may not be possible to remove occupants during a fire, sleeping rooms other than the room of fire origin sometimes must serve as temporary areas of refuge. Therefore, sleeping rooms should be isolated from all other building spaces by fire-rated construction. Partitions should be continuous from the floor slab to the floor or roof above through any concealed spaces, such as those above suspended ceilings. If the building is protected by sprinklers, NFPA *101* and *NFPA 5000* allow these walls to be nonrated, provided the walls resist the passage of smoke, and they are permitted to terminate at the ceiling, provided the ceiling resists the passage of smoke (see Figure 20.15.6 for typical floor plan for a health care facility).

There has been much discussion in the past about the operational considerations versus the fire safety considerations of equipping patient room doors with door closers. NFPA *101* and *NFPA 5000* do not require door-closing devices on patient room doors. The current opinion is that a health care facility's functional needs prevail, and other fire safety and operational features a health care facility provides are adequate alternatives to door-closing devices.

Any penetration of fire barriers by building service equipment should be protected in order to maintain the required fire resistance rating. All spaces around piping and duct penetrations should be sealed tightly with a noncombustible material having adequate fire resistance and capable of retarding the transfer of smoke. Transfer grills should not be used within such doors or partitions.

Smoke Barriers. Every floor used by inpatients should be subdivided into at least two compartments by smoke barriers that also have a 1-hour fire resistance rating. A horizontal exit, when constructed to satisfy the additional criteria imposed on construction of smoke barriers, is a desirable alternative. Smoke barriers and smoke compartments play a very important fire safety role in health care facilities. Subdividing each floor minimizes the number of occupants exposed to a single fire. More importantly, the barriers allow for horizontal evacuation of occupants to an area of refuge on the same floor. In a protect-in-place occupancy where evacuation is difficult, having the capability to evacuate horizontally is extremely important.

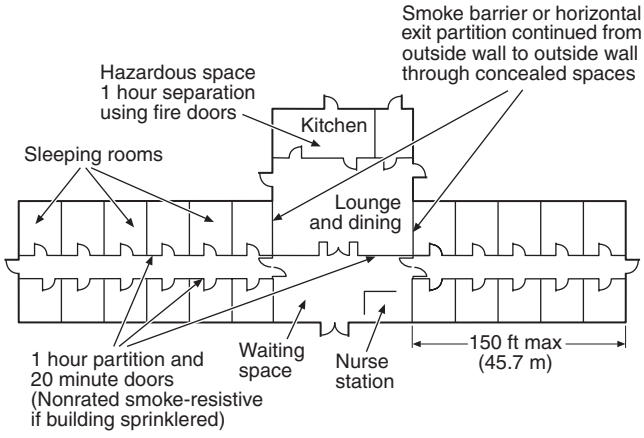

FIGURE 20.15.6 Typical Floor Plan for a Health Care Facility

In new health care construction, smoke barriers are generally required to subdivide into at least two compartments every story used for inpatient sleeping and treatment and any story in the building, regardless of occupancy, that has an occupant load of greater than 50 people. In existing facilities, subdividing a space with a smoke barrier is required only on stories with patient sleeping areas that can accommodate more than 30 patients. Several exceptions to the general requirement for smoke barriers in new health care construction are found in NFPA *101* and *NFPA 5000.*

For stories that must be subdivided, there are two limitations on how large the smoke compartment formed can be related to area and travel distance from any point to a door in a smoke barrier. No smoke compartment can exceed 22,500 ft^2 (2100 m^2) nor can the travel distance from any part of a smoke compartment to the door in a smoke barrier exceed 200 ft (60 m). One exception for existing health care occupancies is that the travel distance to reach the smoke barrier door need not be limited where neither the length nor width of the smoke compartment exceeds 150 ft (45 m). Figures 20.15.7 and 20.15.8 illustrate the basic dimensional criteria and features that constitute an appropriate smoke compartment arrangement for new and existing health care facilities. In addition to the features shown in Figures 20.15.7 and 20.15.8, accumulation space must be provided on both sides of a smoke barrier to accommodate a certain number of people in an emergency based on factors that range from 30 net ft^2 (2.8 m^2) per patient for hospitals and nursing homes to as low as 3 net ft^2 (2.8 m^2) per person on floors with non–health care spaces.

Protection of Vertical Openings

Fire, smoke, and other toxic products of combustion tend to spread vertically within a building. Special effort is required to prevent fire on one level from threatening the occupants above; this is especially important in health care facilities.

All shafts should be provided with fire-rated enclosures. Vertical openings connecting not more than three floors should be enclosed with fire barriers having a minimum 1-hour fire resistance rating. Two-hour rated enclosures should be provided for vertical openings connecting more than three floors. Openings to shafts should be limited to those necessary, and such openings must be protected.

When designing partitions to enclose vertical shafts, consideration should be given to the varying durability of materials. In spaces where partitions may be subject to mechanical injury, materials used to provide floor-to-floor separation should be able to resist damage in order to maintain the required fire resistance.

Means of Egress Design

Exits in health care facilities should be limited to doors leading directly outside of the building, interior stairs and smokeproof

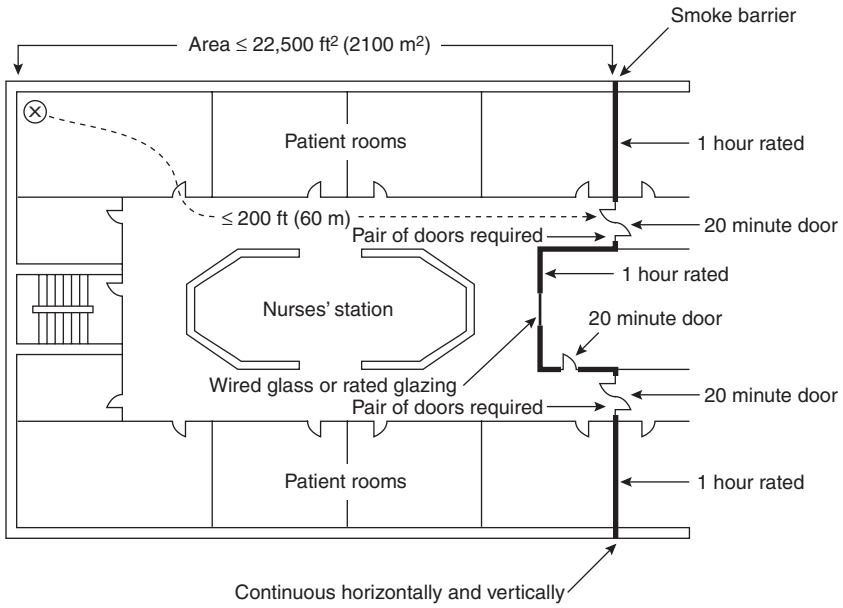

FIGURE 20.15.7 Smoke Compartment in a New Health Care Facility

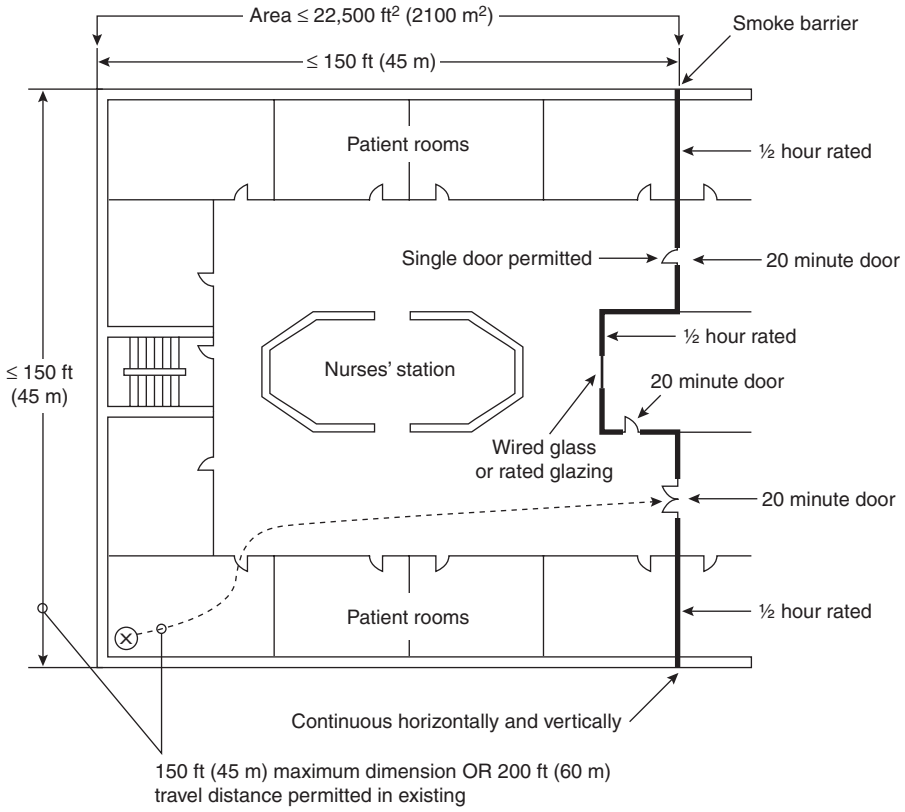

FIGURE 20.15.8 Smoke Compartment in an Existing Health Care Facility

enclosures, ramps, horizontal exits, outside stairs, and exit passageways.

Vertical evacuation of occupants within a health care facility is, at best, difficult and time consuming. Therefore, horizontal movement of patients is of primary importance.

Horizontal passageways and doors opening into corridors and rooms used for sleeping or treatment should be wide enough to allow the horizontal movement of occupants, even those in beds or on gurneys. Relocation of patients is a slow process, even under favorable staff-to-patient ratios. Because of the time required to move patients, exit access routes should be protected against fire effects. Spaces open to the corridor should not be used for patient sleeping or treatment rooms, nor should hazardous contents or activities be permitted within them. NFPA *101* and *NFPA 5000* provide detailed requirements for spaces open to corridors. Such requirements include the installation of smoke detection systems, quick-response sprinklers, direct visual supervision of the open space by staff, or a combination thereof.

Horizontal Exits. Horizontal exits are common in health care facilities. Partitions used as horizontal exits and smoke barriers should provide the fire resistance required for exits and, in addition, should satisfy the criteria for smoke barriers when appropriate. If possible, door openings should be limited to corridors, lobbies, or public spaces. The most desirable arrangement of mechanical systems is one in which the partitions forming the horizontal exit are not penetrated. If penetration by utilities or piping occurs, the space around the piping should be filled tightly with noncombustible materials and maintain the barrier's required fire resistance. If ducts penetrate partitions intended to be smoke barriers, combination fire/smoke dampers that close if smoke detectors within the duct activate should be provided.

Two-hour fire barrier walls must be used to create horizontal exits. Such barriers must be vertically continuous and must penetrate any ceiling and continue to the floor or roof deck above. NFPA *101* and *NFPA 5000* require such barriers to be continuous to the ground. The fire barrier is allowed to be omitted on any story below, provided the floor below the lowest level on which the barrier exists and all supporting members are of a 2 hour fire-resistive construction. Figure 20.15.9 illustrates the vertical continuity of walls forming horizontal exits.

Because a horizontal exit implies that occupants will be transferred from one side of a partition to the other (horizontal evacuation), adequate space must be available to house occupants after movement. In hospitals, at least 30 net ft^2 (2.79 m^2) per patient should be available on each side of the horizontal exit, allowing for accumulation of the total number of patients in adjoining compartments.

Interior Stairs. Exit stairs should be designed to satisfy the criteria for interior stairs. Stairs should be enclosed with fire barriers, and openings into stair enclosures should be limited to those necessary for access and discharge purposes. Stairs must be properly protected from the effects of fire.

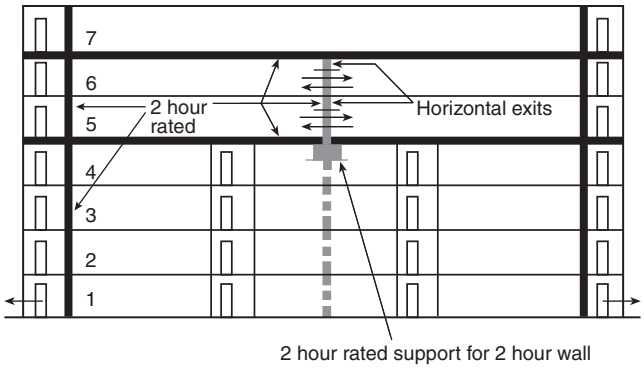

FIGURE 20.15.9 Building with Horizontal Exits on Some Floors

Exit Features

Life safety from fire in health care facilities relies on a "defend-in-place" principle. Horizontal exits or smoke barriers are required to subdivide each story of a health care facility to provide an area of refuge on each floor.

The original concept for the design of exits for health care facilities was derived from studies conducted in the early 1900s. A practice evolved of using exit stair enclosures as areas of refuge. Exit capacity for health care facilities was set conservatively to offset slow travel rates and to create space within exit enclosures for "storing" patients on litters and in wheelchairs.

Means for horizontal evacuation are provided for each story, using either a smoke barrier or a horizontal exit. A barrier subdivides each story to provide an area of refuge for patients without traversing stairs. Furthermore, it is common—indeed, it is required since the 1991 edition of NFPA *101*—to install automatic sprinklers throughout all new health care facilities. Automatic sprinklers limit fire size and complement the defend-in-place strategy currently in use.

Egress capacity in nonsprinklered health care facilities is set at 0.6 in. (15.24 mm) per person for travel over stairs, whereas the capacity through doors and level passageways is calculated at 0.5 in. (12.7 mm) per person. Where automatic sprinklers are provided throughout a building, exit capacity is increased to 0.3 in. (7.62 mm) per person for travel over stairs and 0.2 in. (5.08 mm) per person for travel over level passageways.

Capacity is calculated using a "flow rate" principle. Flow rates assumed are for able-bodied persons because it is presumed that evacuation over stairs will involve only staff, visitors, and ambulatory patients. Nonambulatory occupants are expected to remain in the building under the defend-in-place concept, with those patients on the floor of fire origin being moved horizontally to an adjoining smoke or fire compartment.

Limits on travel distance reflect anticipated slow movement. Travel distance normally should not exceed the following:

1. 100 ft (30 m) between an exit and any room door intended for use as an exit access
2. 150 ft (46 m) between an exit and any point in a room

3. 50 ft (15 m) between any point in a sleeping room or suite of sleeping rooms and the exit access door of that room

Increases in corridor travel distance are permitted in sprinklered buildings.

Because smoke barriers and areas of refuge play such an important role in fire safety, travel distances to smoke barriers is also restricted in NFPA *101*. Travel distance from any point on a floor to reach a door in a smoke barrier is limited to 200 ft (61 m).

Elevators are not permitted to serve as required exits in health care occupancies because they possess numerous shortcomings that may prevent their use during a fire. In the cases of critically ill patients, patients in body casts or balkan frames, and others who would be difficult to move, however, elevators provide the only practical evacuation method from upper stories of the facility. If separate banks of elevators are located in separate smoke compartments, and if the staff are well trained, it may be possible to devise a plan in which using elevators during fires is safe.

Suites

The design of suites has been addressed by NFPA *101* for many years. These requirements, however, were previously dispersed among several topic areas in the code. In the 2006 editions of NFPA *101* and *NFPA 5000,* the terms "suite," "non-sleeping suite," and "sleeping suite," were defined in the context of health care occupancies, and their requirements were consolidated under the provisions for means of egress arrangement.

The suite concept permits groups of rooms in health care occupancies to be treated as one large "room" subject to specified limitations. Normally, rooms in health care occupancies must be provided with direct access to a corridor without traveling through an intervening room. Rooms within suites are not subject to the usual corridor separation requirements, and the circulation spaces within suites are not subject to the strict use limitations imposed on corridors. The creation of suites has long been a cost-effective solution to address the needs of groups of patients having similar health issues or needing similar levels of staff monitoring and care. Suite configurations are often used for specialty care patient sleeping units, such as intensive care, cardiac care, or pediatric care units. Suites can also be used effectively for treatment areas such as a radiology department or operating room suite. In prior editions of NFPA *101* and *NFPA 5000,* sleeping suites were limited in size to 5000 ft^2 (460 m^2) and required direct visual supervision by staff.

Some facility designers and architects have attempted to create sleeping suites larger than 5000 ft^2 using alternative measures (equivalency) to substitute for the requirement of "direct visual supervision by staff" and as a means of providing a cost-effective environment for patients. Based on the prevalence of the suite size limitation issue, the 2006 editions of NFPA *101* and *NFPA 5000* have increased the sleeping suite area limitation from 5000 ft^2 (460 m^2) to 7500 ft^2 (700 m^2) if the suite is provided with smoke detection, sprinkler protection, and direct visual patient supervision by staff. Direct supervision is typically provided from a normally attended staff location. Separation by glass walls is permitted provided that staff can visually see into the patient sleeping room. The use of cubical curtains at patient beds is also permitted; solid walls and doors would not facilitate the required direct visual supervision.

The Technical Committee on Health Care Occupancies recognized that there are practical safety concerns pertaining to how good visual supervision is for patient sleeping rooms within suites. In sleeping suites that do not exceed 5000 ft^2 (460 m^2), any room that lacks direct visual supervision can be used for patient sleeping only where such room is provided with automatic smoke detection arranged to activate the fire alarm. This option only applies to suites that are 5000 ft^2 (460 m^2) or less. Sleeping suites exceeding 5000 ft^2 (460 m^2) are required to provide a total coverage automatic smoke detection system throughout the sleeping suite and provide direct visual patient supervision. It is important to note that although smoke detection can substitute for direct visual supervision in smaller sleeping suites, it is intended that staff are constantly present in the suite.

Several other revisions to the requirements for suites in NFPA *101* and *NFPA 5000* allow for design flexibility without compromising occupant safety. Where two means of egress from a suite are required because of its size, at least one must lead directly to a corridor. The second means of egress is permitted to lead through another suite. See NFPA *101* and *NFPA 5000* for additional details on suite arrangments.

Exit Marking and Exit Illumination

Readily visible signs should mark all exits. Where access to exits is not immediately visible, access routes also should be marked.

The entire means of egress must be continuously illuminated whenever the building is occupied. In some cases, normal street lighting is adequate for illumination of exit discharge. However, consideration should be given to the conditions that would result from a power failure.

Emergency power is also required to illuminate the means of egress and exit marking. In hospitals, this power should be supplied by the life safety branch of the hospitals' essential electrical system. Luminescent, fluorescent, or reflective material should not be substituted for required lighting.

Emergency power supplies should maintain illumination automatically in the event of a power failure without any appreciable interruption during the changeover from normal to emergency power. Where a generator is provided, the delay should not be more than 10 seconds. Where emergency power is supplied by a central system with an engine-driven generator, the design should minimize the probability of any single emergency simultaneously interrupting both normal and emergency power supplies. The switch(es) that transfers power from normal to emergency circuits is one place where normal and emergency circuits are required to merge. If this switch(es) is exposed to fire, it could simultaneously interrupt power to both normal and emergency circuits. The transfer switch and other electrical distribution panels and switch gear should be separated from the generator, as well as from the remainder of the building. See NFPA 99, *Standard for Health Care Facilities,* NFPA *101,* NFPA 110, *Standard for Emergency and Standby Power Systems,* and *NFPA 5000* for additional details on emergency power for health care occupancies.

Fire Alarms

Every health care facility should be equipped with a fire alarm system. When actuated, the system should sound alarms that can be heard above ambient noise levels throughout the facility. Visible alarm indicating devices are permitted in critical patient care areas in lieu of audible alarm devices. The fire alarm should also transmit automatically to the fire department. Any fire detection or fire suppression system that activates should automatically activate the building alarm system.

Alarm systems, including detection devices, should be provided with an emergency power supply and designed according to *NFPA 72®*.

The activation of any sprinkler system, manual fire alarm box, or detection device should provide automatically an alarm for staff and/or occupants within the affected zones initially. Means to notify staff and occupants in other zones as needed should be provided. In sprinklered health care facilities, positive alarm sequence in accordance with *NFPA 72* is permitted. Although the use of a general evacuation alarm is permitted, it may be more appropriate to use the private operating mode as described in *NFPA 72* because occupants may be incapable of evacuating without assistance. The private operating mode recognizes that health care facility staff will perform and direct evacuation procedures within patient areas affected by the fire. The private operating mode requires that the notification method for staff provide a means to identify the zone, area, floor, or building in need of evacuation.

FIRE SUPPRESSION EQUIPMENT

Automatic Sprinkler Systems

A proven effective, practical, and reliable approach to life safety in health care facilities is to use automatic fire suppression—in particular, automatic sprinkler systems. Although persons in the area of origin may still be seriously threatened, those in adjoining spaces—and, in a number of cases, in the same room—are protected.[2,3,7,12] NFPA *101* and *NFPA 5000* require all new health care facilities to be protected by automatic sprinklers.

The 1991 edition of NFPA *101* was the first to require sprinkler protection for all new health care facilities. Two multiple death nursing home fires occurred within seven months of each other in 2003—one in Hartford, Connecticut, on February 26, 2003, that resulted in 16 deaths, and another in Nashville, Tennessee, on September 25, 2003, that resulted in 15 deaths. These fires resulted in calls to require automatic sprinkler protection in all existing nursing homes. As a result, the 2006 edition of NFPA *101* became the first edition to retroactively require that all buildings containing nursing homes be protected throughout with electrically supervised automatic sprinkler systems.

Full sprinkler protection obviously increases the level of fire protection and life safety in nursing homes; however, the impact on scarce health care funding must also be addressed. Although the design, installation, and maintenance of sprinkler systems in nursing homes will have a measurable cost (which can be affected by the availability of an adequate water supply), there are associated savings, including the following:

- Some buildings of noncompliant construction types could "become" compliant, negating the need for equivalencies, other alternate means of protection, or waivers.
- Increased allowable travel distances permitted in sprinklered facilities could solve existing egress problems and/or facilitate building additions.
- Hazardous area enclosures would change from 1 hour fire barriers to smoke partitions—facilities might save money because firestopping of penetrations above the ceiling would no longer be necessary.
- Some areas would be allowed to be open to the corridor.
- Corridor walls would be required to be smoke resistant rather than fire rated—facilities might save money because firestopping of corridor wall penetrations above the ceiling would no longer be necessary.
- The requirement for smoke dampers in duct penetrations of smoke barriers in fully ducted HVAC systems would be eliminated—facilities could disconnect existing dampers, fix them in the open position, and save money on future testing and maintenance.
- Newly introduced upholstered furniture and mattresses could be less expensive because they would be exempted from ignition resistance and heat release rate standards.

The ability of automatic sprinklers to provide a survivable environment for building occupants has been debated at length. Full-scale tests have shown that standard sprinklers can extinguish many fires while maintaining a survivable atmosphere outside the room of fire origin.[2,5] In addition, sprinklers have been shown to be effective in limiting carbon monoxide to nonlethal levels outside the room. Tests have also shown that privacy curtains may interfere with sprinkler discharge.[13] To obtain full sprinkler effectiveness, the influence of any building design feature or furnishing that would impair sprinkler discharge should be evaluated carefully.

The quick-response or fast-response sprinkler has been shown in most instances to maintain a survivable atmosphere within the room of fire origin. Full-scale tests at NIST have documented this performance.[13]

Where fire defenses are based on automatic sprinkler systems, fast-response sprinklers should be considered for the entire building. At a minimum, fast-response sprinklers should be used throughout compartments having sleeping rooms. This is required for new health care facilities by NFPA *101*.

Automatic sprinkler systems should comply with NFPA 13, *Standard for the Installation of Sprinkler Systems.* Sprinkler operation should sound the building fire alarm automatically. The sprinkler system and components should be electrically supervised to ensure reliable operation and should include valve tamper switches with a local alarm at a constantly attended location when the valve is closed. If pressure tanks are the primary source of water, air pressure, water level, and temperature should be supervised. If fire pumps are provided, electrical supervision should monitor the fire pump in accordance with NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection.*

Portable Fire Extinguishers

Portable fire extinguishers should be placed in all buildings, as they may provide an opportunity to control a fire during its early stages. In all cases, however, the fire department should be notified before or at the same time that occupants are attempting to fight the fire. Delayed alarms have allowed fires to grow to large scale and, in turn, threaten occupants before fire department notification and arrival.

Smoke Control

Although operable windows were required in every patient sleeping room for many years, neither NFPA *101* nor *NFPA 5000* requires them. Outside windows are required but need not be operable. Windows in atrium walls are considered to be equivalent to outside windows in health care facilities.

Special forced-air systems or, in some cases, the adaptation of conventional building air-handling systems can permit venting of products of combustion early in the fire. Such systems may also make it possible to create a pressure difference across physical barriers, such as floors or partitions, and prevent smoke transfer. The effectiveness of fire partitions often improves significantly by the use of such systems.

Where adaptation of the building air-handling system is contemplated for smoke removal, its design should be in accordance with NFPA 92A, *Standard for Smoke-Control Systems Utilizing Barriers and Pressure Differences.* Consideration should be given to alternative power supplies and electrical supervision of critical system components.

PROTECTION OF HAZARDOUS AREAS

Areas with contents more hazardous than those normally found in health care facilities should be arranged to minimize occupant exposure if a fire occurs. NFPA *101* and *NFPA 5000* address hazardous areas in general and also address hazardous areas in the specific occupancy chapters. The general provisions require one of the following:

1. Enclose the hazardous area with fire barriers having a 1-hour fire resistance rating and without windows.
2. Protect the area with an automatic extinguishing system.
3. Apply the protection of both (1) and (2) where the hazard is severe or where otherwise specified by the occupancy chapters.

When the 1 hour enclosure is used, the doors must be ¾ hour fire rated, self-closing, and positive-latching doors. Typically, in new construction and in any health care occupancy, when a hazardous area is sprinkler protected without having a fire resistance rated enclosure, the area must be protected with at least a smoke-resisting enclosure equipped with smoke-resisting self- or automatic-closing doors. In health care facilities, corridor doors are normally required to latch. Doors in hazardous areas are typically required to be self- or automatic-closing doors and self-latching.

The health care occupancy chapters of NFPA *101* and *NFPA 5000* detail the specific areas that must be addressed as hazardous areas; however, the listed areas are not intended to be all-inclusive, and the general provisions must be met if an area poses unusual fire hazards in the health care facility.

There are provisions related to other hazardous areas, including gift shops, laundry and trash chutes, cooking facilities, and laboratories. Gift shops must be protected as hazardous areas when they are used for storing or displaying combustibles in quantities considered hazardous. Trash chutes and linen chutes can pose significant fire risks for health care occupancies. These areas should comply with NFPA 82, *Standard on Incinerators and Waste and Linen Handling Systems and Equipment.* Laboratories, anesthetizing locations, and medical gas systems should comply with the provisions of NFPA 99, which relate to the protection of hazardous areas. New heliports must comply with NFPA 418, *Standard for Heliports.* Cooking facilities are required to be protected in accordance with NFPA 96, *Standard for Ventilation Control and Fire Protection of Commercial Cooking Operations.*

Building Service Equipment

Building service equipment should be installed and maintained in accordance with appropriate NFPA standards. Special consideration should be given to the design and installation of heating and air-conditioning systems.

Portable heating devices are unsafe in patient-occupied portions of health care facilities. All heating devices should be designed and installed to prevent ignition of combustible materials. Approved suspended unit heaters may be used, except in means of egress and patient sleeping areas, if they are high enough to be out of the reach of persons using the area.

Air for combustion and ventilation in boilers, incinerators, or heater rooms should be taken directly from, and discharged directly to, the outside of the buildings.

OPERATING FEATURES

Smokers cause many fires in health care facilities. Adoption and enforcement of suitable smoking regulations are essential.[7] Smoking should be prohibited in any room, ward, or compartment where flammable liquids, combustible gases, or oxygen is used or stored. Such areas should be posted with no-smoking signs. Smoking by patients who are under sedation or who are not considered responsible should be prohibited. Smoking should be permitted in a sleeping room only when authorized by medical staff and then only under direct staff supervision. Metal containers with self-closing covers should be available for disposal of smoking materials in all areas where smoking is allowed.

Most hospitals and many nursing homes have established no-smoking policies. JCAHO requires hospitals to be smoke free. Nursing homes are becoming smoke free on a voluntary basis. These are very positive steps in improving the level of fire safety in health care facilities.

Visitors sometimes give patients smoking materials without the staff's knowledge. Health care facilities need to address this serious issue. In 1989, 12 residents died in a Norfolk, Vir-

ginia, nursing home fire attributed to a visitor giving a resident smoking materials.

Window draperies and curtains should be made of noncombustible material or material that has been rendered and maintained flame retardant. These window hangings should be capable of passing NFPA 701, *Standard Methods of Fire Tests for Flame Propagation of Textiles and Films.* Furnishings, decorations, and other objects should not obstruct exits or exit access routes. Combustible decorations should be prohibited.

Exits and mechanical devices provided to control or limit fire should be maintained to ensure reliable operation. Inspections and tests should be performed, as required, to verify satisfactory performance.

In facilities with locked exits, adequate staff should always be present to release occupants and direct them away from the fire area to a place of safety during an emergency.

Care should be exercised during construction and repair operations to ensure that such activities do not reduce life safety.

EMERGENCY PLANNING

In no occupancy are staff training and emergency planning more important than a protect-in-place occupancy housing a significant number of occupants incapable of self-preservation. Every health care facility must have a fire and evacuation plan, including a disaster plan, with which all personnel must be familiar. NFPA 99 provides guidance for both internal and external disasters that affect health care facilities. In addition, personnel should be trained to use fire extinguishers and hose cabinet lines if provided. They must also know how to sound an alarm, move or evacuate patients, and contain the fire.

Each facility should have a safety officer whose primary responsibility is to recognize hazards, act as liaison with the fire service, and arrange for training personnel. While training health care personnel is straightforward and can be accomplished on the job, orienting members of the fire service to health care facility problems is more difficult.

Copies of the fire and evacuation plan should be available to all personnel. The plan should contain specific instructions for key—that is, supervisory—personnel if there is a fire. A copy of the plan also should be posted for reference. All employees should be periodically trained to ensure readiness.

Emergency drills should include transmission of a fire alarm signal and simulation of emergency conditions insofar as possible without jeopardizing occupants. Drills should be conducted on each shift at least quarterly, with at least 12 drills held every year. The drills should be varied to test the alertness of all shifts and, if possible, should be unannounced. Use of the building alarm during drills also verifies its normal operation.

The fire and evacuation plan should include the following fundamentals:

- Training personnel to use the alarm and alarm equipment
- Transmission of alarm to the fire department
- Details of the fire location
- Evacuation practices for all areas
- Preparation of building spaces for evacuation
- Fire extinguishment

During drills, emphasis should be on immediate notification of the fire department; many fires have spread because of delayed alarms.

FIRE SAFETY EVALUATION SYSTEM

NFPA codes contain the fundamental statement of the "equivalency concept," which provides for the use of alternatives to the methods, materials, devices, systems, and so on that are prescribed and/or specifically detailed by the codes. Key to the concept of equivalency is the submission of technical documentation acceptable to the authority having jurisdiction. One method of providing technical documentation for health care facilities is to appropriately apply and utilize the *Fire Safety Evaluation System for Health Care Occupancies (FSES),* which provides a formalized equivalency methodology specific to health care occupancies. The documentation and procedure for the use of this fire safety evaluation system are found in NFPA 101A, *Guide on Alternative Approaches to Life Safety.*

The *FSES for Health Care Occupancies* has, since the 1981 edition of NFPA *101,* provided a basis for developing alternatives that achieve a level of safety equivalent to that mandated by the *Life Safety Code.* The *FSES* was developed to provide a rational basis for achieving the level of safety intended by the *Life Safety Code* without necessarily meeting all of its prescriptive requirements. This can be especially important for existing buildings in which physical conditions may not allow strict compliance or where retroactive compliance may present an economic hardship.

The *FSES* involves the evaluation and comparison of the risk factors and safety features present or proposed for a health care occupancy. The *FSES* methodology for health care occupancies is based on the evaluation of individual "zones," which are generally the spaces separated by floors, horizontal exit barriers, or smoke barriers. The risks of a zone consider the number of people affected by a given fire, the density of the people in the zone, the mobility of the patients, the age of patients, the location of the zone, and the ratio of patients to staff in the given zone.

In addition to the risk aspects of the *FSES,* each zone must consider the ability of the building and its fire protection features to provide measures of safety commensurate with the risk. Safety parameters that are evaluated include building construction fire resistance, interior finish, corridor partitions/walls, corridor doors, zone dimensions, vertical openings, hazardous areas, smoke control, egress routes, fire alarms, fire detection, and automatic sprinklers. Redundancy of the safety features is an important aspect of the *FSES.* By evaluating the redundancy of safety features, the methodology intends to ensure that the failure of a single protection feature or device will not result in major failure of the entire system.

The approach is quantitative in that the *FSES* awards positive point values for strong life safety and fire protection features and negative point values for lesser conditions. With appropriated selection of alternative features a number of both positive and negative factors can be balanced in a manner that results in establishing a level of life safety equivalent to NFPA *101* without complying with all of its prescribed requirements.

The *FSES* methodology has a long and proven track record, but it is not the only approach available for establishing equivalency. NFPA *101* formally recognizes performance-based options for the design and analysis of alternatives to the prescriptive requirements of the code. Additional discussion of the performance-based option can be found in Section 3, Chapter 10, "Performance-Based Codes and Standards for Fire Safety."

AMBULATORY HEALTH CARE

The provisions for ambulatory health care facilities intend to fulfill the needs of facilities that do not pose the risks of 24 hour health care facilities such as hospitals but do pose a greater risk than medical office buildings (business occupancy) that provide for routine doctor visits.

The definition of an ambulatory health care occupancy has three key elements:

1. An ambulatory health care occupancy is a building or portion of a building used to provide services or treatment simultaneously to four or more patients.
2. The services or treatment provided is done solely on an outpatient basis and renders the patients incapable of taking action for self-preservation under emergency conditions without the assistance of others.
3. Anesthesia is provided solely on an outpatient basis and renders the patients incapable of taking action for self-preservation under emergency conditions without the assistance of others.

The distinguishing features of an ambulatory health care occupancy are that 24 hour sleeping accommodations are not provided and services are rendered solely on an outpatient basis. This effectively means that patients walk in and walk out of the facility but may be subject to treatment or anesthesia that temporarily renders them incapable of self-preservation, including postoperative recovery in a bed.

The life safety and fire protection features specified in NFPA *101* and *NFPA 5000* for ambulatory health care occupancies are a blend of those used for both health care occupancies and business occupancies. In fact, many of the provisions for ambulatory health care facilities are simply addressed by references to the provisions for business occupancies. Construction type requirements are less restrictive than those required for health care occupancies but more restrictive than allowed for business occupancies. Several egress requirements are more restrictive than those permitted for business occupancies. Also, there are specific provisions for mixed occupancies, smoke compartments, and fire alarm features that will affect the design of an ambulatory health care occupancy.

SUMMARY

Total building fire protection for life safety is more necessary in health care facilities than in other occupancies because of the nature of the occupants. A significant percentage of occupants in hospitals and nursing homes are incapable of self-evacuation or are ambulatory but incapable of perceiving a fire threat and choosing a rational response. Therefore, fire protection is based on a "defend-in-place" principle and cannot depend on any one safeguard. As a result, health care facility design and operation must incorporate methods by which a fire can be detected early, contained, and fought rapidly and successfully. Fire safety requirements include fire-resistive construction, compartmentation, fire-alerting facilities, and control of smoke movement. In addition, it is critical that every health care facility have a fire and evacuation plan, including a disaster plan, with which all personnel are familiar. Personnel should be trained in emergency procedures, including how to sound an alarm, move or evacuate patients, and contain the fire. Emergency drills should be conducted on each shift at least quarterly, with at least 12 drills held every year.

This chapter addresses fire protection for storage and warehouse operations. Due to the nature, quantity, and arrangement of inventory in these occupancies, intense fires can develop rapidly. Developing and implementing a comprehensive fire protection plan are essential to minimize the potential for significant fire loss and disruption of operations.

Modern storage practices aim to maximize storage efficiency by piling products high and leaving minimal aisle space between storage piles or racks. As a result, enormous volumes of combustible material are often located in a single fire area or building. In addition, many warehouses contain large quantities of plastics as both products in storage and as packing materials. Most plastics burn rapidly, have a high rate of heat release, and generate copious amounts of smoke, soot, and toxic products of combustion.

Most facilities have some sort of storage or warehousing area to store raw stock, in-process goods, or finished products. The area may be called a storeroom, parts crib, or central sterile supply, depending on the type of facility and the materials in storage. Fortunately, the incidence of fires in storage areas is relatively low compared to other occupancies. Unfortunately, when storage and warehousing fires do occur, they tend to be severe.

This chapter reviews basic fire protection principles for the protection of warehousing and storage areas. It presents an overview of the fire protection features that a comprehensive fire protection program needs and highlights materials and storage occupancies that pose unusual fire protection challenges.

NFPA STORAGE STANDARDS

NFPA has developed standards that provide an effective means of preparing fire protection plans for various types of storage occupancies. Design requirements for sprinkler system protection of general indoor storage, rack storage, rubber tires, roll paper, baled cotton, and other commodities have been consolidated into NFPA 13, *Standard for the Installation of Sprinkler Systems*.

The fire protection for commercial warehousing and storage occupancies depends on the type of storage and the methods of storage. In most cases, the protection standards contemplate dedicated storage areas with storage heights exceeding 12 ft (3.7 m). NFPA 13 addresses fire protection for miscellaneous storage not meeting this criteria, as well as the protection requirements for dedicated warehousing and storage areas of most commodities.

Miscellaneous storage typically does not exceed 12 ft (3.7 m) in height and is incidental to the primary operations in a facility. For example, small areas used for parts storage along an assembly line would generally be considered incidental storage. A storeroom in a business occupancy would also usually be considered incidental storage. NFPA 13 describes the various types of storage and the design of automatic sprinkler protection for each type and configuration of storage.

The requirements contained within NFPA standards, such as NFPA 13, are based on full-scale fire tests and past fire experience. The standards do not address storage arrangements where

Jeffrey Moore, P.E., is a senior fire protection engineer with Hughes Associates, Inc., in Cincinnati, Ohio.

test data are not available or where valid conclusions could not be drawn from the extrapolation of available data, judgment, or experience. For storage arrangements beyond the scope of a specific NFPA document, engineering judgment and other sources should be utilized. In some cases this may require actual fire testing of the materials and configurations encountered or contemplated.

OCCUPANCY CHARACTERISTICS

A study of warehouse fires conducted by NFPA and several major property insurers showed that over a 4 year period, warehouse and storage fires comprised only 14 percent of the reported fires, but these fires caused nearly 40 percent of the damage incurred. The study further determined that, on average, a warehouse fire occurs every 22 hours, and that a warehouse fire that results in a loss of over $500,000 occurs every 11 days.[1]

Storage occupancies are buildings, or portions of a building, used to store or shelter goods, merchandise, products, vehicles, or animals. Storage facilities can be separate and distinct facilities or part of a multiple-use occupancy. Storage occupancies pose a wide range of fire protection challenges, including large open fire areas, high values concentrated in a relatively small area, limited access for fire suppression operations, and fuels arranged in arrays conducive to rapid fire development and spread. Examples of storage occupancies are warehouses, freight terminals, parking garages, aircraft hangars, grain elevators, and outdoor storage areas. Table 20.16.1 shows the estimated frequency of fires in various warehousing and storage occupancies.

NFPA 13 classifies storage occupancies as light-, ordinary-, or extra-hazard, or a combination of these where mixed commodities are stored together without separation. NFPA *101®*, *Life Safety Code®*, and *NFPA 5000®, Building Construction and Safety Code®*, divide storage occupancies into low-, ordinary- and extra-hazard. Factors affecting the hazard classification are burning characteristics of the material stored, combustibility of packaging, method of storage and packaging, and the quantity stored.

Current material handling technology permits storage in automated storage and retrieval systems to heights exceeding 100 ft (30 m). Computer-controlled stacker cranes are now being used to move and place commodities in rack storage areas. Distribution warehouses may cover several acres under one roof and may contain multilevel mezzanines. These large, open areas pose a major fire threat. Fortunately, storage occupancies usually have a limited number of occupants in relation to total floor area. The presence of fewer people generally translates into a lower incidence of fire. Although some warehouses with automatic storage and retrieval systems are fully automated, the workflow in most warehouses usually requires employees to move materials through the facility using industrial lift trucks.

Contents

The contents of storage occupancies may consist of raw materials, goods in an intermediate stage of production, or finished products. These materials may be found in bulk storage, solid piling, palletized storage, or rack storage arrangements. Bins and narrow shelves are also used, usually in stockrooms and small storage areas. The major difference between these storage arrangements is the exposed surface area of the storage. As the exposed surface area of the storage increases, the speed at which a fire develops increases. Other storage occupancies, such as parking garages, grain elevators, and aircraft hangars create other problems due to the nature of operations in the building. The problems posed by these and other storage operations are addressed later in this chapter.

Mini-Storage Facilities

Mini-storage facilities for rental to the general public consist of several small rental spaces ranging from 40 to 400 ft^2 (3.7 to 37 m^2) in one building or several adjacent buildings. These facilities pose some unique fire problems of their own. There is little control over the type and amount of materials that may be stored in rental areas because they are accessible to renters on a 24 hour basis. Automatic sprinklers are typically not installed in these buildings and fire-resistance-rated walls or barriers do not usually separate the individual rental spaces from each other.

HAZARDS ASSOCIATED WITH OCCUPANCY

Contents

In determining the hazard classification of storage, consideration should be given to the product, product container, and packaging materials. The fire hazard of a warehouse or storage occupancy is a function of the commodity or material in storage, the method of packaging, and the storage arrangement. Fire development in a storage area depends on the material, ease of ignition, flame spread rate, and the rate of heat release. All too often a judgment concerning the hazard of the storage is based on the commodity with little thought given to the methods of packaging and the storage arrangement. For example, a metal part stored on a wooden pallet poses a low threat of fire. However, if the same part is packaged inside a multilayer cardboard carton with expanded polystyrene foam packing material, the fire hazard is greatly increased. Plastics are increasingly used as part of the product as well as the packaging.

Package Commodity Storage. A packaged commodity must be considered as a whole—that is, the way it burns. For example, bottled beer would be considered a low hazard, but when stored in cardboard or wood containers, it becomes an ordinary-hazard commodity. Washing machines have very few combustible components. However, they can burn rapidly and produce large volumes of smoke where packaged in cardboard boxes and surrounded with plastic packing materials.

Mixed Storage. In areas with mixed storage, the hazard classification should be based on the most hazardous storage. This mixed condition is common in most warehouses supplying department stores, hardware stores, and automotive parts stores. High-hazard materials or materials that require special consideration can sometimes be segregated from other storage to keep

TABLE 20.16.1 Reported U.S. Structure Fires in Warehouse-Type Storage Properties, 1994–1998 Annual Averages

Type of Storage Facility	*Fires*	*Civilian Deaths*	*Civilian Injuries*	*Direct Loss (in Millions of Dollars)*
WAREHOUSE (excluding refrigerated storage)	5489	3	73	237.2
General item storage (excluding wharf or pier, ice storage)	2893	2	37	103.3
General warehouse	1338	1	25	77.3
Freight terminal	75	0	1	2.5

Note: These are fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. Fires, deaths, and injuries are estimated and direct property damage rounded to the nearest hundred thousand dollars. Sums may not equal totals due to rounding errors. Damage has not been adjusted for inflation.

Source: National estimates based on NFIRS and NFPA survey.

them from influencing the overall hazard classification. Examples of high-hazard materials are rubber tires, plastic products, combustible fibers, paper and paper products, hanging garments, carpeting, pesticides, flammable liquids and gases, and reactive chemicals. NFPA 13 details the specific sprinkler requirements for areas containing such commodities.

Flammable Aerosol Products. Flammable aerosol products pose an extreme hazard. When heated in a fire, the containers rupture, produce fireballs, and can rocket throughout the storage area. This results in the ignition of multiple fires that can quickly overwhelm the automatic sprinklers. Bulk storage of aerosols should meet the requirements of NFPA 30B, *Code for the Manufacture and Storage of Aerosol Products.* Smaller quantities of flammable aerosol storage should be segregated in a specially protected room or in flammable liquid storage cabinets.

A 1982 fire in a K-Mart distribution warehouse, located in Falls Township, Pennsylvania, vividly illustrated this hazard. The fire started in palletized storage of petroleum-liquid-based aerosol containers. Exploding aerosol cans quickly overwhelmed the automatic sprinklers and destroyed the 1.2 million ft^2 (111,500 m^2) distribution center.[2] The rapid spread of the fire was due in great part to rocketing aerosol cans that spread the fire throughout adjoining areas.

The 1982 K-Mart distribution warehouse fire is just one of many similar incidents that illustrates the need for proper segregation and protection of flammable aerosols. A single pallet of flammable aerosols is sufficient to burn a general storage warehouse to the ground. Such materials need to be stored in a special area with fire protection features designed in accordance with NFPA 30B.

Storage Arrangement

The arrangement of stored materials impacts the potential for fire spread. It also affects the efficiency of materials handling in the warehouse, and, unfortunately, this is where fire protection and materials-handling efficiency generally conflict with each other. Each feature that is desirable to enhance fire safety usually has a negative impact on the operating efficiency of the warehouse.

Aisles are required in storage areas to permit access by materials-handling equipment. For maximum storage efficiency, these aisles are normally as narrow as possible and spaced as far apart as possible. These same aisles provide access to the area for manual fire suppression operations during a fire and act as fire breaks between storage piles or racks. From a fire safety standpoint, wide aisles spaced at short intervals are preferred. Such arrangement permits maximum access to the area while decreasing the probability of fire spread across an aisle due to radiant heat or from a pile collapse. See Figure 20.16.1 for an example of a typical rack storage arrangement. Note that aisles

FIGURE 20.16.1 Typical Rack Storage Arrangement (Courtesy of Jeffrey Moore)

provide access for materials-handling equipment as well as acting as fire breaks between the storage racks.

Horizontal air spaces formed by the pallets in palletized storage create open channels that feed air into the center of the storage and serve as pathways for fire spread throughout the pile. Rack storage compounds this problem by exposing multiple surfaces of the storage, permitting them to burn simultaneously.

Storage height is another area where fire protection and materials-handling efficiency clash. In general, the higher the storage is stacked, the greater the fire control challenge. Higher storage means more surface area exposed to burning and a greater total quantity of fuel available. The rate of heat release will also be greater as the height of the storage is increased.

As storage expands and available warehouse space decreases, the trend is to increase the storage height. This can be done safely as long as the automatic sprinkler protection is designed to meet the additional challenge posed by the higher storage. Even one extra tier of storage can be enough to burn a warehouse to the ground if that extra tier increases the storage height beyond the protection capabilities of the sprinklers.

OPERATIONAL HAZARDS AND FIRE PREVENTION PRACTICES

Storage occupancies often encompass large open spaces occupied by only a few people. With few occupants in the area, fires in the incipient stage may go undetected for an extended time period, particularly in spaces not protected by automatic fire detection or suppression systems.

Common hazards and ignition sources generally associated with storage occupancies are incendiarism, hot work operations, failure of electrical equipment, careless disposal of smoking materials, and ignition from materials-handling equipment.

Incendiarism

Storage occupancies are vulnerable to incendiary acts because they often present an inviting target for those who wish to cause a great deal of damage and disruption. Often an arsonist can enter and start a fire without being detected. Even where security personnel are present but access is not tightly controlled, arsonists may ignite a fire in a location beyond their sight. Such fires can grow to disastrous proportions before detection, particularly if multiple fires are set.

Hot Work Operations

Hot work operations, such as cutting, welding, and grinding, should be prohibited in storage areas unless there is no other method of accomplishing the work. If hot work is conducted in a storage occupancy, extraordinary precautions must be taken to prevent ignition of the stored materials. Such operations should not begin until all combustible materials have been removed from the area or covered with a fire-retardant cover. Portable fire extinguishers or small hose lines should be ready for use before the operation begins. A fire watch must be present at all times during operation and for at least 30 minutes after its completion. Consideration should be given to using mechanical fastening devices and saws when repairing or replacing steel racks to avoid cutting or welding. All cutting and welding must be conducted in accordance with NFPA 51B, *Standard for Fire Prevention During Welding, Cutting, and Other Hot Work.*

Lighting and Heating Appliances

Sufficient clearance must be provided between storage and any lighting fixtures or heating appliances in the area. The appropriate NFPA standards, such as NFPA 70, *National Electrical Code*®, should be consulted to determine the minimum required distances from electrical equipment. Special care is needed when using temporary or portable lighting or heating appliances. Relevant NFPA codes and standards must be strictly observed for all types of heating and electrical distribution system equipment in storage areas.

Smoking

Smoking should be prohibited in storage areas. Effective implementation of a smoking control program requires facility management to conscientiously enforce the smoking prohibition and also provide a safe area for employees to smoke. Such areas should be confined to specific areas set aside from storage. The areas must be kept clean and appropriate disposal containers must be provided.

Housekeeping Practices

Proper housekeeping practices prevent the accumulation of combustible waste that can serve as the point of origin for a fire. Packing or unpacking operations generally result in the generation of significant quantities of loose packing materials such as paper, cardboard, and polystyrene beads or cocoons. Procedures must be in implemented to remove excess materials from the building before they pose a significant hazard.

Idle Pallet Storage

Piles of empty wooden pallets are an ideal configuration for rapid development of a fire. The pile is essentially multiple layers of combustible fuel each separated by a layer of air. The built-in flues provide a means for fire to spread throughout the pile and for air to carry oxygen to the layers of burning fuel. Their large surface area to mass ratio also makes the pallets easy to ignite. Plastic pallets and shipping containers present similar hazards. Empty pallet storage poses a severe threat of a fast-developing fire. Even where stored in areas protected by automatic sprinklers, idle pallet fires can cause extensive damage. Pallet pile sizes should be limited, and the pallets should preferably be stored outside, away from any buildings (Figure 20.16.2). If pallets must be stored inside the building, they should be in a segregated area with automatic sprinklers designed for such storage. NFPA 13 contains special provisions for the design of sprinklers to protect idle pallet storage.

Industrial (Lift) Trucks

Industrial trucks, also called lift trucks or forklifts, are an integral part of most storage occupancies. The trucks are usually electric or propane powered, although some may use other fuels. Misuse of the trucks can result in their being an ignition source.

FIGURE 20.16.2 Idle Pallet Storage Should Be Away from Buildings. Here the pallet storage poses a severe threat to the building. (Courtesy of Jeffrey Moore)

There have been many multimillion dollar losses caused by the improper use or application of industrial lift trucks.

The general hazards associated with the use of lift trucks are refueling operations, maintenance, and storage when not in use. Refueling operations should be conducted outside or in a segregated area of the storage building or warehouse. Fuel leakage during refueling operations has been the cause of many fires. Storage and dispensing of the fuel must comply with applicable NFPA codes and standards. Lift trucks used in areas where flammable or combustible liquids are stored must be specifically listed for use in such areas. NFPA 505, *Fire Safety Standard for Powered Industrial Trucks Including Type Designations, Areas of Use, Conversions, Maintenance, and Operations,* designates the type of truck that can be used in a hazardous area.

LIFE SAFETY CONSIDERATIONS

The life safety hazard in a storage occupancy depends on a number of factors. These include the materials stored, the storage configuration, construction of the building, the type and design of the fire protection systems provided, and the number, arrangement, and location of the exits provided. Fire in a storage area can develop and spread rapidly. Although the occupant load is generally light in a storage occupancy, the means of emergency egress is a concern. In single-story buildings with high ceilings, smoke and heat may have a place to accumulate before descending to a level that obscures or obstructs the means of egress. In buildings with low ceilings, the opposite occurs. In multilevel buildings, smoke and heat from fires below can rapidly block a means of egress on an upper level. (The thermal gradient normally causes the smoke and products of combustion to rise to the ceiling.) In buildings protected by automatic sprinklers, operation of the sprinklers may contain the spread of fire, but it also usually upsets the thermal gradient in the space. This can cause smoke to hang close to the floor, disrupting egress from the area.

In older multiple-floor warehouses, unprotected vertical openings for freight elevators and other materials-handling systems are common. These permit rapid smoke and heat spread to upper floors.

Egress Design

NFPA *101®*, *Life Safety Code®*, and *NFPA 5000®*, *Building Construction and Safety Code®,* address life safety from fire and similar emergencies. They detail the features required to provide the minimum level of fire safety to occupants of a storage or warehouse occupancy, including the number of exits required and the arrangement of the means of egress.

NFPA *101* and *NFPA 5000* classify the materials stored in a warehouse or storage occupancy as low-, ordinary-, or high-hazard based on the expected speed of fire development. The codes contain significantly different requirements for different hazard classifications. For example, the maximum travel distance to an exit in a warehouse with low-hazard contents is essentially unlimited, whereas the maximum travel distance to an exit in a warehouse with high-hazard contents is 100 ft (30 m) where

sprinklers are provided, and 75 ft (23 m) where the building is nonsprinklered. Where a warehouse or storage area contains storage of different classifications in the same area, the requirements for the most hazardous classification apply. Sound judgment must be used when determining the hazard classification of the contents. NFPA *101* and *NFPA 5000* use ordinary-hazard as the basis for general requirements; most storage occupancies fall into this classification. Only rarely does storage fall into the low- or high-hazard classifications.

The requirements for the means of egress in storage occupancies are similar to other occupancies. The principal difference is that storage occupancies typically require fewer exits than other occupancies. Since storage areas and warehouses generally have few occupants, neither NFPA *101* nor *NFPA 5000* assigns occupant load factors to such uses. Rather, occupant load is based on the maximum probable number of occupants present at any time. NFPA *101* or *NFPA 5000* should be consulted to determine the specific arrangement of the means of egress.

Exit doors must remain unlocked from the egress side of the door when the building is occupied. In areas of low- and ordinary-hazard contents, special-listed delayed-egress locks are permitted if an approved automatic fire detection or supervised sprinkler system protects the entire building. Access controlled egress doors are permitted, provided they meet specific requirements in NFPA *101* and *NFPA 5000.* Egress doors from areas of high-hazard contents must swing in the direction of egress travel.

The continual movement of stock within a storage occupancy demands special attention to prevent blocking required means of egress aisles and doors.

Exit Identification

All required exits must be marked as required by NFPA *101* and *NFPA 5000*. The signs must identify the means of egress, exit locations, and be readily visible where the direction of exit access is not obvious. In areas with high-piled storage, exit identification can be a problem. In addition to signage, other means of egress marking may be necessary, such as painting egress travel paths on the floor.

Illumination of the means of egress is also required. This is particularly important in windowless buildings where natural light is not available during all occupied times. Emergency lights must be installed to provide illumination of required egress stairs, aisles, corridors, ramps, and passageways. NFPA *101* and *NFPA 5000* detail the specific requirements for means of egress illumination.

Vertical Openings

Vertical openings, such as conveyor openings in multistory buildings, must be provided with automatically closing fire doors, fire shutters, or fire dampers on each opening. Convenience openings are permitted provided they connect not more than two stories (they pierce only one floor), are separated by a fire barrier from unprotected vertical openings serving other floors, are separated from corridors, and do not serve as a required exit.

Fire Alarm Systems

Although a fire alarm system is often provided in a warehouse or storage occupancy due to property protection concerns, a fire alarm system is not generally required in warehouses to meet the requirements of NFPA *101* or *NFPA 5000,* unless the warehouse stores high-hazard commodities or exceeds 100,000 ft^2 (9300 m^2). However, due to the large areas and the limited number of employees that may be working in widely scattered areas of the building, a fire alarm system should be considered to alert all occupants in the event of a fire. A fire alarm system provides timely notification of building occupants who can then initiate emergency action and notify the fire department or private fire brigade.

Fire alarm systems for occupant notification must include audible and visible notification appliances installed in accordance with *NFPA 72®*, *National Fire Alarm Code ®*. Fire alarm system actuation may be manual, through the use of manual fire alarm boxes, or automatic, through the use of fire detectors or sprinkler waterflow alarms. Fire alarm systems must be installed, tested, and maintained in accordance with *NFPA 72*. The fire alarm signal must be separate and distinct from any other audible signals used in the facility. All new fire alarm systems must use the American National Standard evacuation signal to initiate evacuation as required by *NFPA 72*, unless otherwise permitted by the authority having jurisdiction.

BUILDING CONSTRUCTION AFFECTING HAZARDOUS CONDITIONS

Most construction types are suitable for a storage occupancy, although the use of noncombustible construction is preferred. Combustible construction, although permitted by most building codes, adds to the fire load and may contain combustible concealed spaces that contribute to rapid fire spread.

Materials

The combustibility, flame spread rate, smoke production, heat release potential, and structural stability of materials used in building construction should all be considered. Certain expanded plastic insulation core panel walls should be used only in buildings with automatic sprinkler protection, and the panels should be covered with fire-resistant material. Most building codes limit the use of exposed, expanded foam plastic insulation. Lightweight steel and wood truss construction now commonly used in newer buildings is susceptible to early structural collapse when exposed to an intense fire as is expected in most storage occupancies. Steel columns within storage racks over 15 ft (4.6 m) high may require additional protection, such as automatic sprinklers installed in the column web or enclosing the columns in fire-rated construction.

The rack structures used in automated storage and retrieval systems may double as the structural frame of the building. Properly designed, installed, and maintained automatic sprinkler protection is necessary to prevent extensive damage or total destruction of storage buildings using any of these lightweight methods of construction.

Buildings up to 100 ft (30 m) high used for such rack storage are not uncommon. Fully automated rack systems usually have narrow aisles between racks. Providing fire suppression within the racks may be difficult even in buildings protected by automatic sprinklers. Fires involving upper portions of high-rack storage present unusual problems and severe risks to fire suppression forces. Access to the upper portion for complete extinguishment and overhaul is limited. Using ground ladders inside buildings is difficult, dangerous, and generally limited to the length of a typical fire department ground ladder, about 35 ft (10.5 m). Storage damaged by the fire or wetted by sprinklers and hose streams often falls from the racks blocking aisles and posing a hazard to fire fighters.

Smoke and Heat Venting

Smoke and steam generated during a fire can obscure visibility, making it difficult for fire suppression forces to locate the fire. Venting aids in smoke removal, which, in turn, aids fire-fighting operations and rescue. Installation of heat and smoke vents in storage occupancies provides a method for fire fighters to vent accumulated heat and smoke from the building. The vents may be automatic or manually operated. Although there is some disagreement between various fire protection groups, the vents installed in buildings protected by automatic sprinklers should generally be arranged for manual operation because the sprinkler design criteria in NFPA 13 are based on a building without automatic venting. In buildings without automatic sprinkler protection, venting combined with draft curtains or curtain boards can reduce the horizontal smoke and heat spread along the ceiling. In some cases roof vents may be supplemented or replaced by mechanical heat and smoke exhaust systems. Special mechanical ventilation systems should be considered for large-area storage occupancies. The systems should be designed and installed in accordance with NFPA 92A, *Standard for Smoke-Control Systems Utilizing Barriers and Pressure Differences.* See Section 18, Chapter 4, "Venting Practices."

Smoke and heat venting facilities, as well as automatic sprinkler protection, are essential for life safety in windowless buildings and underground structures. The installation of smoke and heat venting should be in accordance with NFPA 204, *Standard for Smoke and Heat Venting.*

Separation

Buildings used for both manufacturing and warehousing should be separated by properly constructed fire walls with all openings protected by automatic closing fire doors. Incidental areas, such as boiler rooms, maintenance areas, and offices, should also be separated from storage areas by rated fire barriers. The rating depends on the requirements of the applicable codes and standards, and the site-specific fire risk management objectives.

AUTOMATIC SPRINKLER PROTECTION

Automatic sprinkler protection, supplemented by manual fire-fighting operations and sound storage and housekeeping practices, is a proven effective and practical means of protecting warehouse and storage occupancies from fire. The automatic sprinklers for a warehouse or storage occupancy must be specifically engineered to match the hazards posed by the storage, installed in accordance with NFPA 13, and inspected, tested, and maintained in accordance with NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems*.

Basic Approaches

Current automatic sprinkler technology provides three basic approaches to providing sprinkler protection of storage operations: standard spray sprinklers, large drop sprinklers, and early suppression fast response (ESFR) sprinklers.

Standard Spray Sprinklers. The standard spray sprinkler category includes standard orifice, large orifice, and extra large orifice (ELO) sprinklers. Any of these sprinklers may be equipped with fusible elements for standard response or fast response.

Large Drop Sprinklers. Large drop sprinklers produce much larger water droplets with more mass to better penetrate a fire plume and reach the seat of high-challenge fires, such as those involving rubber tires or roll paper. The standard spray sprinkler and large drop sprinkler are designed to control a fire and limit its spread until the arrival of a trained fire suppression force that can extinguish the fire.

EFSR Sprinklers. The ESFR sprinkler incorporates a fast response operating element and a large orifice. They are designed to operate at relatively high pressures and discharge up to 175 gpm (662 L/min) each during the initial stages of a fire. The ESFR sprinkler is the only sprinkler designed to extinguish a fire. Refer to Section 16, "Water-Based Fire Suppression Equipment," for more detailed discussions regarding the design and operation of the various types of sprinklers and sprinkler systems.

Most building codes require automatic sprinkler systems in high-hazard storage occupancies. Some codes require sprinkler protection when materials are stored in racks or piles more than 12 ft (3.7 m) high. Most building codes permit low- and ordinary-hazard storage buildings of unlimited floor area when they are protected by sprinkler systems.

Effective Sprinkler Operation

Properly designed automatic sprinkler protection is essential to control a fire and limit damage in a warehouse or storage occupancy. It follows then that a major factor contributing to large-loss fires in warehouses and storage areas is the inability of the sprinkler system to control the fire. This may result from a change in the type, volume, height, or configuration of storage that raises the hazard level beyond that for which the sprinkler system was designed. Any change in the storage or configuration must be accompanied by a comprehensive hazard analysis to assure the change does not outstrip the capabilities of the sprinkler system.

Impairment of the sprinkler system, such as broken piping, shut valve, or piping obstruction, may prevent the sprin-

klers from controlling the fire. Many serious fires have occurred during periods of sprinkler shutdown. Facility managers must implement an effective impairment-handling program that limits the number, extent, and duration of sprinkler system impairments. Complying with the requirements of NFPA 25 minimizes the probability of sprinkler system impairment when a fire occurs.

SUPPLEMENTAL FIRE PROTECTION

Although they are the most important fire protection feature, automatic sprinklers are not the only fire protection necessary for a fully protected warehouse or storage occupancy. Although sprinklers may extinguish a fire, most sprinkler systems are designed to control a fire until trained fire suppression personnel can extinguish it with portable fire extinguishers or hose lines. Other provisions, such as hose systems, portable extinguishers, and effective prefire planning and fire prevention efforts are essential ingredients of any complete warehouse fire safety program.

Large and Small Hose

Warehouses of moderate area close to public hydrants present no special manual fire suppression problems. Where the smaller dimension of a warehouse exceeds about 200 ft (61 m), hose lays from public hydrants to the far side of the building are difficult and time-consuming. Strategically located private hydrants on the building perimeter near building access doors are important to the overall facility fire protection plan. Private hydrant spacing of 250 ft (76 m) is common in such situations. NFPA 24, *Standard for the Installation of Private Fire Service Mains and Their Appurtenances,* provides guidance on the number and location of private hydrants.

Indoor hose connections are recommended in high-piled or rack storage buildings for use on incipient fires. Their relatively good reach and unlimited supply make them more effective than portable fire extinguishers in most situations. However, they do not eliminate the need for portable fire extinguishers. Although not a requirement, the supply for hose connections should come from a system separate from the automatic sprinklers protecting the area. This permits the hose connections to remain in service even if the sprinkler system must be shut down for inspection, testing, or repair.

Provision of interior hose connections requires that the connections, nozzles, and attached hose be inspected, tested, and maintained in accordance with NFPA 25. OSHA regulations require that occupants expected to use the hoses during a fire be trained in their use.

Multistory, large-area, and high-hazard warehouses should be equipped with a standpipe system. A Class III standpipe system provides 1½ in. (38 mm) hose lines for use by building occupants trained in their use and a 2½ in. (64 mm) connection for use by the fire department or a fire brigade. Connections should be located so that all portions of the area can be reached. Providing hose connections for high-rack systems, particularly automated storage and retrieval systems, requires special consideration. In addition to connections at floor level, additional connections may be needed at various heights to enable hose lines to reach all levels. Standpipe systems should be installed in accordance with NFPA 14, *Standard for the Installation of Standpipe and Hose Systems.*

Portable Fire Extinguishers

Portable fire extinguishers should be located throughout the premises in accordance with NFPA 10, *Standard for Portable Fire Extinguishers*. They can be effective during the incipient stages of a fire if used by properly trained operators. All employees should be familiar with the locations and use of portable fire extinguishers. Extinguishers should be in visible, readily accessible locations. Employee training should stress the importance of sounding an alarm and notifying the fire department before attempting to fight a fire with portable fire extinguishers. Up to half the required extinguishers may be replaced by hose connections equipped with hose and a nozzle.

Pre-Emergency Planning

Action in an emergency is seldom effective unless it is carefully planned and executed. Facility management must develop a program that identifies the types of fires and other emergencies likely to occur in the facility. The plans should detail how employees should respond to each type of incident. A program must then be implemented to train employees in the proper methods of response to each type of emergency.

In most cases, employees are not expected to respond to fires and participate in fire suppression operations beyond the incipient stage. Nevertheless, certain information will assist warehouse personnel to understand the interrelationship between fire protection systems and manual fire-fighting operations.

Fire tests and actual fire experience show that even when automatic sprinklers are properly designed and are successful in controlling a warehouse fire, they will not usually extinguish a fire. Personnel trained and equipped for manual fire suppression operations must accomplish final extinguishment. This may be the facility fire brigade, the public fire department, or a combination of the two. Even under the most favorable conditions this is a challenging task that requires careful planning, training of employees, and coordination with public response agencies.

OSHA regulations require that all facilities with more than ten employees have a written emergency action plan (EAP). The plan must identify and explain emergency egress routes and any required emergency procedures. Emergency procedures might include the shutdown of hazardous processes, closure of fire doors, or other operations that make the facility safer during a fire. If specific employees are designated to remain behind to complete critical tasks until their evacuation becomes necessary, the EAP must detail these requirements. The plan must also include procedures to account for employees after building evacuation. Employees must be given the names and contact information for individuals who have additional information about the plan. The employer is also required to review the plan with each employee at the time of development or at the time of initial job assignment. Facility managers should consult 29 CFR 1910 Subpart E for the complete OSHA requirements related to emergency planning.

All planning should be developed in coordination with the public agencies that respond to the facility during an emergency. Plans that are not developed and practiced with the cooperation of the public fire department are unlikely to be effective during an actual emergency. A later section of this chapter provides detailed information for use by fire brigades and public fire departments in developing prefire plans for warehouse and storage occupancies. NFPA 600, *Standard on Industrial Fire Brigades,* and NFPA 1620, *Recommended Practice for Pre-Incident Planning,* should be consulted for additional guidance.

Fire Prevention

Fire prevention efforts to eliminate common sources of ignition are the most effective method of limiting fire loss in warehouses and storage occupancies. Among the leading causes of fires in storage facilities are incendiarism or arson; open flames; exposure to fire from another structure, such as an adjoining building; malfunction or failure of electrical distribution equipment, particularly wiring; and heating equipment. Table 20.16.2 shows the leading causes of warehouse fires.

Fire prevention efforts should be directed toward reducing or eliminating any potential sources of ignition in the warehouse or storage area. This should include proper installation and maintenance of electrical equipment, prohibition of smoking and other sources of open flames, limiting access by unauthorized personnel, and proper installation and maintenance of heating equipment. Facility management should make routine tours of the warehouse to look for and correct any potential ignition sources.

SPECIAL STORAGE FACILITIES

Cold Storage

Cold-storage warehouses are used primarily for extended storage of food and other products at temperatures that prevent or retard spoilage. Products such as pharmaceuticals, antibiotics, and unstable chemicals may also require refrigerated storage.

Depending on the products or processes involved, cold-storage warehouse temperatures may reach a low of –50°F (–46°C) or lower. Despite low temperatures, cold-storage warehouses are not immune to fire hazards. Low temperatures present unusual fire prevention and control problems. Combustible materials in such warehouses include cork or expanded plastic insulation; wood dunnage, pallets, boxes, and baskets; fiberboard containers; paper and cloth wrapping; plastic containers and boxes; and grease- or wax-impregnated materials. These pose a large loss potential.

Construction. Refrigerated warehouses may be constructed of combustible or noncombustible material or a combination of both. The current trend is to build larger and higher buildings in which automated storage racks are structural units supporting the walls and roofs of the buildings. Such construction is acceptable if the rack structure supports wind and snow loads. Although the structural materials themselves are noncombustible, such buildings must be properly sprinklered to protect both the structure and the stored material. When cork or foam insulation ignites, it can generate temperatures high enough to weaken structural steel members.

Polyurethane foam, either in sheets or foamed-in-place, and polystyrene foam are two common insulation materials. When used in walls or ceilings, these materials should be protected by an approved thermal barrier or by a ½ in. (12.7 mm) coat of cement plaster on metal lath attached to the building's framing. For polystyrene, the barrier also may be either ½ in. (12.7 mm) Type X gypsum wallboard or ¾ in. (19 mm) fire-retardant plywood supported by studs or furring attached to the framing. To meet sanitary standards, these thermal barriers must be coated with a U.S. Department of Agriculture (USDA) approved washable finish. If used in the floor, the insulation should be covered with concrete and the joint between floor and wall provided with a cove or curb. Automatic sprinklers should be provided below suspended ceilings, and the space above the ceiling should be protected against fire spread and sprinklered if combustible.

Refrigerant Gases. Refrigerant gases present two basic hazards: toxicity and flammability. Sprinklers are very effective at mitigating the fire hazard because the spray dilutes, disperses, and cools escaping gases.

Storage Arrangements. As in other warehouses, storage arrangements in refrigerated warehouses can be in bulk, solid piling, palletized, or in racks. One exception to this arrangement is the hook storage of meat and poultry products awaiting further processing. This storage method poses a minimal fire hazard because of the absence of combustible packaging.

Sprinkler Protection. The same sprinkler system design used for nonrefrigerated buildings is appropriate for refrigerated storage, except that it must be a dry-pipe or other nonfreeze-type system. In chill rooms and coolers, sprinkler systems of the electrically operated pre-action type are preferable to dry-pipe systems. In freezers or holding rooms, systems are often a combination preaction/dry-pipe system. Figure 20.16.3 shows such a system. In this system, a ⅛ in. (3.2 mm) orifice in a bypass maintains water pressure under the dry-pipe valve. A deluge valve holds back the main water supply. A separate fire detection system electrically activates the valve. Where racks are used for storage, it may be necessary to use in-rack sprinklers.

All sprinklers in refrigerated warehouses should be designed and installed in accordance with NFPA 13. They should be designed so that they can be easily inspected and disassembled to remove ice plugs that commonly form due to moisture condensation in the piping.

The combination dry-pipe deluge system shown in Figure 20.16.3 minimizes the potential for filling the piping with water should there be accidental actuation of a dry-pipe valve. When this arrangement is used, note the following requirements:

1. The dry system should be manifolded to the deluge valve.
2. The protected area should not exceed 40,000 ft^2 (3716 m^2).
3. The distance between valves should be as short as possible.

TABLE 20.16.2 Reported U.S. General Warehouse Structure Fires, 1994–1998 Average Annual Values, by Form of Heat of Ignition

Form of Heat of Ignition	*Fires*	*Percentage*	*Civilian Deaths*	*Percentage*	*Civilian Injuries*	*Percentage*	*Direct Property Damage (in Millions of Dollars)*	*Percentage*

Total	1338	100.0	1	100.0	25	100.0	77.3	100.0

Note: These are fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. Fires, deaths, and injuries are estimated and direct property damage rounded to the nearest hundred thousand dollars. Sums may not equal totals due to rounding errors. Percentages are based on the total number of fires reported between 1994 and 1998 and not on the total annual average in the table. Damage has not been adjusted for inflation.

Source: National estimates based on NFIRS and NFPA survey.

4. The chamber between deluge and dry-pipe valves should be pressurized from the supply side of the deluge valve.
5. An approved ball drip valve should be installed on the dry-pipe valve.

Properly located heat detectors in the protected area automatically actuate the deluge valve. An electrically actuated deluge valve is preferred.

Figure 20.16.4 shows an acceptable alternative to the deluge valve/dry-pipe valve combination. Approved equipment should be used throughout, and all electrical equipment should be compatible. The piping to the heat-actuated devices should be supervised. The control piping should be arranged so both loss of sprinkler piping air pressure and operation of a heat-actuated device occur before the deluge valve release mechanism operates.

Piers and Wharves

Warehouses often form the superstructure of piers and wharves. They may be called "sheds" and often project great distances over the water. They share the same general characteristics as other warehouses, but present more fire protection and suppression problems. Among these are reduced accessibility for land-based fire department vehicles; the usual combustible nature of the substructures, which can be exposed to floating burning debris

or flammable liquids; the danger of water supply mains freezing; and the hazard of ships colliding with piers. More favorably, commodities tend to be piled low because of the temporary, transfer nature of the storage—that is, ship-to-shore or shore-to-ship.

NFPA 307, *Standard for the Construction and Fire Protection of Marine Terminals, Piers, and Wharves,* requires a water supply for both hose streams and sprinkler systems to be available for at least 4 hours—about double the usual requirement. To protect the combustible underside of the pier, sprinklers should be either standard pendant sprinklers in the upright position or old-style sprinklers in the upright position to wet the undersurface of the substructure.

Parking Garages

There are two types of parking garages: those in which vehicles are parked exclusively by attendants or mechanical means and those in which customers park the vehicles. NFPA *101* and *NFPA 5000* address the egress requirements of garages in which the customer parks the vehicle.

For more information on parking garages, see NFPA 88A, *Standard for Parking Structures*.

Occupancy Characteristics. Parking garages may be several levels above or below grade and may be enclosed or open. A garage is considered open when there are uniformly distributed openings in exterior walls on not less than two sides totaling not less than 40 percent of the building perimeter.

Parking garages are often found in conjunction with other uses, such as hotels, apartments, and office buildings. In garages used for both parking and repairs, the repair area should be separated from the parking area and treated as an industrial occupancy.

Hazards Associated with Garages. Motor vehicles generally contain fast-burning fuels, including gasoline, diesel fuel,

27. Deluge valve

* Valves are normally closed

FIGURE 20.16.4 Pneumatic Dual-Release Automatic Water Control Valve

or LP-gas. Major parts of newer model vehicles are made of plastic. These materials can cause severe fires that produce copious amounts of smoke. Gasoline is dispensed in some garages. NFPA 30A, *Code for Motor Fuel Dispensing Facilities and Repair Garages,* and NFPA 88A list requirements for this type of operation. In addition, NFPA *101* and *NFPA 5000* contain special requirements for garages where gasoline is dispensed.

Only a few persons at any one time usually occupy parking garages. However, structures that are located near large assembly occupancies, such as civic centers or theaters, can be occupied by a large number of persons at one time after a show or event ends. During this time, many people move throughout the structure, either going to their vehicles or waiting in their vehicles to exit the parking garage.

Life Safety Considerations. Every floor level of a parking structure must have access to at least two separate exits, arranged so that the travel path is in two different directions. Vehicle ramps can serve as exit access under special conditions. The travel distance permitted to reach an exit depends on whether the building is open or enclosed and whether automatic sprinklers protect the garage.

Special consideration must be given to the location of fuel pumps to avoid trapping occupants if there is a fire or explosion at the pumps. Travel in any direction must lead to an outside exit at the same level or to properly arranged egress stairs. Where parking areas are located below gasoline dispensing pumps, each floor must have direct access to the outside. This arrangement minimizes the potential for gasoline vapor accumulation in enclosed exit stairs.

The means of egress should be provided with illumination and emergency lighting when the garage is used at night or has no natural lighting from windows or other openings during the day. Most people using a parking garage are unfamiliar with the location of exits. Exits and access to the exits must be marked and identified.

Enclosed parking garages must have a fire alarm system when the total aggregate floor area exceeds 100,000 ft^2 (9300 m^2). Open-air parking structures and parking structures protected throughout by an approved automatic sprinkler system do not require fire alarm systems. In general, automatic sprinkler protection is required in enclosed garages located below grade and in those over 75 ft (23 m) in height.

Grain and Other Bulk Storage Elevators

Grain and other bulk storage elevators structures move, store, and process grain, such as wheat, corn, oats, soybeans, and sunflower seeds (Figure 20.16.5). Commodities are stored in bulk form in concrete and steel silos, wooden bins, and steel tanks. Handling the commodity generates dust, making the grain stream susceptible to fire and explosion. NFPA 61, *Standard for the Prevention of Fires and Dust Explosions in Agricultural and Food Processing Facilities,* lists fire protection and

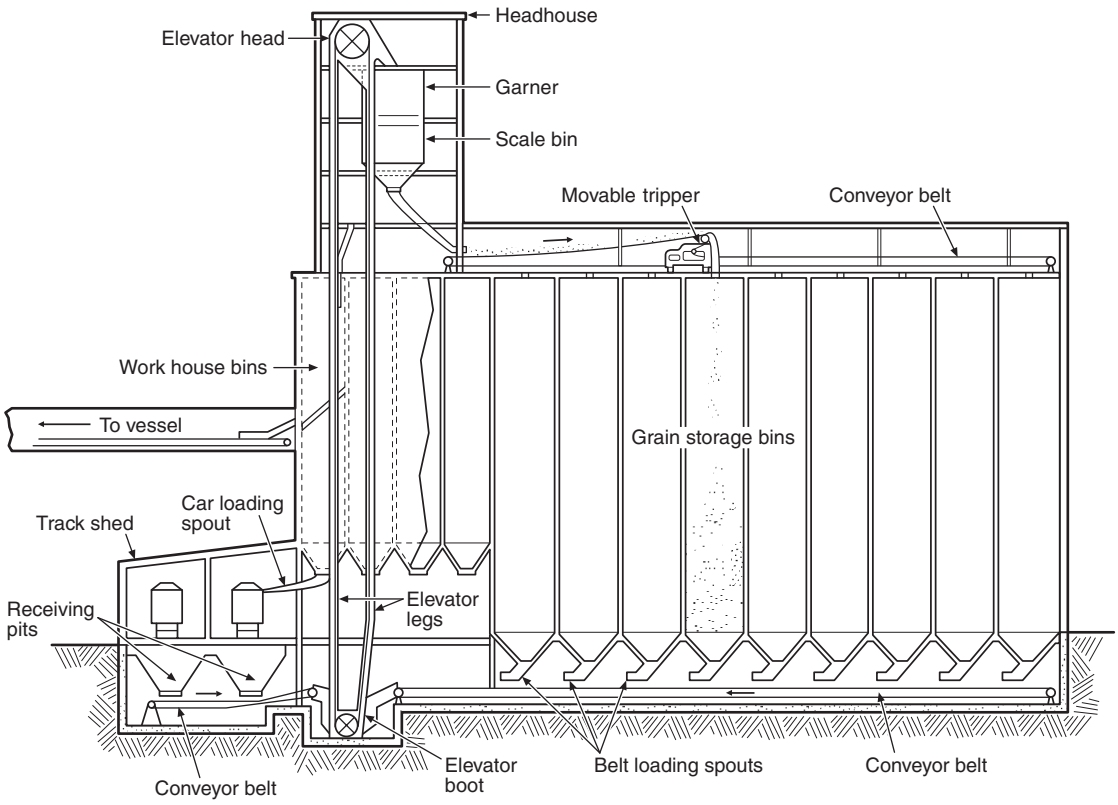

FIGURE 20.16.5 Grain and Bulk Storage Elevator

safety requirements for the installation and operation of grain elevators.

Structures of this type are unique and particularly dangerous. They pose serious life safety hazards for all occupants. Grain elevators account for some of the largest loss-of-life incidents in storage occupancies. In many dust explosions, the primary or only means of exiting from the upper parts of an elevator may be damaged or destroyed by the initial explosion, trapping workers on top of the structure.

NFPA *101* addresses life safety considerations based on the occurrence of fires. Basic life safety requirements require that at least two means of egress be available. The exits must be arranged to be remote from each other. These means of egress should be available from all working areas and from the headhouse located on top of the storage structure. All working areas should have access to at least one stairway leading to an exit discharge point at ground level. This stairway should be constructed within a dust- and fire-rated enclosure.

In addition to the stairway, an alternative means of escape is required. This secondary means should provide a continuous path to the ground from the top of the elevator structure, but it need not meet all provisions for a means of egress. This secondary escape can consist of exterior stairs or basket-type ladders accessible from all working levels of the headhouse. This escape means provides passage to the ground or to the top of adjoining structures.

An exterior stair or basket-type ladder should be provided from the top of storage structures such as silos, conveyors, galleries, and gantries. This secondary escape should be located at the end of the structure opposite the headhouse.

Most grain elevators have underground passages for conveyors beneath the silos. These spaces should have at least two means of egress without dead ends. One means of egress can be a ladder or other escape method that leads to a window, hatch, or panel that can be opened to permit escape.

For more information on grain elevators, see Section 9, Chapter 7, "Storage and Handling of Grain Mill Products."

Aircraft Hangars

An aircraft hangar is a structure for the storage or maintenance of aircraft. Because it is generally impractical to remove all fuel from aircraft before moving them into a hangar, large quantities of flammable or combustible liquids are usually present inside the structure. Some maintenance procedures use highly flammable solvents and unstable toxic chemicals. Fire during maintenance and servicing operations can pose hazards to personnel in the hangar and potentially endanger aircraft worth millions of dollars. Special precautions for ventilation and control of ignition sources are needed.

Aircraft hangars provide a particular challenge when designing adequate exiting and egress facilities. The large open area needed for aircraft, especially commercial airliners, requires extended travel distances to reach exits. The presence of flammable and combustible liquids compounds this problem. Exits must be located at intervals not exceeding 150 ft (46 m) along all exterior walls of the hangar. Each part of the hangar or servicing area must have access to at least two exit locations. If approved interior horizontal exits are provided, then exit locations along the wall must be provided at intervals not exceeding 100 ft (30 m). Since a large hangar door cannot be left open in poor weather, small access doors can be installed in hangar doors. Egress from mezzanines must be arranged so that an exit can be reached within a maximum travel distance of 75 ft (23 m). These exits must lead directly to an approved enclosed stairway that discharges directly to the outside, to another fire-separated area, or to outside stairs.

For life safety purposes, a fire alarm system is required in hangars not protected by automatic sprinkler systems if the total floor area exceeds 100,000 ft^2 (9300 m^2). For additional requirements related to constructing and protecting aircraft hangars from fire, refer to NFPA 409, *Standard on Aircraft Hangars.*

Isolated Storage Buildings

Some high-value warehouses are needed for only a few years, such as those for construction projects in remote areas. At times, these warehouses may contain large quantities of electrical and electronic equipment, wire, cables, fixtures, and production equipment. Experimental or mining sites may also have large warehouses. These remote areas often lack public water mains or fire departments. Several factors must be weighed, such as the importance of the building to the project and the time needed to replace vital contents. Standards and building codes do not apply rigidly in these situations. Good loss prevention and control practice is to separate unprotected warehouses into small units, to provide fully adequate private protection, or to compromise and use protection systems with a limited water supply. Increased vigilance over guard service, housekeeping, maintenance, and smoking control should accompany any compromised physical protection.

Underground Storage

Large underground warehouses can be a boon to energy conservation because rock caverns have a nearly constant temperature and humidity. In the United States, some caverns have stored compressed gas, and old mines are used for records storage. Caves used for warehousing and storage should be protected with automatic sprinklers.

In general, the problems associated with underground structures include egress, venting smoke and heat, and limited access for fire fighting. Automatic sprinkler protection installed under constructed floors and ceilings is vital to protect combustible storage and personnel. NFPA 520, *Standard on Subterranean Spaces,* provides minimum requirements for the design, operation, and maintenance of developed subterranean spaces for safety to life and property from fire and similar hazards.

Air-Supported Structures

For warehousing in temporary or remote locations, such as at construction sites, or as a low-cost adjunct to more permanent conventional buildings, large air-supported structures are sometimes used (Figures 20.16.6 and 20.16.7). These structures are plastic-coated fabric envelopes resembling balloons and are kept rigid by internal positive air pressure. Structures less than

FIGURE 20.16.6 Typical Air-Supported Structure Suitable for Warehouse Purposes (Source: Air Structures American Technologies, Inc.)

FIGURE 20.16.7 Interior of a 100 ft by 300 ft (30 m by 91 m) Air-Supported Warehouse Showing Storage (Source: Air Structures American Technologies, Inc.)

150 ft (46 m) in width or diameter should comply with NFPA 102, *Standard for Grandstands, Folding and Telescopic Seating, Tents, and Membrane Structures,* which deals with wind resistance, strength, load distribution, and pressurizing air-supported structures. A trend toward using a cable harness net system to encapsulate the envelope in all directions increases the structure's stability during wind loading.

Because these structures cannot support overhead piping, conventional automatic sprinkler protection is not generally feasible. Such buildings are unsuitable for long-term storage of high-value or hazardous materials. When reasons to use these structures are compelling, a number of separate smaller units are preferable to one large structure.

WAREHOUSE FIRE-FIGHTING OPERATIONS AND PRE-INCIDENT PLANNING

The following information is intended primarily for fire brigade officers and public fire officials who must develop and implement a pre-incident plan for a warehouse. It will also assist fire officials in command positions who are responsible for tactical and strategic decisions made on the fireground.

Because automatic sprinkler protection is the most effective—and in many instances, the only—method to successfully control a warehouse fire, all fire-fighting operations should be geared toward support of the sprinkler system where present. This support not only increases the likelihood of fire control but also maximizes fire fighter safety because it is unnecessary for fire fighters to be exposed to the hazards of an interior fire attack.

After effective support for the sprinklers has been established, the fire emergency can be considered stabilized. This provides sufficient time to carefully organize a safe and successful fire suppression operation. In addition, sprinklers buy time and help maximize safety and operational effectiveness—hurried fire-fighting operations are not only disorganized but are also unsafe and often ineffective.

The overall success of a warehouse fire-fighting operation is determined long before the first smoke is visible—in fact, it is determined before actual ignition occurs. The operation's success is determined as the warehouse pre-incident plan develops.

The pre-incident plan must be a cooperative effort among the building owner, plant emergency teams, and the public fire department expected to respond to the fire. Other agencies may also provide valuable input to the prefire plan. Such agencies include plant security forces, plant engineering staff, public utility companies, and the insurance carrier.

Developing a Pre-Incident Plan

The pre-incident planning process begins with a warehouse tour. Arrangements should be made with the building owner for someone with a working knowledge of the facility and its operations to accompany the fire department representatives on the tour. Building owners should cooperate fully with the public fire department when they develop a pre-incident plan. Architectural drawings and diagrams of the facility showing the building layout, construction, storage configurations, and the design of the fire protection systems and equipment should be provided for examination prior to the tour.

The tour's purpose is to gather information that the fire department will use to predict the type of fire anticipated and the possible complications encountered during fire suppression operations. Information gathered should include at least the following:

- Evaluation of building size and construction characteristics to determine a fire's probable effect. For example, a roof

supported by lightweight steel bar joists or trusses can be expected to collapse early during a serious fire.

- Location of fire walls, fire barriers, and fire doors that separate the storage area from the surrounding operations. Fire doors should be checked for proper operation because they must be relied on during an emergency to inhibit the spread of the fire.
- Identification of the commodities stored within the warehouse. Knowledge of their burning characteristics is essential. For example, burning aerosol products, flammable liquids, or similar materials may be beyond the capabilities of the sprinkler system.
- Determination of the method of packaging materials in the warehouse. For example, cardboard cartons can be expected to collapse quickly into the aisle, and plastic straps attaching materials to pallets can be expected to melt quickly.
- Identification of storage method, for example, racks, solid piles on the floor, or palletized.
- Evaluation of normal and maximum storage levels. Stock levels must be assessed as to relative stability from season to season. Pre-incident plans should be based on the worst case. For example, the worst-case fire in a department store warehouse might occur in September or October when it is filled to capacity with holiday sale merchandise.
- Determination of the type and design of the automatic sprinkler systems. Obtaining complete information on the capability of the sprinkler systems is very important so it can be compared to the hazards the storage in the warehouse pose. If sprinkler design is inadequate for the storage type and arrangement, fire control is unlikely.
- Determination of minimum flow and pressure required to supply sprinkler systems. To evaluate the adequacy of the available water supplies, water supply demands for the sprinklers must be known. If the water supply is inadequate, sprinklers will not perform as designed. If current water supply test results are not available, tests should be conducted to obtain current information.
- Identification of the type and number of water supplies available for fire protection and information on how to start fire pumps so that fire fighters may start them manually, if necessary.
- Location of public hydrants and fire department sprinkler connections. Fire apparatus should not steal water from the sprinkler systems by connecting to yard hydrants. The location of suitable public hydrants and static water sources to supply fire apparatus must be noted and evaluated.
- Arrangement of interior standpipes and hose connections. Are they fed from overhead sprinklers? Can they remain in service with the sprinklers shut off? All hose connections must have the same hose threads as those used by the public fire department.
- Assessment of type, capacity, and method of operation of any automatic or manual heat and smoke venting facilities. How can exhaust fans be activated? How is the power supply to the fans arranged? Will power be lost when electric power for the warehouse shuts down during an emergency?
- Determination of primary and alternate means of access to the warehouse. What security features make access more difficult? Are security guards or guard dogs normally in the warehouse after normal working hours?
- Determination of type of training provided for the plant emergency organization. Also assess how many members will be available during a fire, and what procedures they follow in a fire.
- Assessment of types of manual fire suppression equipment available to the plant emergency organization and whether the public fire department can utilize this equipment.
- Assessment of general storage practices in the building. Are piles neat and orderly? Are they sloppy and in disarray, indicating poor housekeeping practices conducive to rapid fire spread?
- Investigation of aisle storage. Even so-called temporary storage blocks access to the aisles in an emergency and can cause rapid bridging of a fire across aisles.
- Determination of the materials-handling equipment available during overhaul operations to move stock out of the building. Will employees be available to operate the equipment or must fire fighters be trained to use the equipment?

After this basic information has been gathered, development of the actual pre-incident plan begins. The plan, of course, should be developed in conjunction with the building owner so that everyone knows their specific responsibilities during an emergency incident. Employees and the plant emergency organization should be instructed in the procedures for reporting a fire, making sure that employees are evacuated, checking to ensure that sprinkler control valves are open, and closing fire doors to prevent fire spread.

Strategic Fire-Fighting Considerations

The strategy employed in fighting structure fires is to confine the fire to the smallest possible area after arrival of the first fire department unit. In most cases, this means confining the fire to the room or compartment of origin. Even in large commercial buildings, fire fighters can usually depend on at least some degree of compartmentation to at least slow a fire's spread and intensity. When compartmentation works as intended, fires are "simple" room-and-contents fires.

Unfortunately, modern warehouses often lack such compartmentation. Warehouses with several hundred thousand square feet (100,000 ft^2 equals 9300 m^2) of floor area under a single roof with few, if any, true fire walls or fire barriers are not uncommon. Conveyor openings, drive-through doors, and holes for utilities to pass through often compromise existing fire walls and fire barriers. Firestopping or automatically closing fire doors may or may not properly protect these openings.

Sizing up a warehouse fire can, and most likely will, be very difficult. A serious fire may be burning in a large warehouse, but very little smoke may be visible from outside. Smoke visible from the building's exterior may not indicate the location of the fire within. Because most warehouses have few if any windows, there may be no easy method of determining the fire's size, location, or current status. This makes having an up-to-date pre-incident plan even more important.

Sprinkler System Support

Sprinklers begin fighting the fire before the fire department arrives, discharge water directly into the fire area, and are unaffected by poor visibility, heat, and toxic gases. The best course of action is to support the sprinkler system's operation by pumping into the fire department sprinkler connection at full capacity. The higher the pressure available to the sprinkler system, the more water discharged from the operating sprinklers and the better will be the chance of controlling the fire. After support for the sprinklers has been established, the fireground commander has time to carefully size up the situation to determine the best use of available resources.

To support sprinklers, the fire department must pump into the fire department sprinkler connections and ensure that proper pressures are maintained within the system. Steps must also be taken to ensure that water for manual fire suppression operations is not taken from the sprinklers or that fire apparatus connected to yard hydrant systems do not rob water from sprinklers. In cases where water supplies were marginal, fire departments have taken water from the system, causing pressure within the sprinkler system to drop to critically low levels. Fire fighters should understand that, although a flow of 1000 gpm (63 L/sec) may be a high rate of flow for many fire types, the sprinkler system in a warehouse may require from 1500 to over 3000 gpm (95 to 190 L/sec) to operate effectively.

Arriving fire companies may face a number of different situations that hinge mostly on the effectiveness of the automatic sprinkler system. Such situations are discussed in the following paragraphs.

No Sprinklers Provided. If the warehouse has no automatic sprinklers and the fire is beyond the incipient stage, controlling it will be very difficult. Saving anything in the compartment of origin may be unlikely, and efforts should be directed toward preventing the fire's spread beyond the compartment currently involved. This can be accomplished by closing fire doors, using hose lines to prevent the fire's spread through unprotected openings in fire walls and fire barriers, and using master streams through doorways to contain the fire. Entry into the fire area can be extremely dangerous due to the speed with which the fire spreads and the probability of early structural collapse. A good water supply should be secured as soon as possible to supply the large hose streams required to control the fire and protect exposures.

Sprinklers Provided but Not Operating. If sprinklers are provided but not yet operating when fire companies arrive, one of two situations has occurred:

- It is possible that the fire has not yet grown large enough to actuate any sprinklers. In this case, hose lines can be advanced into the area to control the fire.
- Sprinklers may not be operating because the sprinkler system is impaired. One or more valves may be closed for maintenance or repair. Also, someone may have intentionally closed the sprinkler valves in an incendiary incident. Personnel should always be assigned to verify sprinkler control valves and water supplies are in service. At least one engine company should be assigned to support the sprinkler systems by pumping into the sprinkler connection, which may be arranged to bypass closed valves.

Sprinklers Operating and Controlling the Fire. If sprinklers are operating on arrival and appear to be controlling the fire, a first arriving engine company should be assigned to pump into the sprinkler connection. Increasing the pressure available to the sprinklers results in quicker, more effective, fire control. After the sprinklers have controlled the fire, there will be time to plan operations needed for final extinguishment, overhaul, and salvage.

Sprinklers Operating but Not Controlling the Fire. If the sprinklers are not controlling the fire on arrival, pressure in the sprinkler system must be increased immediately by connecting to and pumping into the fire department sprinkler connection. There will be very little time to establish support for the sprinklers before the sprinkler systems are overwhelmed. If only one sprinkler connection is available, it should be used to maximum advantage by connecting multiple hose lines to it. Additional water can be supplied to the sprinkler systems by pumping into wall hydrants or private yard hydrants, if available.

Hazards Posed by Stock

Personnel at a warehouse fire must be familiar with specific hazards of stock in the warehouse. Materials such as flammable liquids, flammable aerosols, and toxic chemicals pose obvious hazards. Hazards of other materials are often overlooked. For example, baled materials, such as scrap paper or paper pulp, can be deadly. These materials absorb water from fire suppression operations and can collapse on fire fighters operating inside the building. Another hazard of materials as they absorb water is that they may expand when wet. If materials such as paper pulp are packed into a building against masonry walls, it is possible that, as the material expands, it may push walls outward, causing local or total collapse of the structure. When developing preincident plans, such possibilities must always be considered.

Materials stored in cardboard cartons also may collapse as the cartons become wet and weak. In fact, in some cases a pile collapse is considered advantageous from a fire control standpoint because it exposes fire in the pile's interior to discharge from the sprinkler system. Fire fighters should understand that fire protection engineers may want a pile in a warehouse to collapse to facilitate fire control.

An example of the hazards of collapsing stock occurred in Idaho where three members of an industrial fire department and two other employees died during a fire in a sprinklered paper warehouse. The noncombustible storage building was 46 ft by 72 ft (14 m by 23 m) and fully protected by automatic sprinklers. Part of a paper mill, it stored scrap paper baled for recycling to a height of about 15 ft (4.6 m). An employee discovered a fire started by welding and grinding operations, and the plant fire department was notified. Arriving fire fighters found the building heavily charged with smoke and sprinklers operating at the ceiling. They entered the building with hose lines to find the seat of the fire. One crew of fire fighters was only 10 to 12 ft (3 to

3.7 m) into the building when bales of paper collapsed on them and trapped two fire fighters. Other fire fighters and employees outside the building rushed in to assist the trapped fire fighters. A second collapse trapped seven would-be rescuers. By the time the incident ended, the collapsing bales killed two employees and three fire fighters. All victims died of suffocation. Seven other fire brigade members were injured in the incident. The NFPA investigative report on the incident said, "This fire clearly illustrates the hazard to fire fighters of the collapse of storage materials which expand with the absorption of water. The hazard is particularly acute in sprinklered warehouses and must be considered in the pre-incident plans of fire departments that protect plants or storage facilities involving such commodities."[3]

Personnel must also be aware of the potential of stock falling from racks. In many cases, racks may be over 30 ft (9.1 m) high. Some warehouses have storage heights exceeding 100 ft (30.5 m). Burning stock falling from such heights could easily be fatal to anyone unfortunate enough to be working in the aisles. Regardless of the type of stock, the storage arrangement, or the design of the fire protection systems, fire fighters should always be alert to the possibility of collapsing stock and protect themselves accordingly.

Visibility

Visibility inside a warehouse during a fire incident is usually limited. Most warehouses are built with limited access and few windows. Natural lighting may not exist, resulting in poor visibility, especially if electric power to the building is cut as often happens when a fire occurs. When smoke fills the building, visibility is reduced even further.

Like a hose line discharged into an enclosed area, sprinklers operating in the fire area disrupt the thermal layers normally present in a fire. Contrary to what some believe, sprinklers do not "drive" smoke to the floor. As they operate, steam forms and cools the atmosphere in the fire area. As every fire fighter knows, cool, damp smoke is difficult to vent. However, the automatic sprinklers should never be shut down in an attempt to improve visibility until it is verified the fire is extinguished or under control. A fire fighter should remain at the sprinkler control valve in case the system needs to be reactivated.

Ventilation

Ventilation is important in a warehouse fire, as in any other structure fire. Automatic smoke and heat vents or mechanical smoke exhaust systems may aid fire fighters. If no heat and smoke venting facilities are provided, ventilation may be accomplished by more traditional methods, such as opening the roof. Cross-ventilation may be accomplished by opening overhead doors or breaking eave-line windows, if they are present.

It is important that fire-fighting personnel not be committed to the roof of a steel-frame building unless the sprinklers have positively controlled the fire. If the fire is not under control, the lightweight steel structural members could quickly fail, causing the roof to collapse. Personnel should also never be committed to the roof of a wood-truss-supported structure. Wood-truss buildings can collapse quickly and without warning during a fire.

Charged hose lines should be available before venting because ventilation, although necessary to improve visibility, may increase fire intensity. As mentioned in the visibility discussion, properly operating sprinklers cause steam to form in the fire area, and smoke saturated with steam becomes difficult to move. Cross-ventilation may be the best method of clearing the building. Positive pressure ventilation may also be used.

Fire Fighter Orientation

Warehouses are typically large buildings. Aisles and storage pile arrangements can become confusing. If fire-fighting personnel are not careful, they can easily become disoriented and lost in the building, especially when visibility is limited. Personnel operating inside a warehouse should always maintain contact with a hose line or a lifeline that they can follow outside to safety.

Logistics

The logistics of a warehouse fire-fighting operation must not be underestimated. Even under ideal circumstances, successfully fighting a fire requires large numbers of personnel and supplies. Physical demands on fire fighters due to the sheer size of the building require regular rotation of personnel out of the fire area for rest and rehabilitation. Pre-incident plans should contain provisions for assembling a large pool of trained personnel to assist in fire-fighting operations.

Other required supplies include air cylinders. Most self-contained breathing apparatus (SCBA) have only a 30- to 45-minute rating and probably last only half that long during strenuous fire-fighting operations. Fire fighters who must walk 300 ft (91.5 m) into the building to the actual fire area may only be able to spend 5 to 7 minutes fighting the fire before they must replenish their air supplies.

Materials-handling equipment for moving stock during overhaul and salvage operations must also be available, as well as qualified personnel who can operate it under emergency conditions. This may require that the operators be trained to use SCBA so they can assist with overhaul operations.

Fire Control Priorities

After ensuring life safety, the primary problem confronting the fire department on arrival at a warehouse fire is controlling the fire. Establishing control simply means preventing the fire from spreading. Assuming that sprinklers are operating, water damage should not be a concern until the fire has been extinguished.

If building owners or tenants complain about water flowing into the building, fire fighters may feel pressure to shut off the sprinklers to prevent further water damage. They must ignore such pressure.

Overhaul

As effectively as sprinklers control a warehouse fire, final extinguishment must be accomplished manually. This means that personnel must break open smoldering pallets, extinguish residual fire inside loads, and then remove them from the warehouse. If possible, personnel should accomplish this under the protec-

tion of operating sprinklers. At the very least, multiple-charged hose lines must be available in the area.

Overhauling a warehouse fire can present several challenges, especially if rack storage is involved. For example, how can fire fighters and hose lines reach the 30 ft (9.1 m) or the 80 ft (24.4 m) level in a high-rack storage area for final extinguishment and overhaul? The pre-incident plan must address such problems and should be practiced during on-site drills.

Rekindling

Fire may rekindle during overhaul operations when cartons of stock are broken open. If the sprinklers are shut down, someone with a radio should be stationed at the sprinkler control valve(s) to restore the system quickly to service if rekindling occurs.

In general, basic rules for shutting down the sprinkler system are as follows:

- Do not shut the sprinklers off until fire extinguishment is positively determined. If there is any doubt, the sprinklers should remain in operation.
- Make available charged hose lines in the fire area(s) before sprinklers are shut down.
- Station someone with a radio at the sprinkler control valve(s) to reopen the valve(s) if rekindling occurs.
- Restore the sprinkler system to full operation as soon as possible.

Limitations of Manual Fire Suppression

The best method of protecting a warehouse is to install a properly designed automatic sprinkler system and maintain it in proper working order. If sprinklers are not provided or they are not in service due to poor maintenance, the chances of saving a warehouse involved in a fire are greatly reduced. Personnel should not be committed to dangerous positions in an attempt to control an uncontrollable fire. The best-equipped fire department can never compensate for the lack of an effective sprinkler system.

OUTDOOR STORAGE

Truly engineered fire protection is difficult to achieve for outdoor storage. Depending on the hazard, monetary value, and storage area, a basic fire protection plan can be developed. For small amounts of incidental and transitory outdoor storage, appropriate protection might consist merely of good security fencing and outdoor lighting. On the other hand, very large, high-value storage yards warrant more elaborate safeguards.

Choosing the Site

Size. The storage area should be large enough to hold the quantity of stored material, with allowance for spacing between piles. If the area is inadequate, additional sites should be found. Congestion can be a major factor in fire spread.

Terrain. The ground should be leveled, if possible. Sloping terrain is undesirable because it makes piles unstable and complicates fire-fighting operations.

Exposure. Adequate clearances to adjacent properties should be maintained to minimize mutual fire exposure. Zoning regulations often specify clear distances to a property line. If no such regulations exist, the nature of future development on adjacent property should be considered, as it may affect the size of the storage area.

Other exposure considerations include protection from grass, brush, or forest fires, as well as protection from potential ignition sources, such as sparks generated by rolling railroad equipment, incinerator stacks, electrical transformers on poles, or lighted cigarettes discarded from nearby cars.

Fire Protection. Because fixed automatic systems are usually not an option, manual fire protection features available dictate the arrangement of outdoor storage, including pile size and the clearances required from adjacent piles, buildings, and property boundary lines. Local fire protection features, such as public water supply and its reliability, the available fire flow, fire department location and travel time, and the means available for notifying the fire department, should be evaluated.

Floods and Windstorms. Areas subject to flooding or windstorms should be avoided. Windstorms present a particular problem in some coastal areas. Fires occurring during high winds pose an exposure problem against which protection is almost impossible. Winds can carry burning materials and brands over considerable distances, even though the fire may be confined to a relatively small area.

Preparing the Site

Site Clearance. Vegetation should be cleared away so that it cannot dry out and become fuel for ignition or fire spread. The site should be leveled as much as possible and then paved. If the entire yard is not surfaced, care should be taken to ensure that fire apparatus can easily maneuver throughout the yard. This requires properly developed roadways capable of supporting heavy trucks. Proper site drainage is also essential.

It is good practice to paint lines within the yard to show aisles and roadways, as well as the location of yard hydrants, extinguishers, and hose houses.

Site Layout. A site plan should be developed. It should detail where specific materials are stored, the proper separation distances between piles, and access points to all site areas, including fences and gates.

The density of stored materials influences the manner in which the material burns. Lumber stacked in solid, orderly piles to a height of 20 ft (6 m) does not present the same problem as lumber stored in "stickered" piles, or wood stacked with spaces between to enhance air flow. In the latter case, fire develops more rapidly because of air spaces in the piles. Pulpwood is sometimes stored in piles 200 ft (61 m) in diameter and 100 ft (30 m) high; the logs' rough and varied shapes create air spaces and pockets in the piles, which accelerate burning.

Certain materials burn quickly and produce a great deal of heat. Baled cotton, hay, lumber, packing materials, pallets, plywood, pulpwood, and rubber are examples of such materials,

and considerable clearance should be provided between and around these piles. Aisle widths equal to the height of the pile are desirable for these types of commodities.

Both the yard itself and the piles within the yard must be easily accessible for fire fighting. Access to storage close to railroad spurs is often difficult because of boxcars and other railroad equipment left on the tracks. Driveways at least 15 ft (4.5 m) wide should be provided to permit fire department apparatus to reach all portions of the storage area. Aisles of 10 ft (3 m) or more should be provided to reduce the likelihood of fire spreading from pile to pile. In unusually large storage yards or moderate-size yards with valuable commodities, main aisles or firebreaks subdivide the storage much like firewalls do indoors. Overall, ideal aisle width depends on a number of factors, including the type of material, how it is stored, storage height, anticipated wind conditions, fire-fighting capabilities, and fire-fighting equipment.

In some cases, packaging and palletizing affect storage methods, particularly of irregularly shaped or small materials. Combustible pallets may present an added hazard. Some materials are packed in heavy crates. Usually, they do not increase hazard except after severe weathering or where handling has caused breakage or splintering. Tarpaulins and other weather-resistant materials used to cover stock should be of fire-retardant-treated material.

A stable pile under normal conditions may present a severe hazard in a fire. It is wise to anticipate how fire and water affect the stability of piles when planning their sizes and configurations. Collapsing piles may enhance fire spread and hamper fire-fighting operations.

Areas used to service and maintain equipment should be designated, marked, and separated from the storage. Flammable and combustible liquids, such as fuel for lift trucks, should be stored in accordance with NFPA 30, *Flammable and Combustible Liquids Code*. Fuel storage tanks should be located so spills do not flow under or around storage and, conversely, so that a fire in a storage area will not expose any flammable or combustible liquid storage area.

Installation of Fire Protection. Fire protection features and equipment should be installed during site preparation. Depending on the site's size and location, installing private water mains and hydrants throughout the yard may be necessary.

In planning for hydrants and yard mains, the water supply, whether from public mains or private sources, should be able to furnish the needed fire flow.

Properly marked portable fire extinguishers, preferably the nonfreezing water type, should be placed so that the distance to the nearest unit is 75 ft (23 m) or less. For active and normally occupied sites, fully equipped hose houses should be provided and personnel trained to use them in a fire.

A means to notify the fire department is essential. A system that directly signals the fire department is best; minimally, a telephone should be accessible.

Security Measures. Outdoor storage yards may have problems with trespassing, vandalism, and theft. Security measures, such as installing fencing and lighting, can minimize these problems. A fence, however, must not prevent ready access to the yard by the fire department. The fire department should be consulted about incorporating remote gates in the fencing to provide additional access under fire conditions.

Security guards can provide fire protection and loss control surveillance for outdoor storage yards. NFPA 601, *Standard for Security Services in Fire Loss Prevention,* covers the selection, duties, instruction, and training of such personnel.

Utilizing the Site

Management. When a yard is selected and laid out, the maximum amount of material to be stored in it is also established. Frequent inspections should monitor the quantity of the material and other fire prevention and protection features, including disposal of waste materials.

In general, management's attitude toward the yard's fire protection provides an example that employees are likely to follow.

Fire Protection and Prevention. All fire protection equipment, including hydrants, fire pumps, fire extinguishers, and any suppression, detection, or alarm systems on the storage site, must be properly inspected, tested, and maintained. All materials-handling equipment at the site should be equipped with a multipurpose portable fire extinguisher suitable for any type of fire.

The locations of all hydrants, hose houses, portable extinguishers, alarm boxes, and other fire protection equipment should be properly marked, preferably with elevated signs. Arrows and signs painted on the pavement are the minimum markings required.

If material to be torch cut or welded cannot be moved from the storage yard to a remote location, work should be done only after taking appropriate precautions (see NFPA 51B).

Smoking should be prohibited or restricted to specific areas that are remote from combustible storage. Adequate signs should be displayed and regulations strictly enforced.

A private fire brigade of employees can provide initial fire-fighting capabilities. If there are enough employees to organize a fire brigade, the availability and ability of a public fire department normally govern the level of organization, training, and equipment provided to the brigade. The larger the storage yard and the more valuable its contents, the greater the need for a private fire brigade for immediate response to an incident. NFPA 600 provides minimum requirements for their organization and training.

Maintenance and Housekeeping. Repairs to fencing, lighting, and the yard surface should be made promptly, and materials-handling equipment should be kept in good condition. Suitable safeguards should be provided to minimize the hazard of sparks from equipment, such as refuse burners, boiler stacks, vehicle exhausts, and locomotives.

Good housekeeping also includes controlling weeds and vegetation. Weeds, grass, and other vegetation should be sprayed with an acceptable herbicide or ground sterilizer. Dead vegetation should be removed.

In many instances, scrap lumber, broken pallets, broken containers, bales, or pieces of material stored on the site are

discarded into the clear space around the yard. Daily checks should be made for such discarded materials; where found, they should be properly removed. Care should be taken to prevent the accumulation of windblown debris and other combustible materials around the storage.

Outdoor Storage of Specific Materials

A discussion of safe storage practices for a few common materials follows. As a source for good practices, see the NFPA publications previously referenced and industry or insurance company standards. Many times, the application of inside storage guidelines for a commodity is a good starting point for devising outdoor storage guidelines.

Wood and Wood Products. Because wood is moved from the forests only at certain times of the year, large quantities of logs are stored at sawmills, paper mills, and pulp mills. Large circular piles with logs dumped on the top are called "stacked piles." Logs stacked parallel, like matches in a box, are called "ranked piles." Stacked piles are usually much larger, with pile heights often approaching 100 ft (30.5 m). Ranked piles are usually 10- to 15-ft (3- to 5-m) high. Because maintaining separation and aisles is much easier for ranked piles, fire protection for them is also much easier (Figure 20.16.8).

Controlling log yard fires can require large quantities of water. This can require that many portable turrets and monitor nozzles, each discharging about 1000 gpm (3785 L/min) operate simultaneously. A looped underground fire main system with hydrants spaced throughout the yard is good practice. Monitor nozzles on towers are advantageous in log yards, especially those with high-stacked piles. Burrowing fires in large stacked piles are difficult to extinguish even after surface burning is under control.

Chip storage has replaced log storage at many pulp and paper mills. Two completely different types of fires occur in chip piles: surface fires and internal fires. The amount of water needed to control a chip pile fire varies, depending on the pile size. Weather conditions, operating methods, geographic location, wood chip type, and the degree to which wetting may be employed all influence fire conditions. Exposure to long periods of hot, dry weather with no regular surface wetting creates conditions under which fast-spreading surface fires occur.

Frequency of pile turnover and operating methods influence the potential for fires. Piles built using methods that allow a concentration of fines (the dust and small pieces of material in the pile) are subject to internal heating, which, if undetected, can cause intense internal fires. This is also true of piles stored for long time periods with no turnover.

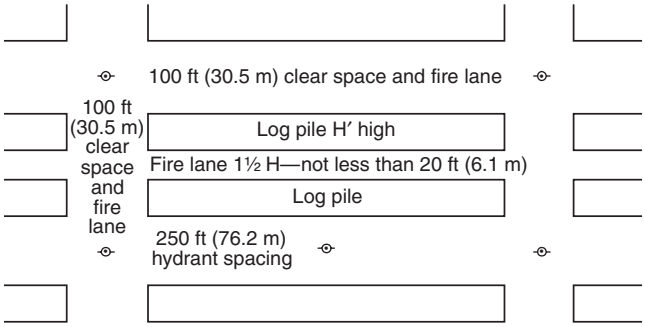

FIGURE 20.16.8 Good Layout for Ranked Piles of Logs in a Storage Yard

Paper and Paper Products. Some paper and paper products are stored outdoors. Roll paper is normally stored in large rolls weighing 2 tons (1814 kg) or more. Tightly wound paper is difficult to ignite; however, roll paper stored outdoors is more vulnerable. Once ignited, the rolls burn with great intensity as the paper exfoliates and exposes more paper to burning.

Baled wastepaper does not produce as intense a fire as roll paper does, but instead tends to produce burrowing fires. Broken bales are difficult to handle after wetting. A motorized vehicle with a shovel may be needed to move debris in order to complete extinguishment. Spontaneous ignition can occur in wastepaper if foreign materials subject to spontaneous heating become trapped in bales. Fire protection for wastepaper storage is generally the same as for other outdoor storage.

SUMMARY

Fires in warehousing and storage areas pose a number of fire protection challenges that must be addressed in a facility fire protection plan. The provision of a properly designed, installed, and maintained automatic sprinkler system is the best method of controlling a storage fire until it can be extinguished by the facility fire brigade or the public fire department. Effective action during a fire can limit the loss; such action must be carefully planed in advance. Ideally, the building owner and the public fire department must partner to develop an effective response plan.

Chapter 17

Library and Museum Collections

Danny L. McDaniel

Chapter Contents

Causes of Cultural Property Fires
Fire Prevention Principles
Fire Protection for Library and Museum Collections
Construction Considerations
Fire Emergency Management
Damage Limitation
Fire Safety Implications of Automation and New Technology
Fire Protection Decisions
Historic Buildings and Sites

Key Terms

bookstack, compartmentation, cultural resource properties, historic building, means of egress, museum, place of worship

This chapter discusses the incidence of fire in cultural resource properties, analyzes the differences between fires in which large and minimal losses occur, and describes principles and practices for managing cultural resources to reduce the risk of fire occurring in them and to minimize losses when they do occur.

At first glance historic buildings, libraries, museums, and places of worship seem quite different because of the nature of their use, contents, and degree of public access. Nevertheless, most museums contain libraries, many libraries feature exhibits of art or other culturally significant objects, most museums and many libraries and places of worship are in historic buildings, many places of worship house important collections of artifacts, art objects, and library materials, and all contain archival records essential to understanding our cultural heritage. Moreover, the fire protection problems are similar. Cultural resource properties nearly always include large quantities of combustible, high-value, and often irreplaceable materials. Another striking similarity is that although places of worship, libraries, and museums are public assembly occupancies, the open construction and extraordinarily high fuel loads are more typical of warehouse occupancies.

From a fire protection viewpoint, places of worship, libraries, and museums are mixed-use occupancies with significant public assembly and storage components but also may include cooking and eating facilities, laboratories, child care facilities, and even sleeping accommodations. A popular program in museums, for example, is to allow groups, usually children, to camp overnight in a gallery. Such programs have long been part of the educational outreach offered by historic sites and living history museums, and, of course, some places of worship provide shelter for the homeless and other disadvantaged persons as part of their community outreach. The fire risk in these occupancies should not be underrated. Public areas, such as assembly areas, library reading rooms, and museum exhibit galleries, generally are no-smoking areas with low fuel loads and high standards of housekeeping, and they may be monitored by staff or security officers. Nevertheless, such areas regularly suffer costly fires.

Nonpublic areas, such as storerooms, bookstacks, collection storage, work areas, exhibit preparation areas, food preparation areas, and conservation laboratories, present additional special hazards. Fuel loads are much higher in these areas, and housekeeping and smoking are more difficult to control.

A review of fire experience in NFPA 909, *Code for the Protection of Cultural Resource Properties—Museums, Libraries, and Places of Worship,* and NFPA 914, *Code for Fire Protection of Historic Structures,* clearly demonstrates the risk to cultural resource properties. Recent fires worthy of special attention include those at the Los Angeles Central Public Library (two in 1986 and one in 1988); the Hampton Court Palace in Richmond on Thames, England, in 1986; the Louisiana State Museum in New Orleans in 1988; the Library of the USSR Academy of Sciences in St. Petersburg, Russia, in 1988; Windsor Castle in Berkshire, England, in 1992; the Hofburg Palace in Vienna, Austria, in 1992; the Norwich Central Library in Norwich, England, in 1994; La Fenice Opera House in Venice, Italy, in 1996; and the First Presbyterian Church in Lexington, Virginia, in 2000.

Danny L. McDaniel, CPP, CSP, ASSE, ASIS, ICOM, AAM, is director of security, safety, and transportation for the Colonial Williamsburg Foundation in Williamsburg, Virginia. He is a member of the NFPA Cultural Resources Committee.

CAUSES OF CULTURAL PROPERTY FIRES

In 1999, the Federal Emergency Managment Agency implemented Version 5.0 of the National Fire Incident Reporting System, which changed some of the cause codes used in earlier versions. Therefore, only relative comparisons can be made between leading causes of fires from data collected before 1999 and data collected thereafter. Tables 20.17.1, 20.17.3, and 20.17.5 show leading cause data for fires in libraries, places of worship, and museums for the period 1980 through 1998. Tables 20.17.2, 20.17.4, and 20.17.6 show the same data for the period 1999 through 2002.

Arson is the leading cause of fires in libraries and places of worship (Tables 20.17.1, 20.17.2, 20.17.3, and 20.17.4), both in the number of fires and in the value of property damaged. Arson also was the second most frequent cause of fires in museums during the period 1980 through 1998 (Table 20.17.5) and the third leading cause in the period 1999 through 2002. From 1980 to 1998, arson accounted for 85 percent of the property loss in library fires, including the disastrous Los Angeles Central Public Library fire in 1986, and in the same period, arson accounted for 42 percent of the property loss in places of worship fires, and 26 percent of the fire losses in museums (see Table 20.17.5). In the period 1999 through 2002, arson accounted for 13 percent of the property losses in libraries and 20 percent in places of worship. The second most significant cause of fires in libraries and places of worship, and the third leading cause in museums in the period 1999 through 2002, have been failures in electrical distribution equipment. Electrical distribution equipment fires accounted for 13 percent of the property damage losses in libraries, places of worship, and museums during 1980 to 1998 and 21 percent in the period 1999 through 2002. Together, incendiary and suspicious causes and electrical distribution equipment problems accounted for nearly half the fires in cultural properties from 1980 through 1998 and about 33 percent of the fires from 1999 through 2002.

FIRE PREVENTION PRINCIPLES

Fire prevention is the cultural property's first line of defense against fire. Fire prevention consists of controlling and separating ignition sources from the supply of fuel.

Ignition Control

Ignition control involves identifying all sources of heat that could cause ignition in combustibles and isolating these sources from the fuel.

Arson. Arson is a difficult crime to prevent, and the arsonist is an unpredictable variable in the fire prevention program. A determined arsonist can circumvent even the most carefully defined fire prevention program. However, most arsonists are not so determined and have no special knowledge of fire or safety systems. Although preventing all deliberately set fires may be impossible, a fire prevention program that incorporates a strong security program can limit risk.

Fundamental precautions against arson are a strong access control program backed by detailed opening and closing procedures and strong measures to deter and detect unauthorized entry. At a minimum a security program should include the following:

1. A detailed, written, access control policy with two objectives: (1) to control (define) legitimate access and (2) to prevent illicit or unnecessary access. These objectives can be met by establishing levels of access to spaces and degrees of access to protected areas or objects. Legitimate access to grounds or buildings does not mean access to nonpublic areas. Access to storage does not necessarily mean access to protected objects. Likewise, access does not mean uncontrolled access. Visitor escorts are a legitimate means of access control.

   An effective access control policy includes the following provisions:

   - Identification of those who may obtain access (both routine and occasional) to nonpublic spaces and under what circumstances, for example, employees, scholars, researchers, visitors, service vendors, emergency response personnel, and others.
   - Procedures to obtain legitimate access to nonpublic areas. The policy should identify which staff can grant access, how much access they may grant, and on what basis. The policy should identify who must be escorted in nonpublic areas.
   - Responsibility for keeping access lists up-to-date and for making sure they are used routinely.

2. The best access and key control program is of little value if the facility is improperly opened or closed. Following written opening and closing procedures is the safest way to make the transition from one condition to the other. Standardizing how the facility is opened and closed establishes a baseline condition of the facility during each period. In the risk assessment process, these baseline conditions dictate the additional physical security tools needed to achieve acceptable security levels. Opening and closing procedures should:

   - Identify who may open or close. As the basis of the facility's access control program, designating, in writing, who has authority to open a building or controlled area establishes both the responsibility and authority to control access.

TABLE 20.17.1 Major Causes of U.S. Library Structure Fires, 1980–1998 Annual Averages

Major Cause	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Dollars)*	
Incendiary or suspicious	78	(40.0%)	0	(NA)	0	(24.5%)	4,018,200	(84.5%)
Electrical distribution	38	(19.6%)	0	(NA)	0	(10.0%)	281,400	(5.9%)
Other equipment	16	(8.3%)	0	(NA)	0	(0.0%)	16,700	(0.4%)
Open flame, ember, or torch	12	(6.2%)	0	(NA)	0	(10.3%)	17,800	(0.4%)
Smoking materials	11	(5.9%)	0	(NA)	0	(11.4%)	65,300	(1.4%)
Heating equipment	11	(5.7%)	0	(NA)	0	(32.5%)	143,200	(3.0%)
Cooking equipment	8	(4.0%)	0	(NA)	0	(0.0%)	14,900	(0.3%)
Appliance, tool, or air conditioning	7	(3.8%)	0	(NA)	0	(11.4%)	31,200	(0.7%)
Child playing	5	(2.3%)	0	(NA)	0	(0.0%)	56,600	(1.2%)
Natural causes	4	(2.0%)	0	(NA)	0	(0.0%)	30,900	(0.6%)
Exposure (to other hostile fire)	3	(1.3%)	0	(NA)	0	(0.0%)	78,100	(1.6%)
Other heat source	2	(0.9%)	0	(NA)	0	(0.0%)	300	(0.0%)
Total	195	(100.0%)	0	(NA)	1	(100.0%)	4,754,400	(100.0%)

Note: This table shows the causes of structure fires (incident type 11) in libraries (fixed property use 151). These are fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. Fires, civilian deaths, and civilian injuries are expressed to the nearest one and property damage is rounded to the nearest hundred dollars. Sums may not equal totals due to rounding errors. Property damage figures have not been adjusted for inflation. The 12 major cause categories are based on a hierarchy developed by the U.S. Fire Administration. Fires in which the cause was unknown were allocated proportionally among fires of known cause.

Source: National estimates based on NFIRS and NFPA survey.

TABLE 20.17.2 Leading Causes of Structure Fires in Libraries, 1999–2002 Annual Averages

Cause	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Dollars)*	
Intentional	32	(26%)	0	(NA)	0	(NA)	171,000	(13%)
Electrical distribution and lighting equipment	17	(14%)	0	(NA)	0	(NA)	441,000	(33%)
Cooking equipment fires	11	(9%)	0	(NA)	0	(NA)	16,000	(0%)
Identified cooking equipment	4	(3%)	0	(NA)	0	(NA)	2,000	(0%)
Confined cooking fire	7	(6%)	0	(NA)	0	(NA)	2,000	(0%)
Heating equipment	8	(7%)	0	(NA)	0	(NA)	2,000	(1%)
Smoking materials	6	(5%)	0	(NA)	0	(NA)	34,000	(0%)
Torch	5	(4%)	0	(NA)	0	(NA)	2,000	(3%)
Contained trash or rubbish fire	10	(8%)	0	(NA)	0	(NA)	16,000	(0%)

Note: These are the leading causes, obtained from the following list: intentional (from the NFIRS field "cause"); playing with fire (from factor contributing to ignition); confined heating (including confined chimney and confined fuel burner or boiler fires), confined cooking, and contained trash or rubbish (from incident type); identified heating, identified cooking, clothes dryer or washer, torch (including burner and soldering iron), electrical distribution and lighting equipment, medical equipment, and electronic, office or entertainment equipment (from equipment involved in ignition); smoking materials, candles, lightning, and spontaneous combustion or chemical reaction (from heat source); and mobile property involved (from mobile property involved in ignition). Exposure fires include fires with an exposure number greater than zero, as well as fires identified by heat source or factor contributing to ignition when no equipment was involved in ignition that were not intentionally set. The same fire can be listed under multiple causes, based on multiple data elements.

These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires, deaths, and injuries are rounded to the nearest one. Direct property damage is rounded to the nearest thousand. Property damage has not been adjusted for inflation.

- Establish locking, unlocking, entry sequences, and paths. When opening or closing a building, a clearly defined entry and exit procedure should assure continuity and complete coverage. Opening and closing procedures should be designed so the person opening the building starts at one selected point and the person closing the building finishes at the same point. This procedure assures that all critical areas are consistently checked.
- Establish procedures to inspect the building for stay-behinds. Large buildings usually have many places where someone intent on remaining in the building can avoid detection. The first step in dealing with stay-behinds is to make it as difficult as possible for unauthorized persons to get into areas where they can hide. Nonpublic areas, such as utility closets, mechanical areas, office spaces, and the like, should be locked while visitors are in the building. In some cases isolated spaces should have local daytime intrusion detectors to alert staff if an unauthorized person enters one of them. At the end of the day, it is important to search the building in a systematic way, usually starting at the top and working down and out. If possible, lock or secure building areas as they are inspected to prevent an intruder from moving back into a space after inspection. Opening and closing procedures should highlight areas that are particularly vulnerable to stay-behinds for special consideration. Where installed, the intrusion detection system may be zoned so that it can be activated in sections to help keep cleared areas secure.
- Identify other specific features of concern in the building.

3. Windows and doors should be secured with good-quality locking devices. Panic hardware on emergency exit doors allows doors to be opened from the inside and remain locked from the outside. Doors into nonpublic areas should be kept locked to prevent uncontrolled access by the general public.
4. Windows and doors should be equipped to provide an alarm on any unauthorized opening. In some communities intrusion alarms may be connected directly to the police or fire department. Alarm monitoring services also are available from commercial organizations.
5. Closed-circuit television can be extremely useful for monitoring little used spaces, exhibit areas, print rooms, and other collection study facilities, as well as emergency exits. In addition, the presence of a camera often is a psychological deterrent to illegal behavior.
6. Exterior lighting is an important element in the security program. Illuminating concealed building areas, potential entry points, and large windows let police, security patrols, and others in the neighborhood observe activity around the building. Where public utilities do not provide it, lighting should be added at all concealed approaches to the building.
7. Libraries should eliminate book drops used for after-hours book return, isolate them from the building by fire-resistant construction, or equip them with an automatic fire suppression system. Book drops are favorite targets for arsonists and vandals.[1]
8. If feasible, security patrols should inspect the building along well-planned and monitored routes at irregular intervals.
9. Staff should regularly and closely inspect ashtrays, waste receptacles, soiled linen hampers, electric heating appliances, and other places that can support fire development. Although not specifically an arson prevention measure, this routine can uncover hazards that could involve incendiarism, such as a filled wastebasket hiding a time-delay igniter, or other unusual conditions.

Electrical System. Wiring installed in accordance with the requirements of NFPA 70, *National Electrical Code®*, is equipped with overcurrent protection that opens the circuit before current flow reaches a level that dangerously overheats the conductor or its insulation. Nevertheless, overcurrent devices may fail, and under some conditions overloaded or partially grounded wiring may generate enough heat to ignite combustibles without blowing fuses or tripping circuit breakers.[2] For example, circuits subjected to flooding when a water line breaks or a steam line leaks, must be thoroughly dried. Otherwise, water can partially ground the circuit, generating excessive heat when current is applied.[3] The most common example of problems leading to failure of overcurrent protection, however, involves improperly altering the circuit by installing an improperly sized fuse or circuit breaker.[4] A comprehensive preventive maintenance program for the building's electrical distribution system is an essential element in the fire prevention program.

The proliferation of information processing equipment (computer terminals, word processors, PCs, modems, printers, and facsimile and photocopying machines) adds significant electrical loads that can exceed the existing building wiring system's capacity. More often, however, the problem is either a shortage of electrical outlets to accommodate the equipment or a shortage of outlets where they are needed. The temptation is to make the existing arrangement work by adding multiple outlet adapters to expand the capacity of an existing outlet or to use extension cords to bring power from a less conveniently placed outlet. Neither solution is acceptable. Multiple outlet adapters encourage overloading of the electrical circuit and should never be permitted. Extension cords are not an acceptable substitute for fixed wiring for the following reasons: (1) they are subject to mechanical damage, and (2) they can be overloaded easily. Extension cords usually are made with smaller gauge wire than the fixed wiring in the building. Electrical resistance increases significantly as wire size decreases and length increases. Where permitted, extension cords must be for temporary, short-term use only. The conductor must be rated to carry the current load expected over the distance it will be used. In addition, where extension cords have multiple outlet assemblies, they should have a circuit breaker at the output end to provide overcurrent protection for the extension cord. Extension cords must be protected from mechanical damage and never concealed under carpets. (See Section 8, Chapter 13, "Electrical Systems and Appliances.")

Surface temperatures of incandescent lamps vary widely. Spotlights, for example, easily can reach the ignition temperature of paper or textiles. Incandescent bulbs near, or in contact with, combustible materials may ignite them even if their surface

temperature is below the ignition temperature of the combustible material. Steady application of a heat source below a combustible material's ignition temperature can generate enough heat to ignite the material, given enough time.

The cooler surface temperatures of fluorescent lamps do not present the ignition hazards of incandescent bulbs. Nevertheless, ballasts in fluorescent light fixtures generate heat and are potential ignition sources, particularly when installed in a way that traps heat. For example, ballasts mounted flush against combustible, low density, cellulose fiberboard or other materials of similar combustibility present a potentially severe fire hazard. Fluorescent light ballasts also may be a source of ignition when they fail. At a minimum, a failing ballast may generate significant quantities of acrid smoke.

Heating Equipment. Heating equipment malfunction or misuse is an important potential cause of fires. Boilers and furnaces of central heating systems should be isolated in a fire-resistant enclosure, either separate from or attached to the cultural resource property. Fixed or portable space heaters and portable heaters should not be used in combustible collection storage areas.

Because cellulosic materials, such as wood, paper, or textiles, store heat, they may ignite after prolonged contact with hot objects that are well below the materials' usual ignition temperature. Such materials should not be in contact with steam piping, heat ducts, or other low-grade heat sources.

Appliances. If not prohibited entirely, space heaters, hot plates, microwave ovens, coffee makers, and other small appliances should be rigidly regulated and closely monitored. Where permitted, each appliance should satisfy the following conditions:

- Listed by an independent testing laboratory
- Placed on a noncombustible base
- Located so they are adequately separated from combustible materials
- Located where air circulation prevents heat buildup

Those responsible for closing the building or area should have a listing of the location of each heating appliance and should inspect them as part of the building closing procedure. The inspection should ensure that the appliance works properly, that combustible materials are not touching or close to the appliance, and that appliances not necessary for building protection are turned off. If the facility has security officers, they should also have a listing of each heating appliance and should check each appliance during their rounds. Where feasible, heating appliances should be unplugged when not in use.

Smoking. Most cultural resource buildings are smoke-free facilities. Where permitted, smoking should be limited to those places, such as administrative offices, staff rest areas, and designated visitor lounges, where fire-safe practices can be monitored and controlled. As more facilities ban smoking, however, it is important to recognize that a total ban may result in surreptitious smoking in unsupervised locations, thus actually reintroducing the risk of fire from smoking practices. Where smoking is banned inside the building, adequate facilities should be provided outside the building to accommodate those who wish to smoke.

Open Flame Devices. Open flames used in building repairs, laboratory operations, or in the interpretation of historic environments are severe ignition hazards, as are hot metal sparks or slag from welding and cutting. Candles are a large part of many worship services, including both lit candles fixed in place and lit candles carried by worshipers. Use of open flame devices should require the written approval of a responsible management official. Before signing such an authorization, the official should evaluate the risk to life safety and collection materials, and should prescribe protective measures as conditions of the authorization. Management conditions for authorization should include at least:

1. Relocating combustible materials, especially irreplaceable, valuable, sensitive materials as in an exhibit or collection, a safe distance from the ignition source.
2. Requiring a fire watch of one or more trained persons with appropriate fire-extinguishing equipment. The fire watch should be on site continuously, with no other duties, while the hazardous activity is performed and should remain in the area long enough to ensure the discovery of any hidden fire after interruption or termination of the activity. A fire watch should monitor the area for at least 30 minutes after welding and cutting torches have been used.

Fuel Control

Fuel control must include all combustible contents, including any collections and ancillary records, as well as furniture, interior finish, packaging materials, and flammable liquids. Control measures include arrangement of storage to limit fire spread and separation of fuel from ignition sources. Much of this can be accomplished through good housekeeping practices. (See Section 11, Chapter 2, "Housekeeping Practices.")

Flammable Liquid Storage and Handling. Where possible, flammable and combustible liquids should be stored in fire-resistant structures isolated from the building. Where this is not feasible, small quantities of flammable or combustible liquids may be stored in approved, self-closing, flammable liquid storage cabinets. All flammable or combustible liquids permitted inside the building should be contained in safety cans. When in use, only that quantity of flammable or combustible liquid required during an 8 hour shift should be permitted outside the flammable liquid storage cabinet. It must be in safety cans until actually used. Special attention is required to ensure adequate ventilation, and ignition sources must be eliminated or carefully controlled. (See Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids.")

Spontaneous Heating. Oil- and solvent-soaked cloths and rags, such as those used with oil-based paint, mineral spirits, and some cleaning products, can heat spontaneously. They should be placed in a metal can with a tightly fitting metal top immediately after use and completely removed from the building no later than the end of each day.

Fuel Geometry and Overcrowding. A useful way to consider the combustible materials contained in a cultural resource building is to see them as arranged in fixed fuel packages: exhibit cases, bookstacks, desks, tables, chairs, pews, hymnals, heavy curtains or drapery, and so on. These fuel packages also may contain quantities of movable fuel, such as loose paper, which can vary the total fuel load and radically change the ignition characteristics of individual fuel packages. Although these fuel packages usually are not contiguous, and indeed may be housed in a noncombustible building shell, they may become contiguous because of combustible interior finishes. Increasing the distance between the fuel packages and using interior finish materials, such as carpet, wall coverings, and draperies, with a low flame spread rating, minimizes the risk of fire spreading from one package to another.

Interior Finish. Interior finish materials with high flame spread rates, such as fiberboard and some textile coverings (analogous in composition to carpet floor coverings) when vertically oriented, negate the effectiveness of distance as a tool to isolate fuel packages. For example, flame can spread in low-density cellulosic fiberboard and acoustic ceiling tile, as shown in Figure 20.17.1, as fast as people can run. Decades ago flame spread index ratings for low-density cellulosic fiberboard and acoustic ceiling tile products were reported to range from 225 to 350.[5,6]

Although building test fires in 1959 demonstrated this flame spread potential, these materials still may be found in some cultural resource properties across North America.[7] Where such low-density finish materials still exist, they should be replaced. During removal it is especially important to also remove any adhesive used to attach the tile to ceilings or walls. The adhesive has been identified as a key factor in the rapid flame spread over ceiling tiles.[8] If replacement is not feasible, these materials should be encapsulated behind fire-rated gypsum board. Treatment with intumescent paint may not provide the intended protection unless this application is approved by the listing laboratory and maintained as the manufacturer prescribes.[9] Textile coverings may present a similar hazard when used in exhibits or when applied to wall surfaces unless they are specifically tested to establish an acceptable rate of flame spread when vertically installed.

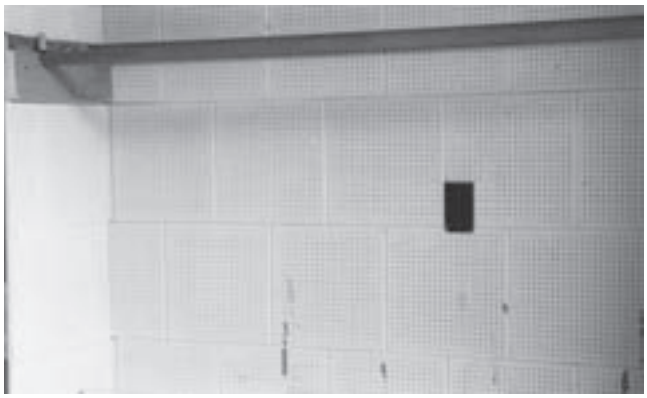

FIGURE 20.17.1 Typical Low-Density Cellulosic Acoustical Tile

Inadequate Space. Museums and libraries collect; therefore, growth of the collection is inevitable. As collections grow, staffing levels tend to grow also. Adding space is expensive and usually the last resort. These conditions cause overcrowding of both collections and staff, reducing the space between fuel packages. Overcrowding increases the risk that a fire will grow by spreading to adjacent fuel packages rather than burning itself out. Periods of overcrowding, therefore, require compensating emphasis on other elements of the fire prevention program, especially control of ignition sources.

FIRE PROTECTION FOR LIBRARY AND MUSEUM COLLECTIONS

Experience shows that early detection followed by quick action to stop fire growth can prevent large fire losses. A common element in most large-loss fires is the absence of automatic suppression systems to control or extinguish fire in its early stages. Some preservation specialists—museum curators, librarians, and archivists—believe water is a greater hazard to the building and collections than fire. They emphasize fire prevention almost exclusively, limiting fire protection to the installation of automatic detection systems. Cultural resource property fires continue to occur despite this heavy emphasis on fire prevention. Table 20.17.7 shows that 24 percent of all reported library fires occur between 9 p.m. and 9 a.m.; an additional 23 percent start between 5 p.m. and 9 p.m.—times when libraries have little or no staff on duty.[10] These off-hour periods also account for about half the property loss. However, fires have steadily declined in cultural resource properties (Tables 20.17.8, 20.17.9, and 20.17.10).

Total dependence on fire prevention and manual extinguishment places the cultural resource property at serious risk of catastrophic loss when prevention fails. The 1986 fire in the Los Angeles Central Library illustrates the point clearly. In this fire, smoke detectors warned building occupants, who evacuated safely. Nevertheless, despite timely notification to the Los Angeles Fire Department, lack of an automatic suppression system allowed the fire to spread. Bringing it under control took more than 7 hours. The fire destroyed more than 400,000 objects, and 700,000 wet books were placed in cold storage to await restoration.

Because fire prevention efforts can lessen, but not eliminate, the possibility of fire, knowledge of the options available to limit fire spread is essential. Local fire and building codes provide minimum requirements for the survival of the building and for the life safety of its occupants. Nevertheless, sole reliance on code provisions will not adequately preserve building contents, especially highly valuable collections. Fire protection features to protect the building contents are needed over and above minimum requirements that local codes impose.

Systems Approach to Fire Safety

A systems approach to fire safety is a useful management tool for selecting the appropriate level of fire protection to limit fire loss to an acceptable level. The systems approach uses decision tree analysis, failure modes and effects analysis, and other

systems techniques to identify hazards, assess probability, establish maximum acceptable fire loss, and identify fire defense alternatives.

A critical element in the systems approach is to develop fire safety objectives for the facility based on life safety considerations, the value and vulnerability of the collections, and obligations for continuity of service. The fire safety objectives adopted by the Library of Congress in Washington, DC, may provide a useful reference point.[11] The General Firesafety Objectives and Critical Space Objectives, shown graphically in Figure 20.17.2, are similar to those the U.S. General Services Administration (GSA) originally adopted for federal office buildings nationwide.[12] This graph shows the fire safety objectives for Library of Congress buildings and represents the desired minimum probability of success in limiting a fire's growth from its start to full building involvement. Adoption of

acceptable limits of fire loss should reconcile the cost of the fire defense system to achieve those limits with the resources available to the institution.[13]

Designing the Fire Safety System

The specific design selected for the fire protection system in a typical cultural resource property depends on the value of the exhibits, collections, or other unique contents and the value and characteristics of the building and its fuel load. At a minimum, the system should include fire detection, alarm notification, emergency communication, manual extinguishment, automatic fire suppression, protection for special hazards and other passive construction elements for safe occupant egress, limiting fire spread, and isolating hazardous operations and building systems.

Detection and Alarm. A fire detection and alarm system should be installed throughout the building. The system should include smoke detectors in all exhibit galleries, reading rooms, and collection storage areas; smoke, heat, or flame detectors, as appropriate, should be installed in other parts of the building. From 1994 to 1998, 39 percent of reported U.S. structure fires in churches and related properties and 70 percent in museums and libraries were reported with automatic fire detection present.

A detection and alarm system should alert building occupants of an unwanted fire before it becomes a threat. A properly designed and installed system will alert occupants in time to evacuate in an orderly manner. The system also will facilitate prompt notification of the fire service. Ideally the detection system also provides an opportunity for trained building staff to extinguish the fire before automatic fire suppression equipment activates or the fire service arrives. (Section 14 of this handbook describes types of detection and alarm systems.) Care and good judgment are imperative, however. Fire in concealed spaces can burn for a considerable period before activating detection equipment. In 1994–1998, roughly 10 percent of reported U.S.

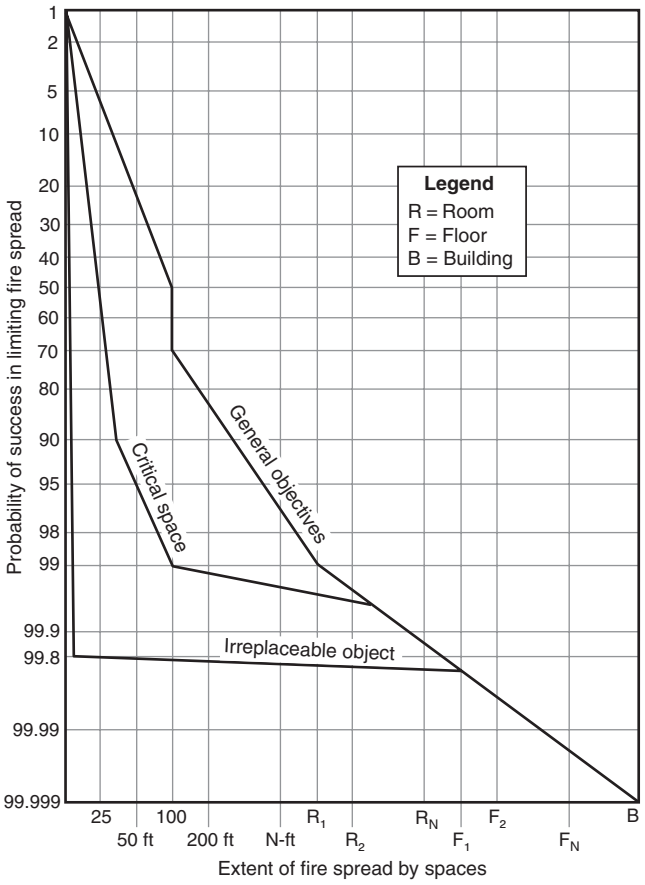

FIGURE 20.17.2 Illustrative Graphic Probability Analysis of Fire Safety Objectives

structure fires in libraries and museums and roughly 15 percent in places of worship began in concealed spaces. Those responding to investigate an alarm must be alert to signs that fire is well established. If there is any doubt, evacuate. Attempting to manually suppress a well-established, concealed space fire can lead to tragedy. When the fire breaks out of the concealed space, it can spread very quickly.

An automatic sprinkler system also can provide the alarm when the first sprinkler opens and water begins to flow in the system. However, this detection occurs at a later stage of fire development when fire and smoke may hamper orderly evacuation. Quick-response (QR) sprinklers may be an exception because they respond to heat at an earlier stage of fire development than standard sprinklers—in some configurations only seconds later than smoke detectors. For this reason some libraries, including the National Library of Canada, the National Library of Scotland, the New British Library, the U.S. Library of Congress, and the U.S. National Archives are installing QR sprinklers to protect their collection storage areas. (See Section 16, Chapter 6, "Residential Sprinkler Systems.")

In addition to sounding an alarm throughout the building, the detection and alarm system should be connected to a central station, the local fire department, or some other acceptable monitoring facility. The value of a detection system is as a communications tool. The detection system itself takes no action to control or extinguish fire. A local alarm may be adequate for evacuating building occupants, but a local alarm alone does not summon the fire department or other emergency assistance. This is particularly true when the building is unoccupied. For this reason connection of the detection system to a central station or equivalent is recommended.

A qualified fire protection specialist or engineer with experience in cultural resource property protection should design the fire detection and alarm systems to ensure proper building coverage and to minimize the risk of unwanted alarms. The designer must have knowledge of, and experience in, fire behavior in the type of facility to properly select fire detectors for the threat and the ambient environment. The designer must also be well versed in the requirements of applicable codes and standards.

After installation and acceptance tests have been completed, a regular test and maintenance program should be established. This is very important because testing is the only way to determine that no part of the detection and alarm system has failed.[14] Furthermore, because the sensitivity of smoke detectors can change as dust and dirt accumulate, periodic inspection and cleaning are needed to keep the detector working within its intended sensitivity range. (See Section 14, Chapter 2, "Automatic Fire Detectors.")

Communication. A public address system should be considered, especially in very large facilities, to provide emergency voice instructions and information to facilitate evacuation. Cultural resource properties can have complicated egress routes. If unfamiliar with the building layout, the general public may experience difficulty finding appropriate means of egress. Egress routes should be properly marked by illuminated exit signs as required by NFPA *101®*, *Life Safety Code®*, and *NFPA 5000®*, *Building Construction and Safety Code®*.

Manual Extinguishment. Portable extinguishers in the hands of trained users constitute an institution's first line of fire attack. To prevent the use of the wrong class of extinguisher on a particular fire, some institutions provide only multipurpose portable extinguishers. These should be appropriately located and regularly inspected and maintained, so they are fully charged and operational when needed. (See Section 17, Chapter 5, "Fire Extinguisher Use and Maintenance.")

Occupant-use standpipe hose lines require specific hands-on training and drills to avoid personal injury and unnecessary property damage. Hose lines must be inspected at least annually and should be service tested when doubtful conditions are identified. Unfortunately, because many building occupants are not trained to properly use a fire hose and because of a general tendency not to inspect and test hoses as required, municipal fire departments may arrive at a fire to find the occupant hose used ineffectively, sometimes dangerously, or not at all.

Obviously, the fire department also provides manual extinguishment. In buildings without automatic sprinkler systems, it follows occupant fire suppression efforts as the second and final line of fire suppression defense to control loss from fire. If the fire area has reached 2500 to 3000 ft^2 (232 to 279 m^2) at the time of water application, the fire may be confined but not readily extinguished. Figure 20.17.3 suggests that the probability of fire department success actually begins to drop rapidly when fire areas exceed 750 to 1500 ft^2 (70 to 140 m^2).[15]

The most significant concern with manual extinguishment is that once fire enters the free burning phase, fire damage increases exponentially until the fire is under control.[16] Fire protection systems that depend entirely on manual extinguishment risk disaster if human response is delayed or unavailable.

Automatic Sprinklers. As stated earlier, lack of an automatic suppression system is a major contributing factor to large-loss fires in cultural resource properties. Sprinkler systems have been shown to reliably and effectively minimize the risk of large-loss fires in cultural properties.[16] A Factory Mutual Research Corporation (FMRC, now FM Global Research) study found that the average dollar loss in fires with adequate sprinkler protection in the 5 year period 1984 through 1988 was 5.8 times less than the average loss during the same period in fires studied without adequate sprinkler protection. For this study, fires where adequate sprinkler protection existed were those reported to FMRC in which (1) sprinklers were in service, (2) there were no sprinkler system or water supply deficiencies, and (3) sprinkler density was appropriate for the risk.[17] In 1994–1998 U.S. structure fires reported to local fire departments, sprinklers were present on only 4 percent of fires in places of worship and 32 percent of library and museum fires. Average dollar loss per fire was reduced by sprinklers by 32 percent in places of worship and by 72 percent in libraries and museums. This is roughly consistent with the general finding that average loss is reduced by one-half to two-thirds.

For many years, cultural resource management professionals opposed automatic water sprinkler protection, fearing water damage even more than fire damage. Many library and museum planning references reflect this attitude.[18–20] Through the years libraries and museums have experienced water damage from various sources: roof leaks, storm damage, plumbing problems, rivers overflowing, and so on. By comparison, water damage from sprinklers is rare.

Water damage is more likely, however, when fire department hose lines are used to fight fires. Automatic sprinklers actually minimize the potential for water damage. An automatic sprinkler releases 20 to 25 gpm (76 to 95 L/min) in a spray pattern, in contrast to the 150 to 250 gpm (568 to 946 L/min) of pressurized water from each fire fighter's hose stream. Most fires in buildings with automatic sprinklers are controlled with fewer than five sprinklers opening, which collectively release less water per minute than one hose stream. Hoses can sweep materials from shelves and displays into a disorganized mass on a flooded floor. Prospects of salvaging wet materials that remained in place under the relatively gentle action of sprinklers are much better than for materials knocked to the floor, soaked, and possibly trampled on.

Another consideration is that sprinklers discharge water directly in the area of the fire. Sprinklers respond to heat, and only those in the direct fire area become sufficiently hot to open. Fire department hose streams, on the other hand, must be directed to the general area of the fire until smoke clears sufficiently for fire fighters to find and soak the concentration of fire. Therefore, whereas sprinklers tend to restrict damage to the room of origin, fire department hose streams can spread water damage much more widely.

Finally, sprinklers operate early in fire growth, reducing the amount of water needed to extinguish the fire. Fire department hose streams are used much later in the growth of the fire, usually after free burning begins. Therefore, extinguishing fire with a fire department hose stream requires significantly more water. The combination of more water flowing, more area to cover, and more water needed for extinguishment means that fire department hose streams pour huge quantities of water on a fire. This water has to go somewhere: it floods out of the fire area through every available drain and crack and drains to the building's lowest point. Therefore, fires on upper floors can result in extensive water damage to materials many floors below. The

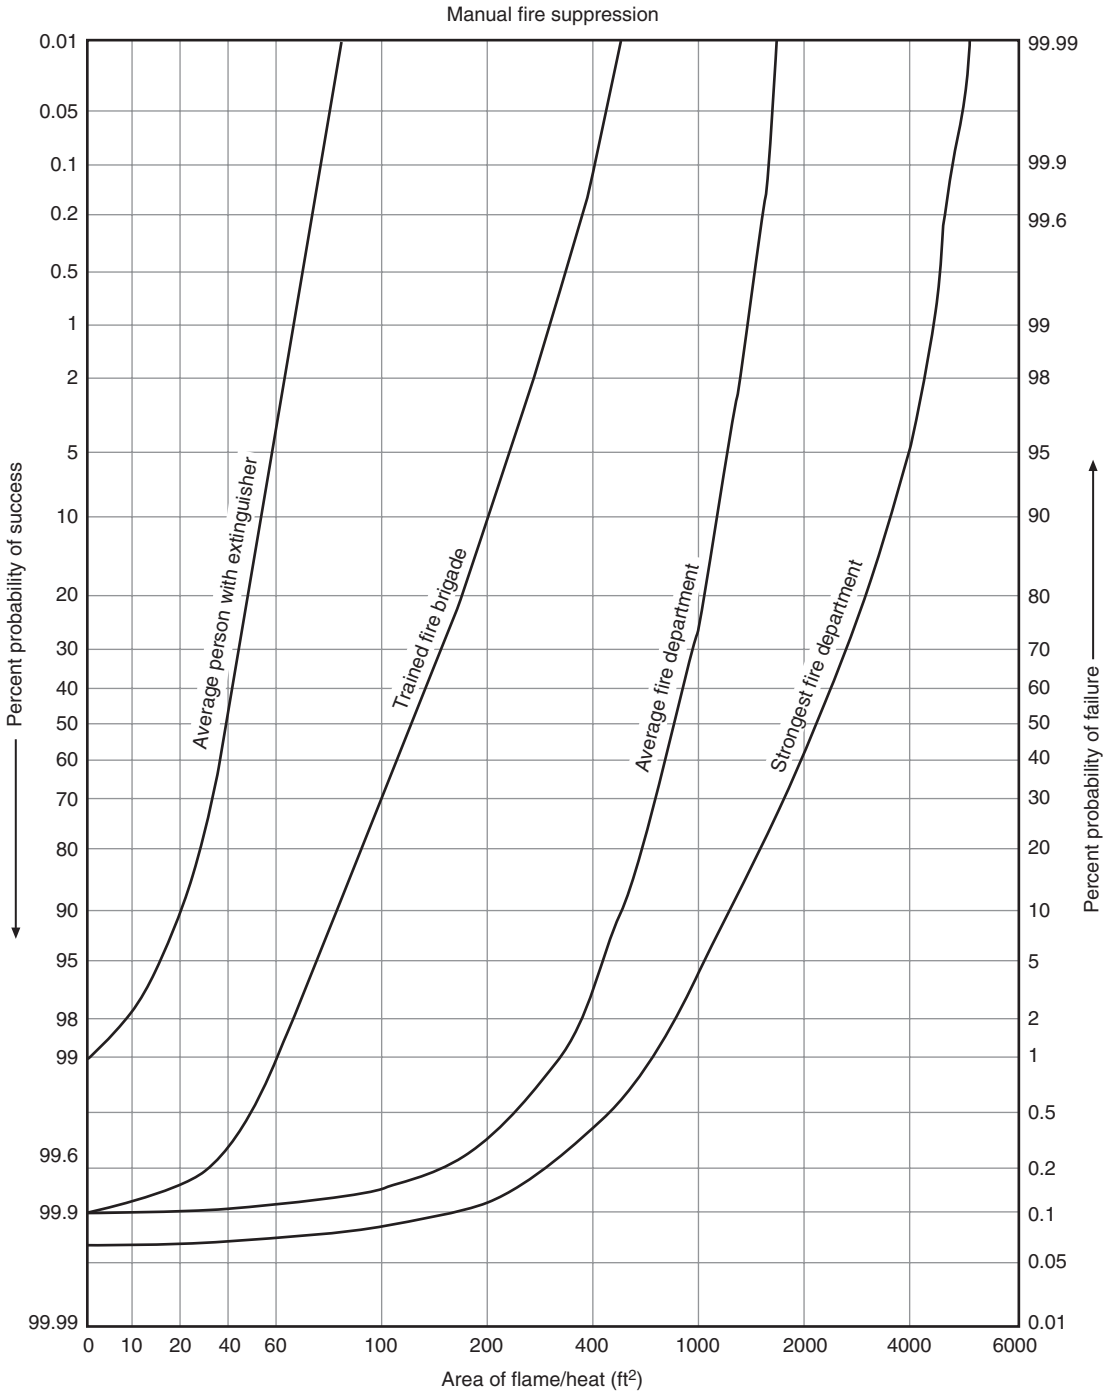

FIGURE 20.17.3 Illustrative Graph of Probability of Success at Different Levels of Manual Extinguishment

use of high-density compact storage modules on lower floors and in basements has magnified this problem in recent years. Compact movable storage modules for libraries significantly increase floor load requirements, and, especially in retrofits, only the ground floor or basement of a building has sufficient floor loading capacity. This concentrates collections in a building's lowest areas, so fighting a fire on an upper floor, or on the roof, can result in significant water damage.

Alternatives to the standard wet-pipe sprinkler system, such as on/off sprinklers and automatic recycling systems, minimize water damage after a fire has been extinguished.

Another alternative, the preaction sprinkler system, may be used where fear of water damage from damaged sprinklers or broken piping is a significant concern. The preaction sprinkler system piping is dry until a signal from an automatic fire detection system opens the water supply valve. Failure of the fire

detection system, however, eliminates the automatic operation of a preaction sprinkler system and requires manual operation of the water supply valve. The fire detection system, then, is a single point of failure in a preaction system, reducing its reliability below that of a wet-pipe sprinkler system. Furthermore, preaction systems require higher levels of regular maintenance to preclude additional potential failure modes. This further reduces their reliability relative to wet-pipe systems. Higher installation and maintenance costs, and less reliability, are the trade-offs for any increased confidence that a preaction system is less likely to accidentally release water than a wet-pipe system. For reasons of reliability, maintainability, and cost, facility owners may elect to install wet-pipe sprinkler systems or even convert their preaction systems to wet pipe.

Corrosion damage in dry pipe and preaction sprinkler systems is emerging as a significant concern in museums and libraries. Oxidation caused by water trapped at low points in sprinkler piping, microbiologically influenced corrosion (MIC), or a combination thereof, can cause severe damage to pipe walls and joints in a relatively short time. Over the last 3 years, for example, one museum has replaced severely damaged systems in two of its buildings—one less than 10 years old and the other 20 years old. At a minimum, where such systems are installed, pipe interiors should be inspected regularly in accordance with NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems.*

Sprinkler systems retrofitted into operating cultural resource facilities can pose a problem when the system is initially charged with water. Final acceptance testing of a sprinkler system requires a 2-hour 200 psi (1034 kPa) hydrostatic test on all piping, fixtures, and sprinklers. Newly installed sprinkler systems can leak, at least a little, when the system is first charged. This is unacceptable where collections are still in place. One solution, used by the Office of the Architect of the U.S. Capitol in the installation of wet-pipe sprinkler systems in Library of Congress bookstacks, requires pneumatic testing of each system before proceeding with normally required hydrostatic testing.

Where sprinkler systems are used in special or high-value areas, those items especially vulnerable to water damage should be stored in cabinets, manuscript boxes, or other appropriate containers. This practice serves several purposes: (1) containerized materials are more difficult to ignite, (2) the containers not only shield contents from water spray in the event of sprinkler discharge but also from intrusion of water from other sources (for example, roof leaks, plumbing problems, etc.), and (3) containers protect contents from smoke damage.[21]

Since about 1970, a number of new and existing libraries and museums have installed automatic sprinkler systems to achieve fire safety objectives and to keep fire risk within manageable, and often insurable, limits. The reduction in insurance premiums can pay off the sprinkler system's installation cost in a few years.[22] Even if the presence of automatic sprinklers does not reduce insurance premiums, their presence may make the facility a more attractive and marketable risk. This can be a significant advantage in getting competitive bids on a facility's property insurance program. (See Section 16, Chapter 1, "Principles of Automatic Sprinkler System Performance," and Section 16, Chapter 2, "Automatic Sprinklers.")

Protection for Special Risks. Areas containing highly valuable or especially vulnerable collections or equipment, or areas essential for continuity of operations, may require a higher level of fire protection to minimize damage or to keep interruption of service within acceptable limits than the combination of a smoke detection system with automatic sprinklers can provide.[22] NFPA 550, *Guide to the Fire Safety Concepts Tree,* is an excellent tool to help managers assess the effectiveness of fire protection strategies, such as installing special fire protection systems or other techniques to achieve higher protection levels within the limits of affordability.[23]

In devising protection strategies for special risks, particular attention should be given to passive fire protection, for example, using special fire- and water-resistant vaults, cabinets, manuscript boxes, or other containers to protect highly valuable collection items. Passive features may be less expensive to install and maintain and may, over time, be more reliable than more complicated alternatives. Nevertheless, relatively low levels of heat can destroy film and other heat-sensitive materials. Therefore, passive features are not a substitute for timely detection and suppression; rather, a combination of active and passive fire protection elements increases the likelihood that sensitive, highly valuable contents, furnishings, and finishes can survive a fire intact. (See Section 9, Chapter 8, "Protection of Records.")

Some items may be so valuable, rare, or vulnerable that their protection becomes one of the institution's highest priorities: the only acceptable level of loss is zero. When this is true, the institution may opt for a special protection system in addition to automatic sprinklers to provide nearly instantaneous response. Such special systems may include sophisticated air-sampling smoke detection, flame detectors, linear heat detectors, or other rapid-detection devices that automatically activate special fire suppression systems, using a gaseous agent or a water mist system. Everything else being equal, a fire in a space protected with a special protection system will be extinguished in the first seconds of combustion, thus limiting damage to the lowest possible level.

Unless it at least matches the automatic sprinkler system's reliability and maintainability, the special system installed for this purpose should be used in combination with, and not as a substitute for, the sprinkler system. The installation cost of a special system to augment a standard automatic sprinkler system should be justified based on the extraordinary value and/or irreplaceability of the items it protects or because it is required for continuity of operations that cannot accept any downtime, such as in the control room for the facility fire protection/security systems and building utilities. The justification should demonstrate a need for a very high probability of success in confining fire growth to an area significantly smaller than would be possible using standard automatic sprinklers alone—for example, less than 100 ft^2 (9.3 m^2). A sprinkler system is a vital backup to the special protection system, however, if the special system fails to extinguish the fire.

Halon 1301 often was used to provide this extra level of protection. Cultural institutions found it particularly attractive because it could be used in normally occupied areas, rapidly extinguished the flaming portion of fires, left no residue, and was not known to harm objects chemically or physically. The envi-

ronmental issues associated with halon 1301, however, have rendered its use impractical for the majority of applications. See Section 17, Chapter 6, "Halon and Halon Replacement Agents and Systems," for more information on halon 1301 and halon alternatives.

Water Mist. Water closely fits all requirements of the ideal fire suppression agent. It is safe for the environment and for people, it has excellent extinguishment properties, and it has the advantages of being both inexpensive and abundant. A relatively recent development in fire protection, water mist technology promises to provide all advantages of water with less subsidiary damage and much faster response. In addition, facilities in remote locations, where the cost of installing a water supply for a sprinkler system is prohibitive, may find that water mist systems with self-contained water supplies, or with relatively small water supply tanks, can provide cost-effective fire protection. For more information, see Section 16, Chapter 8, "Water Mist Fire Suppression Systems."

Other Special Hazards. Although the same fire safety principles are applicable to all cultural resource properties, several activities common to museums and some libraries require special attention. These include the following:

- Storing art and other valuable objects
- Packing and unpacking traveling exhibits
- Storing shipping crates and packing materials
- Cleaning and restoring art and other objects
- Constructing and renovating displays

Areas where these activities occur should be isolated and sprinklered. Good practice limits storage of combustible materials to the minimum required for the current exhibit(s) under preparation or being dismantled, with all other materials stored off-site.

Places of worship also house activities requiring special attention. These include the following:

- Storing combustible decorative materials used in services, lawn mowers, and other gasoline powered equipment, and candles
- Operating kitchen and cooking facilities
- Operating child-care and nursery facilities
- Operating temporary shelters for the homeless

These activities should be monitored carefully and the areas should be protected by an automatic fire suppression system. Storage should be controlled to limit the quantity of combustible materials, and all flammable materials or gasoline-powered equipment should be stored away from the structure.

CONSTRUCTION CONSIDERATIONS

Intrinsic design features should include fire safety aspects of site planning, fire-resistant construction, interior finish smoke control, water supply for fire protection, and special requirements for underground structures. Topics deserving special attention in this chapter are compartmentation, means of egress, lighting, and gallery flexibility.

Compartmentation

A well-protected building is subdivided into compartments where walls provide barriers to the spread of fire. Compartments should be as small as possible, and walls should be designed to resist the estimated fire duration, based on maximum fuel loads in the compartments. Where small fire compartments would restrict flexible use of space, the installation of automatic sprinkler systems permits larger compartment areas and compensates for heavy fuel loads in places like collection storage areas and bookstacks.

Smoke damages valuable contents and harms occupants. Fire barriers should confine smoke to the compartment of fire origin. Fire doors protecting openings in these walls must be self-closing or automatic-closing. Self-closing fire doors must never be propped open by wedges, "kick-down" doorstops, or other unapproved means. Where it may be necessary for efficient operations to hold open these doors, this may be done only where automatic devices, such as electromagnetic hold-open devices installed in compliance with NFPA *101,* and *NFPA 5000,* automatically release the door on a signal from a smoke detector or from the fire detection system. In the past, some building codes allowed fusible link assemblies to be used to hold doors open with automatic door closers. They are not acceptable for smoke control or life safety because they depend on heat at the door to release them. By the time the fusible link reaches its release temperature, the fire has already made the door opening unusable, and smoke, which precedes the fire, has already spread beyond the space.

High-hazard contents areas where large quantities of combustible material are used or stored should be separated by fire walls from areas with large exposure of people or sensitive, valuable contents, such as exhibit galleries, reading rooms, other public areas, bookstacks, and collection storage areas. These high-hazard contents areas include carpenter shops; display or exhibit preparation shops; research, restoration, and conservation laboratories; paint rooms; packing rooms; and restaurant kitchens, among other places. When possible, hazardous materials such as flammable liquids, including some paints, should be housed in a structure separate from the building. Fire barrier walls protecting high-hazard areas should be designed to withstand fires involving the maximum fuel loads they will enclose rather than the minimum building code requirements.

Means of Egress

Library and museum security arrangements commonly require all patrons and employees to enter and leave the building at one or two closely monitored points. Unfortunately, this often means that other doors required by NFPA *101* and *NFPA 5000* for exit access or egress are locked. This problem most often arises in museums and libraries with valuable collections and in libraries with heavily used reference collections, such as college and university libraries. Use of electromagnetic and electromechanical door locking systems is gaining acceptance as a way to resolve this conflict between life safety and security. Such systems should include features that provide a level of life safety equivalent to that NFPA *101* and *NFPA 5000* require.

NFPA *101* and *NFPA 5000* allow delayed release locks, with strict limitations, in assembly occupancies, provided automatic sprinklers or fire detectors protect the entire building. Also see NFPA 909 and NFPA 914. Places of worship typically lack the need for such close monitoring and may not limit the number of points of entry.

Attendance in exhibition galleries and reading rooms varies with the exhibit's popularity and the season. For example, a blockbuster museum exhibit draws thousands of visitors each day. Places of worship will see peak attendance in conjunction with religious holidays and certain events, such as weddings. During periods of high attendance, museums and libraries must control occupant loading of the building to ensure egress capacity is not exceeded.[24] Particularly at peak times, a complete emergency plan and a well-trained staff are critical. Staff must take the lead in helping visitors evacuate safely, especially those with disabilities that might make emergency evacuation difficult. As mentioned previously in this chapter, the use of voice communications should be considered for large facilities or those with high attendance or complex egress paths. Voice communications facilitate coordination and reduce occupants' fears and anxieties during evacuation.

Lighting

Art museums typically use as much natural light as possible. They often have features such as glass roofs, light-diffusing glass ceilings, and window walls, which all increase the museum's vulnerability to fire exposure. Conversely, to protect collections from ultraviolet radiation and achieve complete light control, some museums have minimal wall and roof openings. Complex wiring systems carrying unusually heavy electrical loads compensate for the absence of natural light in these buildings. In addition to general area lighting, museums use independent light sources for case and exhibit lighting. Therefore, museums need numerous electrical outlets in floors, walls, and ceilings to provide flexibility for frequent exhibit changes and to avoid dangerous use of extension cords. Electrical installations should comply with NFPA 70.

Gallery Flexibility

Movable walls, temporary furring, and lightweight partitions facilitate rearranging exhibit spaces and changing exhibits. Such features, however, should not be allowed to impede occupants' movement in an emergency, nor should materials used increase fire risk by adding significant quantities of combustible material to the building's fuel load.

FIRE EMERGENCY MANAGEMENT

Managing a cultural resource facility fire involves decisions and actions necessary to mitigate the consequences before, during, and immediately following an incident. Effective management includes continuous monitoring to ensure that fire protection systems and features are always operational and never degraded or defeated by space changes or other building modifications. This also includes providing emergency electric power to support emergency lighting, communications, security systems, and fire protection systems. (See Section 10, Chapter 1, "Emergency and Standby Power Supplies.")

At a minimum, a viable fire emergency plan should provide for planning with the fire department and pre-emergency training of all building staff in evacuation and salvage operations. (See Section 12, Chapter 18, "Pre-Incident Planning for Emergency Response.") The decision to establish fire brigades should depend on whether the building(s) are close enough to a municipal or county fire department for timely response and whether employees are expected to use portable fire extinguishers and standpipe hose lines. In deciding whether to require employees to use fire-fighting equipment, management must be prepared to comply with state and federal regulations for protective clothing, training, and maintenance of fire-fighting equipment.[25] (See Section 12, Chapter 9, "Fire and Emergency Services Protective Clothing and Protective Equipment.") In addition to safety considerations, emphasis should be placed on minimizing water damage and protecting or removing endangered, highly valuable collections. Prefire planning also must provide security for valuable materials after their removal from the building.

DAMAGE LIMITATION

Using freeze/vacuum drying techniques, library preservation specialists have been successful in limiting damage to water-soaked library, archival, and other collection materials. However, water is only one hazard to which collections are vulnerable during a fire. Others include smoke, acids contained in combustion products, and chemical agents used in fire fighting. These hazards perhaps endanger museum collections more than water.

Damage Limitation in Places of Worship and Museums

With much higher values per item and fewer items than libraries, museums and places of worship must concentrate damage limitation efforts on removing endangered collections from the fire area to a safe location as quickly and carefully as possible. Conservation-oriented fire-fighting strategies and techniques enhance salvage efforts and minimize collection losses.

The Winterthur Museum in Wilmington, Delaware, has developed fire-fighting techniques that other museums and libraries might adopt.[26,27] Fire-fighting efforts are divided into three concurrent phases that the fire marshal and staff direct: (1) collection protection and damage limitation operations, led by the housekeeping supervisor and staff; (2) security for collections removed from the fire area, which is the responsibility of the security supervisor and staff; and (3) overall coordination, provided by the building superintendent or a designee.

Damage Limitation in Libraries

The success and cost of limiting damage in water-soaked library collections depend on advance planning and how wet the materials are. Freeze/vacuum drying very effectively removes water and smoke odors, while using ethylene oxide, a sterilizing agent, during the process arrests the mold growth. Freeze/vacuum dry-

ing cannot, however, restore physical damage inflicted by hose streams, trampling, or mishandling.

Before the Fire. Planning for damage limitation efforts before a fire must include the following:

1. Establishing priorities. This facilitates decision making under emergency conditions by identifying, in advance, the items or collections to save first.
2. Identifying preservation specialists who can provide needed guidance
3. Identifying sources of materials, equipment, and facilities to support damage limitation that are available on short notice
4. Organizing and training employees who will be needed in the damage limitation effort during and after the fire
5. Orienting and training the fire service to understand where vulnerable or especially valuable collections or objects are stored. The fire department should prepare a prefire plan that takes these factors into account and provides ongoing damage limitation during fire suppression operations.

During the Fire. Damage limitation efforts during the fire include:

1. Removing endangered highly valued collections if this can be done without placing staff at risk. Where this is not possible, the fire service may perform this function with guidance.
2. Using tarpaulins or plastic sheeting to protect materials that remain in or near the fire area, but are not directly involved in the fire, from water. Here, too, staff must be alert to hazards and must not place themselves at risk to save objects. A well-developed fire department prefire plan will include provisions to accomplish these objectives.

After the Fire. Damage limitation efforts after the fire include:

1. Wrapping and freezing damaged articles
2. Obtaining guidance from a preservation specialist experienced in damage limitation
3. Determining appropriate restoration procedures

Much less damage limitation and restoration work should be needed in facilities protected by automatic sprinklers. Water absorption is minimized when materials are left on shelves undisturbed by the gentler action of automatic sprinklers, as opposed to hose streams' more forceful action. An automatic sprinkler system also greatly reduces the quantity of materials requiring restoration by limiting the size of the fire area to that covered by the operation of one or just a few sprinklers.[28]

FIRE SAFETY IMPLICATIONS OF AUTOMATION AND NEW TECHNOLOGY

Automation of Library Catalogs and Museum Accession Records

Automation has replaced traditional card catalogs and paper museum accession records in most libraries. Continuity of public service increasingly depends on computers and necessitates a high level of fire protection including automatic suppression to ensure continuity of operation. Duplicates of magnetic media containing a library's computer-based catalog or a museum's accession records should be maintained in a safe, remote, offsite location.

Bookstacks

Multitier Bookstacks. Bookstacks, modeled after those developed for the U.S. Library of Congress in 1893, have been used for several decades in many libraries (Figure 20.17.4). Typically, unprotected iron or steel columns and beams at intervals of 7 ft (2.14 m) support decks or tiers. Vertical openings between decks permit heating of bookstack areas by convection or air currents. (See "Deck slit" in Figure 20.17.5.) Under fire conditions, these same openings function as flues to accelerate vertical fire spread to the tiers above.

Smoke barriers should be installed in these vertical openings, or deck slits, to facilitate smoke detection on the tier or deck of fire origin. This was not done when the smoke detection system was installed in the multitier bookstack of the Los Angeles Central Public Library because a ducted ventilation system had not been installed for bookstacks. When an arsonist set a fire on the fifth tier, the first detectors to activate were on the sixth tier, one tier above the tier of fire origin. A delay in finding the fire resulted, and occupants lost the opportunity to stop the fire with portable extinguishers while it was small, with catastrophic results.[29] It took nearly 350 fire fighters and over 70 pieces of fire apparatus 7 hours to extinguish the ensuing inferno.[30]

Modern versions of these systems are still sold but without vertical openings in the modules (Figure 20.17.6). Unprotected steel support structures are vulnerable to collapse in a fire, however. Cast iron and steel structural members lose strength at high temperatures encountered in fires and may collapse. For this reason, the fire service may not be able to enter a multitier bookstack for manual fire suppression. This also applies to any variation on this bookstack design that uses exposed steel structural elements. Because it may be impossible for the fire service to provide manual fire suppression in bookstacks of this or similar design, it is essential that the bookstacks be equipped with automatic fire suppression systems to defend against fire.

In new library construction, multitier bookstacks replace freestanding bookstack ranges installed on structural fire-resistant floors. The difference in fuel load between multitier stacks and freestanding stacks is substantial. All levels in a multitier system are usually considered as one fire compartment, due to the absence of vertical fire barriers between tiers. Fire loads depend on the number of tiers in the bookstack. With shelf loading at 70 percent of capacity, the expected fire load in each tier would be 55 to 65 lb/ft^2 (268 to 317 kg/m^2). Thus, for a multitier bookstack with 10 tiers in a single fire compartment, fire duration is estimated at 70 to 85 hours. Conversely, a fire in a free-standing bookstack that is seven shelves high and set on a fire-resistant floor, would be limited to a single tier and a fire duration of 7 to 8 hours.

Compact Storage or Track Files. Bookstack shelving units, or ranges, mounted on carriages that roll on tracks are common in

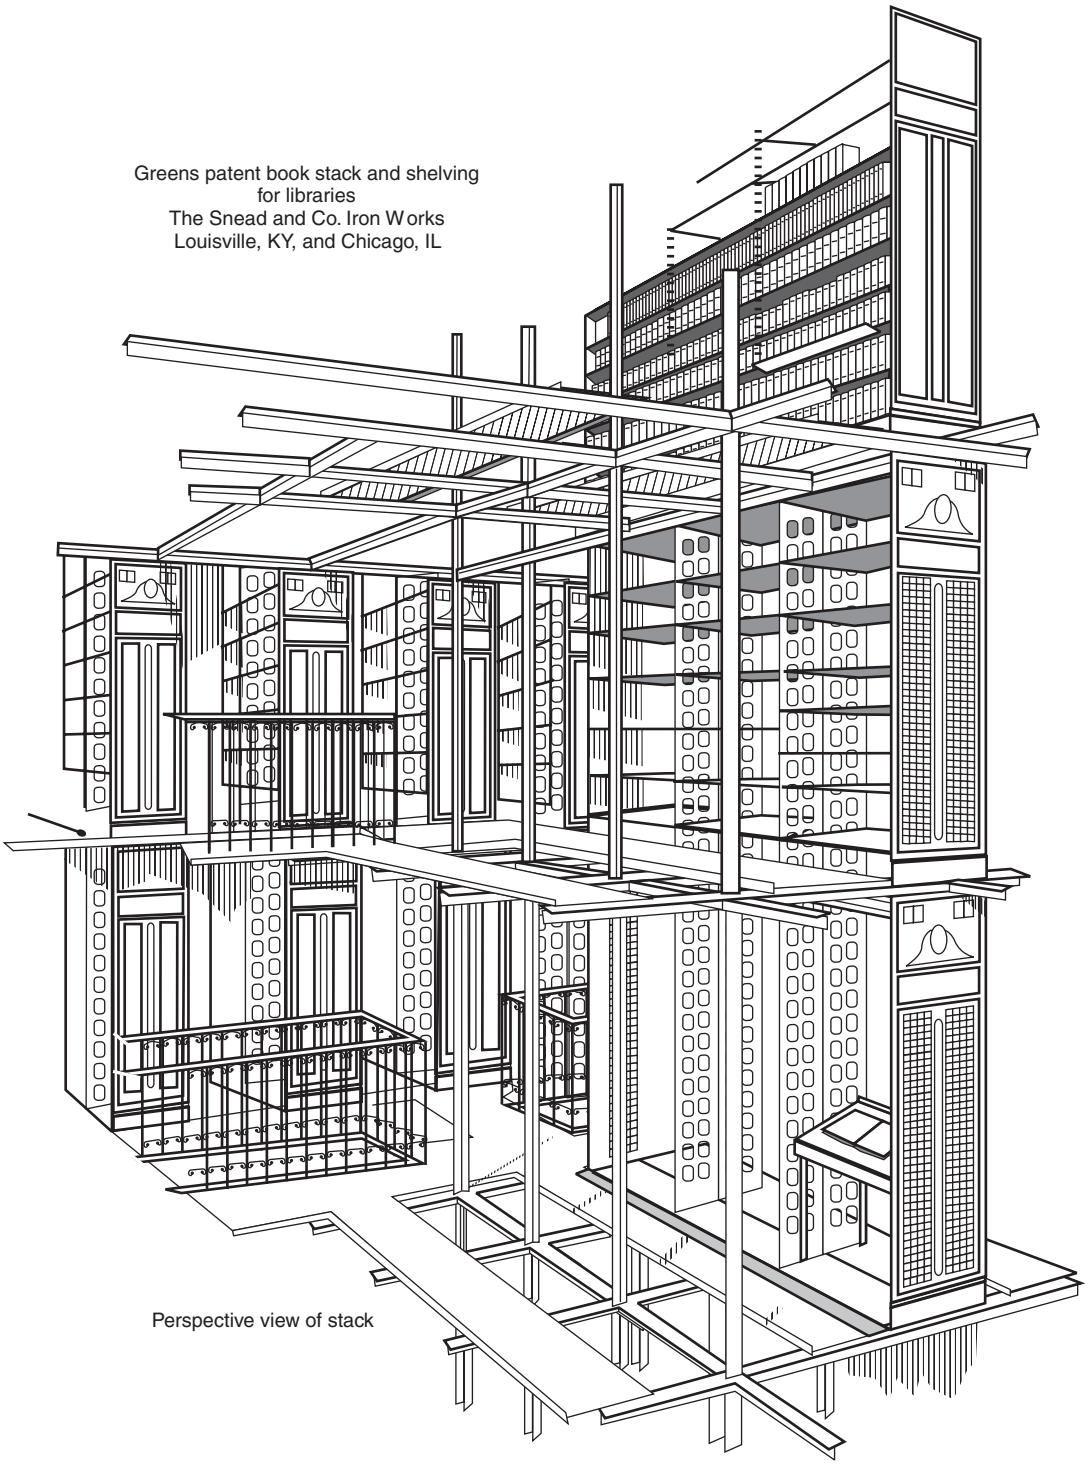

FIGURE 20.17.4 Multitier Bookstack as Installed in the Library of Congress, Circa 1893

new library and museum construction and in renovations. In this space-saving storage system, one moving aisle serves several ranges. The track systems are modular, with two or more mobile ranges between two fixed-end ranges in each module (Figure 20.17.7). This storage method can create fire loads exceeding 120 lb/ft^2 (586 kg/m^2) and fire durations exceeding 15 hours. This is more than enough to challenge the most fire-resistant barriers and construction prescribed by building and fire codes.

The NFPA Technical Committee on Protection of Cultural Resources recommends automatic sprinkler protection for compact storage installations. Without such protection, a fire in a facility with this type of storage system endangers not only the

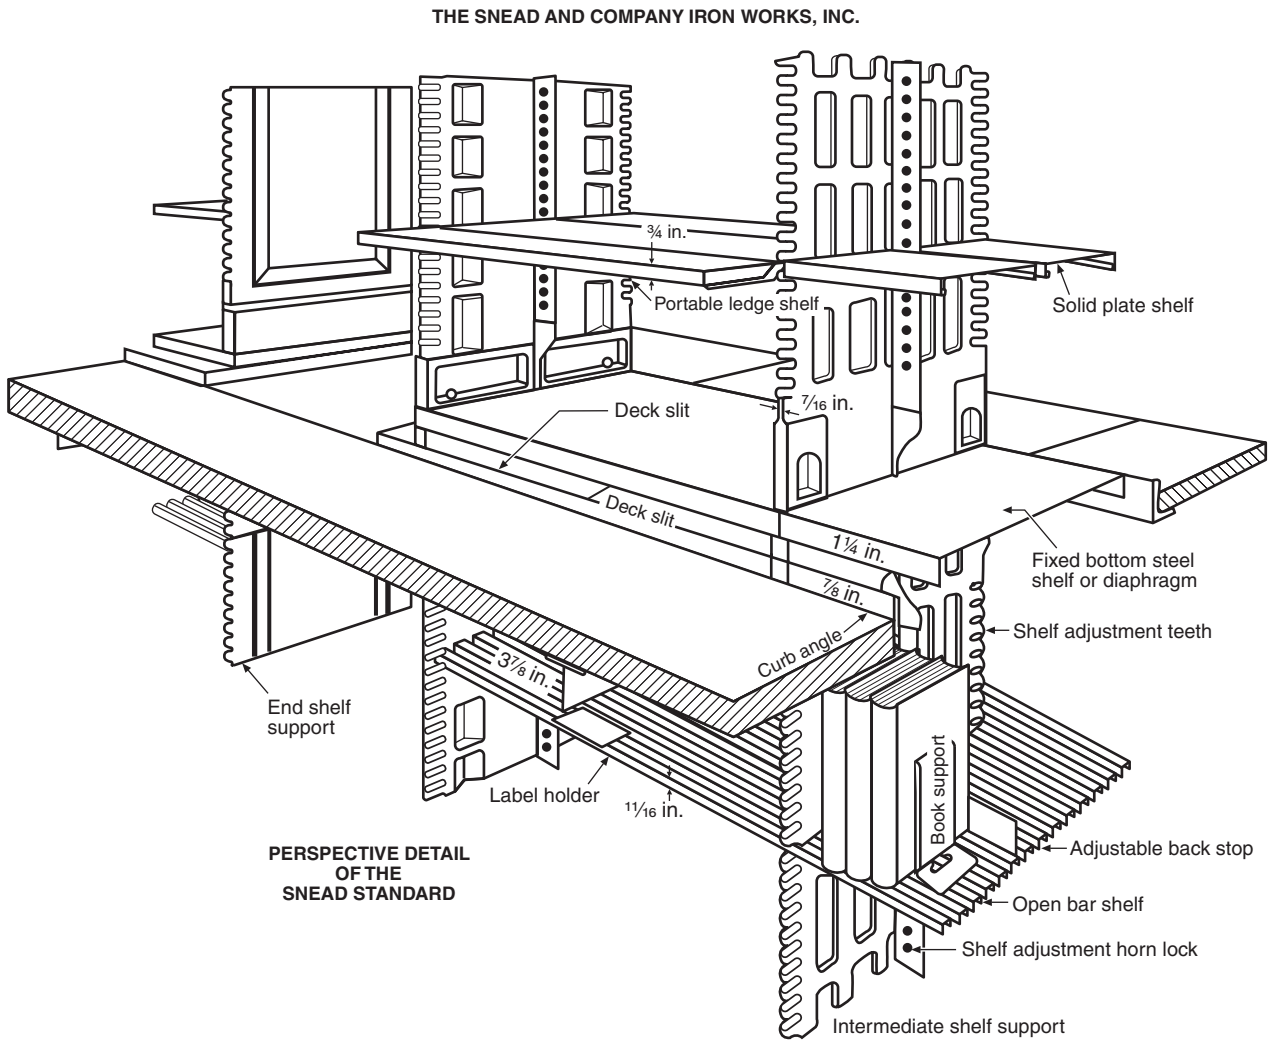

FIGURE 20.17.5 Multitier Bookstack—Showing Section Through Deck Flooring, Deck Slit, Fixed Bottom Shelf, and Adjustable Shelves

collection, but may cause severe structural failures and perhaps building collapse as well. An independent analysis[31] of fire tests conducted to evaluate sprinklers' effectiveness on a compact storage system[32] concluded that sprinklers, installed over a compact storage module, will most probably prevent a fire that originates in the module from damaging building structural elements outside the module. Furthermore, the tests showed (1) there is a good probability that sprinklers will prevent fire spread across 4 ft (1.22 m) aisles between compact storage modules, and (2) sprinklers may effectively prevent fire spread between back-to-back shelves of adjacent modules when a sheet metal panel with a 1 in. (25 mm) air space between adjacent panels backs each shelf. Thus, automatic sprinklers can be expected to limit fire development to that portion of the module of fire origin between the fixed-end range and the open aisle. Nevertheless, total loss of contents within that portion of the storage module is possible (see Figure 20.17.7).

Facility designers must carefully consider the following points in designing compact storage systems:

1. More efficient use of space results in greater density or concentration of values. That is, it increases the number of items subject to fire damage per unit volume of storage space. This risk should be considered in determining the maximum number of ranges to include in each module.
2. Existing automatic fire detection and fire suppression systems may have to be modified, and gaseous agents may be ineffective. In an existing facility with sprinkler protection where compact storage systems are retrofitted, particular attention must be given to water density, ceiling clearances, and structural features of the space. Tests conducted for the National Library of Canada clearly showed that for compact storage systems installed where "explicit compliance with current installation standards" is not possible, it may be necessary to go well beyond normal sprinkler design criteria to achieve adequate protection.[33]
3. Compact storage modules may conceal the origin of smoke, thereby compounding the difficulty in locating and extinguishing a fire.

FIGURE 20.17.6 Modern Multitier Bookstack Installation

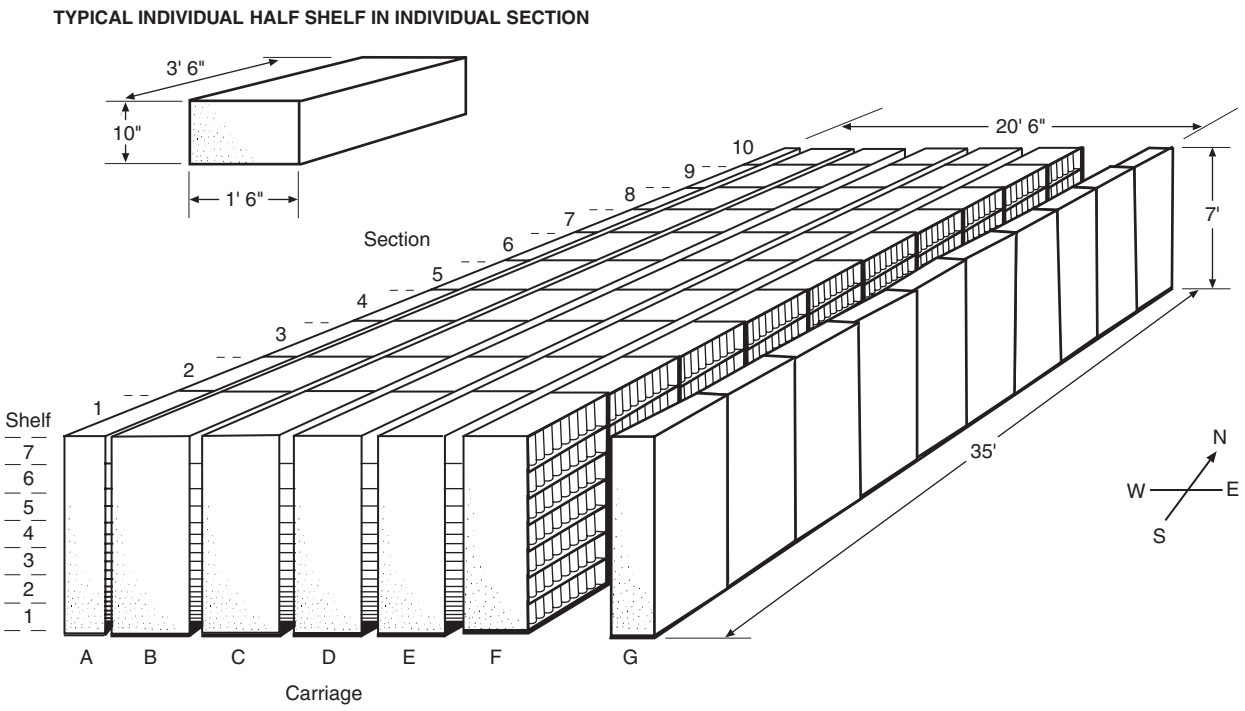

FIGURE 20.17.7 Compact Mobile Shelving

4. Compact storage modules prevent penetration of water from hose streams for fire extinguishment and delay detection by trapping smoke and heat. Consider designing the system so that ranges can be parked with a 5 in. (12.7 cm) gap between them during inactive storage periods. Underwriters Laboratories tested this arrangement with satisfactory results for the U.S. National Archives and Records Administration using quick response sprinklers. Paper record loss was limited to 10 ft^3 (0.28 m^3) and computer record loss to 3 ft^3 (0.08 m^3).[34]
5. Water mist fire suppression test results in bookstack scenarios show promise for special application to the burrowing fire problem in compact storage. It may be possible to design water mist systems for compact storage that limit fire and water damage loss even more effectively than the sprinkler system design tested for the U.S. National Archives and Records Administration.[34]
6. Bookstack ranges may be moved electrically or manually. In compact storage systems that are moved electrically, the electric motor in each bookstack range is a potential ignition source.

FIRE PROTECTION DECISIONS

The elapsed time between a fire's discovery and the beginning of effective manual suppression can easily be too long to prevent unacceptable loss, especially when the building is unoccupied. Faced with this reality, directors of museums and libraries and their governing bodies are deciding to incorporate automatic fire suppression systems as the primary defense against fire loss.

In a 1989 survey of museums of various sizes, including 30 of the largest in the United States, 77 percent reported that they use automatic sprinkler protection.[16] The list of museums that made this decision includes the 15 Smithsonian museums: National Air and Space Museum, National Museum of American History, National Museum of Natural History, National Portrait Gallery, the Sackler Gallery, National Museum of African Art, National Museum of the American Indian, and so on. It also includes the J. Paul Getty Museum, the High Museum of Art in Atlanta, the Phillips Gallery in Washington, DC, and the Dewitt Wallace Museum and Abby Aldrich Rockefeller Folk Art Museum in Williamsburg, Virginia, to name a few.

Similarly, the list of libraries, large and small, equipped to defend their collections against fire loss by installing automatic sprinkler systems continues to grow. Examples include city libraries in Atlanta; Dallas; Houston; Los Angeles; Portland, Maine; and Portland, Oregon, as well as many academic libraries, the State Library of Michigan, and national libraries, such as the Saudi Arabian National Library, the U.S. Library of Congress, the National Library of Canada, and the National Library of Scotland, and the British Library at St. Pancras.[35]

NFPA 909 and other chapters of this handbook provide guidance for procuring, installing, testing, and maintaining fire protection systems.

HISTORIC BUILDINGS AND SITES

Historic buildings house museums, places of worship, office buildings, residences, schools, libraries, restaurants, hotels, restaurants—to name a few. Historic sites include structures as small as covered bridges or as large as entire communities. Historic buildings and sites are often off the beaten path and at a considerable distance from organized fire-fighting services. Often it is as important to protect the structure of a historic building or site as it is to protect the contents. Fire can damage decorative architectural features quickly and burned historic building fabric is lost forever.

Life safety issues in historic buildings may be complicated as well. Historic structures may contain highly combustible structural materials and finishes, and means of egress may be inadequate by today's standards. Fire develops and spreads rapidly via open stairways or where fire and smoke barriers and other smoke and fire control features are absent.[36,37] Historic buildings may not have modern exit signs and emergency lighting, which may cause confusion in an emergency. Building managers must control the occupant load and have a well-developed evacuation plan where such conditions exist.[36]

Historic Building Fires

Fire service reports classify buildings by occupancy type, so data on the frequency or causes of fires in historic buildings are incomplete. Those that are coded as historic buildings experienced 35 U.S. structure fires per year reported to local fire departments from 1994 to 1998. Nevertheless, where data are available, the reported fire causes, in order of 1994–1998 frequency, are arson; electrical distribution equipment, such as fixed wiring; heating equipment; natural causes, such as lightning; cooking equipment; smoking; appliances; open flame; children playing; and exposure from newly burning structures, grass, and woodlands.[36,37] Historic buildings often contain outdated mechanical and electrical systems, and many historic building museums use candles, fireplaces, forges, stoves and other open-flame devices as interpretive aids.

Fire can grow and spread in historic buildings because of inadequate barriers, absence of sprinklers or other means of automatic protection, and delayed discovery and reporting of the fire. The first few minutes after ignition can be critical, particularly in historic buildings of combustible construction. Absence of automatic fire detection or other automatic protection leaves discovery of a fire to a night guard or to chance. Historic buildings require painstaking attention to details to preserve historic authenticity, but experience shows that it is possible to provide appropriate levels of fire protection for the structure and safety for staff and visitors while maintaining original construction or historical appearance.[38,39]

Historic Building Fire Safety

Each historic building or site is unique and the planner must address merits and problems individually. A fire protection plan that systematically achieves fire safety goals includes compartmentation, structural analysis, alarm and communications, means of egress, smoke control, fire suppression, water supply, ignition prevention, fuel control, and impact on authenticity.[38] Managing a historic building for fire safety includes the following:

- Examining the physical conditions and developing a fire defense plan

- Incorporating automatic detection and alarm or fixed extinguishing systems or both
- Providing or having available a trained, properly equipped fire-fighting and salvage organization
- Instituting management and operational practices that eliminate causes of fire, and promoting organized training of personnel so they act effectively when called on

Other Considerations

Chimneys. Flues should be examined for deteriorated mortar joints that may permit sparks or excessive heat to pass into wood framing or other combustible material. Chimneys should be lined and repointed before they are used. If the condition of a flue is questionable or if it cannot be repaired without seriously affecting the building structure around the chimney, then it should not be used.

Electrical Service. Electrical wiring should be approved. Old wiring systems may include deteriorated materials, fittings, and connections that do not meet current codes. A licensed electrician or engineer should inspect and evaluate electrical circuits and wiring. Inadequate or unsafe components should be replaced, and fuses and circuit breakers should be labeled to indicate the areas they control.

Exposure Fires. The fire safety plan should consider exposure of the structure to outside fires. Structures in or adjacent to forests or tall grass must have fire lanes and cleared areas to protect the property from a forest or grass fire. Other nearby structures may present an exposure fire threat where insufficient clear space exists to reduce fire spread from one structure to another. If the historic building is wood frame construction, fire-resistive roofing and siding may help protect it, although eaves, cornices, and windows may still be exposed. Strategically located exterior sprinklers at window openings, along combustible cornices and walls, and on combustible roofs provide protection. See Figure 20.17.8 for an example of automatic sprinklers utilized for exposure fire protection. Fire doors or fire shutters that automatically close in a fire can protect openings in brick and masonry walls. Careful architectural planning can minimize the impact of these protective devices on the historic fabric or appearance of the structure.

Open Flames. Historic building museums use fireplaces and stoves for cooking and heating and to create the desired atmosphere and often use candles and lamps—oil, gas, and kerosene—for illumination. Any flame is a potential ignition source that must be safeguarded and monitored.

Housekeeping. Good housekeeping is a vital element in fire prevention. Clutter and waste invite fire. Rubbish and trash should be removed regularly and exterior housekeeping should be monitored. Debris, tall grass, brush, and fallen leaves that can cause fire to spread should be removed.

Fire Suppression. Even small communities usually have a fire department. However, if the structure is isolated or distant from a fire station, on-site emergency equipment and personnel training for its operation are prudent. The fire service must know the location of hydrants or alternative sources of water such as streams, rivers, ponds, or cisterns if hydrants are not available and must carefully plan how to use alternative sources effectively. It may be prudent to install a dry hydrant with the supply line beneath the frost line so the fire department can use an alternate water source.

FIGURE 20.17.8 Typical Sprinkler Protection for Exposure Fires

Performance-Based Design

Designing fire protection systems in historic buildings requires imagination and innovation to minimize the intrusion on authenticity. A team that includes a fire safety professional with experience in protecting historic buildings, preservation specialists, the building owner or manager, and the authority having jurisdiction should evaluate the building and consider acceptable alternatives. The planning team may conclude that traditional codes and standards do not provide practical solutions to correcting the fire protection deficiencies. To meet this challenge, NFPA 914 contains performance-based alternatives for solving fire protection problems in historic buildings. NFPA 914 provides a road map, written in code language, for designers developing performance-based alternatives that may be acceptable to the authority having jurisdiction. It also includes provisions to include management operating systems as acceptable elements of the overall fire safety system.

SUMMARY

Places of worship, libraries, and museums are mixed-use occupancies that present unique fire protection challenges. Although the public areas of these cultural resource properties usually have low fuel loads and high standards of housekeeping, these

areas do suffer costly fires. Fire prevention in cultural resource properties is the first line of defense against fire. Early detection and quick action to stop fire growth can prevent large fire losses. Useful fire protection features include a systems approach to fire safety and a specifically designed fire protection system. Construction considerations, such as compartmentation, means of egress, lighting, and gallery flexibility, must be considered in fire safety planning.

The effective fire emergency management of cultural resource facilities includes continuous monitoring of fire protection systems, providing emergency electric power to support fire protection systems, planning with the local fire department, and prefire training of all building staff.

Chapter 18

Industrial Occupancies

David P. Demers

Chapter Contents

Loss History
Hazard Assessment and Evaluation
Building Construction
Occupant Characteristics
Fire Protection Features
NFPA *101* and *NFPA 5000*
Prefire Planning

Key Terms

computer fire models, general industrial occupancy, high-hazard industrial occupancy, industrial occupancy, industrial fire brigade, special-purpose industrial occupancy

Industrial occupancies encompass a broad spectrum of purposes. Some employ many people to work in a single building. Other facilities house large items of equipment but have very few employees. Industrial occupancies are generally divided into two categories: general-purpose industrial, which are low- and moderate-hazard facilities, and high-hazard facilities. Examples of industrial occupancies include factories, power plants, refineries, and laundries.

This chapter discusses the loss history of industrial occupancies; general risk assessment; occupancy and occupant characteristics; fire protection features available; NFPA *101*®, *Life Safety Code*®, and *NFPA 5000*®, *Building Construction and Safety Code*®, criteria; and prefire planning.

For additional information relevant to life safety in industrial occupancies, see Section 11, Chapter 5, "Control of Electrostatic Ignition Sources"; Section 18, Chapter 1, "Confinement of Fire in Buildings"; Section 18, Chapter 2, "Interior Finish"; and Section 20, Chapter 20, "Occupancies in Special Structures." Explosion suppression devices are covered in Section 17, Chapter 8, "Explosion Prevention and Protection." Section 3, Chapter 5, "Introduction to Fire Modeling," provides information on computer fire models.

LOSS HISTORY

Industrial and manufacturing facilities experienced 11,400 structure fires reported to U.S. local fire departments in 2002, with associated losses of 11 civilian deaths, 342 civilian injuries, and $774 million in direct property damage.[1] The number of fires declined more than 73 percent from 1980, whereas civilian deaths declined by 50 percent (Table 20.18.1 and Figure 20.18.1). The variety of industrial and manufacturing activities is reflected in the loss history (Table 20.18.2), although certain activities stand out with larger shares of the fire problem.

Of the 25 costliest U.S. fires and explosions in history (as of the end of 2002), after adjusting for inflation, nine involved industrial or manufacturing facilities, and all but two of those occurred in the last decade and a half of the twentieth century—a 1989 Texas polyolefin plant fire (number 5 costliest of all time), a 1999 Michigan automobile manufacturing complex power plant fire (number 9), a 1995 Massachusetts textile mill fire (number 11), a 1947 Texas ship and chemical plant fire (number 13), a 1988 Louisiana petroleum refinery fire (number 14), a 1987 Texas chemical plant fire (number 21), a 1975 Alabama nuclear power plant fire (number 22), and a 1999 Louisiana aluminum plant fire (number 24).

The same 1989 Texas polyolefin plant fire and a 1991 North Carolina chicken processing plant fire are the most recent examples of the continued potential for major life loss in these facilities, as more than 20 people died in each incident.[2]

However, the deadliest recent industrial fire in the world by far occurred in a toy factory in Thailand in 1992.[3] That fire killed 188 workers, surpassing the death toll of 145 in the Triangle Shirtwaist Company fire of 1911, which is still the deadliest manufacturing plant incident not involving an explosion in U.S. history.

Another fire, this one in 1992 in China, occurred in a doll factory and took the lives of 81 occupants.[4] These and other less deadly incidents around the world underline the need for a higher standard of global industrial fire safety. Setting that standard starts with recognizing the many ways

David P. Demers, P.E., is president of Demers Associates, Inc., a fire protection consulting firm in Lunenburg, Massachusetts, and deputy chief of the Lunenburg Fire Department.

TABLE 20.18.1 Structure Fires in Industrial and Manufacturing Properties by Year, 1980–2002

Year	Fires	Civilian Deaths	Civilian Injuries	Direct Property Damage (in Millions of Dollars) As Reported	Direct Property Damage (in Millions of Dollars) In 2002 Dollars
1980	42,100	21	775	609	1331
1981	39,000	31	1322	659	1302
1982	35,000	50	1118	450	837
1983	29,900	51	1091	727	1312
1984	30,400	88	853	804	1389
1985	30,900	37	779	569	950
1986	26,400	24	821	516	847
1987	25,800	44	991	542	858
1988	24,100	30	847	676	1028
1989	21,700	60	783	1796	2606
1990	18,700	79	830	689	949
1991	18,300	21	641	647	854
1992	17,500	11	545	539	691
1993	16,400	13	893	566	705
1994	18,000	16	648	567	689
1995	16,300	32	587	1254	1479
1996	16,500	8	540	786	902
1997	17,800	16	485	709	795
1998	16,100	20	520	632	698
1999	17,200	29	609	1116	1204
2000	14,000	9	566	688	719
2001	12,700	17	321	846	859
2002	11,400	11	342	774	774

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest hundred, civilian deaths and injuries are rounded to the nearest one, and direct property damage is rounded to the nearest million dollars.

in which serious fires can occur in industrial and manufacturing facilities. Table 20.18.3 shows the cause patterns for fires and associated property damage in industrial and manufacturing properties. The wide variety of potentially hazardous industrial and manufacturing process is clearly reflected in these figures, but so are more familiar hazards associated with heating, electrical service, arson, and smoking. Although the process or manufacturing area that defines the facility's activity and purpose is the leading area of fire origin, most fires and losses occur in fires that began somewhere else (Table 20.18.4).

Even when they occur, industrial fires need not be deadly and need not be costly. Many factors typically contributed to turn an industrial fire into a major loss of life or property. One common factor is the lack of functioning fire suppression systems in a structure. From 1994 to 1998, 59 percent of reported structure fires in industrial and manufacturing facilities were in properties without sprinklers. When sprinklers were present, the chances of dying were 30 percent lower and the average loss per fire was 66 percent lower.[1]

A factor that has contributed to large loss fires in sprinklered industrial occupancies is a change in the hazard for which the sprinkler systems were originally designed. When the hazard or fuel load changes, suppression systems need to be re-evaluated. Yet another factor is improperly designed egress systems. Unfortunately, locked exits still contribute to fatalities. Locked and blocked exits contributed to the 25 deaths in the 1991 North Carolina chicken processing plant fire. An important cause of the loss of life in the 1992 Thailand toy factory fire was inadequate exit arrangements. It is only one example of how major industrial fires tend to involve a failure to follow well-established fire safety requirements. NFPA *101* and *NFPA 5000* provide requirements for designing appropriate egress systems.

HAZARD ASSESSMENT AND EVALUATION

To provide adequate life safety for an industrial occupancy, the relative degree of fire and life safety risk must be evaluated. Since the industrial classification is so broad, the hazards involved vary greatly. The first concern is the amount of time available for evacuation. Both the contents of the building and the interior construction affect this, as well as the materials of the building itself if they contribute to the fire during occupant evacuation. Examples of items to consider are interior finish, rate of fire spread, burn rate, toxic fume evolvement, potential ignition sources, fuel load, and smoke generated. After employees evacuate, the problem becomes one of property protection.

Many resources exist to aid in hazard assessment. Examples include talking to plant operators, reviewing building blueprints, and so on. The NFPA codes contain valuable information on various hazards. Insurance companies and records of previous fires also provide useful information. Section 20, Chapter 1, "Assessing Life Safety in Buildings," describes methods for assessing life safety from fire in buildings.

Computer models can assist in assessing an occupancy's hazard. After determining the appropriate potential fire, a computer model can help predict the impact of fire on a facility. This is valuable in determining the possible time available for occupants to exit the area or facility before conditions become untenable. The ASET, FPETOOL, and CFAST models do this. (See Section 3, Chapter 5, "Introduction to Fire Modeling.") The assessment can be done in conjunction with egress analysis. Required safe egress time is a model to analyze egress. Combined models can evaluate whether there is sufficient time for the occupants to exit before conditions become untenable. This particular method of assessing hazard and evaluating life safety is common practice in code-enforcement systems that accept performance-based designs.

Because explosions are probably the most destructive industrial accidents in terms of life and property loss, they require special attention. Flammable dust, vapor, mist, or gas presents an explosion hazard. A carefully designed system is needed to ensure life safety from explosive forces. Two primary ap-

TABLE 20.18.2 Structure Fires in Industrial and Manufacturing Facilities, 1999–2002 Annual Averages

Occupancy	*Fires*	*Civilian Deaths*	*Civilian Injuries*	*Direct Property Damage (in Millions of Dollars)*

Unclassified or unknown-type utility, defense, agriculture, or mining	400	1	5	13
Manufacturing or processing	10,500	7	382	571
Total	13,800	17	460	856

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest hundred, civilian deaths and injuries are rounded to the nearest one, and direct property damage is rounded to the nearest million dollars. Property damage has not been adjusted for inflation.

Source: NFIRS and NFPA survey.

proaches to the problem exist: prevent the explosion—obviously the better choice—and control the damage from the explosion. Specialized equipment designed to detect, suppress, and control damage from explosions is available. NFPA 69, *Standard on Explosion Prevention Systems,* provides additional information.

BUILDING CONSTRUCTION

NFPA *101* does not include construction requirements for industrial occupancies; however, *NFPA 5000* does. The varying types of industrial occupancies use many different types of construction. Smaller facilities might be constructed of unprotected wood, corresponding to Type V in NFPA 220, *Standard on Types of Building Construction,* and *NFPA 5000,* whereas larger buildings might be of fire-resistive construction, Type I. Additionally, buildings can range from totally enclosed high-rises and windowless buildings to open structures providing equipment protection from weather. The type of construction is generally based on local building codes for the type of use rather than on life safety concerns.

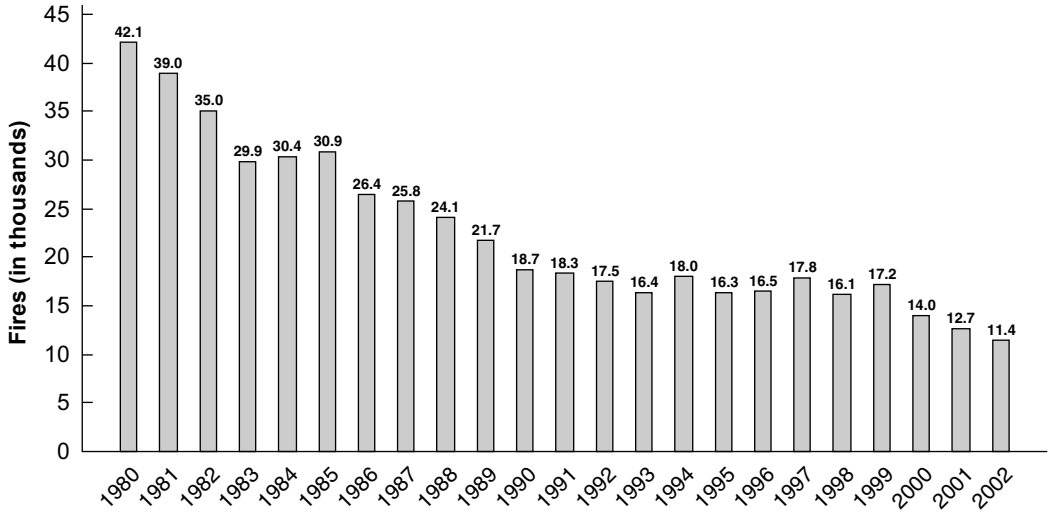

FIGURE 20.18.1 Structure Fires in Industrial and Manufacturing Properties by Year, 1980–2002 (Source: U.S. Fires in Selected Occupancies, NFPA, 2006)

TABLE 20.18.3 Leading Causes of Structure Fires in Industrial and Manufacturing Properties, 1999–2002 Annual Averages

Cause	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*	
Shop tools or industrial equipment, except torches	3500	(25%)	3	(19%)	192	(42%)	167	(20%)
Electrical distribution and lighting equipment	1400	(10%)	4	(25%)	33	(7%)	94	(11%)
Heating equipment fires	1400	(10%)	0	(0%)	30	(6%)	47	(5%)
Identified heating equipment	1000	(7%)	0	(0%)	23	(5%)	46	(5%)
Confined heating equipment fire	400	(3%)	0	(0%)	6	(1%)	2	(0%)
Torch (including burner or soldering iron)	1000	(7%)	1	(6%)	51	(11%)	53	(6%)
Intentional	700	(5%)	6	(36%)	14	(3%)	73	(9%)
Cooking equipment fires	500	(4%)	0	(0%)	11	(2%)	17	(2%)
Identified cooking equipment	400	(3%)	0	(0%)	10	(2%)	13	(2%)
Confined cooking fire	100	(1%)	0	(0%)	1	(0%)	4	(0%)
Smoking materials	500	(4%)	0	(0%)	13	(3%)	29	(3%)
Spontaneous combustion or chemical reaction	500	(4%)	0	(0%)	11	(2%)	38	(4%)
Exposure to other fire	400	(3%)	0	(0%)	3	(1%)	15	(2%)
Contained trash or rubbish fire	500	(3%)	0	(0%)	2	(0%)	0	(0%)

Note: These are the leading causes, obtained from the following list: intentional (from the NFIRS field "cause"); playing with fire (from factor contributing to ignition); confined heating (including confined chimney and confined fuel burner or boiler fires), confined cooking, and contained trash or rubbish (from incident type); identified heating, identified cooking, clothes dryer or washer, torch (including burner and soldering iron), electrical distribution and lighting equipment, medical equipment, and electronic, office, or entertainment equipment (from equipment involved in ignition); smoking materials, candles, lightning, and spontaneous combustion or chemical reaction (from heat source); and mobile property involved (from mobile property involved in ignition). The statistics on smoking materials and candles include a proportional share of fires in which the heat source was heat from an unclassified open flame or smoking material. Exposure fires include fires with an exposure number greater than zero, as well as fires identified by heat source or factor contributing to ignition when no equipment was involved in ignition and the fires were not intentionally set. Because contained trash or rubbish fires are a scenario without causal information, they are shown at the bottom of the table if they account for at least 2 percent of the fires. Casual information is not routinely collected for these incidents. The same fire can be listed under multiple causes, based on multiple data elements.

These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest hundred, civilian deaths and injuries are rounded to the nearest one, and direct property damage is rounded to the nearest million. Property damage has not been adjusted for inflation.

OCCUPANT CHARACTERISTICS

In general, occupants of an industrial facility are able-bodied adults. Statistically less at risk of injury from fire, they are ambulatory and capable of responding quickly to a fire. These occupants should be familiar with facility hazards and emergency exit locations. The likelihood also exists that employees in an industrial setting have received some emergency training. As density of the occupant load varies significantly, it must be considered in exit system design. Facilities employing many physically and mentally disabled people require supplemental prefire planning to ensure safe evacuation.

FIRE PROTECTION FEATURES

A primary life safety feature of an industrial occupancy should be an automatic sprinkler system. Originally developed as a property protection feature, it has proved effective in preventing loss of life. Automatic sprinklers mitigate the effects of fire, thereby allowing occupants sufficient time to evacuate the building. In addition, the sprinkler system waterflow alarm can alert building occupants of the fire earlier and thereby give them more time to react. Several sources have documented the effectiveness of sprinkler systems. The U.S. Department of Energy (DOE) reported on the effectiveness and reliability of the sprinkler systems protecting DOE facilities during the years 1952 to 1980.[5] Several conclusions resulted from the study:

- Sprinkler systems are over 98 percent effective in controlling or extinguishing fires.
- Considering only building fires, sprinklers reduce the loss by at least a factor of 5.
- About one-third of all fires may be completely extinguished with only one sprinkler head operating.

TABLE 20.18.4 Structure Fires in Industrial and Manufacturing Properties by Area of Origin, 1999–2002 Annual Averages

Area of Origin	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*	
Process or manufacturing area or workroom	2500	(18%)	3	(18%)	167	(36%)	182	(21%)
Machinery room or area or elevator machinery room	1300	(10%)	3	(19%)	52	(11%)	73	(9%)
Storage room, area, tank, or bin	600	(5%)	0	(0%)	14	(3%)	50	(6%)
Maintenance or paint shop area	600	(4%)	1	(3%)	27	(6%)	58	(7%)
Duct for HVAC, cable, exhaust, heating, or air conditioning	500	(3%)	0	(0%)	8	(2%)	13	(2%)
Unclassified equipment or service area	500	(3%)	1	(4%)	20	(4%)	37	(4%)
Unclassified area	400	(3%)	2	(11%)	10	(2%)	48	(6%)
Heating equipment room	400	(3%)	1	(3%)	11	(2%)	16	(2%)
Attic or ceiling/roof assembly or concealed space	400	(3%)	0	(0%)	2	(1%)	18	(2%)
Exterior roof surface	400	(3%)	0	(0%)	5	(1%)	7	(1%)
Exterior wall surface	400	(3%)	0	(0%)	4	(1%)	9	(1%)
Unclassified storage area	400	(3%)	2	(11%)	21	(5%)	62	(7%)

Trash or rubbish chute, area, or container	300	(2%)	0	(0%)	4	(1%)	6	(1%)
Storage of supplies or tools or dead storage	200	(2%)	0	(0%)	5	(1%)	16	(2%)
Kitchen or cooking area	200	(2%)	0	(0%)	5	(1%)	4	(0%)
Switchgear area or transformer vault	200	(1%)	1	(8%)	13	(3%)	18	(2%)
Confined chimney or flue fire	200	(1%)	0	(0%)	5	(1%)	0	(0%)
Shipping, receiving, or loading area	200	(1%)	0	(0%)	8	(2%)	59	(7%)
Ceiling/floor assembly or concealed space	200	(1%)	0	(0%)	0	(0%)	10	(1%)
Office	200	(1%)	1	(4%)	1	(0%)	11	(1%)
Confined fuel burner or boiler fire	200	(1%)	0	(0%)	1	(0%)	1	(0%)
Unclassified technical processing area	200	(1%)	0	(0%)	14	(3%)	7	(1%)
Conveyor	200	(1%)	0	(0%)	2	(1%)	13	(2%)
Laboratory	200	(1%)	0	(0%)	15	(3%)	6	(1%)
Computer room, control room or center	200	(1%)	0	(0%)	1	(0%)	8	(1%)
Lawn, field, or open area	100	(1%)	1	(4%)	0	(0%)	3	(0%)
Confined cooking fire	100	(1%)	0	(0%)	1	(0%)	4	(0%)
Conduit, pipe, utility, or ventilation shaft	100	(1%)	0	(0%)	2	(0%)	2	(0%)
Laundry room or area	100	(1%)	0	(0%)	1	(0%)	3	(0%)
Garage or vehicle storage area	100	(1%)	0	(0%)	2	(1%)	6	(1%)
Lavatory, bathroom, locker room, or check room	100	(1%)	0	(0%)	4	(1%)	4	(1%)
Confined compactor fire	100	(1%)	0	(0%)	0	(0%)	0	(0%)
Unclassified service facility	100	(1%)	0	(0%)	3	(1%)	6	(1%)
Confined incinerator fire	100	(1%)	0	(0%)	3	(1%)	2	(0%)
Dark room, printing, or photo room or area	100	(1%)	0	(0%)	2	(0%)	6	(1%)
Crawl space or substructure space	100	(1%)	0	(0%)	0	(0%)	3	(0%)
Chimney	100	(1%)	0	(0%)	0	(0%)	1	(0%)
Unclassified outside area	100	(1%)	0	(0%)	0	(0%)	6	(1%)
Other known service or equipment area	200	(1%)	0	(0%)	3	(1%)	12	(1%)
Other known assembly or sales area	100	(1%)	1	(4%)	1	(0%)	4	(0%)
Other known means of egress	100	(1%)	0	(0%)	5	(1%)	4	(1%)
Other known function area	100	(1%)	1	(4%)	3	(1%)	7	(1%)
Other known vehicle area	100	(1%)	0	(0%)	6	(1%)	4	(0%)
Other known area	200	(1%)	0	(0%)	5	(1%)	20	(2%)
Contained trash fire	500	(3%)	0	(0%)	2	(0%)	0	(0%)
Total	13,800	(100%)	17	(100%)	460	(100%)	856	(100%)

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest hundred, civilian deaths and injuries are rounded to the nearest one, and direct property damage is rounded to the nearest million dollars. Property damage has not been adjusted for inflation. Nonconfined and noncontained structure fires in which the area of origin was unknown or not reported have been allocated proportionally among fires with known area of origin. Totals may not equal sums due to rounding errors.

Source: NFIRS and NFPA survey.

Additionally, a book from the Australia Fire Protection Association on the performance of automatic sprinklers in Australia and New Zealand, 1886–1968,[6] includes a detailed analysis of fire involving different occupancies. The section on industrial occupancies is broken down into different categories. Sprinklers operated effectively over 98 percent of the time. Life loss in these facilities was minimal, nil in the majority of incidents.

Both these studies were limited to special groups of facilities in which design, usage, or maintenance may tend to be better than the average U.S. practice. As noted earlier, NFPA analysis of industrial and manufacturing facility fires reported to U.S. fire departments indicates sprinklers reduce the average loss per fire by two-thirds.

To be effective, a system must be operable. A closed sprinkler control valve was a contributing factor to a 1993 fire at a Newark, New Jersey, electrical power plant in which three workers died.[4] Programs must be in place to provide for inspection of control valves to ensure they are open and for maintenance of associated trim for alarm piping, dry-pipe valves, and preaction and deluge systems. For preaction and deluge systems, the associated detection systems must also be operational.

NFPA *101* AND *NFPA 5000*

Classification of Occupancy

To design the appropriate exit system for an industrial occupancy, the life safety industrial occupancy hazard classification per NFPA *101* and *NFPA 5000* must be established. The three basic classifications include general industrial, special-purpose industrial, and high-hazard industrial occupancy.

General-Purpose Industrial Occupancy. General-purpose industrial occupancies involve low- and ordinary-hazard industrial operations occurring in any type of building, be it single-story, multistory, or multiple tenant. These occupancies normally have a higher density of employees than other classifications. Examples are a laundry or a vehicle assembly plant having low- or moderate-hazard operations.

Special-Purpose Industrial Occupancy. Special-purpose industrial occupancies also involve low- and ordinary-hazard industrial operations. They are characterized by low employee density with most of the floor area occupied by equipment. An example is a structure built to protect large processing equipment from weather, where people associated with the process work in a separate control room, thereby reducing employee exposure to fire. These occupancies have slightly different egress requirements that are generally more lenient, such as an increase in the travel distance allowed. Also, egress is designed for the actual number of employees in the structure, rather than the calculated occupant load. A telephone switch building or a turbine generator building at a power plant meets the definition of low or moderate hazard and very reduced number of occupants.

High-Hazard Industrial Occupancy. A high-hazard industrial occupancy differs from low- and ordinary-hazard industrial occupancies by the materials used and the potential results and by-products of their use. High-hazard industrial occupancies include structures in which there are processes involving highly combustible, highly flammable, or explosive materials, or structures in which materials are likely to burn with extreme rapidity or to produce poisonous fumes or gases. Also included are industrial facilities in which flammable liquids are routinely handled, used, or stored in large quantities or those in which explosive dusts from grain, wood, flour, plastic, aluminum, magnesium, or other explosive-dust-generating materials are produced. Plants such as a grain handling facility or a gasoline refinery are examples of high-hazard industrial occupancies.

Structures with adequately protected, incidental high-hazard uses do not have to be classified as high-hazard facilities. These structures may include specific fire prevention measures such as a small flammable liquid storage room designed to meet NFPA 30, *Flammable and Combustible Liquids Code.* The restricted use of flammable liquids does not require a high-hazard classification. An example is a metalworking plant, normally classified as low hazard, that has a flammable solvent dip tank coater. Although adequate means of egress away from the coater are required, the classification of the entire facility does not change to high hazard.

The classification of the life safety hazard of an industrial occupancy must be carefully considered. The goal is to evaluate the hazard of the contents, process, and other factors affecting fire development. The time available for occupants to evacuate can be very much affected by the growth of the fire. Many resources are available to assist in the determination. Review of pertinent NFPA literature, including the codes and this handbook, is helpful. Officials in other jurisdictions with similar occupancies and plant operators can provide additional valuable information. Chapter 34 of *NFPA 5000* contains a comprehensive package of requirements for buildings that contain high-hazard contents.

Means of Egress Design Requirements

Designing the egress system for a building requires consideration of many factors. Some involve distance requirements, such as travel distance, common path of travel, and dead ends. These distances vary based on the life safety hazard classification and the absence or presence of automatic sprinklers. Egress distance limitations are shown in Table 20.18.5. To use some of the greater distances involves special requirements, such as application to one-story buildings only, with automatic sprinklers mandatory and smoke and heat venting.

High-hazard occupancies are very restrictive on means of egress distances allowed, with no dead ends or common paths of travel permitted. Generally, two exits are required from every story or section. However, NFPA *101* and *NFPA 5000* provide exceptions to this requirement. By careful design, the listed requirements can be met. The addition of exit tunnels, overhead passageways, or horizontal exits can aid in meeting prescribed distance limits.

Fire Alarm Systems

As illustrated by Figure 20.18.2, industrial and office park facilities coexist side by side and can be large and complex.

TABLE 20.18.5 Egress Distance Limitations

	Travel Distance			Dead End	Common Path of Travel	
Industrial Occupancy	*Unsprinklered ft (m)*	*Sprinklered ft (m)*	*Special ft (m)*	*ft (m)*	*Unsprinklered ft (m)*	*Sprinklered ft (m)*
General purpose	200 (61)	250 (76)	400 (122)*	50 (15)	50 (15)	100 (30)
Special purpose	300 (91)	400 (122)	—	50 (15)	50 (15)	100 (30)
High hazard	NP	75 (23)	—	0	0	0

*Special requirements in NFPA *101* and *NFPA 5000* for this travel distance in general-purpose industrial occupancies.
NP = Not permitted.

Due to the size and complexity of most industrial facilities, a fire alarm system is a valuable tool for life safety. It can alert designated personnel, such as an industrial fire brigade, to a fire and allow for prompt response to evacuate occupants, fight the fire, shut down equipment, and other actions, as required. NFPA *101* and *NFPA 5000* require a fire alarm system for most industrial occupancies. Exceptions are based on occupant load, where total capacity is less than 100 persons and fewer than 25 persons are located above or below the level of exit discharge. In low- and ordinary-hazard industrial occupancies, the fire alarm must sound an audible alarm at a continuously attended location to initiate emergency action. At high-hazard industrial occupancies, in addition to the foregoing, the fire alarm must initiate an occupant evacuation signal. In these occupancies, early notification can be critical to life safety.

PREFIRE PLANNING

Individual preplanning is appropriate for property protection. Training in the use of fire extinguishers for incipient fires must be provided if employees are expected to use them. Designated employees need to be trained to check that fire protection equipment is operating as designed—for example, that sprinkler control valves are open. The responding fire department should be made familiar with the facility, and an employee should be designated as their primary contact. Hazardous materials should be identified and their location noted on a building plan. Full participation in drills is necessary to completely test the plan.

The prefire plan should be evaluated routinely through simulated fire exercises. Such exercises are critical to identify deficiencies in the plan. If possible, request the participation of the responding fire department.

If there are industrial fire brigades at the site, they must be adequately trained. Training should include brigade organization and responsibility, the basics of fire behavior, special on-site fire and health hazards, and hands-on training with the fire equipment they are expected to use (see NFPA 600, *Standard on Industrial Fire Brigades*). Available equipment might include fire extinguishers, standpipes, hoses, and hydrants. Appropriate use of this equipment on incipient fires can contribute to a major reduction in the risk of fire loss and loss of life in industrial occupancies. Restricting the spread of fire also reduces the threat to life.

FIGURE 20.18.2 Fire at the Large River City Business Park in Iowa (Source: Davenport Fire Department)

SUMMARY

Industrial occupancies must be adequately evaluated to determine fire hazard. Fire hazard affects the potential for life loss and property damage. Loss history can be used to see whether current designs and requirements are effective. NFPA *101* and *NFPA 5000* requirements for industrial facilities are briefly discussed. It is important that building design and fire protection systems allow for safe occupant egress in the event of fire. The effectiveness of sprinklers has been documented from two sources in particular.

NFPA 140, *Standard on Motion Picture and Television Production Studio Soundstages and Approved Production Facilities,* provides minimum requirements for the design, construction, operation, and maintenance of soundstages and approved production facilities, as defined here. Now in its second edition, the standard defines motion picture and television studios as buildings, portions of buildings, or groups of buildings designed and constructed for use by the entertainment industry to produce motion pictures, television shows, or commercials, or to broadcast television programs utilizing a soundstage. Although NFPA 140 covers all pre- and postproduction facilities including construction shops, warehouses, soundstages, control rooms, editing facilities, and other exterior filming locations on the studio property, the requirements of NFPA 140 are focused on soundstages and approved production facilities. An approved production facility is an existing building, portion of a building, or group of buildings that has been altered to be used for motion picture, television, or commercial production and that has been approved by the authority having jurisdiction (AHJ) for that purpose. Approved production facilities function as soundstages.

The motion picture and television industry is dynamic in nature, and soundstages and production facilities need to be flexible. As a result, the fire protection needs of these types of facilities must be evaluated based on the hazards present, which change from production to production, and the industry's operational needs. Many occupancies and hazards found at a studio are similar to those in typical light industrial facilities.

This chapter, therefore, focuses primarily on fire protection issues relating to soundstages and approved production facilities. It does not deal with locations or exterior production areas that might be found on a studio lot. For instance, construction shops for building sets contain the same hazards as many other shops or factories and should be treated as such. Warehouses on studio property can also be treated like other warehouses, while bearing in mind their contents' dynamic nature. Administrative areas, control rooms, and commissaries can also be treated from a fire protection and life safety standpoint like other similar occupancies. However, soundstages, which are specifically designed for filming or live broadcasts, have special operational needs, and an understanding of their specific fire protection hazards and features is required.

See also Section 20, Chapter 1, "Assessing Life Safety in Buildings"; Section 20, Chapter 9, "Assembly Occupancies"; and Section 20, Chapter 18, "Industrial Occupancies."

OCCUPANCY CHARACTERISTICS

A soundstage is a building or a portion of a building, usually insulated from outside noise and natural light, used to produce motion pictures, television shows, or commercials. Soundstages like the one shown in Figure 20.19.1 are specifically designed and constructed to create a controlled environment that can be isolated from exterior noise and light.

Raymond A. Grill is the fire area business leader for Ove Arup & Partners in the Americas.

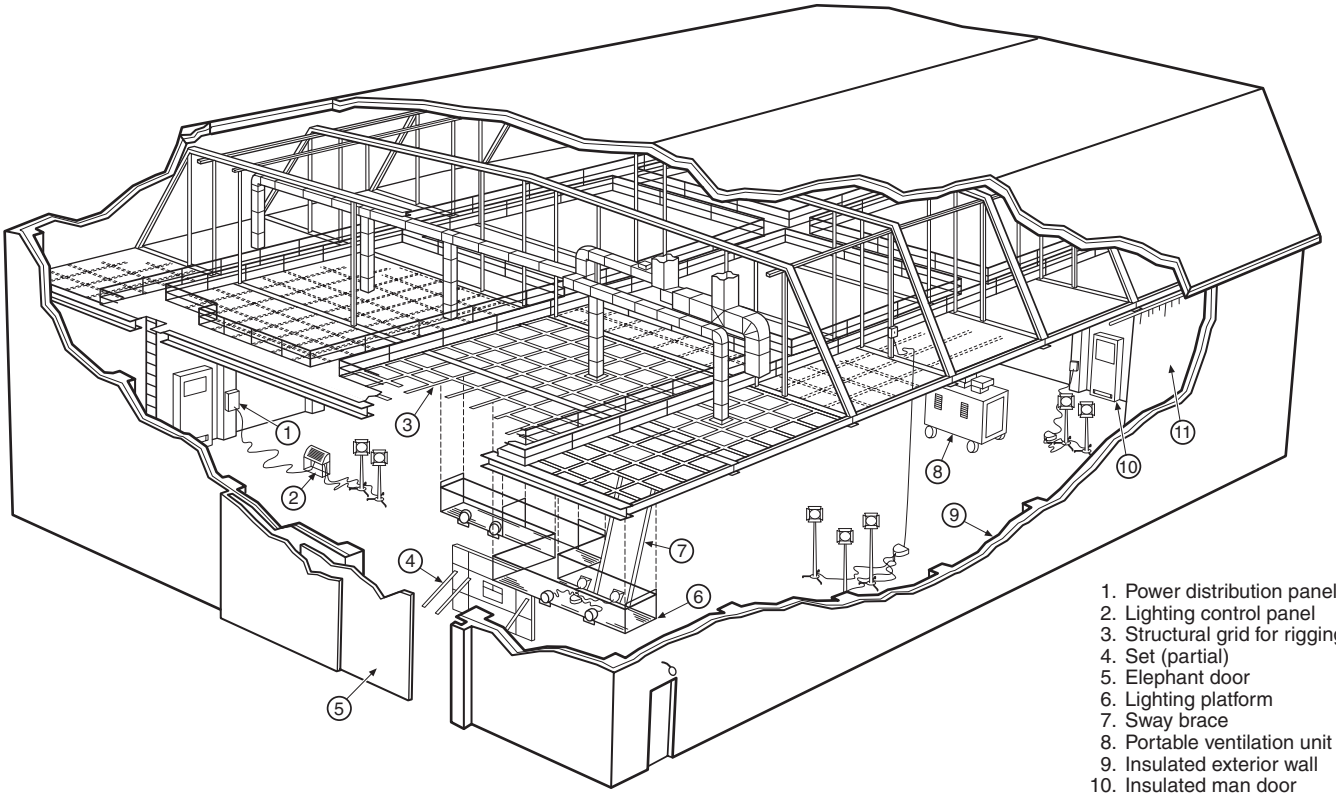

FIGURE 20.19.1 Typical Soundstage

Soundstages are often stand-alone buildings but can also be a room within a larger mixed-used building. Mixed use is often found in television production and broadcasting. Multiple soundstages can also be located within a single building.

The motion picture and television production industry commonly converts existing buildings to soundstages. This process may or may not include a change of occupancy classification for the existing facility. Vacant warehouses have been the primary type of existing facility converted into soundstages because of their openness. Its contents make a soundstage unique and the contents and configuration can change frequently to meet the needs of the production.

Live broadcast facilities, such as those for the production of network news broadcasts, incorporate production activities within other activities, such as newsrooms and offices. Some productions also include live audience environments within the soundstage. Introducing a live audience, depending on its size, can impact occupancy classification and other life safety and fire protection issues. These issues are discussed later in this chapter.

Sets within soundstages can be very elaborate. The duration of their use varies significantly from production to production. Some sets for television series may be used for years; others are specifically constructed for an episode. A set may be developed to simulate an entire building or series of buildings within the soundstage. Sets are typically constructed of wood and generally treated as temporary structures.

HISTORICAL FIRE EXPERIENCE

In 2006, the National Fire Protection Association Fire Analysis and Research Division analyzed fire losses in motion picture and television studios based on annual averages between 1999 and 2002.[1] The information gathered was based on data from NFPA's annual stratified random sample survey and the United States Fire Administration's National Fire Incident Reporting System (NFIRS).

Between 1999 and 2002, an estimated nine structure fires were reported annually to U.S. fire departments as occurring in motion picture studios and resulted in an average total fire loss of $65,000 in property damage per year. During the same period, an average of 18 reported structure fires in radio or television studios annually resulted in a yearly average of $71,000 in direct property damage. Due to the small number of fires, extreme caution should be used in interpreting these statistics.

Motion Picture Studios

Thirty-eight percent of the reported motion picture studio fires were unintentional, 27 percent were intentionally set, and 27 percent were caused by a failure of equipment or heat source. In 27 percent of these fires, electrical wire or cable insulation was the item first ignited; 18 percent of the fires began with upholstered furniture. Electrical arcing was the heat source in 27 percent of these fires.

Radio and Television Studios

Forty percent of the reported 1999–2002 radio or television studio fires were unintentional, 30 percent resulted from a failure of equipment or heat source, and 14 percent were intentionally set. Eleven percent of the fires were confined chimney or fuel burner fires; causal information is not routinely collected for these incidents. Electrical distribution equipment was involved in 18 percent of the fires in these properties. Including the confined fires, heating equipment was involved in 16 percent. Electrical wire or cable insulation was the item first ignited in 18 percent of these fires.

OCCUPANCY HAZARDS

Due to the unique nature of motion picture and television production, the contents of a soundstage and its combustible load vary from time to time. Soundstages themselves may also include combustible materials as part of their construction. Supplemental and temporary equipment, as well as set construction, contributes to the potential hazard within the soundstage. Introduction of occupants (performers and audiences) also needs to be addressed from a life safety exposure and egress perspective.

Combustible Fuel Load

Production sets can consist of simple platforms, backdrops, or very elaborate structures. Sets are typically constructed of wood framing. They may consist of a simple platform to provide for appropriate camera angles or may include walls and ceilings to simulate a room or building. Some model building codes generally exempt motion picture and television sets from permit requirements. Sets are typically considered temporary because changes occur regularly. *NFPA 5000®*, *Building Construction and Safety Code®*, mandates compliance with NFPA 140.

Set construction might obstruct sprinkler protection and other fire protection features. Ceilings of sets may be movable or built with materials that are not self-venting and, therefore, obstruct heat flow and sprinkler operation.

Set Construction/Hot Work

The use of arc welders, oxyacetylene torches, and grinders is common during set construction. NFPA 51B, *Standard for Fire Prevention During Welding, Cutting, and Other Hot Work,* provides comprehensive criteria for managing the potential hazards of these operations. Requirements include management responsibilities as well as operators' responsibilities. Fires caused by hot work can best be prevented by separating combustibles from ignition sources or by shielding combustibles. Regular inspections should be conducted to verify that compressed gas cylinders are adequately secured, hoses and cables are in good condition, combustible materials and flammable liquids are appropriately separated, and adequate fire-fighting equipment is provided.

Electrical Considerations

Electrical equipment and installations should comply with applicable sections of NFPA 70, *National Electrical Code®*. Specific articles in NFPA 70 address theaters, audience areas of motion picture and television studios, and similar locations. These articles include specific requirements for equipment, switchboards, lighting, and grounding. They address portable wiring, which is extensively used in motion picture and television production.

Mobile power generators are routinely used in motion picture production. Soundstages are not constructed to accommodate the temporary power needs of all production activities. Therefore, portable generators often supplement normal building power. When routing auxiliary power cables, care should be taken not to obstruct or interfere with fire ratings of walls, doors, or windows. NFPA 140 prohibits cables from being routed through fire-rated windows or doors. NFPA 140 allows cables to pass through fire-rated assemblies, when the penetrations are protected in accordance with NFPA 221, *Standard for High Challenge Fire Walls, Fire Walls, and Fire Barrier Walls*. Temporary electrical equipment can also obstruct egress and fire-fighting operations. When laying cables and locating portable generators, exit routes should be carefully avoided.

The location of portable generating equipment is subject to the approval of the AHJ based on NFPA 140.

The location of portable power-generating equipment should include consideration of the following:

- Potential exposure to the soundstage and adjacent structures
- Potential obstruction of egress or fire-fighting access
- Service and fueling needs

Portable power generators should be regularly inspected for leaks and adequate portable fire extinguishers should be available for use on this equipment.

Portable Heating, Venting, and Air Conditioning

Auxiliary heating, venting, and air-conditioning equipment often supplements the built-in capacity of a soundstage. These units should be listed by an approved testing laboratory and located so they do not obstruct egress or access. Flexible ducts used with these systems should be noncombustible and also arranged not to block egress and access.

Special Effects

Special effects might significantly impact the safety of soundstage occupants. Special effects may include pyrotechnic materials, gas, or other open flames, theatrical smoke, or fuel-powered vehicles. Clearly, special effects' impact is greater when there is an audience.

Pyrotechnics. Based on NFPA 140, use of pyrotechnic special effects is subject to the approval of the AHJ. Therefore, the proposed use of pyrotechnics on a soundstage must be reviewed with the AHJ prior to use.

NFPA 1126, *Standard for the Use of Pyrotechnics Before a Proximate Audience,* applies to the indoor display of pyrotechnic special effects in television and movie production only if the production is before a proximate audience. Special effects are

partially defined as visible or audible effects for entertainment purposes, frequently an illusion. NFPA 1126 defines proximate audience as "an audience closer to pyrotechnic devices than allowed by NFPA 1123, *Code for Fireworks Display*." This NFPA standard contains requirements on storage, permits, operator qualifications, labeling of preloads and use of pyrotechnics. It should be consulted when pyrotechnic special effects will be used indoors before an audience.

NFPA *101*®, *Life Safety Code*®, addresses pyrotechnic devices in its chapters on assembly occupancies by requiring compliance with NFPA 1126.

Open Flame. Based on NFPA 140, use of open flames is subject to the approval of the AHJ. Therefore, the proposed use of open flames on a soundstage must be reviewed with the AHJ prior to use. NFPA *101* also addresses open-flame devices in assembly occupancies. It allows open flame on stages and platforms as a necessary part of a performance, when precautions satisfying the AHJ are taken to prevent ignition of combustible material or injury to occupants. It permits gas lights under similar conditions. Prior to the performance, use of open flame or gas lights before an audience should be worked out with the AHJ.

Smoke. Theatrical smoke used as a special effect should not obscure exit signs, particularly if an audience is present. If no audience is present, and dense smoke is integral to the production, those affected by the smoke should be trained and drilled regarding egress routes.

Decorations

Combustible drapes, drops, hangings, cycloramas, cut greenery, and other decorative materials are required by NFPA 140 to be maintained in a flame-retardant condition. Depending on the material and the duration of use, this may necessitate periodic reapplication of fire retardant.

Foam plastic materials used for decorative purposes, scenery, or props must be limited to materials with a maximum heat release rate of 100 kW when tested in accordance with UL 1975, *Standard for Fire Tests for Foam Plastics Used for Decorative Purposes*.

Housekeeping/Smoking

Combustible waste and other combustible materials should be stored in a manner that limits their potential of coming in contact with ignition sources. Approved self-closing metal containers should be provided for containing combustible waste. Housekeeping hazards include accumulated sawdust or wood scraps; accumulated litter; combustible storage below platforms; storage of props, equipment, and material that may block exits, fire protection equipment, and electrical equipment.

NFPA 140 prohibits smoking on soundstages unless it is required as part of a production.

LIFE SAFETY/EGRESS

A soundstage may have two separate and distinct uses, depending on the presence of an audience. If no audience is anticipated, the soundstage can be considered an industrial occupancy. Means of egress should meet the requirements of NFPA *101* and *NFPA 5000*. Soundstages exceeding 1500 ft^2 (139 m^2) are required by NFPA 140 to have an aisle along the perimeter, clear to 7 ft (2.1 m) above the floor. Motion picture soundstages often maintain a 4 ft (1.2 m) aisle, with that portion of the floor painted yellow to clearly indicate that it is to be kept open. NFPA 140 also limits the travel distance to an exit in a soundstage to 150 ft (46 m).

If an audience of 50 or more people may be present, the requirements for assembly occupancies of NFPA *101* and *NFPA 5000* apply. Other portions of this handbook, NFPA *101,* and NFPA *5000* address exiting from assembly spaces, and the reader should refer to them for guidelines and requirements on number of exits, stair and handrail criteria, aisle and seating arrangements, emergency lighting, and the need for sprinkler and alarm systems.

If an audience is present, maintaining clear and obvious egress paths is important, especially if special effects or other visual illusions are used.

FIRE PROTECTION

Soundstages should be provided with automatic sprinkler protection to control and suppress fires in their incipient stages. New soundstages and new approved production facilities are required by NFPA 140 to be provided with an approved, supervised automatic sprinkler system. The systems are required to be designed in accordance with NFPA 13, *Standard for the Installation of Sprinkler Systems,* and maintained in accordance with NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems.* The design of automatic sprinkler systems needs to consider the special circumstances created by platforms and solid-ceiling sets. In recognition of the temporary nature of platforms and sets it might be necessary to permit omission of sprinklers in these areas when alternative protective means are provided. Such means might include limiting the size of platforms and solid ceilings, limiting use below platforms, and installation of heat or smoke detectors in areas that are shielded from sprinklers. NFPA 140 also recognizes the potential for obstructions. When the design of the building's automatic sprinkler system is increased to Extra Hazard, Group 2 density and area of coverage, NFPA 140 allows obstructions to sprinkler discharge that can be created by construction of sets. When a fire is shielded from sprinklers, it might develop beyond its incipient stage before sprinkler activation. The Extra Hazard, Group 2 design criteria are necessary to control a fire of this type.

Soundstages have unique needs with respect to audible and visible alarms. Audible and visible notification appliances within soundstages are allowed by NFPA 140 to be deactivated during production provided the following conditions are met:

1. Alarm system activation causes notification appliances to activate at a constantly attended location.
2. The attendants of the location have a means of communicating with the building fire command center, if one is provided, and with the occupants of the soundstage.

3. Deactivation of notification appliances on the soundstage activates an appropriately labeled visible signal at an approved location that remains illuminated while notification appliances on the soundstage are deactivated.

This approach is most likely to be utilized in a soundstage that is part of another building having a fire alarm system.

Portable fire extinguishers should be provided throughout soundstages in accordance with the requirements of NFPA 10, *Standard for Portable Fire Extinguishers*.

OPERATING FEATURES

Several other NFPA standards may apply to soundstage operations. These include NFPA 1, *Uniform Fire Code*™, regarding maintenance of systems, waste, and refuge accumulation; and elimination or mitigation of hazards. NFPA 30, *Flammable and Combustible Liquids Code,* and NFPA 58, *Liquefied Petroleum Gas Code,* address flammable and combustible liquids and liquefied petroleum gases, respectively. Welding is addressed by NFPA 51, *Standard for the Design and Installation of Oxygen–Fuel Gas Systems for Welding, Cutting, and Allied Processes,* and NFPA 51B.

Of primary importance in the operation of a motion picture or television production facility is the need to continually monitor and maintain the fire protection provided. Occupancies, uses, and hazards can change daily. Thew operator should assign a person to maintain proper fire protection and life safety who can apply good fire protection practice and common sense to day-to-day operations. This person needs to interface effectively with AHJs and must have enough internal authority to correct or mitigate hazards as they arise.

SUMMARY

Motion picture and television studios and soundstages are part of a dynamic industry. Fire protection needs to take into account the fact that hazards, occupancies, and operational needs will change from production to production. Hazards typical of production facilities that need to be constantly monitored include combustible loading, set construction, hot work, electrical systems, portable heaters and air conditioners, and special effects. Fire protection and life safety measures include clearly marked exits, an alarm system, an automatic sprinkler system, and the presence of portable fire extinguishers.

Chapter Contents

Acceptable Design
Limited-Access and Underground Structures
Mall Buildings
Open Parking Structures
Special Amusement Structures
Piers and Wharves
Water-Surrounded Structures
Membrane Structures and Tents
Grandstands
Towers
Open Structures

Key Terms

air-supported structures, below-grade fires, grandstands, Hartford circus fire, lighthouses, limited-access structures, mall buildings, marine terminals, membrane structures, offshore platforms, open structures, parking garages, piers, Six Flags Great Adventure Amusement Park fire, special amusement structures, tents, towers, underground structures, wharves, windowless structures

Every occupancy has unique needs for fire safety. Other chapters in this section describe fire protection techniques for various general occupancy types. For the most part, the fire protection techniques described in the other chapters are presented without regard to the type of structure. It is generally assumed that occupancies will be situated in "ordinary" structures with no unusual building features.

Some structures, because of their physical arrangement or construction methods, may present additional fire safety challenges that warrant additional protection measures, regardless of the occupancy. Special structures might present impediments to fire-fighting and rescue access, impediments to occupant egress, or fire and smoke management challenges. For purposes of this chapter, special structures include limited-access and underground structures, mall buildings, open parking structures, special amusement structures, piers and wharves, water-surrounded structures, membrane structures and tents, grandstands, towers, and open structures.

This chapter addresses some of the extraordinary fire safety aspects of special structures and presents some particular fire protection features that should be provided, regardless of the occupancy classification, in addition to the occupancy-based features that are described in other chapters in this section.

Another type of special structure, the high-rise building, is addressed in Section 20, Chapter 8, "High-Rise Buildings."

ACCEPTABLE DESIGN

Unique building arrangements of special structures are limited only by the designer's imagination. As a result, it is impossible for model codes, such as NFPA *101*®, *Life Safety Code*®, and *NFPA 5000*®, *Building Construction and Safety Code*®, to anticipate precisely all of the conditions and hazards that such a design could create. It is incumbent upon building owners, designers, and code officials to include those additional, beyond-the-codes, fire safety features that may be deemed necessary due to the uniqueness of the special structure and to the atypical fire safety problems that it may create.

Although the primary goals of fire protection will likely remain unchanged for occupancies in special structures, the prescriptive requirements of codes and standards, which typically apply to ordinary structures, might not be directly applicable. Thus, appropriate levels of fire protection for occupancies in special structures might require a special degree of sound design, engineering judgment, common sense, and cooperation between the designers and code officials.

When it is not possible to follow prescriptive requirements, alternative designs are necessary. Modern codes, including NFPA *101* and *NFPA 5000,* recognize performance-based options

Wayne D. Holmes, P.E., is vice-president of HSB Professional Loss Control, a fire protection engineering consulting firm. He is chair of the NFPA Technical Committee on Industrial, Storage, and Miscellaneous Occupancies; a member of the NFPA Technical Committee on Business and Mercantile Occupancies; a member of the NFPA Technical Committee on Fire Protection Features; a member of the NFPA Technical Committee on Fire Doors; and chair of the NFPA Technical Committee on Nuclear Facilities. He is also a fellow in the Society of Fire Protection Engineers.

as alternate means of achieving compliance. Both NFPA *101* and *NFPA 5000* include a "Performance-Based Option" chapter. Goals, objectives, and performance-based criteria are established, in conjunction with the codes' fundamental requirements, to achieve alternative means of complying with the codes' objectives. In order to develop an appropriate alternative design, basic information must be agreed on. The designer, building owner, and authority having jurisdiction (AHJ) together need to discuss design philosophy and specific performance requirements. The following should be considered:

- Minimum required fire protection systems and features
- Building characteristics
- Operational status and effectiveness of building systems and features
- Occupant characteristics
- Reasonable assumptions, limitations, and safety factors

All aspects of the performance-based design must be documented. NFPA *101* and *NFPA 5000* require that not less than eight design fire scenarios be considered with respect to initial fire location, rate of growth in fire severity, and smoke generation.

Finally, the proposed alternative design should be reviewed. Ultimately, the AHJ will determine if the provisions of NFPA *101* or *NFPA 5000* are met by the performance-based design. NFPA *101* and *NFPA 5000* permit the AHJ to require an approved, independent third party to review the proposed design and provide an evaluation of the design. If the AHJ is uncomfortable reviewing and accepting it, there are several options to consider. One is to have another competent fire protection engineer review the design. Perhaps the review cost can be included as part of the building permit fee. Or the AHJ could work jointly with another competent fire engineer on the review. The design could be sent elsewhere within the same jurisdiction for competent review. However it is done, the design, particularly one involving an extensive, complicated submittal, should be thoroughly reviewed prior to acceptance. The building owner is also required to annually certify compliance with the conditions and limitations of the performance-based design and submit a warrant of fitness acceptable to the AHJ.

Regardless of whether prescriptive code requirements are followed or performance-based fire safety practices are applied, occupancies in special structures should be afforded the same level of fire safety as similar occupancies in ordinary structures. The unique challenges of the special structure must be recognized, addressed, and overcome. This chapter describes some types of special structures and discusses some of the fire safety challenges presented in those structures.

LIMITED-ACCESS AND UNDERGROUND STRUCTURES

The hazards of underground and limited-access (known as "windowless" prior to the 2003 edition of NFPA *101*) structures are very similar. Both of these types of special structures present challenges with regard to smoke and heat venting, access for fire fighting and rescue, and, in some cases, for means of egress for occupants. Therefore, underground and limited-access structures pose similar concerns.

The feasibility of ventilating the structure should be considered in relationship to the classification, nature, and character of the occupancy. In the event that the occupancy is of such a character that a large number of occupants could be present, smoke control and smoke venting capabilities could have a significant impact on the overall level of life safety.

The following features of limited-access and underground buildings make them special structures:

- Due to the lack of windows, there are fewer points of entry into the building for manual fire suppression forces.
- Ventilation during emergencies and removal of products of combustion, such as heat and smoke, depend on mechanical systems and door openings. If there are no mechanical systems designed for ventilation and smoke removal, then emergency operations may be hindered or additional damage/downtime may occur, as compared to buildings with large numbers of access openings or windows.
- Natural illumination is limited or nonexistent. This issue has an impact on egress and emergency operations within the building.
- Limited-access and underground structures may make the fire department's initial size-up more difficult due to the lack of visibility from the exterior. Many times, size-up will be delayed until an initial interior observation can be made.

It is sometimes difficult to determine whether a building that appears to be windowless is a limited-access structure as defined by the codes. It is unusual to find a building that does not have at least a few access points and windows. It is necessary to review the definition of limited-access structures and to understand its intent in order to determine whether the structure meets the definition of a limited-access structure.

NFPA *101* and *NFPA 5000* define a limited-access structure as "a structure or portion of a structure lacking emergency openings." An emergency access opening is a window, panel, or similar opening of certain minimum dimensions and location that is readily identifiable from both the exterior and interior and readily openable from both the exterior and interior.

Emergency access panels provide fire-fighting access for fire control and rescue as well as a means for providing manual ventilation. With respect to emergency access panels, NFPA *101* and *NFPA 5000* state that a building need not be considered a limited-access structure if emergency access panels are provided on two sides of the first story, spaced not more than 125 ft (38 m) apart, and every story above the first floor is provided with emergency access panels on two sides of the building, spaced not more than 30 ft (9.1 m) apart.

Figure 20.20.1 provides an example of a structure that would not be considered a limited-access structure because openings meeting the dimensional and operational requirements of the codes are provided on two sides of the structure, where

$$D_1 \leq 125 \text{ ft } (38 \text{ m})$$

$$D_2 \leq 30 \text{ ft } (9.1 \text{ m})$$

$$x \geq 22 \text{ in. } (560 \text{ mm})$$

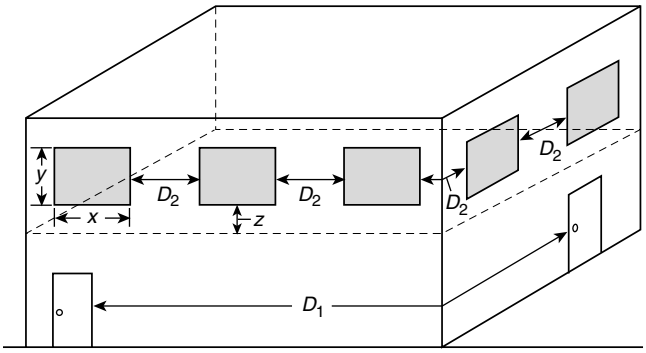

FIGURE 20.20.1 Emergency Access Openings (Source: *NFPA 5000® Handbook,* 2003, Figure 31.1, p. 731)

$y \geq 24$ in. (610 mm)

$z \leq 44$ in. (1120 mm)

Underground structures present additional problems not experienced in most other structures. The two primary issues are lack of accessibility and below-grade fires.

As with limited-access structures, it can be difficult to identify and classify underground structures. Many times, the difficulty occurs when a building or structure is constructed on a site with varying grades. This may result in some levels of the building being below grade on one or more sides and at, or above, grade on other sides. One example is a four-story structure built into the side of a steep hill. Although this arrangement might create a building in which more than 50 percent of the total wall surface is below ground, the building is not necessarily considered an underground structure provided that the levels of exit discharge and adequate accessibility are provided above grade.

NFPA *101* and *NFPA 5000* give specific guidance in determining when a building is considered an underground structure. The lowest floor used as a level of exit discharge may be considered the demarcation point for above and below grade. This may be true even if much of the wall surface of that floor is below grade. NFPA defines an underground structure as a structure or portion of a structure in which the floor level is below the level of exit discharge. A structure is not considered to be an underground structure if the story is provided with not less than 20 ft^2 (1.9 m^2) of emergency access opening entirely above the adjoining grade level in each 50 lineal ft (15 lineal m) of exterior enclosing wall area.

Exits from underground structures having an occupant load of more than 100 persons in the underground portions of the structure and having a floor used for human occupancy more than 30 ft (9.1 m) or more than one level below the lowest level of exit discharge should be arranged as follows:

- Exits should be cut off from the level of exit discharge.
- Exits should be provided with outside smoke-venting facilities or other means to prevent the exits from becoming charged with smoke from any fire in the areas served by the exits.

Furthermore, the underground portions of new underground structures should be provided with approved automatic smoke venting where the underground structure has the following:

- An occupant load of more than 100 persons in the underground portions of the structure
- A floor level used for human occupancy more than 30 ft (9.1 m) or more than one level below the lowest level of exit discharge
- Combustible contents, combustible interior finish, or combustible construction

From a practical standpoint, a limited-access structure has fire protection problems similar to an underground structure, but the windowless building can be constructed more easily to meet natural ventilation and rescue accessibility requirements. An underground structure must meet the requirements of a limited-access structure, and, in addition, some form of smoke management system must be provided. If a limited-access or windowless structure cannot meet the ventilation and rescue requirements, it should be considered equivalent to an underground structure, and the same code requirements should be applied.

Both underground and limited-access structures with occupant loads of more than 50 persons should be provided with approved, supervised automatic sprinkler systems throughout the underground or limited-access portions and all areas and floors traversed in traveling to the exit discharge.

Some examples of how occupancies and occupant loads affect code compliance for these special structures are helpful. For example, an underground space of 6000 ft^2 (560 m^2) housing an ordinary hazard industrial occupancy (occupant load factor of 100 ft^2 [9.3 m^2] per person) has an occupant load of 60 persons (6000/100 = 60). For this underground occupancy, NFPA *101* would require an approved, supervised automatic sprinkler system in all areas and floor levels traversed in traveling to the exit discharge.

For the same 6000 ft^2 (560 m^2) space housing a mercantile occupancy below grade and below the level of exit discharge (occupant load factor of 30 ft^2 [2.8 m^2] per person), the occupant load is 200 persons (6000/30 = 200). For this underground occupancy, NFPA *101* would require both an approved, supervised automatic sprinkler system in all areas and floor levels traversed in traveling to the exit discharge and an approved smoke venting system. It is important to consult specific code requirements for special provisions for occupancies in limited-access and underground structures.

Other general fire safety precautions should be observed for limited-access and underground structures. The use of combustible construction and other than Class A interior finish materials should be avoided. Foam plastics should not be left exposed; rather, they should be protected by a thermal barrier acceptable to the AHJ.

Compartmentation by fire barriers will help limit the extent of spread of fire and smoke. Barriers will help to reduce the severity of exposure to occupants and provide extended time for safe evacuation or relocation of occupants.

Manual fire-fighting equipment, such as standpipe and hose systems and portable fire extinguishers, can provide for quick suppression of small fires when handled by trained personnel.

Drainage of water from automatic sprinklers or from hose streams can be a significant problem in underground structures and requires preplanning. If drainage is required for reasons other than fire protection, it may be possible to use one drainage system for all purposes, provided that it is designed to handle the maximum flow.

For occupancies in underground caverns and similar subterranean spaces, refer to NFPA 520, *Standard on Subterranean Spaces*.

MALL BUILDINGS

Mall buildings are often associated with large shopping centers. However, mall buildings are increasingly being constructed for multiple uses. Mixed uses of mall buildings might include airport terminals, amusement and recreation operations, business operations, restaurants, broadcast studios, and other occupancies in addition to mercantile occupancies. Mall buildings are characterized by large, open areas under a single roof or multiple roofs that might include large populations of people and multiple occupancies. Mall buildings may or may not be subdivided into smaller spaces and are often constructed with multiple levels open to each other.

As used in NFPA documents, a mall is "a roofed or common pedestrian area within a mall building that serves as access for two or more tenants and does not exceed three levels open to each other." In the same context, a mall building is "a single building enclosing a number of tenants and occupancies wherein two or more tenants have a main entrance into one or more malls."

Like limited-access and underground structures, mall buildings can present challenges to smoke and heat venting and access for fire fighting and rescue. In fact, many malls may also be classified as limited-access or underground structures and may need to meet code requirements for such structures. Further, the large open spaces presented by many mall buildings can allow for extensive, uninterrupted spread of smoke and other fire products.

Mall buildings are typically large buildings with an extensive perimeter and may include multiple grade levels. This arrangement, often combined with vehicle parking facilities surrounding the mall building, limits fire department vehicular access to the mall building. There may also be limited building access points to the large enclosed area, which will contribute to the difficulty in providing fire-fighting access.

Large open areas can contribute to the spread of fire and smoke. Building code height and area requirements might limit the size of fire areas and require fire barrier walls to divide sections of the mall building, but openings to the pedestrian mall area may be allowed to be unprotected. Large areas are thus exposed to unimpeded spread of fire and smoke.

Because of the large, open areas, mall buildings should be provided with approved, supervised automatic sprinkler systems throughout the building to suppress fires before they grow to endanger occupants or cause significant property damage. Mall buildings with more than two interconnected levels should be provided with smoke control systems to reduce the danger to occupants in the event of a fire. See NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria, and Large Spaces,* for details on designing smoke control systems for mall buildings. Means of egress, particularly means of egress alternate from the main entrances, should be properly identified by sufficient numbers of exit signs. Fire detection and alarm systems, with appropriate means for occupant notification, will enhance the fire safety of mall building occupants.

OPEN PARKING STRUCTURES

Parking garages that permit drivers to drive their own vehicles to a parking space have been the subject of recurring and ongoing fire safety concerns. The general concern has been for the survival of the structure's integrity when exposed to a fire potentially involving the fuel tank, tires, and other combustible elements and contents of more than one car parked near a structural element. However, research has consistently shown that the effect of permanently open exterior walls on the dissipation of smoke and heat prevents a serious threat to the structure, even with an unusually challenging initial fire scenario.

Numerous tests in the United States and elsewhere have demonstrated the validity of this conclusion. One such test, known as the "Scranton Fire Test," was conducted in 1972 by the American Iron and Steel Institute (AISI) in a multistory, open parking structure with exposed structural steel members.[1] Three automobiles parked next to each other, each with a fuel tank containing 10 gal (38 L) of gasoline, were used as the test ignition and fuel source. The center automobile was gutted 48 minutes after crumpled newspapers in the rear seat were ignited. The contents of its fuel tank were spilled or consumed, but the fire did not spread to the adjacent automobiles and the overhead structural steel was essentially unaffected. The temperature of the steel remained far below critical levels throughout the test. A similar test conducted by the British at the Borehamwood Fire Test Station yielded similar results.[2] These results do not necessarily apply to aboveground enclosed garages or to underground garages.

Building codes, such as *NFPA 5000,* recognize the test results and permit noncombustible parking structures of unlimited area up to 75 ft (23 m) high to have no structural fire protection, as long as they are used for no other purpose and have ample permanent wall openings for the free dissipation of smoke and gases. Applicable building codes should be consulted for minimum amounts of exterior wall openings and construction requirements. NFPA *101* contains means of egress requirements specific to parking structures and NFPA 88A, *Standard for Parking Structures,* contains fire protection requirements.

SPECIAL AMUSEMENT STRUCTURES

Special amusement structures, whether used to house permanent rides or exhibits (amusement parks), temporary rides or exhibits (fairs and carnivals), or seasonal exhibits (haunted houses), present unusual situations for fire and life safety. Such venues are often dark and intended to deceive or confuse occupants. The occupants often include young children with immature decision-making skills who are easily deceived. In some cases,

the structure or interior details might be quickly and haphazardly constructed of light materials that can contribute to rapid fire spread. Unapproved temporary wiring, special lighting effects, pyrotechnics, or other ignition sources might be present. Paths of travel are often convoluted, and the means of egress might be obscured. Most of these structures can be classified also as limited-access structures. In some cases, special amusement buildings might be located on piers, which further complicates fire-fighting and rescue access.

NFPA defines a special amusement building as "a building that is temporary, permanent, or mobile that contains a device or system that conveys passengers or provides a walkway along, around, or over a course in any direction that is a form of amusement arranged so that the egress path is not readily apparent due to visual or audio distractions or an intentionally confounded egress path, or is not readily available due to the mode of conveyance through the building or structure." Special amusement buildings include multilevel play structures in a restaurant or shopping mall, Halloween haunted house displays, and large roller coaster rides located within a building.

History records many fires in special amusement buildings. One of the most significant fires occurred in a "haunted castle" amusement attraction, made up of 17 interconnected commercial trailers, at the Six Flags Great Adventure Amusement Park in Jackson Township, New Jersey, on May 11, 1984.[3] Eight visitors in the structure were unable to immediately exit and died in the rapidly developing fire. Major factors contributing to the loss of life were the lack of properly designed fixed detection and suppression systems, ignition of synthetic foam material from which fire spread to other combustible contents and interior finish, and the difficulty occupants had in trying to escape along a convoluted, smoke-filled path.

Special amusements, whether they are permanent or only intended to last for a few days, must be carefully planned to assure fire safety. Ignition sources must be controlled. Open flames and pyrotechnics should be prohibited. Permanent or temporary electrical wiring should be in strict compliance with NFPA 70, *National Electrical Code®*. Gasoline and gasoline-powered internal combustion engines should not be stored or used inside special amusement structures.

If possible, the structure housing the special amusement occupancy should be of noncombustible construction. All interior finish, contents, and furnishings should have appropriate fire ratings by applicable fire test methods. Exposed foam plastic and other combustible materials should be prohibited.

To provide prompt detection of any developing fire, special amusement buildings should be provided with an approved smoke detection system throughout that alarms to a constantly attended location on the premises. To suppress fires and allow for ample time for safe evacuation, an approved, supervised automatic sprinkler system should be installed throughout special amusement buildings. In addition to providing an alarm, actuation of the smoke detection system or sprinkler system should automatically increase lighting in darkened spaces and immediately terminate any sounds or visual effects that might serve to confuse occupants.

As in all structures, ample exits must be provided for special amusement structures. The exits should be readily identifiable with floor proximity exit signs. Special arrangements to identify the means of egress might be necessary in amusement spaces that include mirrors, mazes, and other confusing paths of travel. Lobby areas should not interfere with egress paths.

Amusement operators are urged to work closely with fire safety specialists and AHJs in the planning and operation of special amusements to help assure the fire safety of occupants.

PIERS AND WHARVES

When piers or related structures partially surrounded by water are used for places of amusement, for restaurants, for mercantile operations, or similar uses, they fall out of the normal use category—that is, mooring of vessels and handling of cargo—and into the special structure category. The question of fire and life safety is of primary concern, because these structures, which may contain large numbers of people, may have limited egress facilities and limited fire-fighting access due to their location or arrangement on the water.

Figure 20.20.2 illustrates Balboa Pier in Newport Beach, California, on which a restaurant is located.

NFPA 307, *Standard for the Construction and Fire Protection of Marine Terminals, Piers, and Wharves,* defines a pier as a structure, usually of greater length than width, projecting from the shore into a body of water with direct access from land that can be either open deck or provided with a superstructure. NFPA 307 deals mostly with property conservation features of piers and wharves and does not include explicit provisions for means of egress or safety to life. NFPA *101* and *NFPA 5000* specifically address the unique characteristics of piers. Any occupancy situated on a pier must meet the applicable

FIGURE 20.20.2 Balboa Pier, Newport Beach, California (Source: *NFPA 5000® Handbook,* 2003, Figure 31.4; © Ron Niebrugge/wildnatureimages.com)

occupancy-specific requirements of the code (for example, those for assembly occupancies in the case of a restaurant with an occupant load of 50 or more) in addition to the special provisions for piers.

Piers used exclusively to moor cargo vessels and to store materials are exempt from a number of means of egress requirements when provided with proper means of egress from structures thereon to the pier and a single means of access to the mainland, as appropriate for the pier's arrangement.

Piers occupied for other than cargo handling and storage and extending over 150 ft (45 m) from shore should also be provided with the following:

- The pier should be arranged to provide two separate ways to travel to shore, such as by two well-separated walkways or independent structures.
- The pier deck should be open, fire-resistive, and set on noncombustible supports.
- The pier should be open, unobstructed, and not less than 50 ft (15 m) in width if less than 500 ft (150 m) long, or its width should not be less than 10 percent of its length if more than 500 ft (150 m) long.
- The pier deck should be provided with an approved, supervised automatic sprinkler system for combustible substructures and superstructures.

WATER-SURROUNDED STRUCTURES

This category includes structures fully surrounded by water, including lighthouses and offshore platforms. Occupant loads could vary from a limited number of people in some cases to hundreds of people on offshore oil platforms. A large, water-surrounded structure could include areas that contain assembly, industrial, or residential occupancies. Egress from the entire structure is limited because of its location.

Other than the fact that the structure is surrounded by water, traditional occupancy requirements and fire protection features remain the same with respect to the actual occupancy classifications being evaluated. The occupancy should be addressed as if it was not surrounded by water, and the particular circumstances created by the special structure should then be applied. The special structure features should be evaluated as they relate to the occupancy at hand.

In some cases, either sufficient outside ground area, such as an island, is needed for refuge or a separate, fire-resistant platform should be provided for this purpose. A communications system and means of transportation for evacuating the occupants from the refuge area may be needed. Means of transportation might be limited to either boats or helicopters depending on the nature and location of these special structures. With limited fire-fighting access from the outside and limited means of egress, preplanning of emergency response for fire fighting and for occupant safety is imperative.

It is possible, as in the case with deep-water oil platforms, that a water-surrounded structure can be more than 100 miles from shore and very remote from any emergency response from outside of the structure. The world's worst water-surrounded structure disaster occurred in the North Sea in 1988. An explosion and ensuing fire on the Piper Alpha oil platform resulted in the deaths of 167 workers.[4]

The structure may be subject to severe environmental conditions, including wind, wave action, and heavy rain. NFPA *101* and *NFPA 5000* exempt water-surrounded structures from their provisions if the structure is under the jurisdiction of the U.S. Coast Guard and is in compliance with U.S. Coast Guard regulations. The additional regulations of the U.S. Coast Guard should be consulted for such facilities.

MEMBRANE STRUCTURES AND TENTS

Membrane Structures

NFPA defines a membrane structure as a building or portion of a building incorporating an air-inflated, air-supported, tensioned-membrane structure; a membrane roof; or a membrane-covered rigid frame to protect habitable or usable space. For cost-reduction, usability, and aesthetic purposes, membrane structures are being increasingly used in modern construction to house numerous types of occupancies. Membrane structures are used for both permanent and temporary structures.

Some membrane structures are of the air-inflated type, where the air pressure is within a series of tubes, which then form the structure and keep it upright. In this case, the occupants are not within a pressurized atmosphere. Others, such as the one shown in Figure 20.20.3 are air supported where the shape is maintained by air pressure and in which occupants are within the elevated pressure area. Also included as membrane structures are cable-supported membrane structures, such as some newer sports stadiums, where cables support the roof and air pressure may or may not be provided. In other types of structures, the membrane is tensioned, and weather protection is usually provided without enclosing walls (Figure 20.20.4). Finally, there are the framework-type structures in which the membrane is stretched over the frame to form enclosing walls and a roof.

The fire and life safety concerns with membrane structures include the combustibility of the membrane when exposed to ignition sources and the structural stability of the membrane

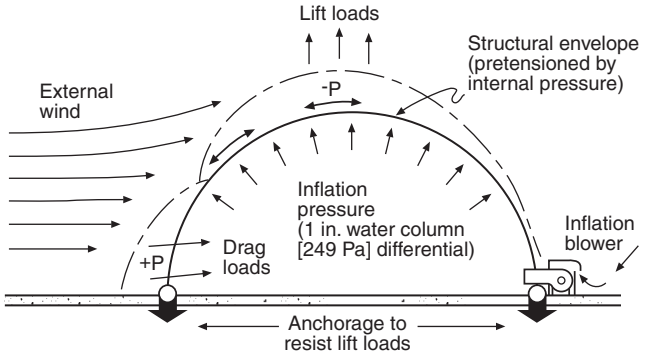

FIGURE 20.20.3 Loads on a Typical Single-Walled, Air-Supported Structure

FIGURE 20.20.4 Example of a Tensioned-Membrane Structure: Denver International Airport (Source: *NFPA 5000® Handbook,* 2003, Figure 32.2; courtesy of the Denver International Airport)

structure when exposed to fire. NFPA *101* and *NFPA 5000* address both of these concerns in their requirements. For permanent membrane structures, membrane materials cannot be used where fire resistance ratings are required for walls or roofs. Both permanent and temporary membrane structures are required to use flame-resistant membrane materials that are satisfactorily tested in accordance with NFPA 701, *Standard Methods of Fire Tests for Flame Propagation of Textiles and Films.* Membranes used in permanent membrane structures must be tested to provide a Class A flame-spread rating. All membrane materials must be tested as weathered-membrane materials. Blowers for air-supported and air-inflated membrane structures must meet special design requirements for reliability. Blowers must be provided with fully automatic standby power systems.

The area around temporary membrane structures must be clear of flammable and combustible materials and vegetation for a distance of at least 10 ft (3 m) to reduce potential fire exposures. Approved portable fire-extinguishing equipment must also be provided for temporary membrane structures.

Tents

The fire and life safety concerns associated with tents as places of assembly were made evident by a disastrous circus tent fire in Hartford, Connecticut, on July 6, 1944, in which 168 people died and 487 were injured.[5] The fire and life safety concerns for tents are similar to those for temporary membrane structures. As such, NFPA *101* applies the same requirements for tents as for temporary membrane structures for flame resistance, clear area around tents, and portable fire-extinguishing equipment. Tents should only be permitted on a temporary basis.

Additionally, tents should not cover more than 75 percent of the premises and stake lines should be not less than 10 ft (3 m) apart to help prevent fire propagation to adjacent tents. Additional spacing should be provided if needed to provide for adequate means of egress.

GRANDSTANDS

Grandstands are typical examples of structures found in places of outdoor and indoor assembly and are structures that can constitute a safety problem. These structures must have adequate aisles, proper distance between rows of seats, strong guard railings, and other means of egress features to ensure rapid and orderly evacuation to areas of safety. Requirements applicable to such installations are found in NFPA *101*. Grandstands should also be designed to withstand predetermined deadweight and live loads, as well as anticipated wind loads.

Since many grandstands are constructed entirely or partially of wood, basic fire protection principles of division of areas and separation from exposures apply. Long, combustible grandstands should be divided by fire partitions or be constructed in smaller sections with adequate separation between the sections.

Frequently, the space underneath a grandstand is used to store materials and for concession booths. The space underneath a grandstand might be become littered with combustible refuse. Refuse under the grandstand was a major factor in the soccer stadium fire in Bradford, England, on May 11, 1985, which claimed 56 lives.[6]

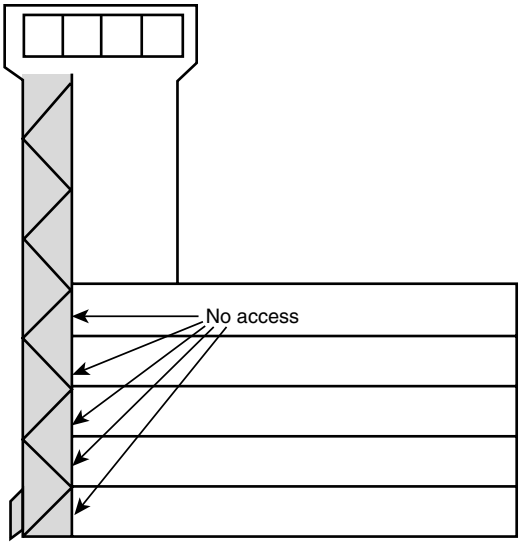
TOWERS

NFPA defines a tower as an enclosed, independent structure or portion of a building with elevated levels for support of equipment or occupied for observation, control, operation, signaling, or similar limited use where (1) the elevated levels are provided to allow adequate observation or line-of-sight for personnel or equipment, and (2) the levels within the tower below the observation level and equipment room for that level are not occupied. This definition does not include towers used for routine industrial, business, or assembly purposes. When a tower is used for these or other traditional occupancy purposes, it must comply completely with the appropriate occupancy classification and code provisions in NFPA *101, NFPA 5000,* and other applicable codes.

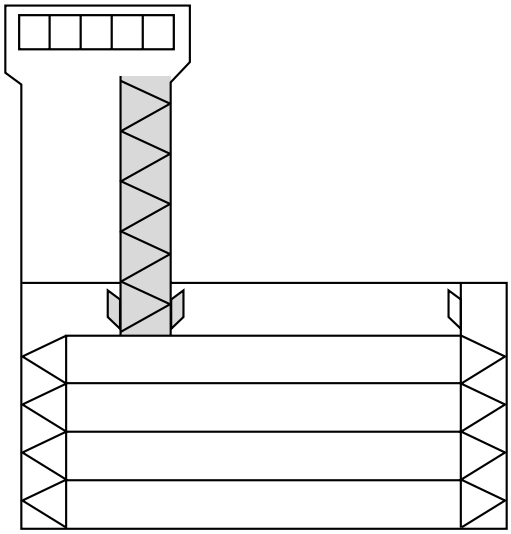
When a tower is being used in accordance with its definition, the special structures chapters of NFPA *101* and *NFPA 5000* apply. In some cases, the means of egress from a tower may be a single exit and, in some cases, may be only a ladder. If only one means of egress exists, caution must be taken to ensure that occupants cannot be trapped. In such cases, occupancy of the tower is limited to fewer than 25 persons, and the tower cannot be used for sleeping or living purposes.

Where a tower with a single means of egress is located above a building, special precautions must be taken to prevent the tower's single means of egress from being compromised by a fire in the building below. In Figure 20.20.5(a), the single exit stair enclosure for the tower is separated from the building by fire-resistance rated construction. Additionally, the single existing stair enclosure has no openings to the floors of the building above which the tower is positioned, thus preventing a fire in the building from rendering the stair unusable.

In Figure 20.20.5(b), the single exit stair positioned above the building serves the tower. It provides direct access to the



(a)



(b)

FIGURE 20.20.5 Single Exit from a Tower (Source: *NFPA 5000® Handbook,* 2003, Figure 31.3)

exit stair enclosure on the left, which also serves the building floors. If a fire prevents the use of the exit stair enclosure on the left, the tower stair permits tower occupants to traverse the top floor of the building and access a second exit stair enclosure on the right.

Fire-resistant or noncombustible construction should be used, with either Class A or B interior finish. There should be no high-hazard occupancies in the tower or immediate vicinity. If the tower is located above a building, the exit enclosure should be separated from the building or an exit enclosure should be provided leading directly to an exit enclosure serving the building and another door allowing access to the top floor of the building that provides access to a second exit serving that floor. Towers with 360 degree line-of-site requirements are permitted to have a single means of egress for a distance of travel not exceeding 75 ft (23 m) or 100 ft (30 m) if the tower is protected throughout by an approved, supervised automatic sprinkler system.

The amount of combustible materials in, under, or around a tower must be carefully controlled. Combustibles should be totally eliminated except for necessary furniture and operating supplies. Careful judgment should be used in determining what combustible materials to allow in the immediate vicinity of the tower. Similar care should be used in evaluating a tower located near high-hazard occupancies. The tower should be separated by a reasonable distance, especially when it has only a single means of egress.

Towers surrounded by water or offshore structures require special consideration and are strictly controlled by the U.S. Coast Guard. Coast Guard regulations and those of similar regulatory bodies in foreign countries normally take precedence over NFPA *101* and *NFPA 5000* requirements.

In small towers where there will be no more than three occupants at any one time, the means of egress may be a fire escape ladder. This might include forest fire observation or railroad signaling towers. Ladders should be arranged according to requirements of ANSI A-14.3, *Safety Requirements for Fixed Ladders,* and must provide continuous access to grade at all times. In towers with a single escape ladder, vertical openings need not be protected because such a requirement does not significantly increase protection for occupants.

In some special cases, towers subject to occupancy by not more than 90 persons are permitted to use elevators as the means of egress. This might include special operations such as aircraft control towers. NFPA *101* and *NFPA 5000* provide special provisions that apply to elevators when they are used as a second means of egress from towers. Among the limitations are the following:

- The tower and any attached structure must be protected throughout by an approved, supervised automatic sprinkler system.
- The primary means of egress must discharge directly to the outside.
- No high-hazard content areas may exist in the tower or attached structure.
- One hundred percent of the required egress capacity must be provided independent to the elevator(s).
- An evacuation plan, specifically including the use of the elevator, must be implemented and staff must be trained in elevator operations and procedures.
- The tower must not be used by the general public.

Further restrictions apply to the elevator, elevator lobby, controls, and operations, including the following:

- The elevator car must have a capacity of not less than eight persons.
- The elevator lobby must have a capacity of not less than 50 percent of the occupant load of the area being served by the lobby.
- On every floor served by the elevator, there must be an elevator lobby with a fire resistance rating of not less than 1 hour, with self-closing or automatically closing 1 hour

rated, temperature-rise-rated fire doors that close in the event of a fire alarm signal.
- Building elements must be used to restrict water exposure of elevator equipment.
- Power and control wiring for the elevator must be supplied from both normal and standby power and must be located and protected to ensure at least 1 hour of operation in the event of a fire.
- The elevators must be provided with fire fighter service controls in accordance with ASME A17.1, *Safety Code for Elevators and Escalators*.
- Elevators must have the capability of orderly shutdown during earthquakes where such shutdown is an option of ASME A17.1.

OPEN STRUCTURES

At the opposite extreme of the limited-access and underground structures are open structures. Whereas limited-access and underground structures are fully enclosed, thus making egress, access, and smoke venting more difficult, open structures are totally unenclosed.

Open structures are those that support equipment and operations not enclosed within building walls. Open structures are most often found in industrial operations, where the structure would come under the guidelines of an industrial occupancy (Figure 20.20.6). It is often difficult to determine whether the occupancy should be classified as general, special-purpose, or high-hazard industrial. The hazard classification usually is determined by the classification of the hazards of the contents that can be present. Occupancies in open structures are commonly classified under special-purpose industrial as defined in NFPA *101* and *NFPA 5000.*

NFPA *101* and *NFPA 5000* have several provisions for special-purpose industrial occupancies. The special-purpose industrial occupancy is typically characterized by a relatively low density of employee population, where most of a structure is occupied by machinery or equipment. Typically, the open structure facilitates access to the equipment by use of platforms, gratings, stairs, and ladders.

FIGURE 20.20.6 Typical Industrial Open Structure

It is sometimes difficult to determine when a structure is open and when it is enclosed. An open structure may include a roof to provide some protection from the elements. Additionally, open structures may be provided with partial walls intended to shield the operations from environmental conditions or to segregate the operations. The AHJ must determine whether the open structure truly meets the definition of an open structure or whether the facility is a building. As a guide, the AHJ could determine whether the structure would react as an enclosed building in the event of fire.

Within a building, walls acting in conjunction with a roof enclose the combustion process and products of combustion, thereby allowing fire to spread both horizontally and vertically to other areas. The advantage of an open structure is that it allows the products of combustion to vent to the atmosphere, instead of spreading to unaffected areas of the structure. This depends on wind and climatic conditions in addition to the design of the structure.

If the roof and walls could direct or channel products of combustion to other unaffected portions of the structure, thereby preventing their free venting to the atmosphere, then that portion of the open structure could be considered a building. It is not uncommon to have buildings constructed within the framework of an open structure, resulting in a mixed classification.

Open structures that are occupied by not more than three persons are permitted to have a single exit provided that the exit can be reached within 200 ft (60 m) from any point. Fire escape ladders are permitted for open structures where the occupant load does not exceed three persons.

Open structures are exempt from NFPA *101* and *NFPA 5000* requirements for capacity of means of egress, travel distance, illumination, emergency lighting, marking of means of egress, protection of vertical openings, and detection and alarm systems.

SUMMARY

Special structures, regardless of type, present out-of-the-ordinary fire protection challenges, independent of the hazards associated with the occupancy in the structure. Often, these challenges include impediments to fire-fighting access and rescue, impediments to means of egress, and impediments to smoke and heat venting. Special structures include limited-access and underground structures, mall buildings, open parking structures, special amusement structures, piers and wharves, water-surrounded structures, membrane structures and tents, grandstands, towers, and open structures.

The unique fire safety complexities of the special structure must be addressed in addition to the fire safety requirements for the occupancy. In some cases, occupancies might be housed in structures that could be classified as multiple types of special structures. For example, a shopping mall might be classified as both a covered mall and a limited-access or underground building. An amusement center might be located in a facility that could be a special amusement structure, a limited-access

structure, and a pier structure. An airport terminal might be classified as a covered mall, a limited-access building, and a tower.

A combination of sound design and engineering judgment, common sense, and cooperation between the designers and code officials might be necessary to ensure an adequate level of life safety and property protection for the unique exposures of occupancies in special structures. Performance-based fire protection analysis and design methods can be useful in creating fire-safe special structures.

Transportation Fire Safety

Carl H. Rivkin

21.1 Passenger Vehicle Fires
21.2 Fire Safety in Commercial Vehicles
21.3 Automotive and Marine Service Station Operations
21.4 Vehicle Fueling Using Gaseous Fuels
21.5 Fuel Cell Vehicles
21.6 Recreational Vehicles
21.7 Fixed Guideway Transit and Light Rail Systems
21.8 Rail Transportation Systems
21.9 Aviation
21.10 Marine Vessels
21.11 Road Tunnels and Bridges

The 20th edition of the *Fire Protection Handbook*® concludes with Section 21 on transportation fire safety. Five of the eleven chapters in this section are new.

The first new chapter is Chapter 1, "Passenger Vehicle Fires," which discusses regulations and standards associated with passenger vehicle fire safety and presents relevant data and research. Also new is Chapter 2, "Fire Safety in Commercial Vehicles," addressing hazards and standards related to commercial vehicle fire safety.

The list of new chapters continues with Chapter 3, "Automotive and Marine Service Station Operations." Automotive and marine service stations, whose operations include both refueling and repairs, present a fire risk because of the storage of flammable and combustible liquids and the transfer and use of these liquids.

The next two chapters deal with the subject of alternative fuels. Chapter 4, "Vehicle Fueling Using Gaseous Fuels," considers the implications of the growing use of alternative fuels, such as compressed natural gas (CNG), liquefied natural gas (LNG), and liquefied petroleum gas (LP-gas). Chapter 5, "Fuel Cell Vehicles," is a new chapter that describes current fuel cell vehicles and operating features being developed to facilitate commercialization and acceptance by the general public and regulatory authorities.

Chapter 6, "Recreational Vehicles," is also new. This chapter discusses the types of recreational vehicles and their development and use, RV standards, the fire and life safety issues associated with RVs, their fire safety record, and existing oversight programs.

Chapter 7, "Fixed Guideway Transit and Light Rail Systems," describes system characteristics and explains underground trainways, underground stations, and surface-level and elevated transit systems.

Chapter 8, "Rail Transportation Systems," identifies different types of rail rolling equipment used by North American railroads, both freight and passenger, and discusses fire hazards associated with them. The chapter generally discusses the rail transportation of hazardous materials and discusses in detail the transportation of hazardous materials in rail tank cars and in intermodal tank containers.

Chapter 9, "Aviation," provides information on airport and aircraft fire safety and aircraft maintenance and servicing.

Fire safety on pleasure craft, small commercial boats, and commercial vessels is presented in Chapter 10, "Marine Vessels." Marine fire hazards and emergency response to ship fires are also discussed.

Chapter 11, "Road Tunnels and Bridges," addresses the unique fire protection and life safety considerations and challenges posed by road tunnels and road bridges. A road tunnel is defined as any enclosed facility through which road vehicles (cars, vans, buses, and trucks) travel. Emergency communications and tunnel fire tests are also discussed.

Carl H. Rivkin, P.E., is principal chemical engineer on the NFPA engineering staff.

Passenger Vehicle Fire Research
Hazard Mitigation Strategies
Design and Safety Considerations

Key Terms

Federal Motor Vehicle Safety Standard (FMVSS), National Highway Traffic Safety Administration (NHTSA), passenger vehicle, tenability

According to the Centers for Disease Control and Prevention, the reduction of the rate of fatalities[1] attributable to motor vehicle crashes in the United States "represents the successful public health response to a great technologic advance of the 20th century—the motorization of America."[2] More than six times as many people drive today as in 1925, and the number of motor vehicles in the country has increased 12-fold since then to approximately 246 million. The number of miles traveled in motor vehicles is 24 times higher than in the mid-1920s. The annual fatality rate has declined from 18 per 100 million vehicle miles traveled (VMT) in 1925 to 1.45 per 100 million VMT in 2005—a 92 percent decrease.[3]

Motor vehicle fire safety has also realized significant improvements over the past several decades. Comparing today's vehicles to model year 1978 and earlier vehicles, the risk of passenger vehicle fire fatality per one million vehicles in use has decreased more than 50 percent. If the comparison is restricted to new vehicles only (defined as 4 years old or newer), in order to eliminate effects attributable to vehicle age, then it is found that the risk of fire fatality per one million vehicles in use is about 25 percent lower for today's vehicles than for model year 1982 to 1986 vehicles.

This risk reduction is even more pronounced when the comparison is done per vehicle mile traveled. The risk of passenger vehicle fire fatality per one billion vehicle miles traveled is almost 70 percent lower for today's vehicles than for model 1978 and earlier vehicles. If only new vehicles (4 years old or newer) are considered, it is found that the risk of fire fatality per one billion vehicle miles traveled is about 30 percent lower for today's vehicles than for model year 1982 to 1986 vehicles.

In terms of total numbers, the number of highway vehicle fires and associated fatalities has decreased by approximately 25 percent over the past quarter century. This reduction has occurred despite the significant increase in exposure to fire risk. In the last 25 years the number of highway vehicles registered in the United States has grown by 60 percent and the number of vehicle miles traveled annually has nearly doubled, growing by 91 percent. The probability of fire increases with vehicle age. Beginning in 1975, people began to hold onto their vehicles longer and scrap them later. Prior analyses indicate that as the median age of vehicles increases, the number of motor vehicle fatalities with postcollision fires grows. Between 1980 and 2004, the median age of passenger cars rose by 50 percent to almost 9 years of age. Similarly, the median lifetime of passenger cars

R. T. Long, Jr., P.E., is a principal fire protection engineer with the thermal sciences practice of Exponent. Exponent is a multidisciplinary scientific and engineering consulting company.

Jeff D. Colwell, Ph.D., P.E., is a senior managing engineer in Exponent's thermal sciences practice and specializes in investigating the origin, cause, and propagation of motor vehicle fires.

Rose Ray, Ph.D., is a principal scientist with Exponent and specializes in data analysis and the application of statistical methods to the evaluation of passenger vehicle performance.

Helene L. Grossman, Ph.D., is a senior scientist in Exponent's statistical and data sciences practice and has experience in the assessment of passenger vehicle safety based on field performance data.

Ben Thomas, Ph.D., is a senior managing scientist in Exponent's health sciences practice and has over 30 years experience in toxicology, pathology, risk assessment, and risk management.

Robert Strassburger is the vice-president of vehicle safety and harmonization with the Alliance of Automobile Manufacturers.

increased by 47 percent to 16.9 years. Finally, the use of plastics and plastic composites in highway vehicles to replace metal materials has increased to 7.6 percent of total weight in 2004 from 5.0 percent in 1978. In 2004, the typical passenger car contained 258 pounds (117 kg) of plastic materials, up 78 pounds (35 kg) from 1978.[4] The increased use of plastics increases the amount of combustibles available to ignite and/or contribute to a fire.

Nevertheless, advancing motor vehicle safety remains a significant public health challenge—one that automakers are addressing daily. Automakers make huge investments in safer vehicle design and technology. According to recent data, in the United States, approximately 32,000 passenger vehicle occupants are fatally injured annually as a result of traffic crashes. Of these fatalities, approximately 1.2 percent (385) are attributable to postcollision fires. In addition, there are approximately 40 passenger vehicle fire fatalities per year that are not collision-related.

This chapter discusses regulations and standards associated with passenger vehicle fire safety and presents relevant data and research.

FEDERAL REGULATION OF PASSENGER VEHICLE FIRE SAFETY

History of the National Highway Traffic Safety Administration

In 1966, the United States Congress passed the Highway Safety Act and the National Traffic and Motor Vehicle Safety Act (Vehicle Safety Act) which authorized the federal government to establish safety standards for motor vehicles. The Highway Safety Act created the National Highway Safety Bureau (NHSB), which later became the National Highway Traffic Safety Administration (NHTSA). The first director of the NHSB, Dr. William Haddon, defined a systematic approach to motor vehicle–related injury prevention. Haddon, a public health physician, recognized that standard public health methods and epidemiology could be applied to preventing motor vehicle–related and other injuries. He defined interactions between host (human), agent (motor vehicle), and environmental (highway) factors before, during, and after crashes resulting in injuries.

Shared Responsibilities for Vehicle Fire Safety

Many changes in both vehicle and highway design have followed since the passage of the Highway Safety Act. As such, safety features for vehicles (agents) have improved substantially over the years, as advancements have been made in air bag design, side impact protection, and fuel tank integrity, to name a few. Vehicles (agents) were built with new safety features including head rests, energy-absorbing steering wheels, shatter-resistant windshields, and safety belts. Roads (environment) were improved by better delineation of curves (i.e., edge and center-line stripes and reflectors), use of breakaway sign and utility poles, improved illumination, addition of barriers separating oncoming traffic lanes, and guardrails.

The fatality rate per 100,000 population dropped from 25.89 in 1966 to 16.46 in 1991 (25 years later) and to 15.86 in 1996 (30 years later). The traffic safety indicator (fatalities per 100 million VMT) dropped from 5.50 in 1966 to 1.91 in 1991 (25 years later) and to 1.69 in 1996 (30 years later).[5]

Changes in driver and passenger (host) behavior also have reduced motor vehicle crashes and injuries. Enactment and enforcement of traffic safety laws, reinforced by public education, have led to safer behavior choices. Examples include enforcement of laws against driving while intoxicated (DWI) and underage drinking, and enforcement of safety belt, child safety seat, and motorcycle helmet use laws.

Enhancing motor vehicle safety is a shared responsibility of government, industry, and consumers. Government and community recognition of the need for motor vehicle safety prompted initiation of programs by federal and state governments, academic institutions, community-based organizations, and industry. State and local governments have enacted and enforced laws that affect motor vehicle and highway safety, driver licensing and testing, vehicle inspections, and traffic regulations. Preventing motor vehicle–related injuries has required collaboration among many professional disciplines (e.g., biomechanics has been essential to vehicle design and highway safety features). Citizen and community-based advocacy groups have played important prevention roles in areas such as drinking and driving and child-occupant protection.

NHTSA FMVSS Standards

As part of its mandate, NHTSA is responsible for adopting and enforcing federal motor vehicle safety standards (FMVSS). These safety standards apply to the manufacture and sale of new motor vehicles and motor vehicle equipment (see 49 U.S.C. 30112). The FMVSS adopted by NHTSA encompass most aspects of motor vehicle safety performance and must be practicable, meet the need for motor vehicle safety, and be stated in objective terms.[6] States and localities are precluded by the Vehicle Safety Act from adopting and enforcing standards for motor vehicles that are inconsistent with these federal standards.

With respect to motor vehicle fires, NHTSA has promulgated a suite of standards to enhance fire safety as outlined below. The two principal federal motor vehicle safety standards addressing motor vehicle flammability, FMVSS 301, *Fuel System Integrity,* and FMVSS 302, *Flammability of Interior Materials,* were the first to be issued by the agency to address flammability issues.

FMVSS 301, *Fuel System Integrity.* Issued in 1968, FMVSS 301,* *specifies* requirements for the postcollision integrity of motor vehicle fuel systems. Its purpose is to reduce deaths and injuries occurring from fires that result from fuel spillage during

*FMVSS 301 was amended on December 1, 2003, to upgrade the rear impact test used to assess fuel system integrity. The final rule replaced the full rear impact test procedure that was conducted at a speed of 30 mph (48 km/h) with an offset rear impact test procedure conducted at 50 mph (80 km/h). See 68 Fed. Reg. 67068.

and after motor vehicle crashes. FMVSS 301 applies to passenger cars, multipurpose passenger vehicles, trucks, school buses and other buses with a gross vehicle weight rating (GVWR) of 4536 kg (10,000 lb) or less. The standard dictates a maximum fuel tank leakage of 28 g per minute after a collision.

FMVSS 302, *Flammability of Interior Materials.* Issued in 1972, FMVSS 302 specifies burn resistance requirements for materials used in the occupant compartments of motor vehicles. Its purpose is to reduce deaths and injuries to motor vehicle occupants caused by vehicle fires, especially those originating in the interior of the vehicle from sources such as matches or cigarettes. FMVSS 302 applies to passenger cars, multipurpose passenger vehicles, trucks, and buses. The standard dictates that all materials used in the passenger compartment should not allow a flame to propagate faster than 4 in./min (0.1 m/min), setting criteria for flammability performance. The test is performed on a sample of material in a horizontal orientation under controlled laboratory conditions.

FMVSS 303, *Fuel System Integrity of Compressed Natural Gas Vehicles.* FMVSS 303 specifies requirements for the integrity of motor vehicle fuel systems using compressed natural gas (CNG), including the CNG fuel systems of bifuel, dedicated, and dual-fuel CNG vehicles. The purpose of this standard is to reduce deaths and injuries from fires that result from fuel leakage during and after motor vehicle crashes. FMVSS 303 applies to passenger cars, multipurpose passenger vehicles, trucks, and buses that have a GVWR of 10,000 lb (4536 kg) or less and use compressed natural gas as a motor fuel, and school buses regardless of weight that use compressed natural gas as a motor fuel.

FMVSS 304, *Compressed Natural Gas Fuel Container Integrity.* FMVSS 304 specifies requirements for the integrity of compressed natural gas (CNG) motor vehicle fuel containers. The purpose of this standard is to reduce deaths and injuries from fires that result from fuel leakage during and after motor vehicle crashes. FMVSS 304 applies to containers designed to store CNG as motor fuel on board any motor vehicle.

PASSENGER VEHICLE FIRE DATA ANALYSIS

Every year in the United States, approximately 32,000 passenger vehicle occupants are fatally injured as a result of traffic accidents. Of these fatalities, approximately 1.2 percent (385) are attributed to postcollision fires. In addition, there are approximately 40 passenger vehicle fire fatalities per year that are not collision-related. There exist several data sources from which an estimate of the number of passenger vehicle fire fatalities may be derived. In this section, these data sources are identified and any differences reconciled to derive the estimate presented immediately above. These statistics illustrate that there are two main categories of interest in postcollision fires. The first category is postcollision fuel-fed fires, and the second category is postcollision fires that originate in the engine compartment and spread into the passenger compartment.

Passenger Vehicle Fire Fatalities

Using data from the U.S. Fire Administration's National Fire Incident Reporting System (NFIRS), the National Fire Protection Association's (NFPA's) annual survey of U.S. fire departments, and the NHTSA's Fatality Analysis Reporting System (FARS), an analysis of passenger vehicle fire injuries and fatalities can be conducted to examine such factors as the fuel involved in the fire, the point of origin of the fire, and the percentage of these fires associated with a crash.

NFPA survey data, as given in "Fire Loss in the United States," indicate that there are approximately 480 civilian fatalities per year due to highway vehicle fires (average for 1999–2004).[7] According to NFIRS data, approximately 88 percent of these fatalities, or 425 per year, are due to passenger vehicle fires. NFPA estimates of fire fatalities only include those that are judged by the fire department investigator to result from the fire itself, rather than related trauma such as a collision. All fatalities occurring up to a year following the fire are included, although tracking subsequent deaths is not always feasible.

These estimates differ from the estimate of 360 annual passenger vehicle fire fatalities for 1999–2003 presented in the NFPA report, "U.S. Vehicle Fire Trends and Patterns."[8] There are several reasons for this discrepancy. The analysis presented here used NFPA survey data directly to estimate highway vehicle fire fatalities. In contrast, the NFPA report used NFPA survey data to estimate *all vehicle* fire fatalities and then used NFIRS data to allocate the data into highway versus nonhighway vehicle fire fatalities. These two methods yield estimates of highway vehicle fire fatalities that differ by about 8 percent.* The advantage to using the direct NFPA survey estimate of highway vehicle fire fatalities is that the NFPA survey follows up on fatalities to distinguish those caused by the fire versus those caused by related trauma, whereas NFIRS does not conduct such follow-up. Hence, the direct NFPA estimate of highway vehicle fire fatalities may be more reliable.

Both the NFPA report and the analysis presented here used NFIRS to allocate highway vehicle fire fatalities into passenger vehicle versus nonpassenger vehicle fire fatalities. However, the NFPA report used NFIRS mobile property type "Passenger road vehicles," which includes passenger cars, buses, motorcycles, offroad recreational vehicles, and trailers, whereas the analysis presented here excludes some of those vehicles (motorcycles, offroad recreational vehicles, and trailers), but includes additional vehicles such as pickups and general-use trucks.

The estimates derived from NFPA/NFIRS data can be compared with those from the NHTSA's FARS. FARS is a census of all highway vehicle fatalities that occur on public roadways and for which the death is attributable to the accident and occurs within 30 days. A query of the FARS system indicates that there are approximately 1635 fatalities associated with highway vehicle fires each year, of which about 88 percent, or 1440 fatalities per year, involve passenger vehicles. The vast majority, approximately 99 percent, of passenger vehicle fires reported in FARS

*The fatality estimates given here are rounded to the nearest 5. The 8 percent difference between the NFPA/NFIRS and FARS estimates is calculated using nonrounded estimates rather than rounded estimates.

*NFPA estimates of highway vehicle fires are taken from NFPA's Fire Loss Series and are allocated into passenger vehicle fires/nonpassenger vehicle fires using NFIRS percentages.

are postcollision fires. However, the number of fatalities that result from the fire, rather than from collision-related trauma, is only about one-quarter of the total fatalities, approximately 390 annual deaths resulting from passenger vehicle fires, of which about 385 result from postcollision fires.* These numbers are averages for 1999 through 2004.

The estimates of fatalities associated with passenger vehicle fires of 425 and 390 per year from NFPA/NFIRS and FARS, respectively, are similar. The NFPA/NFIRS estimates are higher than the FARS estimates by about 8 percent, possibly because some fires that are not accident-related appear in the NFPA/NFIRS estimates, but do not occur on public roadways and are not included in the FARS database. Table 21.1.1 shows the NFPA and FARS estimates of passenger vehicle fire fatalities for 1999–2004.

For this analysis, NFIRS data were used to provide detailed information on the causes and ignition characteristics of fires. Because NFIRS only captures one-third to one-half of fire incidents in the United States, it was necessary to use the NFPA survey data to scale up the NFIRS data to obtain national estimates; the scaling factor depended on the category of interest (i.e., fires, deaths, injuries). Data were analyzed from the 6 year period 1999 through 2004 (2004 is the most recent year for which NFIRS data are publicly available). Fires for which a characteristic was unknown or not reported were allocated proportionally, assuming the same proportions as the fires with a known characteristic. The analyses and results that follow all pertain to passenger vehicle fires.

Based on the NFIRS and NFPA data, approximately half of passenger vehicle fire fatalities (about 220 fatalities per year) result from postcollision fires. However, according to the FARS analysis using the "most harmful event" code, there are approximately 385 fatalities per year resulting from postcollision passenger vehicle fires. It appears that the NFIRS data underestimate the proportion of fires and fatalities associated with collisions, probably due to factors other than "collision" being recorded as the factors contributing to ignition. This is further evidenced by the fact that roughly 50 percent of passenger vehicle fires do not have any factor contributing to ignition recorded (in the analysis discussed here, these unknowns were allocated proportionally). Therefore, the FARS estimate of postcollision fire fatalities and the NFPA/NFIRS estimate of total vehicle fire fatalities were used in this analysis to get a more conservative estimate of fatal passenger vehicle fires.

Results of the statistical analysis presented here are summarized in Figure 21.1.1. As shown in the leftmost part of the figure, the annual number of passenger vehicle fire fatalities is small compared to the total population of passenger vehicle fatalities due to traffic accidents. Of the fatalities due to fires, shown in the center chart, the vast majority are associated with postcollision fires.

Postcollision fires account for 90 percent of all passenger vehicle fire fatalities, while noncollision fires account for 10 percent. Of these noncollision fire fatalities, 5 percent are due to intentional fires and 95 percent are due to unintentional fires. Approximately 50 percent of the fatalities resulting from unintentional passenger vehicle fires involve the occupant being asleep or impaired by alcohol or other drugs prior to the fire.

Case studies of postcollision fires have indicated that there are two major categories: fuel-fed (gasoline) pool fires and engine compartment fires. Fuel-fed fires generally occur when collision damage causes a gasoline leak and then this fuel is the first material ignited. As shown in the rightmost chart of Figure 21.1.1, about 60 percent of postcollision passenger vehicle fire fatalities result from fires in which gasoline is the first material ignited.

Whereas more than half of postcollision fires involve gasoline as the first ignited material, almost half originate in the

*The "most harmful event" code in FARS was used to determine the fatalities resulting from fire. Different states code harmful events differently.

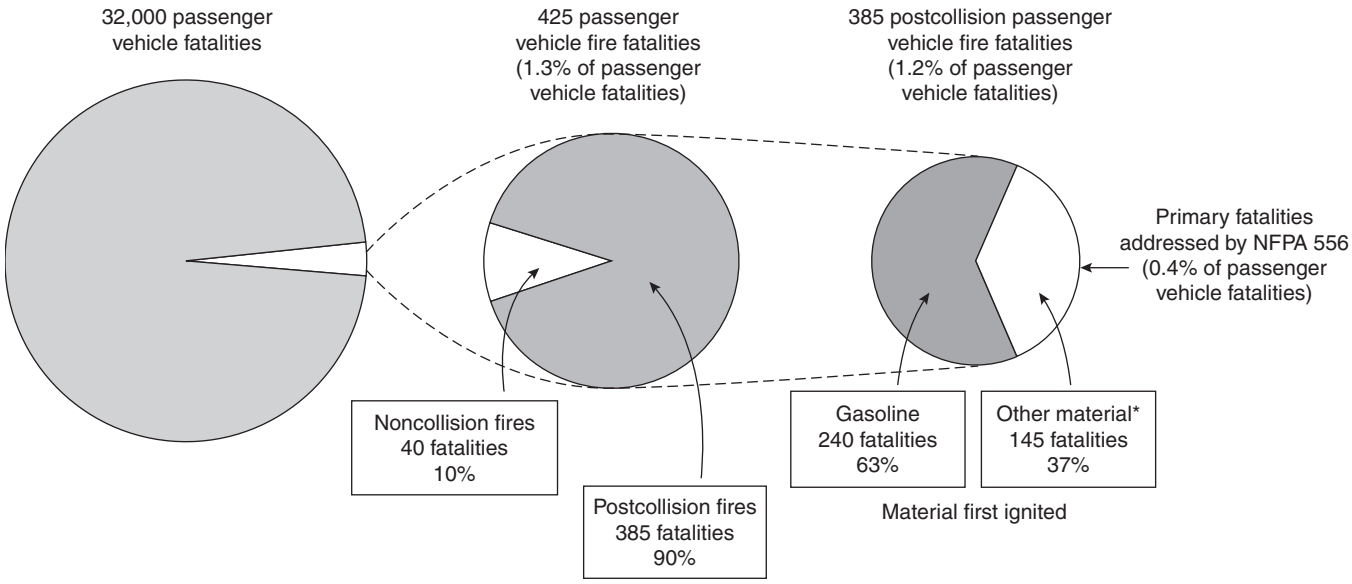

FIGURE 21.1.1 Summary of Statistical Analysis Results. *Includes the category "multiple types of fuels," so it is possible that gasoline was involved. (Sources: FARS, NFPA, and NFIRS 1999–2004 Annual Averages)

engine compartment, as shown in Figure 21.1.2. These facts indicate that fuel-fed fires and those that originate in the engine compartment are two of the most important passenger vehicle fire scenarios. These two fire scenarios have been the subject of extensive research and are discussed in more detail later.

Fire Risk Trends

Passenger vehicle fire safety has realized significant improvements over the past several decades. As shown in Figure 21.1.3, the risk of passenger vehicle fire fatalities per million vehicles in use has decreased from 3.7 per million registered vehicles per year for model year 1978 and earlier vehicles to an average of 1.8 per million registered vehicles per year for model year 1996 through 2004 vehicles, a more than 50 percent decrease.

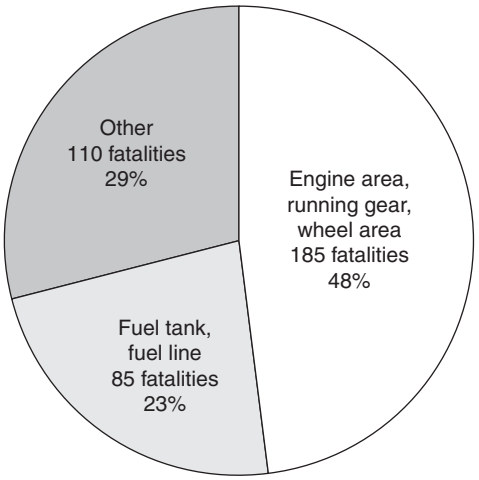

FIGURE 21.1.2 Area of Origin of Fatal Postcollision Fires (Sources: FARS, NFPA, and NFIRS, 1999–2004)

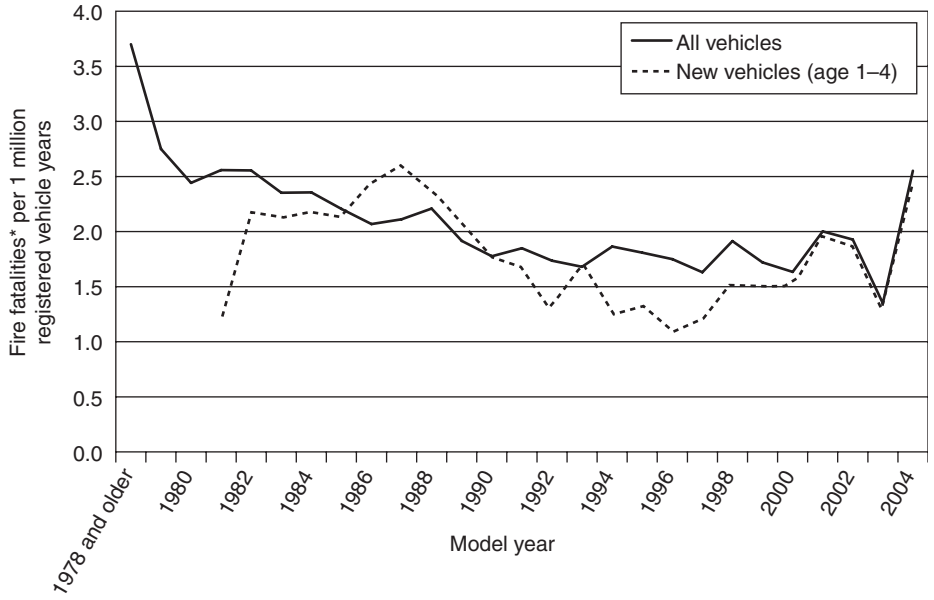
The observed increase in risk for model year 2004 vehicles may be an artifact of small sample size (only 40 fatalities listed in FARS). The lower bound on the 95 percent confidence interval for this risk is 1.8 fatalities per million registered vehicle years, which is equivalent to the average risk for model year 1996 through 2004 vehicles. Thus, the observed increase in risk for model year 2004 vehicles is not statistically significant.

Also shown in Figure 21.1.3 is the risk of passenger vehicle fire fatalities per million registered vehicles per year, restricted to new vehicles (vehicles aged 1 to 4 years). Although it appears that the risk increased between model years 1981 and 1982, the sample size is very small for model year 1981 vehicles aged 1 to 4 years (only 12 fatalities listed in FARS), so this increase is not statistically significant. The average risk for model year 1982 to 1986 vehicles aged 1 to 4 years was 2.2 fire fatalities per million registered vehicle years, whereas the average risk for model year 1996 to 2004 vehicles aged 1 to 4 years was 1.6 fire fatalities per million registered vehicle years. Thus, the fire fatality risk, restricted to new vehicles only, has decreased by about 25 percent between these time periods.

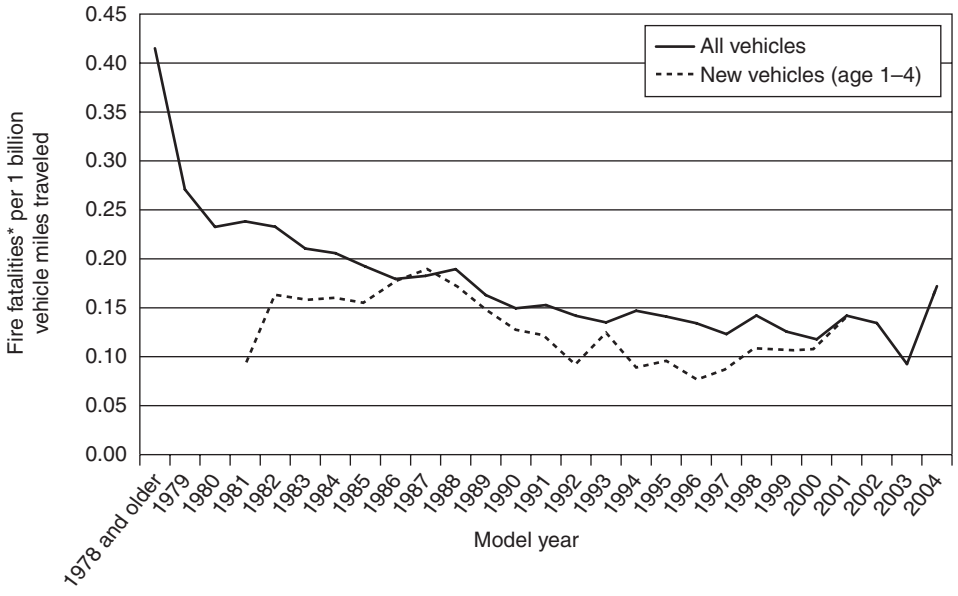
Figure 21.1.4 shows the risk of passenger vehicle fire fatalities per billion vehicle miles traveled. This risk has decreased from 0.42 per billion vehicle miles traveled for model year 1978 and earlier vehicles to an average of 0.13 per billion vehicle miles traveled for model year 1996 through 2004 vehicles, a decrease of almost 70 percent. This analysis takes into account decreases in annual mileage as vehicles age, as determined from the 1995 and 2001 National Household Travel Surveys.[9]

Figure 21.1.4 also shows the risk of passenger vehicle fire fatalities per billion vehicle miles traveled, restricted to new



*Only includes fatalities when fire is coded as the most harmful event for the vehicle.

FIGURE 21.1.3 Passenger Car and Light Truck Fire Fatalities per 1 Million Registered Vehicle Years (RVY), by Model Year of Vehicle, 1978–2005. (Source: FARS and R. L. Polk, 1985–2005)



*Only includes fatalities when fire is coded as the most harmful event for the vehicle.

FIGURE 21.1.4 Passenger Car and Light Truck Fire Fatalities per 1 Billion Vehicle Miles Traveled (VMT), by Model Year of Vehicle, 1978–2005. (Source: FARS, 1985–2005, R. L. Polk, 1985–2005; National Household Travel Survey, 1995 and 2001)

vehicles (vehicles aged 1 to 4 years). As with the risk per registered vehicle year analysis, it appears that the risk increased between model years 1981 and 1982. As discussed previously, the sample size for new vehicles of model year 1981 is small (only 12 fatalities listed in FARS), so this increase is not statistically significant. The average risk for model year 1982 to 1986 vehicles, aged 1 to 4 years, was 0.16 fire fatalities per billion vehicle miles traveled, whereas the average risk for model year 1996 to 2004 vehicles, aged 1 to 4 years, was 0.11 fire fatalities per billion vehicle miles traveled. Thus, the fire fatality risk, restricted to new vehicles only, has decreased by about 30 percent.

PASSENGER VEHICLE FIRE RESEARCH

The statistical analysis demonstrates that, on average, there are 425 fatalities per year attributed to fires associated with passenger vehicles, and that a vast majority of these fatalities (90 percent) are associated with postcollision fires. Other key findings are that about 60 percent of postcollision passenger vehicle fire fatalities result from fuel-fed fires, and about 50 percent result from fires originating in the engine compartment. These findings are consistent with a report prepared for the Motor Vehicle Fire Research Institute (MVFRI),[10] which illustrated that of all the vehicle collision fires reported by the National Automotive Sampling System (NASS), the majority were caused by front-end collisions and were initiated in the engine compartment.

The following sections briefly describe recent research conducted on postcollision fires and a number of strategies to mitigate the risk to occupants of passenger vehicles involved in postcollision fires. The establishment of valid performance criteria is critical before creating a model or test method.

Postcollision Fire Research

One of the most challenging aspects of the research to better understand postcollision passenger vehicle fires is to reproduce the coupling between the impact damage, fire initiation, and fire propagation. Another key component and challenge is the ability to determine when, and by what mechanism, conditions within the passenger compartment become untenable.

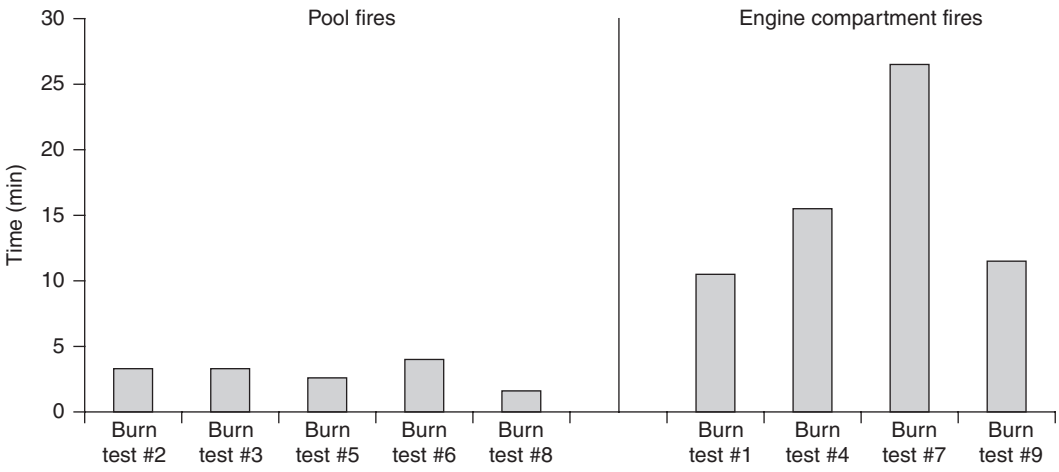
A major milestone in research associated with postcollision fires occurred as part of the DOT/GM Settlement Agreement. This agreement resolved a defect investigation opened by NHTSA into the postcollision fuel tank integrity of General Motors' pickup trucks, model years 1973–1987. As part of the settlement, a 5 year/$10 million vehicle fire research program was initiated to better understand fire initiation and propagation following a vehicle collision.[11] This study is by far the most extensive and detailed study of its kind and provided valuable data related to both understanding postcollision fires as well as mitigating the fire hazard to motor vehicle occupants.

Crash Tests. Consistent with real-world postcollision passenger vehicle fires, the 11 crash tests conducted as part of this study were intended to be severe, providing substantial damage to the vehicle structure, electrical systems, fluid systems, and the fuel tank. Crash test configurations included a moving deformable barrier, similar to the barrier used to assess compliance with the requirements of FMVSS 214,[12] with the vehicle traveling at 53 mph (85 km/hr) for rear impacts and 65 mph (104.6 km/hr) for front impacts, at 34 mph (54.7 km/hr) for frontal pole impacts, and frontal at 37 mph (59.5 km/hr) for oblique barrier impacts (only one oblique test was conducted). The crash tests were conducted with all normal engine fluids (except for the main fuel tank which was filled with Stoddard solvent for the crash test) with the engine running, and were heavily instrumented to attempt to capture the mechanism of ignition and propagation, should a fire occur. Once the crash tests were conducted, carefully controlled and heavily instrumented burn tests were performed in a manner consistent with the expected method of fire causation for each crash test. The data collected from the burn test were then used to calculate the point in time in which conditions would have become untenable for any occupants within the passenger compartment.

Untenable Conditions. One of the important findings from this work was that the time at which untenable conditions were reached was strongly correlated to the time that flames entered the passenger compartment. Regardless of how or where flames entered the passenger compartment, conditions became untenable in a matter of several minutes. It should be noted that untenable conditions depend on where measurements were taken. In larger vehicles, tenable and untenable conditions may occur at the same time in different locations within a burning vehicle. In the case of the pool fire tests, flames from the pool fire underneath the vehicle penetrated into the passenger compartment though gaps around deformed doors or underbody seams created by crash-induced damage. The time to reach untenable conditions ranged from 1.6 to 4.0 minutes, a relatively short period for rescue by emergency personnel. For fires which initiated in the engine compartment, flames entered the passenger compartment in one of three manners: (1) through the windshield when it failed; (2) through the heating and air conditioning system vents; and/or (3) through pass-throughs in the bulkhead. A comparison of the times required to reach untenable conditions for both the pool fires and the engine compartment fires is shown in Figure 21.1.5.

It should be noted that a comparison of individual times to untenable conditions within a given test series must also be analyzed based on the manner and location in which the fire was initiated and the type of crash. Although pool fires are less common than engine compartment fires, they are responsible for a large number of fatalities. In the period from 1994 through 1998, NFPA data indicate that fuel-fed fires accounted for 27 percent of highway vehicle fires, but they were responsible for 56 percent of vehicle fire fatalities. Pool fires (or fuel-fed fires) differ from other vehicle fires in that the power output of the initial fire is controlled not by the material flammability characteristics of the vehicle components but by the size of the fuel pool.

Further, flame penetration times into the passenger compartment vary depending on the condition of the vehicle. Time to penetration can be reduced in postcollision fires, as the



Note: A comparison of individual times to untenable conditions within a given test series must also be analyzed based on the manner and location in which the fire was initiated and the type of crash.

FIGURE 21.1.5 Time to Reach Untenable Conditions in Postcollision Fire Tests.

vehicle structure and metal panels can be torn or otherwise breached, allowing flames and smoke to more quickly enter the passenger compartment. As such, the onset of untenable conditions is linked to the condition of the vehicle and hence whether there has been a collision event. In the case of pool fires, untenable conditions that can cause injuries and fatalities can occur quickly, much quicker than the response times of emergency personnel. (See Figure 21.1.5 reference to NFPA report that has response time information.) Thus the strategies involving fire performance of materials and components inside the vehicle are not expected to have a significant effect on the outcome of a fuel-fed fire.[13]

Material Flammability Research

As part of the NHTSA's mandate to reduce deaths, injuries, and economic losses related to crashes and vehicle fire hazards, the NHTSA not only reviews existing standards internally and evaluates their effectiveness on a periodic basis, but also considers requests from any person or organization to develop new or revised standards. This standard development process incorporates the extensive technical expertise and resources available in the automotive industry. It also provides a mechanism to evaluate and compare the potential safety benefits of a new or revised standard with the associated cost to the public. Furthermore, this process assesses design and safety trade-offs associated with a wide range of interdependent technical issues, including crashworthiness, fire safety, human health, toxicology, environmental impact, and fuel economy.

Small-Scale Testing. As part of an effort to determine the feasibility and benefit of improving the FMVSS 302 test procedure, NHTSA recently funded a Southwest Research Institute (SwRI) study.[14] The purpose of this study was to identify or develop new small-scale test methodologies to rate automotive materials consistent with actual fire performance in full-scale vehicle burn tests and to explore levels of performance for this test methodology that would significantly increase survivability. The study, which addressed materials in the engine compartment, identified the cone calorimeter (ASTM E1354) as the most suitable bench-scale test apparatus to rate the flammability characteristics of automotive materials. The cone calorimeter is a small-scale, or bench-scale, flammability testing apparatus that subjects small 4 in. by 4 in. (100 mm by 100 mm) samples of a material or materials to an applied heat source. The heat source heats the material and the material, if possible, is ignited by means of a spark igniter. The equipment provides a measure of the material's heat release rate (HRR) and ignition time, and can be equipped to collect other data, including quantities of products of combustion produced as well as mass loss rate data, among other things. Using the cone calorimeter data, a model was formulated for evaluating the fire hazard of a particular engine component material. There was no validation of the proposed model, although validation was proposed as part of future work through full-scale vehicle burn tests. No specific performance criteria that would significantly alter the fire outcome in terms of injury or survivability were offered.

The difficulty of establishing a link between bench-scale test results and the performance of materials in full-scale vehicle tests was highlighted in several of the tests associated with the GM/DOT settlement described previously. To examine the influence of fire retardants, a test vehicle was identified from previous testing where the engine compartment fire penetrated into the passenger compartment through the HVAC unit and windshield.[15] These tests set out to examine if a flame-retardant HVAC unit would alter this behavior.

In these full-scale tests, one passenger vehicle was equipped with a factory supplied HVAC unit and the other otherwise iden-

tical vehicle was equipped with the fire-retardant HVAC. Each of these vehicles was crashed in identical crash tests. These crashed vehicles were then burned using identical ignition sources in identical locations within the engine compartment. The instrumentation associated with the burn tests was the same as used in previous burn tests in the GM/DOT research program, such that the time to untenable conditions could be evaluated for each vehicle.

In bench-scale tests, as expected, the polymer material treated with the fire retardant exhibited a significantly lower heat release rate.[16,17] The heat release rate of the material with untreated polypropylene exceeded 200 kW/m^2 whereas the heat release rate of the flame-retarded HVAC unit was approximately 5 kW/m^2.

Full-Scale Testing. Results from the full-scale vehicle burn tests demonstrated that the fire retardant was ineffective. The heat release rates from the two burn tests were essentially identical. As expected with very similar fire growth rates, the times to reach untenable conditions were also essentially identical. These results are in sharp contrast to the bench-scale cone calorimeter and intermediate-scale results described previously and indicate the difficulty in using bench-scale tests to predict behavior in full-scale vehicle burn tests. Not only did the fire retardant not produce an improvement in the time to untenable conditions, the addition of the fire retardant actually degraded fire safety by producing higher levels of toxic gases.

HAZARD MITIGATION STRATEGIES

Role of ASTM E1546

ASTM E1546, *Standard Guide for Development of Fire-Hazard-Assessment Standards,* describes the development of a fire hazard assessment. ASTM E1546 outlines the manner in which scientific data should be compiled in order to ensure that the information is relevant to the assessment of a fire hazard of a product under specific conditions of use.

According to ASTM E1546, the purpose of a fire hazard assessment is to reveal whether a product produces an increase, no increase, or a decrease in fire hazard for all scenarios relevant to the use of such product. As part of this assessment, it is necessary to first determine the nature of the product's involvement in a potential fire (i.e., initial heat source, initial fuel source, principal or largest fuel source, etc.). This factor is critical in assessing the role that the product plays in fire growth and spread, and how its material properties affect the evolution of the fire. Once this determination is made, it is possible to define the material properties that would provide a "significant variation" on the fire hazard of the product. Once the area of greatest concern is determined, it is then possible to define the test methods or calculation procedures that will measure the product's contribution to the fire hazard.

The environment in which the product is used is also of importance. ASTM E1546 states that it is possible to use data from fire tests of isolated parts. However, the relative importance, interaction, and relevance of the fire test response characteristics, individually and collectively, to the hazard posed by the product in real fires must be established by comparison to more thorough assessments, such as established scientific principles, large-scale tests, and analyses of real fires.

This requires that testing and/or analysis be performed not only for the isolated product (i.e., at the component level), but also as a component in a system (i.e., in actual vehicles under actual fire scenario conditions). Apart from the product analysis, it is also important to identify and measure the impact (i.e., reduction in injuries and fatalities) of the product's flammability properties on the outcome of a possible fire.

Application of ASTM E1546 to Vehicle Fire Safety

ASTM E1546 provides general guidelines for fire hazard assessments. In the case of vehicle fires, it is important to take into account the special circumstances involved and to use any available data on such incidents. In particular, emphasis should be placed on types of fires that are likely to result in injuries and fatalities. It is also important to have a clear understanding of the types of fires commonly involved in vehicle accidents and how such fires progress. This information must then be used to assess what factors play the largest role in the evolution and growth of vehicle fires. Only then can the major fire hazards be identified and quantified.

The fundamental requirement to prevent fatalities due to postcollision fires is that egress or extinguishment occurs before conditions become untenable in the passenger compartment. Mitigating the risk of injury to the occupants of passenger vehicles involved in postcollision fires can be accomplished by any combination of the four factors that follow:

1. Reduce the risk of ignition, that is, prevent the fire from occurring
2. Decrease the time necessary to egress or to be extricated
3. Decrease the time required to extinguish the fire
4. Increase the time until untenable conditions exist within the passenger compartment

Reducing the Ignition Probability. The most obvious way to reduce the number of postcollision fire injuries and deaths is to prevent fires from occurring. Limited research has been conducted to evaluate the mechanisms responsible for ignition of postcollision fires, particularly those that did not involve gasoline as the first material ignited. More research is necessary in this area to better understand the processes that cause ignition as a result of collisions and the methods that may be used to reduce the probability of ignition.

Decreasing the Time Required to Egress. In cases where the occupants of the vehicle are incapacitated or trapped, the time required to egress is related to the involvement of bystanders or emergency response personnel. Time to egress is also influenced by specific crash-induced damage to the vehicle and the ability of occupants to egress. The response of emergency personnel depends of a number of complex factors and has been studied extensively. In 1999, NHTSA funded

a study to address the possibility of reducing the crash-to-notification times to 1 minute using an automated collision notification (ACN) system.[18] This system was expected to also shorten the notification-to-arrival time due to automated directions to the site. The system was evaluated by NHTSA,[19] with a program initiated in 1995, in order to assess its effectiveness. In the end, it was found that the ACN produced an unacceptable number of false alarms and was too complicated and costly.

Decreasing the Time Required to Extinguish the Fire. Excluding the possibility of bystanders extinguishing a postcollision fire, the two main methods to decrease the time required to extinguish the fire are decreasing the emergency personnel response time (and associated time to notify emergency responders) or designing and installing an effective on-board fire suppression system. Because fuel-fed fires can become untenable before emergency personnel arrive on scene, one of the leading hazard mitigation strategies in this scenario is an on-board fire suppression system.

The great diversity of collisions and the associated postcollision fires create a complex set of problems which must be overcome in developing a robust, on-board fire suppression system. Factors such as the amount of damage sustained to the vehicle, vehicle movement, wind direction and speed, and reignition after suppressant release can substantially reduce the effectiveness of an automatic suppression system in extinguishing a postcollision fire.[20] Overall, these technologies show some promise, but there is still much research required to improve their reliability and effectiveness in an actual postcollision vehicle fire. Tewarson et al. relayed in their work that one set of tests conducted produced results indicating that it is highly improbable that an on-board fire suppression system would be able to extinguish most engine compartment and underbody fires.[21]

Increasing Tenability Time. Another approach to hazard mitigation of postcollision fires (at least those which do not involve a fuel-fed fire) is to slow the spread of the fire into the passenger compartment. A strategy that has received significant attention is the use of fire retardants in plastic automotive components. Although bench-scale tests have shown that fire retardants can lower the heat release rate of plastics, the ability of fire retardants to increase the time to untenable conditions in the vehicle interior has not been demonstrated in full-scale tests. Whereas the benefits of using fire retardants are unclear, there are numerous potential negative consequences to using fire retardants, many of which are toxic to humans. These include toxic effects of the fire retardant coming into contact with people, the toxic gases produced by fire retardants when they burn, environmental concerns about disposing of these toxic materials at the end of a vehicle's life, and the potential adverse effects that fire retardants may have on the intended function of the component, such as energy absorption, strength, weight, wear, durability, and appearance. Additional research is necessary to evaluate the effectiveness of fire retardants on motor vehicle safety and to ensure that the toxic effects of fire retardants are not a detriment to the public.

DESIGN AND SAFETY CONSIDERATIONS

Other physical properties and component relationships related to vehicle safety other than flammability and fire response must be included in the hazard assessment in order to assess whether changes in component flammability or fire response will adversely affect other safety attributes of the components and the entire vehicle system (i.e., trade-offs).

From the standpoint of fire safety, all vehicle components could theoretically be made of noncombustible materials. This, however, is not feasible, as has been previously discussed in the literature.[22] In the case of a passenger vehicle, the choice of materials to be used in the vehicle should be driven by overall safety and function. For example, it would not be prudent to decrease the fire hazard related to automobile components while increasing the risk of injury during a crash.

Automobile components are specifically designed to be used for extended periods of time, under a variety of environmental conditions and (most importantly) be able to perform well during a crash. Before any additional requirements (such as changes in flammability performance) are suggested regarding vehicle components, it is necessary to determine that these new requirements are not detrimental to other safety properties of such materials. The following is a discussion of some possible considerations.

Need for a Systems Approach

Safe vehicle design requires a systems-level approach, instead of focusing solely on prescriptive, individual material performance requirements. Other physical properties related to the ability to manufacture a working component, the functionality of a finished component or assembly, the durability of the component, occupant protection in a crash, and other safety parameters, are necessary and equally important considerations in designing components for use in passenger vehicles. Changes to the formulation of combustible materials that result in improved flammability and/or fire response characteristics based on bench-scale tests alone could adversely affect other material physical properties and may negatively impact manufacturability, durability, functionality, and crash protection.

Physical Properties

Many of the components in today's vehicles are designed with specific material properties intended to increase the survivability of passengers during a collision or rollover. As an example, some fire mitigation strategies may have adverse and unwanted effects on FMVSS 201* performance such as energy absorption due to change in materials stiffness if new materials were substituted for current materials. Another example is the use of fire retardants that may compromise crash safety performance, because of the reduction in energy absorption due to the increase of material stiffness. In the case of very specialized components, such as airbags or seatbelts, the addition of fire retardants would

*FMVSS 201 specifies requirements for occupant protection in interior impacts.

have to be thoroughly evaluated and analyzed if the materials used in their construction were altered.

Although ordinary fire-retardant treatments have been shown to improve the flammability properties of polymer materials under bench-scale testing, their behavior under real fire conditions is currently not well understood. In one study of automotive material flammability, it was noted that "ordinary fire retardant treatments are not effective in preventing the flame to penetrate the passenger compartment and thus concepts based on modifying the fundamental thermo-physical-chemical and fire properties under high heat flux exposure conditions need to be utilized to enhance the fire retardancy of automotive polymers."[23]

Although the desired performance requirements may be met with the addition of fire retardants in automotive materials, an increase in time to ignition and a decrease in heat release rate performance may yield an increase in toxicity levels and provide no net benefit in overall fire safety. The smoke and fumes inside the passenger compartment during a fire should be considered in a fire hazard assessment. Toxic fumes could overcome passengers that have become entrapped or otherwise incapacitated inside the passenger compartment due to the use of fire-retardant chemicals.[24,25]

Health and Environmental Hazards

Potential health and environmental hazards also need to be evaluated. Next to homes and offices, we spend the most time inside automobiles, an average of 101 minutes per day.[26] During this time, we are exposed to the materials within the automobile in an enclosed space, increasing our contact with any volatiles or contaminated particulates. This means that care must be taken to reduce the toxicity of materials and/or reduce the use of toxic materials within an automobile. Chemicals within a passenger vehicle are exposed to extreme conditions, which may accelerate their decay. Summer air temperatures inside parked vehicles can reach 192°F (88.88°C), with dash surface temperatures of up to 248°F (120°C) recorded.[27] In addition, most vehicle windows transmit long-wave UV light, which can increase the rate of decomposition of materials.

The literature contains numerous papers addressing health and/or environmental concerns associated with the historical use of flame-retardant substances. Asbestos and PCBs are just two examples of materials adopted as flame retardants because of their chemico-physical properties. Only later did scientists and the industry develop an understanding of the biological consequences of that decision.

There are many different potential flame-retardant additives that can be used in plastics in order to meet specified performance requirements. Not all of these chemicals have been thoroughly investigated in terms of their human or ecological health hazard. Prior to their implementation, each of the various chemical options deserves to be assessed fully in order to characterize these hazards.

Another important concern is that when a flame retardant is brought into the marketplace, there is an abundance of opportunities for its distribution into the environment. People may be exposed during the manufacture of the flame retardant. Sometimes, particularly toxic chemicals are necessary to synthesize the agent. From there, the retardant needs to be placed in packages and then shipped. The areas of potential risk can be divided into three main categories: risk to workers, risk to consumers, and risk to the environment. Each area must be examined before making changes in material properties.

SUMMARY

Motor vehicle fire safety has realized significant improvements over the past several decades. Considering new vehicles only (4 years old or newer), to eliminate effects attributable to vehicle age, it is found that the risk of fire fatality per one billion vehicle miles traveled is about 30 percent lower for today's vehicles than for model year 1982 to 1986 vehicles. Nevertheless, advancing motor vehicle safety remains a significant public health challenge—one that automakers are addressing daily. According to recent data, in the United States, approximately 32,000 passenger vehicle occupants are fatally injured every year as a result of traffic accidents. Of these fatalities, approximately 1.2 percent (385) are attributed to postcollision fires. In addition, there are approximately 40 passenger vehicle fire fatalities per year that are not collision-related. These statistics indicate that the current standard has been empirically demonstrated to produce a low risk of fatality.

The complexities of passenger vehicle safety require a broad approach in order to ensure that efforts to increase fire safety performance do not undermine other important safety considerations. Any new motor vehicle fire hazard mitigation strategy must address safety trade-offs, such as the extent to which other critical safety features may be compromised if new strategies are implemented. Potential design changes, such as changing the flammability properties of individual components, will have an effect on other component properties, either immediately or over time.

Research to improve vehicle fire safety involving postcollision fires is in its infancy, and few full-scale vehicle burn tests have been conducted to validate new strategies. Significant additional research is necessary to develop robust, cost-effective hazard mitigation strategies for postcollision fires.

Chapter 2

Fire Safety in Commercial Vehicles

Revised by
Brian Routhier

Chapter Contents

Nature of Vehicle Fires
Federal Regulations Affecting Motor Vehicle Fire Safety
NFPA and Related Standards on Motor Vehicles
Preventing Motor Vehicle Fires
Cargo Tanks (Tank Trucks)

Key Terms

cargo tank, commercial vehicle, Federal Motor Vehicle Safety Standard (FMVSS), hazardous material, motor vehicle, National Transportation Safety Board (NTSB), road trailer, vehicle electrical system, vehicle fuel tank

Many factors influence motor vehicle fire safety. Among these are vehicle design and construction; materials from which a vehicle is constructed or which are carried by a vehicle, particularly upholstery, plastic, wood, fuel, and hazardous materials cargoes; vehicle maintenance, including safeguards against fire during vehicle repair; vehicle operation, including avoidance of collisions and of other accidents, such as those involving smoking materials; and garaging or storage of vehicles.

The degree of fire hazard depends on the vehicle type, such as passenger car, motorcycle, motor home, or tank truck; the use of the vehicle for pleasure driving, commercial service, or off-road; the climate and environment in which it is used; the age, condition, and maintenance of the vehicle; the material and construction standards to which it is built, particularly the fuel and electrical systems; and the type of fuel used—gasoline, diesel fuel, propane, natural gas, or alcohol—and the way the fuel is contained in the vehicle.

Research into causes of motor vehicle fires based on individual crash investigations and collections of crash and other loss data indicate the magnitude of the motor vehicle fire problem and some specific causal factors in motor vehicle fires.

Each year, the United States experiences approximately 6200 highway vehicle fires due to collision and 12.7 million on-the-road vehicle accidents. Yet serious injury from vehicle fires occurs overwhelmingly from crash-related fires—fires that occur at a rate of approximately 1 per 1000 crashes. Three-fifths of fire deaths in motor vehicle fires come in postcrash incidents.[1,2]

In 2000, there were an estimated 325,000 fires involving highway vehicles, causing 450 civilian deaths and 1325 civilian injuries. Table 21.2.1 presents information on the U.S. highway vehicle fire problem for the years 1980 to 2002.

For related topics, see the following chapters in Section 21: Chapter 1, "Passenger Vehicle Fires"; Chapter 3, "Automotive and Marine Service Station Operations"; Chapter 4, "Vehicle Fueling Using Gaseous Fuels"; and Chapter 6, "Recreational Vehicles." See also Section 13, Chapter 6, "Public Fire Protection and Hazmat Management"; and Section 13, Chapter 8, "Managing the Response to Hazardous Material Incidents."

NATURE OF VEHICLE FIRES

As with other fires, motor vehicle fires require a flammable substance, an ignition source, and oxygen. Virtually all motor vehicles carry flammable fuel—gasoline, gasohol, diesel fuel, or another hydrocarbon compound. Vehicle upholstery, insulating and sound-deadening materials, electrical wiring insulation, and plastic body and trim also can fuel a motor vehicle fire. Materials carried as cargo and fare in or on motor vehicles, particularly trucks, also may be flammable.

Ignition sources include electrical short circuits or other electrical malfunctions that cause excessive heating of conductors or components; sparks from an engine ignition system; hot exhaust system components; engine backfire; overheating of tires, brakes, and wheel bearings; friction-generated

Brian Routhier is an automotive engineer with the American Trucking Associations in Arlington, Virginia.

TABLE 21.2.1 U.S. Highway Vehicle Fire Problem, by Year: 1980–2002

Year	*Fires*	*Civilian Deaths*	*Civilian Injuries*	*Direct Property Damage (in Millions of Dollars)*	*Loss in 2002 Dollars (in Millions of Dollars)*
1980	411,300	600	3,350	478	1,044
1981	417,500	680	2,930	477	942
1982	398,400	570	2,850	409	761
1983	405,400	640	3,250	532	959
1984	411,600	550	3,080	592	1,024
1985	417,000	710	3,060	702	1,172
1986	417,600	740	3,180	608	998
1987	429,300	700	2,620	687	1,088
1988	416,000	730	2,520	728	1,108
1989	379,100	520	2,570	751	1,090
1990	383,000	590	2,920	792	1,092
1991	371,200	480	2,500	801	1,058
1992	335,700	590	2,510	758	971
1993	354,600	500	2,380	723	900
1994	330,100	460	1,960	779	946
1995	334,700	380	1,780	790	932
1996	327,800	470	1,520	774	888
1997	355,100	430	1,860	1,025	1,149
1998	313,600	420	1,610	1,010	1,115
1999*	288,000	350	1,150	911	984
2000	252,400	310	1,100	903	943
2001	257,500	390	1,440	1,064	1,081
2002	281,600	480	1,540	1,143	1,143
1980–2002 annual average	360,400	530	2,330	758	1,017
1999–2002 annual average	269,900	380	1,310	1,005	1,038

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest hundred, civilian deaths and injuries to the nearest ten, and direct property damage is rounded to the nearest million dollars.

*NFIRS data for 1999 and later was received in the Version 5.0 format. Due to the many coding changes, the 1999–2002 data can better be analyzed separately from data from previous years.

Source: NFIRS and NFPA survey; Table 697, "Purchasing Power of the Dollar" from U.S. Census Bureau's *Statistical Abstract of the United States: 2004–2005* (124th Edition).

sparks from a collision or from metal components scraping against the pavement; and careless use of cigarettes and other smoking materials. Generally, oxygen in the ambient atmosphere is sufficient for a motor vehicle fire.

Table 21.2.2 summarizes passenger and freight vehicle fires, by area of origin of fires, from 1999 to 2003. More detailed but dated analyses have been developed by the Federal Motor Carrier Safety Administration (FMCSA) of the U.S. Department of Transportation (DOT).

Death and injury in motor vehicle fires can result from direct exposure to heat and from inhalation of toxic combustion products. In major vehicle crashes involving fire, determining with certainty whether death resulted from the crash or from the fire may not be possible. In some cases, injury results from or is exacerbated by the inability of a vehicle's occupant to get out of the burning vehicle—doors or seats are jammed by a crash, or the occupant is injured or stunned.

Hazardous materials in motor vehicles present a particular fire problem. The National Transportation Safety Board (NTSB), the FMCSA, and NFPA all carried out a number of detailed accident investigations into such fires. These investigations led to changes in regulations for hazardous materials containers and in other aspects of the transportation of such cargoes. Despite such precautions, hazardous materials cargo fires and explosions occur.

The NTSB has issued investigative reports on accidents in which hazardous materials exploded or burned following a crash. (These and other NTSB reports are available from the National Technical Information Service, Springfield, Virginia 22161.) As a result of these and other highway crash investigations, the NTSB made numerous recommendations to the FMCSA, the Research and Special Programs Administration (RSPA) of DOT, and to other agencies concerning modification and enforcement of safety and hazardous materials regulations.

TABLE 21.2.2 U.S. Highway Vehicle Fires, by Area of Fire Origin, 1999–2003 Annual Averages

Area of Fire Origin	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions)*	
Engine area, running gear, or wheel area	212,000	(65%)	170	(39%)	740	(49%)	$618	(53%)
Operator or passenger area	53,800	(17%)	90	(20%)	270	(18%)	$264	(23%)
Unclassified vehicle area	14,400	(4%)	50	(11%)	70	(5%)	$55	(5%)
Exterior, exposed vehicle surface	10,200	(3%)	10	(2%)	50	(3%)	$33	(3%)
Cargo or trunk area	9,900	(3%)	10	(3%)	100	(7%)	$44	(4%)
Fuel tank or fuel line	5,400	(2%)	80	(17%)	150	(10%)	$41	(4%)
Unclassified area of origin	4,300	(1%)	10	(2%)	10	(1%)	$22	(2%)
On or near highway, parking lot, or street	4,100	(1%)	10	(3%)	10	(1%)	$17	(1%)
Separate operator or control area	3,200	(1%)	0	(1%)	10	(1%)	$18	(2%)
Other known area	7,900	(2%)	10	(3%)	80	(6%)	$44	(4%)
Total	325,100	(100%)	440	(100%)	1,500	(100%)	$1,156	(100%)

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest hundred, civilian deaths and injuries to the nearest ten, and direct property damage is rounded to the nearest million dollars. Sums may not equal totals due to rounding errors. Property damage figures are not adjusted for inflation. Percentages were calculated on the actual estimates, so two figures with the same rounded-off estimates may have different percentages. Fires in which the area or origin was unknown or not reported were allocated proportionally among fires with known area of origin. A proportional share of fires in which the mobile property type was unknown or not reported are included in this table.

FEDERAL REGULATIONS AFFECTING MOTOR VEHICLE FIRE SAFETY

As you read the statistics in this section, note that the data were current at the time of writing. As always, it is wise to check Federal Motor Vehicle Safety Standards for the most current information.

Federal Motor Vehicle Safety Standards

The National Traffic and Motor Vehicle Safety Act of 1966 authorized the National Highway Traffic Safety Administration (NHTSA) of DOT to set minimum safety standards applicable to new motor vehicles, trailers, and motor vehicle equipment manufactured after the effective date of the standard, or any subsequent amendment. To date, only four fire-related standards have been issued for new vehicles, and none has been issued for vehicles in use. The NHTSA also has the authority to investigate motor vehicle defects, some of which may present fire hazards, and to order manufacturers to notify owners and repair defects.

Federal Motor Vehicle Safety Standard (FMVSS) 301 sets requirements for the fuel system integrity of passenger cars, trucks, buses, and multipurpose vehicles having a gross vehicle weight rating (GVWR) of 10,000 lb (4536 kg) or less. The standard also applies to school buses of more than 10,000 lb (4536 kg) GVWR using fuel with a boiling point of more than 32°F (0°C).

FMVSS 301 is intended specifically to reduce the fire hazard resulting from fuel leakage in crashes. It was first applied to passenger cars manufactured on and after January 1, 1968. Since that time, the standard has been made increasingly stringent.

Under provisions that became effective on September 1, 1977, all vehicles with a GVWR of 10,000 lb (4536 kg) or less must pass prescribed front, side, and rear crash barrier tests and a rollover test. Front tests are conducted at an impact speed of 30 mph (48 km/hr), rear tests at 50 mph (80 km/hr), whereas lateral impact speed is 33 mph (53 km/hr). In the crash barrier tests, fuel leakage cannot exceed 1 oz (28 g) by weight from impact until the vehicle stops moving, 5 oz (142 g) by weight in the 5 minutes following cessation of motion, or 1 oz (28 g) by weight per minute for 25 minutes.

In the rollover test, the vehicle is turned about its longitudinal axis in 90° increments and is held for 5 minutes in each position. Rotation occurs every 1 to 3 minutes. Fuel leakage cannot exceed 5 oz (142 g) by weight in the first 5 minutes of each segment or 1 oz (28 g) per minute for the remainder of the segment.

The school bus test procedure for buses over 10,000 lb (4536 kg) GVWR uses a special, moving, contoured barrier that strikes the test vehicle at the front, rear, and sides. No rollover test is prescribed for these buses. Maximum permissible fuel leakage is the same as indicated above for front, side, and rear barrier crash tests.

FMVSS 302 sets flammability limits for materials used in interiors of vehicles in the driver and passenger space. Its requirements are directed at reducing the hazards of interior fires caused by smoking and matches. Vehicle appointments specifically covered by the standard include seat cushions, seat backs, seat belts, headlining, arm rests, trim panels, compartment shelves, head restraints, floor covering, engine compartment covering, padding, and the surface of crash protection components.

FMVSS 302 specifies a horizontal flame test for all materials and incorporates detailed requirements for the test procedure. Material under test must not burn or transmit a flame across the surface at a rate exceeding 4 in. per minute (1.7 mm/s).

FMVSS 303, *Fuel System Integrity of Compressed Natural Gas Vehicles—Passenger Cars, Multipurpose Passenger Vehicles, Trucks, and Buses,* covers vehicles that have a gross vehicle weight rating of 10,000 lb (4536 kg) or less and use compressed natural gas as a motor fuel. FMVSS 303 also covers school buses (regardless of weight) that use CNG as a motor fuel.

FMVSS 303 specifies requirements for the integrity of motor vehicle fuel systems using CNG, including CNG fuel systems of bi-fuel, dedicated, and dual-fuel CNG vehicles. The purpose of the standard is to reduce deaths and injuries resulting from fires after fuel leakage during and after motor vehicle crashes.

FMVSS 304, *Compressed Natural Gas Container Integrity,* specified requirements for the integrity of CNG motor vehicle fuel containers. FMVSS 304 applies to containers designed to store CNG as motor fuel on board any motor vehicle.

Federal Motor Carrier Safety Regulations

FMCSA administers the Federal Motor Carrier Safety Regulations (FMCSRs), which can be found online at http://www.fmcsa.gov. These regulations apply to vehicles in use, as contrasted with the Federal Motor Vehicle Safety Standards promulgated by the National Highway Traffic Safety Administration (NHTSA) that apply to new vehicles.

The FMCSRs are set forth in Title 49 of the Code of Federal Regulations, Parts 325–399, and apply to commercial vehicles in interstate or foreign commerce. Because most states have adopted these regulations by reference, they also apply, *de facto,* to most commercial vehicles in intrastate commerce.

Provisions of these regulations that address fire safety issues for commercial vehicles include the following:

- A requirement for fire extinguishers and for the driver to check the extinguisher at the start of each trip
- A prohibition against attaching a flame-producing warning device to a vehicle and a prohibition against using flame-producing devices on vehicles transporting certain explosives and tank vehicles transporting flammable liquids or gases (loaded or empty), or any commercial vehicle using compressed gas as a fuel
- Fueling precautions including a prohibition against smoking, a requirement to maintain contact between the tank and the nozzle, and restrictions on fueling buses when passengers are aboard
- Standard for installing and protecting the electrical system, including the battery, and standards for constructing and testing fuel tanks
- Special driving and parking rules applicable to drivers transporting hazardous materials including requirements to periodically check for overheated tires, a requirement that someone be present at the nozzle when the vehicle is being fueled, and a prohibition against smoking in or within 25 ft (7.6 m) of a vehicle transporting specified classes of hazardous materials

Hazardous Materials Regulations

Federal hazardous materials regulations, other than those governing driving and parking, are published in Title 49, Code of Federal Regulations, Parts 105–180. By law, hazardous materials regulations apply to both intrastate and interstate transportation. Many provisions of these regulations have been promulgated specifically to meet the needs of emergency responders by providing essential information pertaining to the materials in transport and to warn the public of those vehicles transporting hazardous materials in excess of specified quantities. For further information on the federal hazardous materials regulations, refer to Section 13, Chapter 6, "Public Fire Protection and Hazmat Management"; and Section 13, Chapter 8, "Managing the Response to Hazardous Material Incidents."

Provisions of the hazardous materials regulations address the following:

- Preparation of shipping documents to facilitate the recognition and identification of hazardous materials including a 24 hour emergency telephone that can be contacted for additional information, if needed
- Job-specific training requirements for employees involved in transporting hazardous materials at any level
- Emergency instructions to be carried in vehicles and kept in motor carrier terminals where hazardous materials are handled
- Marking and labeling of hazardous materials packaging to identify its contents and to indicate that the packaging complies with applicable specifications
- Specifications for bulk packaging such as cargo tanks and portable tanks, and for nonbulk packaging such as cylinders, boxes, drums, and bags used for hazardous materials
- Requirements for shippers that specify the types of packaging to be used for hazardous materials shipments based on the commodity's specific hazard(s)

State Activity

Most states have adopted by reference the provisions of the Federal Motor Carrier Safety Regulations and the DOT hazardous materials regulations. A number of other states have regulations similar to the federal requirements. As these trends continue, they will foster increasing uniformity of legal requirements.

National Transportation Safety Board

The National Transportation Safety Board, an independent federal agency, oversees safety for all types of transportation. Probably best known for its investigations of aircraft accidents, the agency is also concerned with fire-related highway accidents. The NTSB is responsible for making recommendations for improved safety, based on its investigations. The majority of its recommendations deal with suggested changes in the regulations and practices of federal and state government agencies, but they may also be directed at others, such as vehicle manufacturers and users.

Role of Congress

In Congress, the responsibility for legislation and oversight of transportation rests with the Senate Committee on Commerce and the House Committee on Transportation and Infrastructure. These committees take a keen interest in the activities of the federal government in the field of motor vehicle safety. They regularly hold legislative and oversight hearings on FMCSA and NHTSA activities and occasionally on NTSB activities. Reports of these hearings are available from the U.S. Superintendent of Documents or from the committees.

NFPA AND RELATED STANDARDS ON MOTOR VEHICLES

Several NFPA standards contain requirements for transportation by truck of specific hazardous materials. NFPA 495, *Explosive Materials Code,* details fire and explosion prevention related to the transportation of explosive materials, including driver qualifications, vehicle design, placarding, fire-fighting equipment, and vehicle operation. This code is widely used as the basis for state regulations.

NFPA 385, *Standard for Tank Vehicles for Flammable and Combustible Liquids,* and NFPA 407, *Standard for Aircraft Fuel Servicing,* both contain requirements for design and construction of cargo tanks of tank vehicles, for auxiliary equipment, and for operation of tank vehicles. NFPA 407 covers only special requirements for aircraft fuel servicing tank vehicles and aircraft fuel servicing hydrant vehicles.

NFPA 58, *Liquefied Petroleum Gas Code,* contains requirements for transporting liquefied petroleum gases, including requirements for transporting portable containers, for cargo tanks, and for parking and garaging vehicles used to carry LP-gas. NFPA 58 also includes requirements for installing LP-gas systems in vehicles fueled by LP-gas. It has been adopted for regulatory purposes by 47 states and by the DOT for vehicles in interstate commerce.

NFPA 52, *Vehicular Fuel Systems Code,* covers design and installation of compressed natural gas (CNG) engine fuel systems on vehicles of all types and their associated fueling systems. NFPA 52 applies to the design, installation, operation, and maintenance of liquefied natural gas engine fuel systems on vehicles of all types and to their fueling facilities.

NFPA 58 covers parking and garaging of LP-gas cargo vehicles. Another NFPA standard includes provisions relating to parking trucks: NFPA 498, *Standard for Safe Havens and Interchange Lots for Vehicles Transporting Explosives.*

The dependence of the fire service upon motor vehicles is well recognized, and it is particularly important that fire apparatus be safely constructed. NFPA 1901, *Standard for Automotive Fire Apparatus,* and NFPA 414, *Standard for Aircraft Rescue and Fire-Fighting Vehicles,* detail practices that should be followed on these types of apparatus.

Underwriters Laboratories Inc.

Certain over-the-road motor vehicle components and signaling appliances have special fire hazard significance. Underwriters Laboratories Inc. tests and lists them in UL's *Accident, Automotive, and Burglary Protection Equipment* directory. Specific items listed include the following:

1. Electrical equipment such as automobile fuses and switches
2. Fill and vent fittings
3. Fuel equipment such as backfire deflectors, fuel feed systems, electric gasoline gages, automotive-type LP-gas accessories, automotive fuel tanks, and tubing
4. Automotive heaters of the combustion type
5. LP-gas automotive vehicles—that is, farm and road tractors incorporating fuel systems designed for use of LP-gas as engine fuel and LP overfill prevention
6. Mufflers for automobiles
7. Signals and signaling appliances or highway emergency signals

UL also has its own standard, UL 395, *Standard on Automotive Fuel Tanks,* for liquid fuel tanks mounted outside the frame or in other exposed locations on gasoline- or diesel-powered trucks, tractors, or trailers. It has issued UL 307(a), *Standard on Liquid Fuel-Burning Heating Appliances for Mobile Homes and Recreational Vehicles,* and UL 307(b), *Standard for Gas Burning Heating Appliances for Mobile Homes and Recreational Vehicles.*

Society of Automotive Engineers, Inc.

The Society of Automotive Engineers, Inc. (SAE) is concerned with any vehicle that moves under its own power. SAE's standardization program covers passenger cars, trucks and buses, farm and earth-moving machinery, marine propulsion units, aircraft, and space vehicles, as well as the materials and components that go into them. Content of the SAE standards is limited to environmental and operating problems with these vehicles. The *SAE Handbook* contains all the society's surface vehicle documents.

Other Organizations Interested in Highway Safety

American Petroleum Institute (API). Active in the field of truck transportation of petroleum products, API publishes a number of publications of interest and value from the fire safety viewpoint. More information is available at http://www.api.org.

American Trucking Associations, Inc. The association reproduces the federal hazardous materials regulations in their entirety as "Hazmat Transport Regs." The association's safety department sets trucking industry standards for selecting, training, and supervising employees and develops a variety of materials for the use of trucking companies dealing with general safety and safe transportation of hazardous materials. More information is available at http://www.truckline.com.

Canada Safety Council. The council is a national, nongovernmental organization that promotes public safety initiatives in English and French. See http://www.safety-council.org.

Center for Auto Safety. The center is a consumer advocate organization dedicated to improving the safety and value of automobiles, other motor vehicles, highways, and mobile homes. The center regularly issues reports, books, comments on federal rule making, and other materials. See http://www.autosafety.org.

American Chemistry Council. The council has an active technical service on transportation and packaging. It also operates the Chemical Transportation Emergency Center (Chemtrec), 1-800-262-8200, http://www.chemtrec.com, which provides information on hazardous materials involved in emergencies. For more information, see http://www.americanchemistry.com.

Compressed Gas Association, Inc. (CGA). CGA provides technical services on products of interest and concern to its membership. See www.cganet.org.

Consumers Union of U.S., Inc. (CU). A nonprofit consumer information organization with a large technical staff, CU regularly tests automobiles—and occasionally trucks and other motor vehicles—and publishes its findings monthly in *Consumer Reports* magazine. For more information, see http://www.consumersunion.org or http://www.consumerreports.org.

Cooperative Hazardous Materials Enforcement and Development (COHMED). COHMED develops and promotes training programs for personnel responding to hazardous materials emergencies. More information on COHMED, an outreach activity of the U.S. Department of Transportation, is available at http://hazmat.dot.gov/cohmed.htm. Other DOT sites and resources on hazardous materials include the following:

- DOT regulations at http://www.myregs.com/dotrspa
- DOT Hazmat Law at http://www.hazmat.dot.gov/regs/notices/dotbill.pdf
- DOT main page at http://www.dot.gov

Hazardous Materials Advisory Council. The council is concerned with all aspects of hazardous materials transportation affecting shippers, all modes of transportation, and manufacturers of packaging. It also conducts training in the safe transportation of hazardous materials. See http://www.hmac.org.

Insurance Institute for Highway Safety. The institute is an independent, nonprofit, scientific, and educational organization dedicated to reducing losses resulting from crashes on the nation's highways. See http://www.iihs.org.

National LP-Gas Association. This association develops LP-gas standards and provides safety programs for the general public. See http://www.pgas.com.

National Safety Council (NSC). A nonprofit organization dedicated to accident prevention, the council has an extensive program on highway safety geared principally to the motoring public. NSC produces numerous publications on transportation and highway safety. More information is available at http://www.nsc.org.

National Tank Truck Carriers, Inc. (NTTC). NTTC helps members, who are operators of tank truck fleets, solve problems associated with safe handling of flammable liquids, gases, and chemicals. See http://www.tanktruck.org.

Truck Trailer Manufacturers Association. A trade association of manufacturers of truck trailers, it cooperates, through its various committees and representatives, with NFPA, other allied industry associations, and governmental agencies in matters affecting tank transport design and fabrication. See http://www.ttma.net.

Trailer and Truck Box Design and Construction Safeguards

Currently there are no FMVSS, NHTSA, or FMCSA standards for fire retardance of cargo trailers or bodies. In large truck bodies and in freight-carrying trailers, wood is used as flooring. It withstands torsional stresses, impacts, and abrasions encountered in this type of service, and replacement of worn or damaged sections is relatively economical. Wood provides safety benefits because blocking and bracing can be nailed in place to prevent shifting of cargo. It offers a high coefficient of friction for safe forklift operation and a slip-resistant footing for personnel who handle cargo.

Plywood is used for interior lining material in van-bodied trucks and trailers because it effectively protects other structural components from damage that may occur during loading, unloading, and transportation of freight. As with wood flooring, replacing damaged sections is relatively inexpensive.

Plywood flooring is used in buses for essentially the same reasons. Metal flooring would create "tin canning" under torsional stress and a resulting noise level unacceptable to passengers.

These uses of wood do not create any significant fire hazards. In the forms used, the wood is relatively difficult to ignite and burns slowly. Specific provisions of the Federal Motor Carrier Safety Regulations require that flooring be in good condition. The use of flooring permeated with oil or gasoline is prohibited.

In major incidents involving fire, wood can be a contributing factor, but usually only in incidents so severe that their outcomes would have been little affected if wood had not been present.

When the cargo must be covered during transportation on flatbed, open-top, and other types of nonenclosed vehicles, the use of tarpaulins is the only practicable means of providing needed protection. Such tarpaulins normally are not given flame-retardant treatment, but they pose little risk of fire.

Vehicle Fuel Tanks and Systems

The location, construction, and security of fuel tanks are important design features for fire safety in motor vehicles. Liquid fuel tanks for general passenger car use are generally of plastic or thin-gauge steel of various shapes and dimensions, dependent upon other body and chassis characteristics. The vast majority of U.S.-built cars, trucks, and buses have liquid fuel tanks located at the rear of the vehicle, frequently in such a position that

they are not entirely enclosed in the body. The greatest risk of loss of life and property from fire in vehicles, therefore, occurs in fires following rear-end collisions.

The Federal Motor Carrier Safety Administration (FMCSA) has developed fuel tank regulations applicable to commercial vehicles operating in interstate or foreign commerce. These regulations closely parallel Underwriters Laboratories (UL) standards. In 1973, requirements that previously had been limited to gasoline tanks were extended to include tanks for diesel fuel. This action also required protection for diesel fuel crossover lines located below the bottom of a tank or sump. The DOT regulations include requirements for tank construction and installation and for adequate fillpipe closure. Tanks must pass drop, rupture, vent, and spillage tests. Required safety vent systems must limit pressure rise to 50 psig (345 kPa) in a specified fire test.

Tanks must be marked by a manufacturer's certificate to indicate that they meet DOT-FMCSA specifications for side-mounted or non-side-mounted tanks, as applicable.

Efforts have been made to gain DOT approval for plastic fuel tanks for truck service. Despite certain advantages their manufacturers claim, doubts about the safety of such tanks in commercial vehicle operations have not been satisfactorily resolved.

Vehicles using flammable compressed gas as a motor fuel must be equipped with fuel systems constructed and installed in accordance with applicable provisions of NFPA 58 or NFPA 52. Likewise appropriate LNG tanks are required.

Fuel systems must be maintained so they are free of leaks. Fuel tanks must be capped, and connections must be checked regularly. Metal fuel lines are subject to vibration-induced fatigue, and flexible lines may deteriorate with age. Chafing, cutting, or proximity to hot surfaces also can damage lines. In a gasoline system, carburetor flooding due to dirt in the float valve or electric fuel pumps that do not shut down may cause gasoline to overflow onto a hot surface and result in a fire.

These problems are somewhat less critical on diesel-powered vehicles because diesel fuel has a higher flashpoint. Diesel engines are designed to operate at higher temperatures to control exhaust emissions. This, in turn, led to higher fuel temperature in the return flow line, thus making the fuel more prone to ignition if the warmed, leaking fuel contacts a hot surface.

PREVENTING MOTOR VEHICLE FIRES

Fire prevention in motor vehicles requires the attention of everyone involved. Vehicle designers must be aware of fire hazards in their products. Sources of heat and ignition must be kept away from flammable materials as much as possible. Consideration should be given to the vulnerability of fuel system components, in particular to their basic integrity, their location away from the perimeter of the vehicle and from crash-collapsible and intrusive parts, and their location away from potentially hot exhaust and electrical components.

Examples of location hazards were found in 1971–1976 Ford Pintos and 1975–1976 Mercury Bobcats. These cars' fuel filler necks and tanks could separate in a rear-end collision, resulting in fire. Manufacturers recalled 1.4 million of these vehicles for retrofitting of longer fuel filler necks and for installation of protective shields on the front of fuel tanks. Improperly routed fuel lines to the carburetor have been the subject of recalls because of potential rupture and underhood fires.

Because electrical system failures can cause fires resulting in property damage, particular attention must be paid to routing of wiring, aging of insulation and components, and failure modes of components.

To minimize potential fuel leakage in any crash, extraneous plumbing and openings should be eliminated in fuel and hazardous liquid and gaseous cargo containers. Necessary plumbing should be designed so it is protected from potential crash damage.

In vehicle construction, care must be taken to ensure that fuel and electrical lines are correctly routed and connections secure. In addition, location of sharp or pointed components near fuel or hazardous cargo tanks should be avoided.

A major hazard during the vehicle repair process is the use of torches, usually in the repair of exhaust systems and crash damage. Some items used in vehicle repair are particularly flammable, such as paint, solvents, adhesives, and oily rags.

Care must be taken when maintaining and rebuilding damaged vehicles to ensure that their fuel and electrical systems are free of hazards not present in the original vehicle.

Vehicle Electrical Systems

Automotive lighting and accessory circuits are usually 6 or 12 V, but vehicle ignition systems have high voltage and low amperage. Automobile electrical system fire safety is largely a matter of proper installation, fusing, and maintenance. Important checkpoints include the location and protection afforded the battery; battery cable integrity and protection of exposed battery terminals; adequate flame-retardant insulation on all wiring; proper fusing of normal lighting and accessory circuits; proper support, location, and security of all wiring, with adequate protection by rubber insulating bushings where wiring passes through metal; and good ignition system maintenance.

Electrical fires can be fed by oily deposits in and around the engine or by combustible materials, such as interior fabric linings and upholstery. In collision or upset, electrical short circuits can occur and may ignite fuel vapors. It is desirable, particularly on buses and trucks, to provide an approved type of manual battery/generator disconnect switch, preferably one incorporating short circuit supervision. However, use of such devices on vehicles is rare.

Miscellaneous Vehicle Hazards

Proper exhaust system installation is important because the system's hot surfaces can ignite nearby combustible components. Hot carbon particles and hot gases discharged from the exhaust can ignite flammable liquids, grease, or similar exposed materials, such as insulation on electrical wiring.

Catalytic converters in exhaust systems can cause wildland fires, if automobiles are driven through dry grass or vegetation.

Overuse of vehicle brakes can result in sufficient overheating to cause severe smoldering and sometimes fire. Improper adjustment that prevents full release of a brake can lead to similar conditions. Overheated brake drums or rotors can cause ignition of fuel if spillage occurs onto the brakes during refueling.

The problem of overheating brakes increases with the vehicle's size and gross weight. On long downgrades, a driver must rely on the braking effect of the engine for primary control of the vehicle, limiting brake use to slowing for sharp turns or unanticipated, localized, hazardous conditions, and to stop. The engine's maximum braking effect is achieved only in the transmission lower gears. Particularly on trucks and buses, it is essential for the driver to get into a low gear at the top of the grade before the vehicle reaches a speed at which downshifting is no longer possible. Engine braking devices are used on diesel-powered trucks, especially in mountainous regions. Other types of electrically and hydraulically operated retarders are used in special situations.

If one tire of a dual-tire installation runs flat or is seriously underinflated, flexing may cause sufficient internal heat to build up to cause ignition. This possibility also exists if tires are seriously overloaded and may be exacerbated by sustained high-speed operation and high ambient temperature. Occasionally, fire results if dual tires are spaced so closely together that they rub or chafe against each other when the vehicle is in motion.

Provisions of the Federal Motor Carrier Safety Regulations for all heating systems used on vehicles in interstate commerce have been upgraded. Reducing such fires has also been aided by technological advances in heaters.

Fire Hazards of Special Vehicles

Certain types of special vehicles, such as farm tractors, motorcycles, all-terrain vehicles, and others, have special problems resulting from the close spacing of such components as the fuel tank and other parts of the fuel system, the engine, the ignition system and other electrical components, and the exhaust, coupled with minimal protective bodywork that increases the susceptibility of these fire-sensitive components to damage.

The need for care to avoid fuel spillage and sparks from static electricity is especially important when refueling in the field from portable containers.

Vapor recovery nozzles on gasoline pumps introduced a potential fire hazard in fueling motorcycles and other vehicles with small fuel tanks. The depth to which the nozzle must be inserted in order to activate vapor recovery control and permit fuel flow is so great that effective refueling cannot be accomplished in the normal manner. It has become necessary to use a device to bridge the fill-pipe opening. Otherwise, the operator must pull back the bellows with one hand and activate the nozzle trigger with the other to obtain fuel.

Use of Fire Extinguishers

Commercial vehicles operating in interstate commerce must be equipped with fire extinguishers to comply with Federal Motor Carrier Safety Regulations. These regulations provide two minimum levels of protection: a 5-B:C extinguisher (or two 4-B:C extinguishers) is required if the power unit is not transporting hazardous materials in sufficient quantity to require marking or placarding the vehicle, and a 10-B:C extinguisher is required on a power unit used for transporting hazardous materials.

Many states have similar requirements for commercial vehicles, through adoption of applicable provisions of federal regulations or their own regulations. Some state laws require additional or larger extinguishers on tank vehicles transporting flammable liquids or gases, combustible liquids, or Class A and/or Class B explosives.

There are no legal requirements for carrying fire extinguishers in private passenger cars, vans, or light trucks, although many people do keep them in vans and motor homes. As a minimum, the vehicle owner should consider buying a portable extinguisher that can deal with Class B (flammable liquids) and Class C (electrical) fires. Also on the market are extinguishers using multipurpose agents for use on Class A fires (ordinary combustibles), as well as Class B and C fires. Anyone equipping a vehicle with a fire extinguisher must understand that the best chance for its successful use lies in prompt action in the fire's early stages and proper use to avoid wasting the agent and exhausting the extinguisher's contents prematurely. NFPA 10, *Standard for Portable Fire Extinguishers,* gives additional information on ratings and use of fire extinguishers.

Other Fire Hazards

While the vehicle is operating, the driver should be alert for any indication of fire or a fire hazard, such as the smell of something hot, of unusual fumes, or of leaking fuel or lubricant. The driver should check for conditions that can create sufficient heat buildup to cause a fire, such as exhaust leaks and dragging brakes.

Carrying extra gasoline in a can is extremely dangerous because of the possible accumulation of fumes. The hazard increases if glass or plastic containers are used, because they're more likely to break and leak.

Smoking by a driver or passengers presents the potential for fire if sparks, hot ashes, or incompletely extinguished matches get into upholstery or other interior materials. Water or an agent suitable for Class A fires can extinguish such fires; the burn area then must be watched in case it continues to smolder and eventually rekindles.

In an accident, the engines and all electrical accessories of all involved vehicles should be turned off to minimize the danger of fire. At night, headlights can be left on to protect the scene, but persons in the vicinity should be alert for indication of overheated wiring or fire. Smoking and all use of open flames or lights must cease, particularly if leaking fuel is detected. If a travel trailer or motor home is involved, the probable presence of liquefied petroleum gas should be kept in mind, smoking should be prohibited, and open flames and lights should be kept well away from the scene.

When a vehicle fire occurs, the following basic steps should be taken, regardless of the type of vehicle involved:

1. Shut off the engine and all electrical systems that can be reached.
2. Get everyone out of the burning vehicle and well away from it, preferably uphill and upwind. The potential for fire is one justification for quickly moving injured persons from the scene of an accident.
3. Summon the fire department by the best available means.
4. Attempt to fight the fire only if it can be done without endangering anyone's personal safety.

Basic principles to be observed in attempting to fight a vehicle fire with a portable fire extinguisher are:

1. First, see item 4 above. The fire should be fought from the windward side so that wind, if any, will help carry the fire extinguishing agent toward the fire and help blow smoke and flame away from the person attempting to extinguish it.
2. The fire extinguisher should be aimed at the base of the flames.
3. If leaking flammable liquid is involved, work toward the source of the leak in putting out the flames. Ultimate control may depend on the ability to shut off leaking fuel at its source.
4. If flammable gas is burning, allow it to continue to burn until the source of any leak is controlled. Otherwise, extinguishing the fire may permit leaking gas to accumulate, with later fire or explosion likely. If flames impinge on a flammable gas container, the container should be kept cool to avoid a flame-induced weakening and possible rupture or a boiling liquid expanding vapor explosion (BLEVE). If fire-fighting hose streams are not available, RUN. Leave IMMEDIATELY.
5. If no extinguisher is available, throw sand or dirt on a fire to control flames.
6. If stopping to help at the scene of a vehicle fire, park uphill, preferably upwind, and at a safe distance from the burning vehicle.
7. After a fire has been extinguished, do not operate the vehicle until all burned parts are cool and the cause of the fire has been corrected.
8. During an electrical fire, turn off the ignition switch and lights to try to cut off the flow of current and permit faster extinguishment. If tools are available and it can be done safely, disconnect the battery.
9. In fighting an underhood fire, use great care in opening the hood to avoid injury in case of a sudden flareup.
10. Inspect and recharge all extinguishers without delay.

The following special considerations apply to fires and potential hazards involving commercial vehicles:

1. Any hazardous situation should be evaluated to avoid endangering lives and wasting extinguishing agent.
2. If a vehicular combination unit is involved in a fire, the power unit should be unhooked and moved a safe distance away from the vehicle if it can be done safely.
3. Drivers must be alert for the hard pulling characteristics that may indicate dragging brakes and must readjust brakes before a fire develops.
4. A driver must examine each tire on a motor vehicle at the beginning of each trip and each time the vehicle is parked. FMCSA regulations require this practice for a vehicle placarded for transportation of hazardous materials.
5. Drivers should check rearview mirrors frequently for signs of smoke and must stop and investigate any smoke detected.
6. A hot or underinflated tire should be moved well away from the vehicle. As an alternative, the driver should remain with the vehicle until the tire is cool to the touch and then make repairs. If a vehicle is left with a hot tire, the tire may burst into flames, destroying the vehicle and its load. With proper tire-changing equipment and a pair of heavy leather gloves, a driver can safely remove a hot tire that has not burst into flames.
7. Because a tire fire results from internal heat buildup, portable extinguishers normally cannot do more than control open flames. The cooling effect of large quantities of water is required for extinguishment.
8. If fire is suspected inside a closed van body—usually indicated by smoke seeping out around the doors—the doors should be left closed until fire department assistance is at hand. Should the doors be opened, oxygen reaching the fire may cause a sudden flareup. As long as the doors are closed, the fire can only smolder from lack of oxygen.

In the interest of preventing cargo fires, motor carriers generally prohibit smoking while vehicles are being loaded or unloaded, so sparks or hot ashes do not lodge in the cargo and burst into flame later.

Federal Motor Carrier Safety Regulations prohibit smoking during refueling; while loading, unloading, or transporting explosives, flammable liquids, gases, or solids, or oxidizing materials requiring marking or placarding of the vehicle; and while driving an empty tank vehicle that last contained a flammable liquid or gas and that was required to be marked or placarded.

CARGO TANKS (TANK TRUCKS)

Cargo tanks and portable tanks are large containers for hauling liquids and gases in bulk. Cargo tanks are sometimes called "tank motor vehicles" or "tank trucks." Any person offering a hazardous material in a container for transportation must determine that the container used is authorized for the commodity. Specifications for cargo tanks, portable tanks, and all other hazardous materials packaging other than rail tank cars are in 49 CFR, Part 178. Authorized packaging is prescribed in 49 CFR, Part 173, the shipper regulations for the particular material, as listed in 49 CFR 172.101. If a carrier supplies a container, such as a cargo tank, the shipper still must determine that the tank supplied is a proper container for the material being offered. The shipper must either examine the manufacturer's specification marking on the tank or obtain papers from the carrier certifying that the tank is proper for the material, per 49 CFR, Part 173.22.

Cargo tanks are the most common transport vehicles used to move combustible, flammable, and corrosive liquids, as well as compressed gases, both flammable and nonflammable. Hazardous materials in powder or granular form are transported in hopper-type, dump-bodied vehicles. When these hazardous materials are transported in bulk containers, such as cargo tanks, and an accident occurs, the disaster potential is substantial.

To minimize risks involved in transporting hazardous materials and to reduce hazards should an accident occur, the federal government specifies requirements for the manufacture, operation, maintenance, inspection, testing, and repair of cargo tanks.

DOT's hazardous materials regulations apply to interstate and intrastate commerce and are enforced by both federal and state authorities. DOT phased in new cargo tank regulations designed to reduce spillage and to ensure that tanks are properly constructed, maintained in safe condition, and properly repaired. The new cargo tank regulations are designated in 49 CFR, Part 180.

Leakage is likely to occur in both contact and noncontact accidents, leading to high cost in terms of personal injury and

property damage. The major causes of unintentional release of hazardous materials are poor maintenance and deviation from tank specifications.

Potential hazards to fire fighters dealing with cargo tanks transporting hazardous materials are as follows:

1. Multipurpose tanks holding improper commodities for the specific container
2. Multicompartment containers hauling materials in more than one hazard class (corrosive/flammable/poison/oxidizer)
3. Defective or missing safety controls
4. Release of large quantities of hazardous materials
5. Increase of potential fires—extra equipment required to fight fires and control spills
6. Potential for a boiling liquid expanding vapor explosion (BLEVE)
7. Incorrect or missing placarding and identification markings on exterior of cargo tank
8. Missing, incomplete, or incorrect shipping papers

Persons receiving a report of an actual or potential highway transportation hazardous materials emergency should obtain as much of the following information as possible:

1. Location of the emergency
2. Type of commercial vehicle(s) involved, such as cargo tank, flatbed, van, and so on
3. Class(es) of hazardous material(s) as indicated by placards, if visible, including the four-digit identification number, if visible
4. Proper shipping name(s), hazardous class(es), and identification number(s) of hazardous materials, if shipping papers are available
5. Nature of the emergency—Is it a fire? Is there leakage? Are persons affected or injured by hazardous materials?
6. Name and address of trucking company
7. Other vehicles and/or property involved
8. Weather conditions and wind direction
9. Type of area

Upon arriving at the scene, emergency responders should take time to assess the situation and make every effort to ascertain what type(s) of hazardous materials and packaging is involved. The scene should be approached from upwind. Responders must avoid contact with spilled or leaking materials that may penetrate protective or other clothing, resulting in death or injury.

Figures 21.2.1 through 21.2.6 display tank construction, denoting areas where leakage is most likely. All these diagrams

should be considered as guidelines rather than constants. Figures 21.2.7 and 21.2.8 show common tank shapes and internal/external inspection items. Emergency response personnel must be aware that many variations of road trailers, not illustrated here, are used for shipping chemical products. Suggested guides are for the most hazardous products that these trailer types may transport. Recommended guides should be considered as a last resort if the product cannot be identified by any other means.

Many tank vehicles contain hazardous materials of one or more types. These units, which include farm "nurse" tanks, tank trucks, tank trailers, and railroad tank cars, must be treated with equal respect. Each emergency must be sized up quickly and individually, taking into consideration the safety of every person at the scene.

SUMMARY

This chapter has described the magnitude of the problem of commercial motor vehicle fires in the United States and has outlined the several types of regulations and standards directed

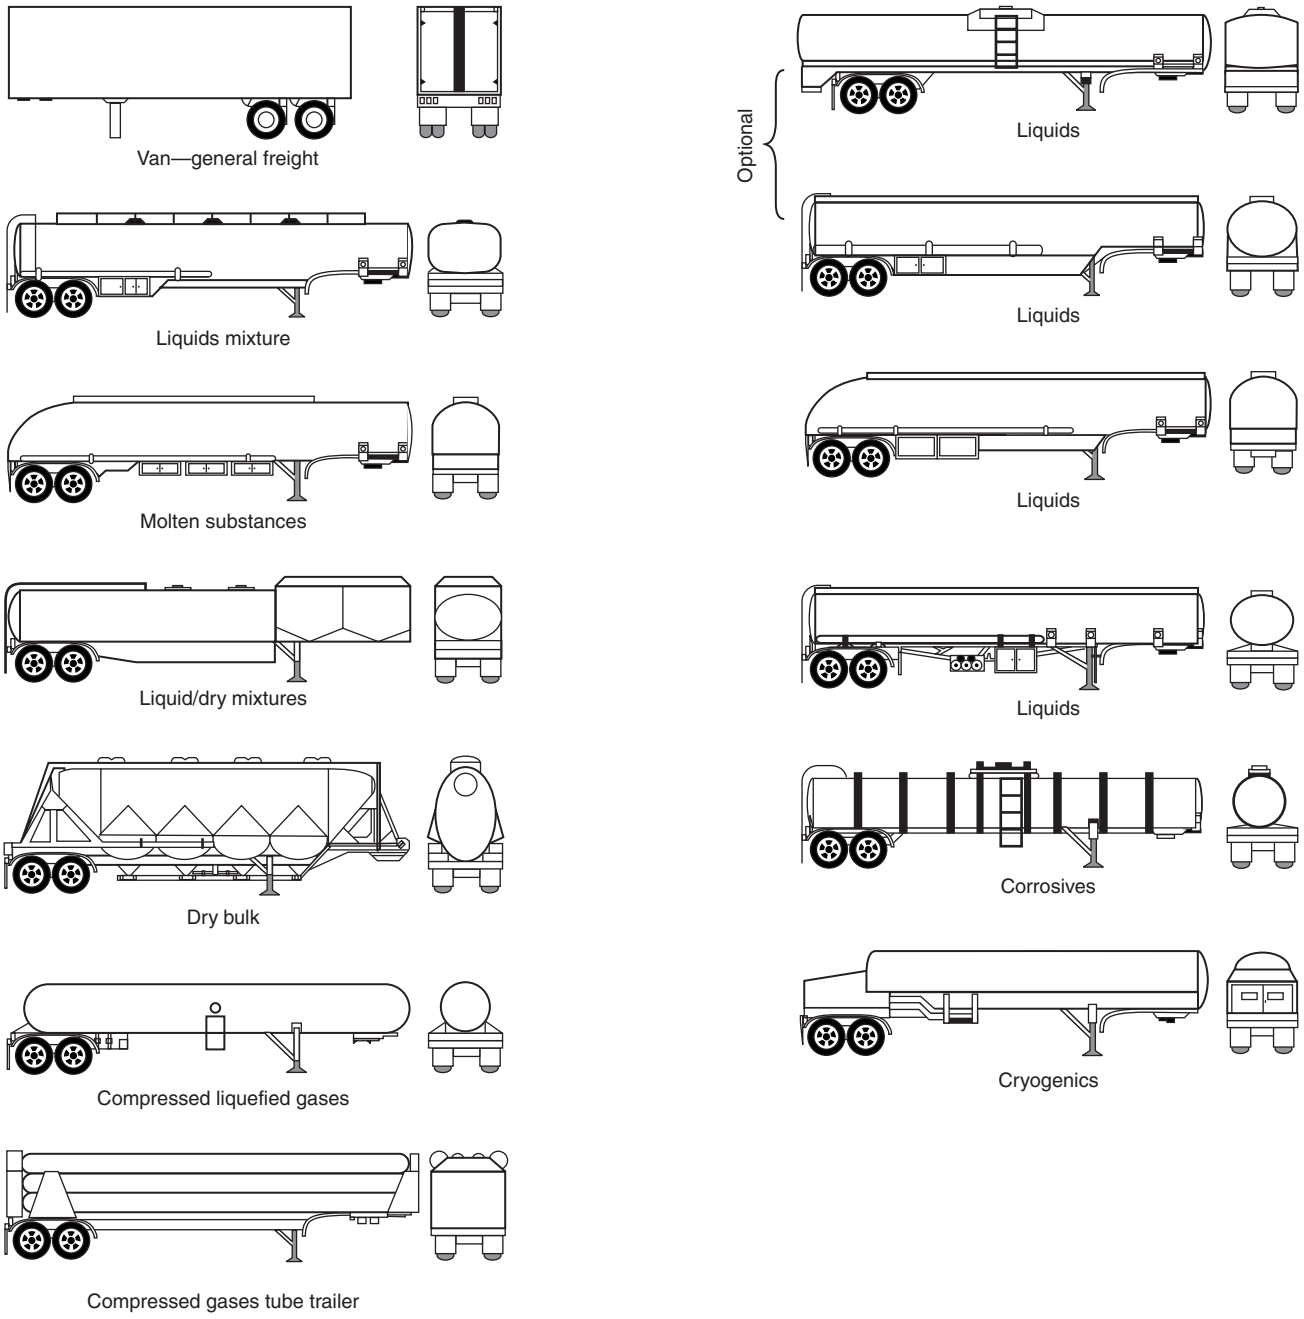

FIGURE 21.2.7 General Shapes of Road Trailers

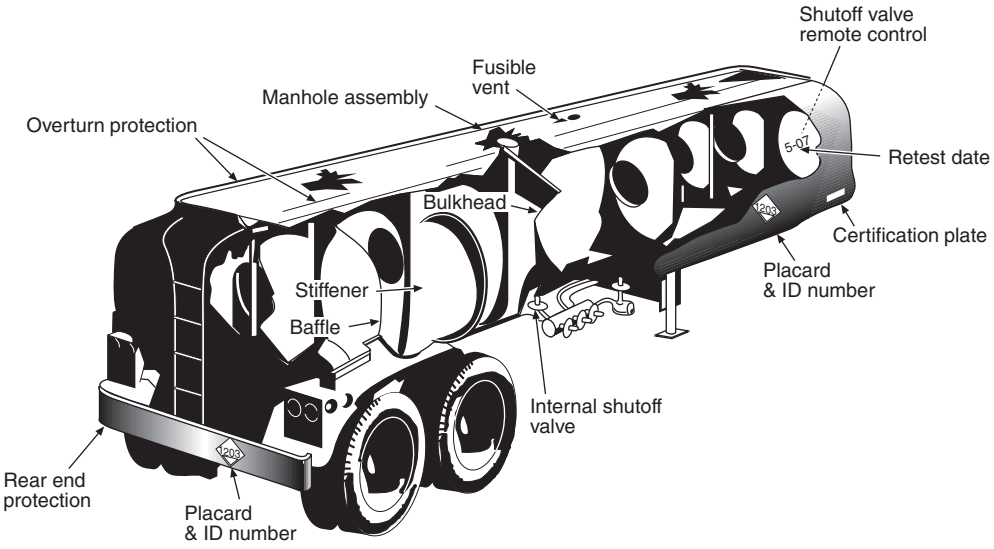

FIGURE 21.2.8 Cargo Tank Inspection Guide (MC 306)

at commercial motor vehicle fire safety. Organizations with an interest in highway safety have been identified. Hazards and safeguards have been outlined.

Operations Safety Requirements
Fire Suppression
Special Requirements for Marine Refueling Facilities
Service Station Maintenance and Inspection

Key Terms

automotive service station, flammable liquid, fuel dispensing system, fuel tank, hazardous material, marine service station, refueling, repair garage, service station

Automotive and marine service stations, whose operations include both refueling and repairs, present a fire risk because of the storage of flammable and combustible liquids and the transfer and use of these liquids. Many of these transfer operations involve the general public, which increases the risk associated with transfer. Unlike an industrial facility, in which personnel involved in flammable liquid* transfer operations can be restricted to those trained in the hazards of the materials and the operations, anyone can use the services of a public automotive or marine service station.

Also, the transfer operations at a service station occur more frequently than at an industrial facility. Service stations that include repair facilities also use flammable liquids in the repair and servicing of vehicles and these operations present additional risks. This chapter covers the hazards associated with flammable liquids at automotive and marine service stations.

For related topics, see Section 6, Chapter 12, "Flammable and Combustible Liquids"; Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 21, Chapter 4, "Vehicle Fueling Using Gaseous Fuels"; and Section 21, Chapter 5, "Fuel Cell Vehicles."

BASICS

Public Service Station Fire Data

NFPA analyzes fire data and prepares reports on topics of interest, including fires at public service stations.[1] Fire data from private service stations are not readily available. Data from public service stations indicate where the greatest fire risk at a service station lies. Over the period 1994 to 1998, 62 percent of fires at public service stations were categorized as vehicle fires. This does not mean that the fire involved the vehicle only. Several of these fires spread beyond the area where the vehicle was located to parts of the facility. Code requirements address vehicle activity in several areas and because vehicle fires account for such a large percentage of the fires documented, these requirements need to be examined.

Another factor potentially influencing the increased percentage of fires at service stations involving vehicles over the 1994 to 1998 time period is the change in the types of products sold at service stations. As of the year 2000, there were approximately 210,000 retail outlets selling motor fuel. Many of these motor fuel retail outlets also have repair facilities, but the trend in motor fuel retail facilities has been toward the sale of other merchandise as well as fuel and repairs. Many service stations are paired with convenience stores or food retail businesses. These new arrangements are bringing increased vehicle traffic through the service station area. Also, vehicles might

*Although "flammable liquids" is referred to throughout this chapter, the term is meant to encompass both flammable and combustible liquids.

Carl H. Rivkin, P.E., is principal chemical engineer on the NFPA engineering staff and the NFPA staff liaison to the Technical Committee on Automotive and Marine Service Stations. He has more than 20 years of engineering experience with hazardous materials safety.

be parked at the service station. These changes could be causing an increased number of vehicle fires at service stations.

Basic Service Station Refueling Components

Figures 21.3.1, 21.3.2, and 21.3.3 provide an overview of the basic refueling components at a service station. Figure 21.3.1 shows double-walled tanks and the associated safety and filling appurtenances for these tanks. The use of the safety devices illustrated in this figure is a code requirement, including pressure relief devices, cathodic protection, and the concrete foundation. The concrete foundation prevents damage to the tank from the supports settling or other movement of the supporting soil. The cathodic protection prevents the tank metal from corroding.

Figure 21.3.2 shows (a) standard installation of aboveground horizontal tank and (b) the basic components of a standard fuel dispenser. Figure 21.3.3 is an illustration of (a) a dispenser with (b) a below-grade cutaway showing the lines that feed the dispenser. Also shown are the breakaway valve at the dispensing nozzle and the shear valve on the fuel-feed line. Both of these valves limit the release of fuel in the event of a break in the fuel piping or hoses.

Properties of Hazardous Materials at Service Stations

Because flammable liquids have varying volatility, they will both vaporize at different rates and migrate at different rates to potential ignition sources. Table 21.3.1 lists flammable liquids commonly found at service stations and repair garages. The data provide indicators about how the material behaves when it is accidentally released and exposed to ignition sources. The information on each material includes the flashpoint, the class under NFPA 30, *Flammable and Combustible Liquids Code* (which is based on the flashpoint), the boiling point, and the minimum ignition temperature in air.

The *flashpoint* is the minimum temperature of a liquid at which sufficient vapor is given off to form an ignitable mixture with the air, near the surface of the liquid or within the vessel used, as determined by the appropriate test procedure and apparatus. NFPA 30 gives additional information about appropriate procedures for determining the flashpoint of a material.

The table data indicate why gasoline is more hazardous than other materials commonly used at service stations and repair garages. It has a flashpoint of –50°F (–40°C), which is 150°F (83°C) lower than that of diesel fuel #1. The flashpoint for gasoline is so low that only under severely cold conditions would it not have the potential to form an ignitable mixture.

DESIGN AND CONSTRUCTION

Design and construction safety requirements for the different refueling and repair components found at service stations are based on NFPA 30A, *Code for Motor Fuel Dispensing Facilities and Repair Garages.*

General Building Requirements

Code Requirements. Building construction requirements apply to general categories of structures in which flammable

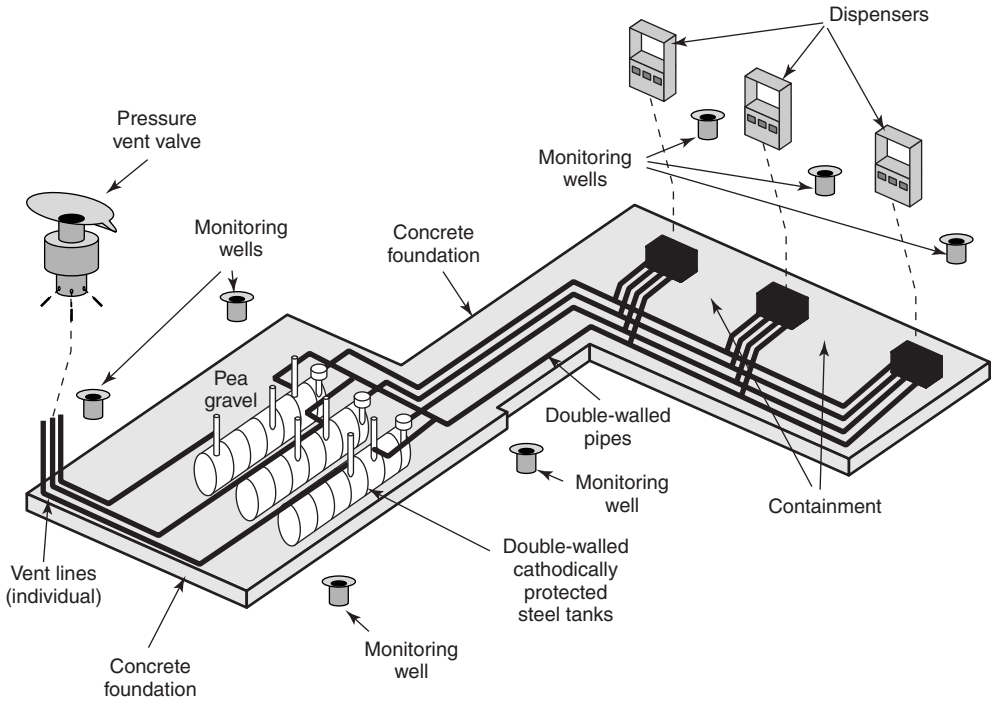

FIGURE 21.3.1 Fuel Dispensing System Assembly (Source: Based on information from Florida Department of Environmental Protection)

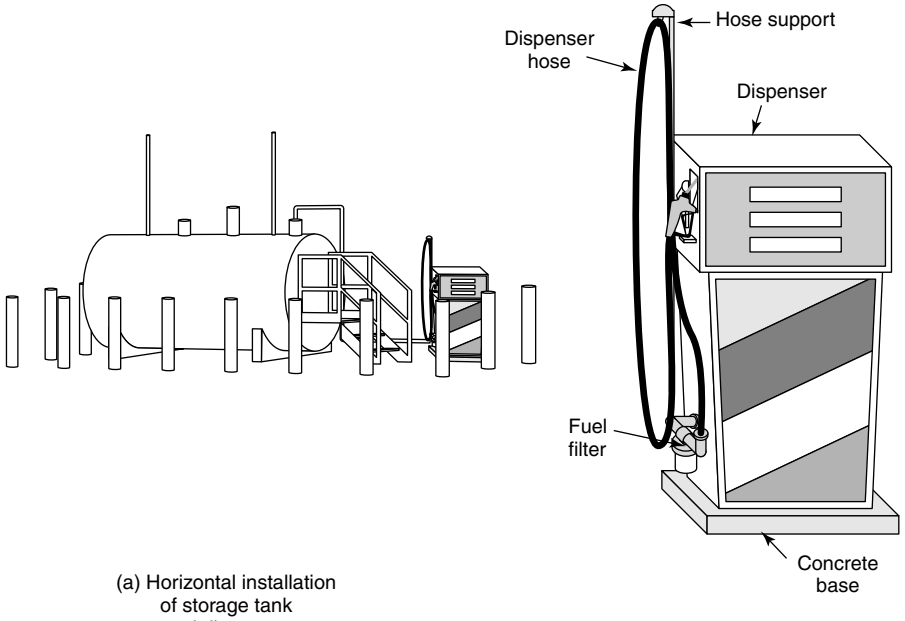

FIGURE 21.3.2 (a) Aboveground Fuel Dispensing System with Dispenser and (b) Standard Fuel Dispenser (Source: Based on information from Florida Department of Environmental Protection)

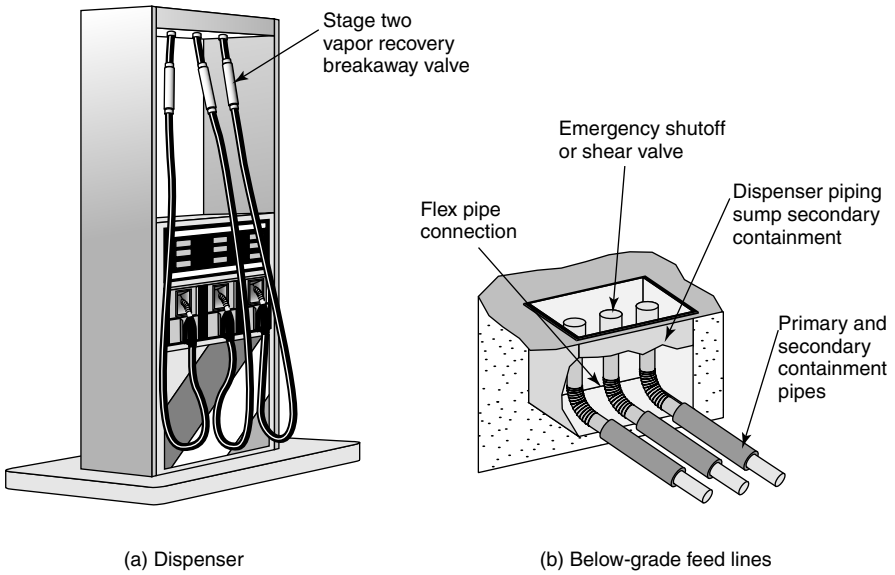

FIGURE 21.3.3 Dispenser Assembly with (a) Dispenser and (b) Below-Grade Feed Lines (Source: Based on information from Florida Department of Environmental Protection)

liquids present a hazard. The two types of structures of concern are buildings housing fuel dispensing operations and repair garages.

Structures that house refueling or repair operations must not have obstructions in egresses that restrict building evacuation. Specific requirements for egress can be found in NFPA *101*®, *Life Safety Code*®, in the chapter on industrial occupancies. Refueling facilities and repair garages are classified as special-purpose industrial occupancies. Such special-purpose industrial occupancies conduct ordinary and low-hazard industrial

TABLE 21.3.1 Properties of Flammable and Combustible Liquids Commonly Found in Service Stations

Liquid	*Flashpoint*	*NFPA 30 Class*	*Boiling Point*	*Minimum Ignition Temperature in Air*
Antifreeze	230°F (110°C)	IIIB	300°F (149°C)	—

Type F transmission fluid	380°F (193°C)	IIIB	>800°F (>427°C)	>800°F (>427°C)
White grease	465°F (241°C)	IIIB	>800°F (>427°C)	>800°F (>427°C)
Windshield washer fluid (methanol/water mixtures)				
100% methanol	54°F (12°C)	IB	148°F (64°C)	725°F (385°C)
50% methanol	80°F (27°C)	IB	—	—
20% methanol	118°F (48°C)	II	—	—
5% methanol	206°F (97°C)	IIIB	—	—

operations in buildings designed for, and suitable only for, particular types of operations. Such occupancies are characterized by a relatively low density of employee population, with much of the area occupied by machinery or equipment.

Spill Control. Spill control must be provided to prevent fuels from flowing either through the floor or into other parts of the building. The drainage system must have an oil trap or separator if it connects to public sewers or waterways.

Fuel Dispensing Buildings

Hazards. Most public service stations do not have indoor fuel dispensing and, therefore, do not have fuel dispensing buildings. Occasionally parking garages include fuel dispensing. Buildings housing fuel dispensing areas present special hazards, and requirements have been developed to address these hazards. Fuel dispensing is more likely to produce a material release than are other components of the refueling system.

Construction, Design, and Location. Dispensing areas within the building must be separated from other portions of the building by 2-hour fire-resistant structures. Openings into the dispensing space must be designed to prevent a fire from moving to other parts of the building. This containment is accomplished by using fire doors and fire dampers.

Fuel dispensing areas must be located at street level, not more than 50 ft (15.2 m) from the building entrance or exit. This requirement prevents the release of material at a location that would be difficult for emergency responders to access. The dispensing areas are also limited to the size required to service four vehicles or fewer.

Safeguards and Controls. The dispensing area must have a dedicated mechanical exhaust system that is interlocked with the dispensing system. If the system were not dedicated, there would be the potential to transfer fuel vapors and vehicle exhaust to other parts of the facility. The system has to provide airflow across all portions of the floor of the fuel dispensing area to prevent the potential buildup of ignitable vapors. Serious accidents have occurred in which vapors released in a part of a facility free of ignition sources migrated into locations where ignition sources were present through pathways that had not been considered before the accident. For specific information on designing ventilation systems see NFPA 91, *Standard for Exhaust Systems for Air Conveying of Vapors, Gases, Mists, and Noncombustible Particulate Solids,* and the American Conference of Industrial Hygienists, *Industrial Ventilation: A Manual of Recommended Practice.*[2]

Repair Garages

Hazards. Repair garages present different hazards from those found in refueling operations because of the use of pits or below-grade areas required to work on vehicles. These areas normally have special ventilation requirements and fixed fire protection to allow personnel to function in the workspace.

Construction, Design, and Location. Pits and below-grade work areas must be constructed of noncombustible materials and be provided with ventilation and means of egress previously described. These areas, although not viewed as confined spaces, can present oxygen-deficient atmosphere risks under certain conditions such as restricted airflow or displacement of air. This is another reason why egress and ventilation are important.

Safeguards and Controls. Fixed fire protection is required for larger repair garages if any of the following situations exist:

- The garage is two or more stories in height, including basements, and any one floor exceeds 10,000 ft^2 (930 m^2).
- The garage is one story and exceeds 15,000 ft^2 (1400 m^2) in floor area.
- The garage is in the basement of a building.

The larger repair garages will likely handle more material, conduct more operations, and therefore present a greater fire risk.

Heating, ventilating, and air-conditioning (HVAC) for repair garages must be independent and designed to provide good airflow and mixing in the ventilated space. Air from below-grade areas should not be recirculated into the building HVAC system.

Heat-producing appliances present an ignition source hazard and must be carefully controlled in repair garages. In several incidents, heat-producing appliances were the ignition source the ignitable vapor eventually located. Cleaning floors with gasoline is a common unsafe practice that can lead to fires and explosions. Heat-producing appliances have to be of types approved for use in a repair garage. Solid fuel burning devices and space heaters are typically not considered an approved type of appliance. Heat-producing appliances must be separate from areas dispensing or transferring Class I liquids, such as gasoline. This separation can be accomplished by placing the device in another room or at least 8 ft (2.4 m) above the floor. At this height, the device should be above any flammable vapors.

Storage

General. All flammable liquids must be stored in either an approved closed container or a tank. In service stations, containers cannot exceed 60 gal (227 L) in volume. Tanks can be located underground, aboveground, or in vaults. A vault is a protective enclosure that does not allow the tanks to contact the ground even if installed below grade. Underground tanks present less fire hazard but they have a greater potential to impact the environment. Environmental regulations place more stringent requirements on underground tanks than aboveground tanks. Vaulted tanks present a potential solution to these conflicting concerns of fire safety and environmental impacts by allowing an above-grade installation with additional fire protection.

All tanks must be constructed to consensus-based construction standards. Underwriters Laboratories is an example of an organization that promulgates these types of tank construction standards.

Underground Tanks. Underground tanks require vent pipes of sufficient diameter to prevent blowback of vapor or liquid at the fill opening while the tanks are being filled. The vent pipes also should not be obstructed, which would effectively reduce their diameter. Undersized vent piping will impede the refilling process because it is more difficult to displace the air in the tank. The discharge point for vent pipes should be at least 12 ft (3.7 m) above ground level for tanks storing Class I liquids (gasoline) and higher than expected snow level for tanks storing Class II liquids (diesel fuel). The discharge point must also be located away from building openings and power ventilation air intakes. Allowing flammable materials to infiltrate a structure could possibly result in material in the flammable range being exposed to

a source of ignition. The vent pipe must also be higher than the fill pipe to prevent spills during tank fill operations.

Underground tanks must be provided with external corrosion protection, either in the form of a cathodic protection system or corrosion-resistant materials. The type of protection employed must be determined on a location-by-location basis.

Underground tanks must be installed so that they are no less than 1 ft (0.3 m) from any wall of a basement or pit and 3 ft (0.91 m) from any property line that can be built on. The tanks must be set on a firm foundation and surrounded by noncorrosive material such as sand or gravel. They also must be buried sufficiently deep or be protected on the surface so that they are not subject to vehicle damage.

Aboveground Tanks. Aboveground tanks must be separated from the property line, important buildings, other fuel dispensing devices, public ways, and other tanks. These distances vary based on the size of the tank and the level of fire protection the tanks are constructed to meet. Aboveground tanks must be provided with spill protection. NFPA 30 provides options for spill control.

All aboveground tanks must be provided with an alarm that sounds when the level inside reaches 90 percent of tank capacity. All tanks must be provided with physical protection to prevent unauthorized access and to protect from vehicle impact. However, it is difficult to prevent all vehicle impact accidents because of the unpredictability of driving behavior and the tremendous force involved in high-speed impact. As an example of this problem, see the following case.

CASE STUDY: South Carolina. In South Carolina in 1991, a driver was killed when his pickup truck careened off the road, striking the piping for two 4000 gal (15,142 L) aboveground fuel tanks located at a convenience store. The collision broke the piping and resulted in the release of gasoline that quickly found an ignition source.

Vaulted Tanks. Gasoline tanks installed in vaults must have ventilation systems and vapor and liquid detection systems. The vapor detection system should sound an alarm when the concentration of vapor in the vault equals or exceeds 25 percent of the lower flammable limit (LFL) for the material.

Piping

Piping is one of the most vulnerable components in a fuel system because vehicle impacts can easily rupture pipes, corrosion can cause leaking, and stresses can cause cracking. Piping must be protected from mechanical damage. Piping that runs through buildings must be enclosed in fire-resistant material. All piping must be identified by color code or some other readily identifiable system to indicate the material contained in the pipe. There are significant differences in the physical characteristics of gasoline and diesel fuel, and confusing the two could result in damage to vehicles.

Fuel Dispensing Systems

The requirements for fuel dispensing systems cover the following seven areas:

1. Dispensing devices
2. Remote or submersible pumps (i.e., pumps not located at the device)
3. Hoses
4. Nozzles
5. Emergency electrical disconnects
6. Vapor recovery systems
7. Hazardous location electrical equipment

The requirements are structured to prevent the accidental release of material either from liquid or vapor leaks in the dispensing system or from overfilling of the container into which the system is feeding liquid.

General Requirements. Two general requirements apply to all fuel dispensing systems. The first is that all portions of the vehicle being refueled must be on the dispensing facility property. The reason for this is straightforward. The vehicle should not be in a position in which it could be struck by other vehicles while refueling. The second general requirement is that fuel not be dispensed by applying pressure to the container in which the fuel is stored but instead by means of pumps. The reason for this requirement is that containers are not constructed to allow external pressure to be used as a means for moving fuel out of the container.

Dispensing Devices. The requirements for dispensing devices address several points in the dispensing process which have the potential for the release of fuel. The first requirement is that the dispensing device not operate when the dispenser nozzle is in the holding bracket or routine rest position. This requirement prevents the release of material when no person is present to stop it.

The dispensing devices must be protected from physical damage that could cause the release of material. This protection should take the form of bolting the dispensing devices to a concrete island situated to keep vehicles not being refueled from passing through the refueling area. Because there are vehicles moving through a refueling area in close proximity to pedestrians (people refueling their vehicles), a major safety concern is vehicles striking pedestrians.

The dispensing devices must incorporate an emergency shutoff in the line that supplies fuel to the dispensing device. This emergency shutoff must be designed to be activated by severe impact or fire exposure. The purpose of the shutoff is to prevent fuel from flowing to the dispensing device in the event of an accident. When installed, the emergency shutoff device must be tested at least annually after the initial test.

CASE STUDY: Saint John, New Brunswick. In January 1974, a fire killed five people at a service station in Saint John, New Brunswick, Canada. A large amount of fuel was released because the emergency shutoff valve failed to operate when the

dispenser was knocked over by a vehicle. The service station was located on the roof of a tire warehouse (the structure was located on a slope so that one side of the service station was on ground level) and the fuel released migrated into the warehouse where it was ignited and exploded. Because the explosion took place in the enclosed warehouse space, there was tremendous damage in addition to the loss of life.

Remote or Submersible Pumps. If fuel is transferred to the dispenser by a pump located outside of the dispenser, such as a submersible turbine pump located in the fuel storage tank, then the pump is subject to additional requirements. The pump must have a device that would detect whether there is a leak in the portion of the dispensing system upstream from the pump discharge. Pumps also must be located at least 5 ft (1.5 m) from building entrances and 10 ft (3 m) from property lines. These separation distances would reduce the risk of fuel being released into the building.

Hoses. Hoses must be listed by an independent testing organization for their intended use. The hose length should be no more than 18 ft (5.5 m). Although this is based on "weights and measures" laws, it also serves to reduce the chance of the hose being damaged or rupturing. If the hose is carrying gasoline, it should be constructed with a breakaway device that will retain the gasoline in the hose. This feature would prevent someone from releasing gasoline by accidentally driving away from a refueling area while the hose is still inserted in the vehicle fill pipe.

Nozzles. Hose nozzles for dispensing gasoline must have an automatic-closing valve to prevent the flow of gasoline when the valve-opening device is not depressed. This device combined with the hose breakaway device should prevent the release of anything but small amounts of gasoline if the person operating the dispenser either drives away from a refueling area with the hose nozzle still inserted in the vehicle fill pipe or neglects to shut off the flow valve for other reasons. Figure 21.3.4 illustrates a standard nozzle, pressure vent valves, and vent pipes.

Emergency Electrical Disconnects. Remotely located emergency electrical disconnects are a critical component in the fuel safety system for two reasons: (1) they will remove an ignition source from areas where there is the potential of an ignitable vapor mixture, and (2) they can stop the flow of liquid if other safety devices do not function, thereby preventing the release of large amounts of liquid.

The emergency disconnect must be located between 20 and 100 ft (6.1 and 30.5 m) from the fuel dispensing device. This range would create sufficient separation distance from the fuel dispensing device for the disconnect to be safely activated without being so far away that it could not be readily activated in an emergency situation. The emergency disconnect device must be interconnected so that if there are multiple emergency disconnects, the activation of any one disconnect device will

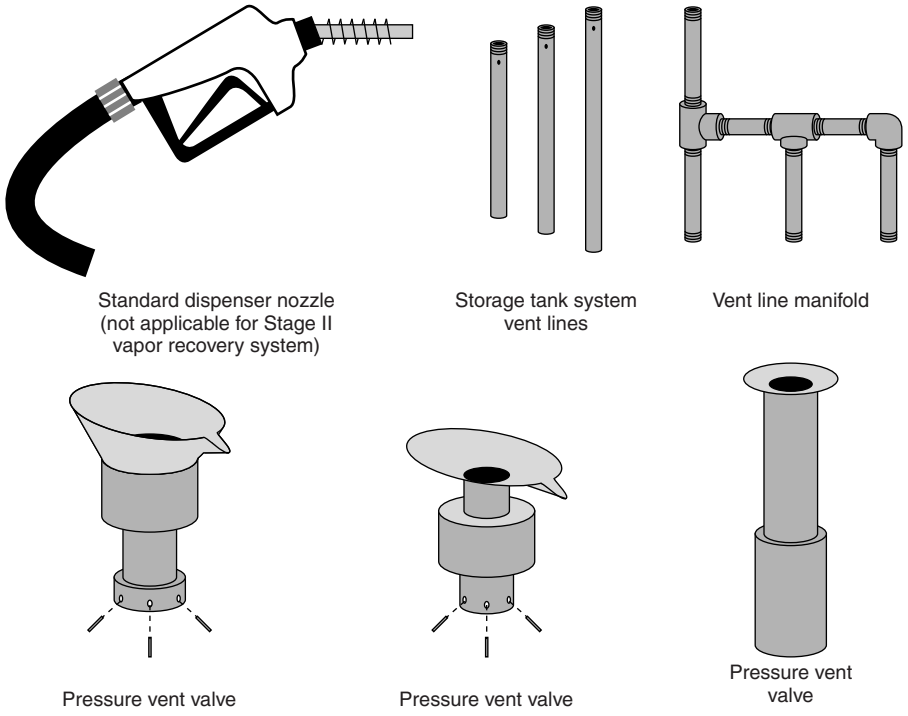

FIGURE 21.3.4 Dispenser Hose Nozzle, Pressure Vent Valves, and Vent Pipes (Source: Based on information from Florida Department of Environmental Protection)

cut off all power in hazardous locations surrounding the fuel dispensing devices.

Vapor Recovery Systems. Environmental regulations require vapor recovery systems in many locations. These devices must be listed for application as vapor recovery devices and must be designed to prevent the release of vapor when they are attached to the dispenser and not being used.

Hazardous Location Electrical Equipment. For a height 18 in. (0.5 m) above grade in a 20 ft (6.1 m) radius from refueling areas, special electrical equipment is required. The following case is an example of how electrical equipment not classified for use in a potentially dangerous area can be an ignition source.

CASE STUDY: Gadsden, Alabama. An explosion occurred at a gasoline station outside of Gadsden, Alabama, in August 1976. In this incident, a tank truck was filling aboveground storage tanks at the station using an electric pump that was missing a cover on the junction box. The lack of a cover allowed the pump to become an ignition source for fugitive vapor emissions lost during the transfer operation. These vapors were ignited, the fire spread to the truck, which exploded, and three responding fire fighters were killed in the explosion.

OPERATIONS SAFETY REQUIREMENTS

Many accidents are the result of improper use of properly designed equipment; therefore, it is important to understand how a construction safety feature is utilized through operational requirements. For example, the requirement that delivery vehicles must be separated from aboveground tanks is an operational requirement that directly connects to construction requirements. If the separation distance from property line and other exposures is met, the separation distance for the refueling vehicle should be less difficult to comply with.

Operations requirements can be divided into those requirements that apply to fueling operations and those that apply to repair operations. Fueling operations include both the filling of tanks at refilling facilities and the refueling of vehicles at these facilities. Because the refueling of vehicles is done so much more frequently than the refilling of storage tanks, these transfers account for a large percentage of the incidents at service stations. However, NFPA incident data have several accounts of serious accidents taking place during tank filling and servicing operations. The following case is an example of this type of incident.

CASE STUDY: Portland, Maine. A gas tank explosion occurred at an abandoned service station in Portland, Maine, in May 1986. This incident resulted from the ignition of vapors that were being removed with a vacuum pump from abandoned tanks at the service station. The vapors were being discharged at street level without any ventilation on a day when there was insufficient natural ventilation to dissipate the gasoline vapor withdrawn from the underground tanks. A vehicle that was allowed in the area where there was the potential for ignitable vapors provided the ignition source. The result was one fatality and three other people injured.

Filling and Fueling Operations

Mass Balance. Inventory records, which must be kept on a daily basis, indicate whether material is being lost from the system. The relatively simple process of performing a mass balance can reveal a small leak before it becomes a large leak and prevent the loss of significant amounts of material and subsequent safety and environmental problems. A mass balance is a comparison between the material going into a system and the material discharged from the system. The difference between these two numbers is the amount lost (leaked) from the system.

Tank Filling. For tank filling operations, 25 ft (7.6 m) must separate the delivery vehicle from any aboveground tank. All parts of the delivery vehicle must be on the premises when the delivery is made. This requirement prevents refilling from taking place at locations where the tank truck could block traffic in the public access road to the facility. Fill covers must identify the tanks that they service (Figure 21.3.5).

Portable Container Dispensing. Dispensing into portable containers is allowed, provided that the containers are approved and labeled and the dispensing is done manually. The container must be on the ground when being filled—not in or on the vehicle. If the container is not secured in the vehicle, a spill could result that would be very difficult to clean.

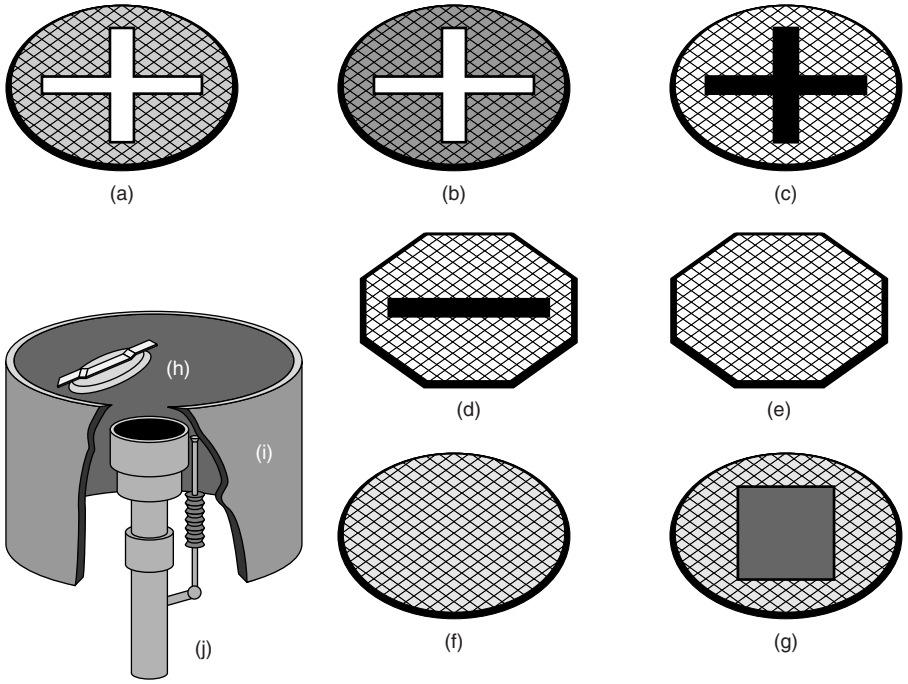
Motor Fuel Dispensing. Motor fuel–dispensing facilities can be divided into attended and unattended operations and many facilities offer both. Attended fueling operations theoretically have an increased level of safety because a human observer can detect problems that would not be observed at an unattended facility. Because of this difference, unattended facilities must have automatic-closing hose nozzles and a telephone or other device to notify the fire department.

Another potential problem in unattended facilities is that persons performing the refueling might reenter their vehicle during refueling and then remove the nozzle from the vehicle after they have built up a static charge from moving across the seat of the vehicle. Persons refueling at an unattended facility are required to stay outside of their vehicle throughout the duration of the refueling operation to prevent this static buildup, which could potentially ignite residual vapors released after the nozzle is removed from the vehicle fill pipe.

Repair Areas

Requirements for repair areas or facilities fall into the following four general categories:

1. Hot work
2. Spray painting and undercoating



(a) Hi-grade fill cover *(red with a white cross)*
(b) Mid-grade fill cover *(blue with white cross)*
(c) Low-grade fill cover *(white with black cross)*
(d) Hi-sulfur fill cover *(yellow with blue dash)*
(e) Low-sulfur diesel fill cover *(yellow)*
(f) Stage I dry break cover *(orange)*
(g) Used oil cover *(a purple square)*
(h) Fill pipe with cap
(i) Fill containment *(spill protection)*
(j) Release valve

FIGURE 21.3.5 Fill Area Assembly with Color-Coded Covers (Source: Based on information from Florida Department of Environmental Protection)

3. Parts cleaning
4. Housekeeping

Hot Work. Hot work is defined in NFPA 51B, *Standard for Fire Prevention During Welding, Cutting, and Other Hot Work,* as "any work involving burning, welding, or similar operations that is capable of igniting fires or explosions." Hot work operations must be performed in specially designed areas, because they present excellent sources of ignition. Performing these operations in a defined, controlled area is the best way to reduce the risk that these operations will become an ignition source for a flammable vapor release.

Spray Painting and Undercoating. Spray painting operations are restricted to work on only small parts of a vehicle and these operations must be located at least 20 ft (6.1 m) from any potential ignition source.

Parts Cleaning. Parts cleaning operations can present a significant risk because they may involve relatively large amounts of heated solvent. To reduce this risk, nonflammable cleaning solvents should be used whenever possible. If flammable solvents must be used, they should be used only under conditions in which the opportunities for creating a flammable atmosphere are also controlled or eliminated. This means that ignition sources should be kept away from the areas where flammable atmospheres could be created. If the solvent is heated, it should have a shutoff device that prevents the solution from getting close to the temperature at which a flammable atmosphere would be created.

Housekeeping. Housekeeping requirements are extremely important for fire prevention. Mixing incompatible materials, such as oxidizing substances and flammable liquids, is one undesired outcome of poor housekeeping. There are some general organizational and cleaning procedures that should be followed to achieve good housekeeping.

The work area should be kept clean and free from obstructions. Materials should be stored in assigned areas and not allowed to be left in work areas as part of ongoing work projects. Combustible rubbish should be placed in covered metal receptacles until removed for disposal. These materials should not be allowed to accumulate. Personnel should know if combustible rubbish is in a waste receptacle to prevent adding an incompatible material to the receptacle.

Most important, a daily inspection should be conducted of the work area to identify and eliminate hazards. This daily

inspection should give facility managers timely information about the storage of materials and the condition of equipment so that they can respond to a hazard before it causes a fire.

FIRE SUPPRESSION

Fixed Fire Protection

Fixed fire protection is often recommended for refueling areas at service stations. It is required at larger repair garages (as defined earlier) because these are facilities where people work and in which operations involving the transfer of flammable liquids occur routinely. These transfer operations are often not as well controlled as in vehicle refueling areas but instead can vary depending on the type of repair and specific vehicle being worked on.

Fire Extinguishers

Each motor fuel–dispensing facility should have one or more listed fire extinguishers that have a minimum capability of 40-B:C. A B:C fire extinguisher is one suitable for use on fires involving flammable liquids, combustible liquids, petroleum greases, tars, oils, oil-based paints, solvents, lacquers, and alcohols (Class B fires) or fires involving energized electrical equipment in which the electrical nonconductivity of the extinguishing media is of importance (Class C fires). The 40 number indicates the relative strength of the extinguisher—the greater the number, the greater the extinguishing power. The extinguishers should be located within 100 ft (30 m) of each pump, storage tank fill-pipe opening, and lubrication or service room.

Materials that obstruct access to fire-fighting equipment or important piping system control valves must not be placed on a pier. Where the pier is accessible to vehicular traffic, there should be an unobstructed roadway to the shore end of the wharf. This roadway is required for access by fire-fighting apparatus.

SPECIAL REQUIREMENTS FOR MARINE REFUELING FACILITIES

Many of the requirements for automotive refueling also apply to marine refueling, but because marine refueling is done on piers, special requirements apply. At marine refueling facilities, a fuel line is often run from a storage tank located on land to a dispensing device located on the pier, wharf, or floating dock. This run of pipe increases the risk for an accidental release of material. The additional safety requirements for marine refueling facilities focus on preventing a release of material from the fuel supply line that runs between the onshore storage tank and the dispenser.

Storage

Storage tanks for marine refueling have to comply with the same requirements that motor vehicle refueling must meet, with a few differences. Pumps that are not a part of the dispensing device must be placed on shore. The tank must have a device that would prevent the gravity flow of liquid if the supply hose were broken.

Piping Systems

Piping systems must be protected against movement that might occur because the dispenser is located on a structure in or at the water. The piping also must be protected against physical damage that could result from its being exposed. A valve is required in each pipeline at or near the approach to the pier and at the shore end of each marine refueling facility to shut off the liquid supply from shore.

Fuel Dispensing System

Dispensing hose must be listed and hose length should be kept to less than 18 ft (5.5 m), if possible. The dispensing device should be designed so that it does not prevent people from leaving the pier in an emergency situation.

Boats should not be berthed (parked) at a refueling area or attached to boats that are being refueled. Boats have several ignition sources and these must be kept away from the refueling area. Unlike automotive refueling, there should always be an attendant on duty when marine refueling is done because of the less routine nature of marine refueling. Fueling should not be undertaken at night except under well-lighted conditions.

Sources of Ignition

Electrical arcs and open flames are the most likely ignition sources in the marine refueling environment. Each dispensing unit must have a clearly identified electrical disconnect to shut off power to all pumps and motors in the dispensing system. All wiring should be located on the side of the structure opposite the piping to reduce the opportunity for the ignition of fugitive emissions from the piping.

During refueling, the fuel nozzle must be electrically bonded by contact to the vessel fill pipe throughout the refueling operation. This contact should reduce the opportunity for potential difference between the nozzle and another surface that would receive the charge and that could create an electrical arc.

Pipelines on piers must be bonded and grounded. In bonding, the pipeline is connected to an electrically conductive material. In grounding, this material is connected to a ground or a conductor that discharges to ground.

Smoking materials, including matches and lighters, should not be used within 20 ft (6 m) of areas used for fueling. The area should be marked to warn people not to use these materials.

Because people are less likely to shut off the motor of a boat during refueling, it is important that the attendant ensure that all motors are turned off during refueling. Hot engines have the potential to act as ignition sources.

Containers and Movable Tanks

Movable refueling tanks and portable containers present a greater fire risk than fixed installations because of the decreased control associated with mobile equipment. Because of this increased risk, the conditions under which movable tanks can be used are limited.

With the approval of the authority having jurisdiction, movable tanks can be used for dispensing fuel at locations inaccessi-

ble to the public. This additional level of approval should reduce the chance of releasing material during transfer operations.

Gasoline should not be put into a portable container unless the container is approved for the storage of gasoline. Only containers less than 12 gal (45.4 L) should be filled on vessels.

Marine Facilities

Marine motor fuel–dispensing facilities should have one or more listed fire extinguishers having a minimum classification of 40-B:C. An extinguisher should be within 100 ft (30 m) of each pump, each dispensing device, and each pier-mounted liquid storage tank.

Piers that extend more than 500 ft (152 m) in travel distance from shore should have a Class III standpipe. A standpipe system is an arrangement of piping, valves, hose connections, and allied equipment installed in a building or structure, with the hose connections located so that water can be discharged in streams or spray patterns through the attached hose and nozzles. This is accomplished by connections to municipal water supply systems or by pumps, elevated gravity tanks, and other equipment necessary to provide an adequate supply of water to the hose connections. A Class III standpipe system has a minimum flow rate for the hydraulically most remote standpipe of 500 gpm (1893 L/min) and a minimum flow rate for additional standpipes of 250 gpm (946 L/min). The total flow rate should not exceed 1250 gpm (4731 L/min).

SERVICE STATION MAINTENANCE AND INSPECTION

The checklist in Figure 21.3.6, which describes the different components of a service station and the applicable fire safety requirements, is designed to assist in a safety inspection of the facility. This checklist is not comprehensive and is intended only to make people aware of the areas of concern. State and federal regulations and codes and standards contain detailed requirements that address these various areas. The checklist parallels the material discussed in this chapter.

SUMMARY

Because the operations of automotive and marine service stations include both refueling and repair and, therefore, involve the storage, transfer, and use of flammable liquids, they present a distinct fire risk. The risk associated with the transfer of

	Dispensing System	*Tank*	*Repair Work Area*
Are hoses listed for use?			
Are pumps and nozzles listed for use?			
Are emergency shutoff devices installed correctly?			
Are ignition sources controlled?			
Are emergency shutoff switches present and properly located?			
Are required operating procedures and warnings posted?			
Is electrically safe equipment being used in areas classified for type of electrical equipment?			
Is physical protection in place for pumps and piping?			
Do tanks have adequate spill control?			
Are proper separation distances being followed for operations involving ignition sources and Class I liquids?			
Is housekeeping adequate?			
Is cleanup routinely performed after operations?

Is any flammable liquid waste properly stored and labeled?			
Are work areas free of combustible waste material?			
Are containers listed for use and properly labeled?			

FIGURE 21.3.6 Continued

flammable liquids is also increased because this operation involves the general public, who are not trained in the hazards of the materials.

This chapter covered construction, design, and location requirements for dispensing areas and repair facilities, including, for example, oil traps or separators for spill control; dedicated mechanical exhaust systems; container and tank storage requirements; as well as special requirements for piping, dispensing devices, hoses, and other system components. This chapter also covered operations safety requirements that include such items as performing a mass balance to detect leaks; dispensing into approved and labeled containers; and following specific requirements when performing hot work, spray finishing, and parts cleaning.

Fixed fire suppression is recommended for refueling areas at service stations and is required at larger repair garages. Each motor fuel–dispensing facility, including marine facilities, should have listed fire extinguishers on hand. Additional safety requirements for marine refueling facilities focus on preventing a release of material from the fuel supply line, controlling sources of ignition, and limiting conditions under which movable tanks can be used.

Chapter Contents

Introduction to the Use of Alternative Fuels
Impact of Clean Air Act Amendments of 1990 on Alternative Fuel Use
Prevention of Unintentional Releases and Required Risk Management Programs
Analysis of the Chemical and Physical Properties and Hazards of Alternative Fuels
Boiling Liquid Expanding Vapor Explosions
Health and Safety Concerns
Applicable NFPA Standards
Vehicle Fueling Stations
Vehicle Components, Design, and Operation
Emergency Response to Alternative Fuel Incidents

Key Terms

alternative fuel, automotive exhaust, boiling liquid expanding vapor explosion (BLEVE), Clean Air Act, compressed natural gas (CNG), compressed natural gas (CNG) vehicle, fuel cell powered vehicle, liquefied natural gas (LNG), liquefied natural gas (LNG) vehicle, liquefied petroleum gas (LP-gas), liquefied petroleum gas (LP-gas) vehicle, odorization, particulate matter emissions, vehicle fueling station

The use of alternative fuels for vehicles is becoming more predominant. Forces driving their use are increasing air pollution and the United States' dependence on foreign oil. Federal regulations such as the Energy Policy Act (EPACT) of 1992 and the Clean Air Act Amendments (CAAA) of 1990 were specifically designed to increase the driving public's use of alternative-fueled vehicles to benefit the environment and to increase the use of natural resources available in North America. From 1992 to 2000, there was a 6.9 percent average annual percent increase in alternative fuel vehicles in use in the United States. As of 2000, they accounted for 0.2 percent of all registered motor vehicles in the United States.[1] This chapter discusses several areas, including properties and hazards associated with different alternative fuels, vehicle fueling stations, vehicle component designs and operation, emergency response to alternative fuel incidents, and federal regulations that may impact alternative fuels users.

For related topics, see the following chapters in Section 21: Chapter 1, "Passenger Vehicle Fires"; Chapter 2, "Fire Safety in Commercial Vehicles"; Chapter 4, "Vehicle Fueling Using Gaseous Fuels"; and Chapter 5, "Fuel Cell Vehicles."

INTRODUCTION TO THE USE OF ALTERNATIVE FUELS

Alternative Fuels Defined

A variety of alternative fuels are currently used in the United States. However, the review of alternative fuels in this chapter is limited to compressed natural gas (CNG), liquefied natural gas (LNG), and liquefied petroleum gas (LP-gas), specifically propane. The scope is limited to these three gaseous fuels because the hazards of alternative fuels, like flammable liquids (alcohols and reformulated gasoline), are better known and generally accepted. Hydrogen is the least used of these three fuels but hydrogen may become a more important alternative fuel as hydrogen vehicle applications and technology continue to develop. Gaseous fuels have recently gained popularity and more information is needed on their use as motor vehicle fuel.

Additionally, the three main alternative fuels are used by over 85 percent of the light alternative fuel vehicles and by over 95 percent of the heavy alternative fuel vehicles. Over 95 percent of the alternative fuel refueling sites are for CNG, LNG, or LP-gas[2] (Tables 21.4.1 through 21.4.13).

The Clean Air Act Amendments (CAAA) define alternative fuels as methanol, ethanol, and other alcohols; reformulated gasoline; reformulated diesel (for trucks only); natural gas; propane; hydrogen; or electricity. The Energy Policy Act (EPACT) includes all fuels listed under CAAA except for reformulated gasoline and diesel. EPACT also defines other alternative fuels, that is, fuels derived from biomass, liquid fuels derived from coal, and alcohol blended with other fuels containing at least 85 percent alcohol by volume.[3]

Carl H. Rivkin, P.E., is a principal chemical engineer in NFPA's Fire Protection Applications and Chemical Engineering Division. He is NFPA's staff liaison to the Technical Committee on Vehicular Alternative Fuel Systems.

Note: Estimates for 2003 are based on plans or projections. Estimates for historical years may be revised in future reports if new information becomes available.

[a]The remaining portion of 85 percent methanol and both ethanol fuels is gasoline.

[b]In 1997, some vehicle manufacturers began including E85-fueling capability in certain model lines of vehicles. For 2002, the EIA estimated that the number of E85 vehicles that are capable of operating on E85, gasoline, or both, is about 4.1 million. Many of these alternative-fueled vehicles (AFVs) are sold and used as traditional gasoline-powered vehicles. In this table, AFVs in use include only those E85 vehicles believed to be intended for use as AFVs. These are primarily fleet-operated vehicles.

[c]Excludes gasoline-electric hybrids.

Beginning in 2000, federal data were derived from the DOE/GSA Federal Automotive Statistical Tool (FAST).

Alternative Fuel Users

Many entities such as private, state, federal, and local government fleets and the general public use alternative fuels to power their vehicles. Fleets using alternative fuels can be small or large and are typically located predominantly in urban areas.

The Clean Fleets Program established by CAAA states that by 1998, serious, severe, and extreme ozone nonattainment areas must purchase alternative fuel vehicles. This applies to fleets with 10 or more vehicles capable of being centrally refueled and located in an area with a population of 250,000 or more. The law excludes emergency, farm, construction, rental, demonstration, and privately garaged vehicles.[3]

EPACT, which took effect in 1992, mandates the purchase of alternative fuel vehicles, with the intent of reducing the United States' dependence on oil imports. Federal and state fleets, as well as private-sector companies that produce alternative fuels, are required to purchase alternative fuel vehicles as a percent of their annual vehicle acquisitions. This can be a phased schedule for fleets of 50 or more vehicles, with at least 20 that can be centrally refueled, and located in an area with a population of 250,000 or greater. The law can extend to include municipal and private fleet owners if the U.S. Environmental Protection Agency (EPA) determines that EPACT's goals cannot be met.

IMPACT OF CLEAN AIR ACT AMENDMENTS OF 1990 ON ALTERNATIVE FUEL USE

Alternative fuel use has increased since the EPA established maximum concentration levels called national ambient air quality standards (NAAQs) for certain pollutants in the ambient air. The standards targeted the following pollutants:

- Automotive exhaust pollutants such as volatile organic compounds (VOCs) that lead to the formation of ozone
- Nitrous oxides (NO_x)
- Carbon monoxide (CO)

set national ambient air quality standards. States and other municipalities must measure ambient air according to an EPA-approved plan to determine whether they meet these ambient standards. Both mobile and stationary sources generate all of these pollutants. Aboveground storage tanks, industrial processes, and diesel-fueled generator sets introduce pollutants into the atmosphere.

A county or area can be designated a nonattainment area when concentrations of any one of these pollutants exceed NAAQ limits. The nonattainment categories are extreme, severe, and moderate. Ozone, PM_{10}, and CO nonattainment are the predominant nonattainment pollutants. Individual states are responsible for attaining each EPA NAAQ. States accomplish this by utilizing state implementation plans, which outline specific actions to reduce emissions. One method of reducing mobile sources of criteria pollutants is using alternative fuels instead of more traditional fuels such as gasoline or diesel.

Automotive Exhaust Pollutants

The use of alternative fuels significantly reduces the production of ozone. Alternative fuels can reduce ozone generation by reducing both the amount of volatile organic compounds (VOCs) in tailpipe emissions and the photochemical reactivity of VOC emissions. Hydrogen used in fuel cells produces no VOC emissions because there is no carbon in the fuel cell feed stream. Ozone is not a direct product of the combustion process but a result of atmospheric photochemical reactions between VOCs and the oxides of nitrogen (NO_x). NO_x is primarily produced when nitrogen and oxygen in combustion air combine at high temperatures. VOCs result from incomplete combustion of hydrocarbon fuels used in motor vehicles.[4]

Simple compounds such as methane and propane predominantly comprise LNG, CNG, and LP-gas fuels. The amount of VOCs these fuels generate is lower than the amount gasoline generates. Furthermore, ozone formation increases when constituents of tailpipe emissions have high photochemical reactivity.[4] Fuels composed of small molecules such as methane generate less ozone because they are unreactive in the atmosphere. Propane is more reactive than methane but significantly less reactive than large molecules of hydrocarbon fuels, such as the constituents of gasoline.

As of the year 2000, 26 states, the District of Columbia, and almost every major urban area in the United States had areas classified as nonattainment for ozone. One area, the South Coast Air Basin (which includes the city of Los Angeles and has a population of over 13,000,000 people), is classified as extreme. Approximately 100,000,000 people in the United States live in a nonattainment area for ozone.[5]

Carbon Monoxide Pollutants

As of the year 2000, there were eight areas classified as serious nonattainment areas for carbon monoxide: Anchorage, Alaska; Fairbanks, Alaska; Denver–Fort Collins, Colorado; Las Vegas, Nevada; Los Angeles–South Coast Basin, California; Phoenix, Arizona; and Spokane, Washington. Several other areas are in the moderate nonattainment class.[5] Approximately 80 percent of CO discharged to the atmosphere is from mobile sources, primarily from emissions from gasoline-powered vehicles. Alternative fuels composed of methane and propane emit much less CO than gasoline does because they have lower carbon to

Note: Light duty includes vehicles less than or equal to 8500 GVWR; medium duty includes vehicles 8501 to 26,000 GVWR; heavy duty includes vehicles 26,001 GVWR and over. Estimates for 2003 are based on plans or projections. Estimates for historical years may be revised in future reports if new information becomes available.

[a]The remaining portion of 85 percent methanol and both ethanol fuels is gasoline.

[b]In 1997, some vehicle manufacturers began including E85-fueling capability in certain model lines of vehicles. For 2002, the EIA estimated that the number of E85 vehicles that are capable of operating on E85, gasoline, or both, is about 4.1 million. Many of these alternative fuel vehicles (AFVs) are sold and used as traditional gasoline-powered vehicles. In this table, AFVs in use include only those E85 vehicles believed to be intended for use as AFVs. These are primarily fleet-operated vehicles.

[c]Excludes gasoline-electric hybrids.

hydrogen ratios. In addition, alternative fuel vehicles do not need to run fuel rich during cold weather like gasoline-fueled vehicles do.[3] This reduced fuel consumption lowers CO emissions.

Particulate Matter (PM) Emissions

PM emissions can be reduced by using alternative fuels because the primary mobile source of these emissions is diesel-powered vehicles.[4] Diesel fuels' high sulfur content and aromatic hydrocarbons contribute to high PM emissions. In gaseous alternative fuels, sulfur is not present in appreciable amounts, and aromatic hydrocarbons are not present at all.

As of the year 2000, there were six serious nonattainment areas for PM_{10}: Clark County, Nevada; Coachella Valley, California; Los Angeles–South Coast Air Basin, California; Owens Valley, California; Phoenix, Arizona; and San Joaquin Valley, California. Additionally, many other areas are classified as moderate nonattainment areas.[5]

Total fuel consumption[a,f]	144,774,683	148,180,046	151,597,859	156,838,150	161,210,087	163,032,677	165,201,691	169,983,219	173,303,895	177,561,958

Note: Fuel quantities are expressed in a common base unit of gasoline-equivalent gallons to allow comparisons of different fuel types. Gasoline-equivalent gallons do not represent gasoline displacement. Gasoline equivalent is computed by dividing the lower heating value of the alternative fuel by the lower heating value of gasoline and multiplying this result by the alternative fuel consumption value. Lower heating value refers to the Btu content per unit of fuel excluding the heat produced by condensation of water vapor in the fuel. Totals may not equal sum of components due to independent rounding. Estimates for 2003 and 2004 are based on plans or projections. Estimates for historical years may be revised in future reports if new information becomes available.

[a]1999 and 2002 estimates have been revised.

[b]The remaining portion of 85 percent methanol and both ethanol fuels is gasoline. Consumption data include the gasoline portion of the fuel.

[c]Excludes gasoline-electric hybrids.

[d]Includes a very small amount of other ethers, primarily Tertiary Amyl Methyl Ether (TAME) and Ethyl Tertiary Butyl Ether (ETBE).

[e]Gasoline consumption includes ethanol in gasohol and MTBE.

[f]Total fuel consumption is the sum of alternative fuel, gasoline, and diesel consumption. Oxygenate consumption is included in gasoline consumption.

NA = Not available.

Sources: 1993–2002 Oxygenate Consumption: Energy Information Administration, Petroleum Supply Monthly. 1993–2004 Traditional Fuel Consumption: Energy Information Administration, Petroleum Supply Annual, Volume 1 (June 2000). Highway use of gasoline was estimated as 97.1 percent of consumption, based on data in the Transportation Energy Data Book: Edition 16, prepared by Oak Ridge National Laboratory for the U.S. Department of Energy (July 1996). Diesel consumption was adjusted for highway use by multiplying by 0.568 derived from Energy Information Administration, Fuel Oil and Kerosene Sales 1999. 2002–2004 Oxygenate and Traditional Fuel Consumption: Energy Information Administration, Short Term Energy Outlook, September 2002. Alternative Fuel Consumption: Science Applications International Corporation 1992–1995, "Alternative Transportation Fuels and Vehicles Data Development." Unpublished final report prepared for the Energy Information Administration (McLean, VA, July 1996) and Energy Information Administration, Office of Coal, Nuclear, Electric and Alternate Fuels for 1996–2004.

As mentioned earlier, nonattainment of ozone, PM_{10}, and CO is the most widespread. Using alternative fuels such as CNG, LNG, and LP-gas can significantly reduce these pollutants.

PREVENTION OF UNINTENTIONAL RELEASES AND REQUIRED RISK MANAGEMENT PROGRAMS

The Prevention of Accidental Releases of CAAA of 1990, Title III, Section 112 R, aims to prevent inadvertent chemical releases at storage locations and to minimize their consequences. Section 112 R of Title III of CAAA exempts the following propane facilities from developing and submitting risk management plans:

- Propane facilities where the propane is stored for use as fuel at the facility
- Facilities that store 10,000 lb (4540 kg) of propane or less
- Facilities where the propane is held for sale and the facility itself is considered a retail facility (one at which more than half of the income is obtained from direct sales to end users or at which more than half the fuel sold, by volume, is sold through a cylinder exchange program)

The requirements of Title III, Section 112 R, apply to existing and new stationary sources in excess of threshold quantities. The list of regulated flammable substances includes methane and propane with threshold storage quantities of 10,000 lb (4540 kg). LNG is composed of 95 to 99 percent methane;

*The remaining portion of 85 percent methanol and both ethanol fuels is gasoline. Consumption data include the gasoline portion of the fuel.

LP-gas is predominantly propane. Assuming commercial automotive grades of LNG and LP-gas, facilities using stationary containers with capacities greater than 2780 gal (10.5 m^3) of LNG or 2380 gal (9.0 m^3) of LP-gas may be required to prepare a risk management plan. The rule should not impact most CNG fueling stations because storage is normally below the threshold storage quantity. Natural gas from a distribution line is usually compressed at the facility, so it is usually unnecessary to store large quantities. Hydrogen is also listed in table 3 to 40 CFR 68.30 of the Risk Management Plan list of regulated flammable materials with a threshold of 10,000 lb.

The risk management program and its implementation consist of three components: (1) a hazard analysis, (2) a program for preventing accidental releases, and (3) an emergency response program. A Risk Management Plan must be submitted to the implementing agency, the State Emergency Planning Committee, the Local Emergency Planning Committee, and the Chemical Safety and Hazard Investigation Board. The three elements of the risk management program must be summarized in a Risk Management Plan and submitted to the above organizations. The report must be reviewed every 5 years. *Risk Management Program Guidance for Propane Storage Facilities* (40 CFR Part 68) is available from the EPA to assist regulated facilities in complying with risk management programs.[6]

Hazard Analysis

Hazard assessment is a determination of the worst-case release scenario, identification of other more likely significant releases of propane or LNG, an analysis of the off-site consequences, and a history of unintentional releases of propane or LNG. Under 40 CFR 112.R, worst-case releases are determined by assuming that in an instantaneous release, all mitigation systems fail. Other more likely accidental releases can include failure of transfer hoses, excess flow valve, emergency shutoff controls, piping, and other significant equipment failures. The rule also states that consequences must be determined from the rate and quantity of the substance lost in the air, the event's duration, the distance to exposures such as single- and multiple-family dwellings, the populations within these distances, and the potential for environmental damage. The owner or operator must maintain a 5 year history that includes such information as the date and time of a release and its quantity and duration.

Program to Prevent Unintentional Releases of Propane

The prevention program's intent is to evaluate potential hazards present at a storage and dispensing station and to find the best way to control them. The program consists of a management system,

process hazard analysis, process safety information, standard operating procedures, training, maintenance, prestartup reviews, management of change, safety audits, and incident investigations.

The rule states that the process hazard analysis must be conducted by using quantitative or qualitative methodologies such as what-if, fault tree analysis, hazard and operability study (HAZOP), or other accepted practices. The process hazard analysis should address the hazards of the process; identify previous incidents that impacted off-site exposures, engineering, and administrative controls; predict the consequences of control or human failures, and stationary source sitting; and qualitatively evaluate possible safety and health effects if controls fail.

Emergency Response Program

Of particular importance to emergency response personnel is the rule that requires the owner or operator of an LNG or LP-gas fueling station to establish and implement an emergency response program for responding to and mitigating unintentional releases. The emergency response must include information on evacuation

routes, employee instructions, descriptions of response and mitigation technologies at the fueling station, and procedures for informing the public and emergency response agencies of a release.

The rule states that procedures for the testing, maintenance, and use of response equipment must be established. In addition, the owner or operator is responsible for training employees in emergency response procedures and documenting all training activities. The rule states that drills or exercises will be conducted and documented, but does not specify the frequency of these drills. However, other regulations, such as those promulgated by OSHA, do establish the required frequency of emergency drills.

The emergency response program requires facilities storing LNG or LP-gas to document first aid and emergency medical treatment procedures necessary to treat persons exposed. The emergency response plan must coordinate with other local emergency response plans developed by the Local Emergency Planning Committee (LEPC) or other local emergency response agencies.

ANALYSIS OF THE CHEMICAL AND PHYSICAL PROPERTIES AND HAZARDS OF ALTERNATIVE FUELS

When a vehicle is being fueled or repaired, release from the vehicle to the fueling or repair facility is a reasonable scenario that requires fire fighters' consideration. The impact of potential releases can be analyzed using computer dispersion models that predict where the maximum ground level concentration for a specific release scenario would occur. The models (of which there are many variations) can predict concentrations at other distances from the release than the distance at which the maximum concentration would occur. A sensitivity analysis could be performed to show which parameter(s) would contribute most to the release impacts and potentially how best to reduce the impacts from a release.

Chemical and Physical Properties

The properties of each fuel require consideration in determining its potential hazard. Whether the hazard becomes "real" depends on various time-dependent conditions, the fuel system design, and the quality of the fuel system's manufacture and installation. This is due to the properties and hazards of the materials, whether release occurs inside or outside of a building, and the release scenario. This chapter discusses the relationships between identified properties and hazards of CNG, LNG, and LP-gas.

Compressed Natural Gas. Mixing and dispersion of gases depend on discharge velocities, vapor density, diffusion characteristics of the gas, and conditions and location of release. CNG can be expected to disperse readily, mix, and quickly form combustible mixtures. Under unconfined conditions, methane gas mixtures dilute rapidly to concentrations below the lower flammable limit. In contrast, the ability to form combustible mixtures rapidly generates a hazardous situation if fuel leaks in confined areas without significant ventilation.

Hydrogen. Hydrogen is used both as a liquid and a gas. Hydrogen has a molecular weight of approximately 1, but hydrogen occurs as a diatomic molecule with an approximate molecular weight of 2. Because of its extremely low density (0.07 relative to air), hydrogen typically is stored at much higher pressures than CNG. This is also the reason why some storage systems use liquid hydrogen with vaporizers to convert the hydrogen to a gas for the specific application. Gaseous hydrogen in the flammable range (4 to 75% by volume in air) can be easily ignited but because it is the lightest gas, it disperses rapidly. Because of its extremely low boiling point, liquid hydrogen boils rapidly if released. Liquid hydrogen releases can cause oxygen to condense out of the air and present this additional hazard.

Liquefied Natural Gas. LNG is natural gas liquefied by cryogenic refrigeration and stored at a temperature of –260°F (–162°C). The vapor cloud above a pool of released LNG is fairly difficult to ignite. However, the very low temperature of LNG causes normally buoyant methane to become heavier than air, creating large volumes of flammable methane-air mixtures that can spread significantly beyond the area of the initial spill. The possibility of ignition increases, and the potentially large volume of combustible gas mixture constitutes a major safety risk in substantial LNG spills.[7] When LNG vaporizes, the gas vapor cloud begins to warm and comes into thermal equilibrium with the atmosphere. LNG and CNG are primarily composed of natural gas; however, prior to liquefaction of LNG, constituents such as carbon dioxide, water, hydrogen sulfide, the odorant, and trace metal oxides are removed because they solidify at LNG storage temperatures.[8]

LP-Gas. One relative safety comparison of the three alternative fuels discussed here found that safety ranking of LP-gas appears to be similar to that of gasoline.[4] This can be attributed to heavier-than-air LP-gas vapors that do not disperse as quickly as those of other alternative fuels.

Automotive grade natural gas contains 95 to 99 percent methane and a mixture of several other gases.[8] Methane is the simplest hydrocarbon, with one carbon molecule bonded to four hydrogen molecules. Other hydrocarbons present include ethane, propane, and butane, in addition to trace amounts of metal oxides, nitrogen, carbon dioxide, water, helium, and hydrogen sulfide.

LP-gas can be either butane, propane, or a mixture of both. However, LP-gas used as an alternative fuel is composed of commercial propane. Commercial propane is not pure, but contains varying percentages of butane, ethane, ethylene, propylene, isobutane, and butylene. Propane is a straight-chain saturated hydrocarbon composed of three carbon atoms and eight hydrogen atoms. Propane is a gas at room temperature, but is liquefied when stored under a pressure equal to its vapor pressure.

Fire Hazards

The need to understand the fire hazards associated with CNG, LNG, and LP-gas grows as the number of alternative-fueled vehicles increases. For example, emergency response personnel need to recognize that these fuels present significantly different fire hazards than traditional fuels such as gasoline and diesel.

Table 21.4.14 summarizes chemical, physical, and fire hazard properties of the three alternative fuels. CNG and LNG have

Notes:

1. Octane values are for pure components. Laboratory engine Research and Motor octane rating procedures are not suitable for use with neat oxygenates. Octane values obtained by these methods are not useful in determining knock-limited compression ratios for vehicles operating on neat oxygenates and do not represent octane performance of oxygenates when blended with hydrocarbons. Similar problems exist for cetane rating procedures.
2. The higher heating value is cited for completeness only. Since no vehicles in use, or currently being developed for future use, have power plants capable of condensing the moisture of combustion, the lower heating value should be used for practical comparisons between fuels.
3. Calculated.
4. Pour Point, ASTM D97 from Reference (c).
5. Based on cetane.
6. For compressed gas at 2400 psi.

similar fire hazards because some natural gas properties do not change between the two different physical states. Flammability limits and autoignition temperature of natural gas are the same in the two physical storage states of CNG and LNG. Its flammable range is narrow, and its autoignition temperature is high. LP-gas produces a flammable mixture in air at lower concentrations than natural gas but has a narrower flammable range.

Fire Hazards of Compressed Natural Gas. Natural gas, which has a vapor density of less than 1, tends to rise at ambient conditions. This is one important property of natural gas to consider because vapor density varies under different temperatures. However, because of the extremely low boiling point of natural gas, the vapor density will be less than air under most conditions. CNG released into the atmosphere at normal temperatures and pressures rapidly rises and disperses into the air. CNG-fueled vehicles provide a high degree of safety if a release occurs outdoors because the compressed methane diffuses rapidly in unconfined locations. If a container relief valve operates or the fuel line piping breaks, the duration of the release is limited because the gas discharges at high pressures.

When CNG vents from a relief device or pipe opening, it forms a gas jet that "blows" into the atmosphere in the direction the hole faces, continually entraining and mixing with air. If the CNG encounters an ignition source, a flame jet of considerable length may form. Flame jets pose a thermal radiation hazard to the vehicle and persons nearby and are particularly hazardous if they impinge on the exterior of adjacent containers. This can lead to the operation of additional pressure-relief devices, increasing the fire's thermal flux. Compressed methane gas releases are of relatively short duration. The ensuing fire usually involves only combustibles on the vehicle because natural gas is rapidly consumed during the jet fire.

A CNG release in an enclosed space can present a higher risk for a deflagration because the contained gas may not readily diffuse. Because methane has a vapor density of 0.6, it rises rapidly and pools if contained by a ceiling. Light fixtures and air-handling equipment normally installed at a building's ceiling or roof can serve as potential ignition sources.

Studies have evaluated the deflagration hazard resulting from a leak in a CNG vehicle fuel system or relief device operation inside parking garages and transit tunnels.[9] A gas utility corporation commissioned a study that examined the consequences of a fuel pipe leak or the operation of a container pressure relief device inside a partially open public parking garage. The study found that a leak in the fuel piping was the most credible event, whereas the operation of the container relief valve was the worst-case event. Recognizing that the three model codes and NFPA 88A, *Standard for Parking Structures,* require a method for mechanically ventilating carbon monoxide exhaust, and that all parking garages have fairly open spaces, vapor dispersion models related to this study were created to evaluate selected leak scenarios. Analyses of the most probable event resulted in no flammable concentrations beyond the leak point's immediate vicinity. The leak did not result in accumulated flammable gas in the garage. The operation of the container relief valve did result in the brief formation of a gas puff that was within the flammable limits of methane. However, the vapor puff was effectively mitigated by the rapid diffusion of the gas in open space and its removal from the garage by the mechanical exhaust system. The study showed that a CNG vehicle poses no extraordinary risk; that is, the CNG vehicle's risk is equal to or less than the risk a gasoline-fueled vehicle poses.

One study[10] compared the flammable vapor clouds formed following a fuel line failure of a hypothetical CNG-powered and gasoline-powered van inside ventilated and unventilated tunnels with various types of ceiling construction. Depending on tunnel ventilation, the hypothetical CNG vehicle would be expected to produce both a smaller and shorter-lived flammable gas region than the equivalent gasoline van. Effective ventilation could be mechanical ventilation by fans or ventilation induced by a vehicle's motion. The study recommended that transportation authorities develop policies limiting the size of vehicles allowed in tunnels.

Fire Hazards of Liquefied Natural Gas. LNG is stored at an approximate temperature of –260°F (–162°C). Studies show that at temperatures less than –180°F (–118°C), LNG is more dense than air at 60°F (16°C).[8] Because LNG is a flammable cryogen, the integrity of the container and piping is of primary concern; a container or piping failure can result in a cryogen liquid spill. However, loss of liquid from a container requires that the outer steel shell, insulation, and inner vessel all fail. All three components are less likely to fail than are single-wall, atmospheric storage tanks found on conventional gasoline- or diesel-fueled vehicles. Nonetheless, the probability of a spill is still a consideration.

The liquid from an LNG spill begins to vaporize rapidly and forms a white cloud as cold vapors condense in air. Initially, the vapor is negatively buoyant and sinks to the ground until it warms to approximately –180°F (–118°C). At this temperature, the vapor becomes positively buoyant and begins to rise.

The vaporization rate and distance the gas cloud travels and disperses depends on the four following factors:

1. *Wind speed.* Wind speed is influential because as velocity increases, the LNG evaporation rate tends to increase. Increased wind velocity helps to induce mixing of methane vapors with air, causing the vapor cloud to disperse into smaller clouds, or puffs. This reduces the flammable atmosphere's area.
2. *Surface area of the spill.* The larger the spill area, the greater its vaporization rate. This can result in larger vapor clouds, increasing the boundary of the flammable atmosphere.
3. *Surface type.* The surface where the LNG spills influences its vaporization rate. Vaporization rates are high on wet surfaces, such as muddy soil, because water acts as a heat sink. Asphalt promotes vaporization because its dark color acts as a heat radiator. If LNG spills onto a good heat-insulating surface, boiling may eventually slow down, but the remaining liquid pool continues to evaporate rapidly. Evaporation maintains the remaining liquid near its boiling point as it absorbs heat from its surroundings.
4. *Time of the incident.* At night, lack of atmospheric heating by the sun and ground reduces the evaporation rate of LNG. While this influences the vaporization rate, it also influences the distance from the source spill in which the vapor

puff remains in its flammable range. At night, the distance is greater because the time needed to heat the vapor until it is lighter than air increases.

Fire fighters should remember that LNG vapor formed during the phase change is colorless and odorless at normal temperature and pressures. They cannot rely on visual or olfactory indicators to establish safe boundaries. Only gas detection equipment designed to detect methane can establish safe exclusion and operating zones when dealing with LNG releases.

Fire Hazards of LP-Gas. LP-gas is stored as a liquefied gas at its vapor pressure and at ambient temperature. At ambient conditions, propane's vapor density is 1½ times that of air. This means that propane released to the atmosphere sinks to the ground and forms a vapor cloud that can follow surface contours over a large area. Because of the vapor density and expansion ratio of LP-gas, this class of materials can challenge fire fighters. Incidents involving LP-gas containers can result in jet fires, vapor cloud ignition, or boiling liquid expanding vapor explosions (BLEVEs). Because the alternative-fueled vehicles on the road are predominantly LP-gas fueled, fire fighters can expect to respond to incidents involving LP-gas more than other alternative fuels.

Two types of LP-gas releases can occur: vapor phase release and liquid phase release. A vapor phase release can occur if a component installed above the liquid line is damaged or the container is punctured or otherwise damaged above the liquid line. During a vapor release, LP-gas vents at a high velocity from the opening, possibly creating some liquid droplets during the process. The velocity of the release reduces with time as boiling inside the container cools the liquid mass. The tank's surface forms a layer of frost due to the refrigeration effect of the liquid being cooled. The gas may continue venting for a considerable time until no liquid is left in the container.

A liquid phase release occurs if an LP-gas component installed below the liquid line is damaged or if the container is punctured or damaged below the liquid line. When the release occurs below the liquid level, the liquefied gas may jet from the hole. The velocity of the liquid discharge depends on the amount of liquid in the container and the gas vapor pressure. During a liquid phase release, large amounts of the liquid flash into gas or vapor. Depending on the temperature and pressure, a propane release in its liquid phase can discharge a large mass of vapor mixed with small droplets suspended as an aerosol. Sometimes, liquid propane pools on the ground surface and typically boils off into gas.

During a vapor phase or liquid phase release, volatile gases and vapors, if not ignited immediately, form a plume that moves downwind of the container. If the plume contacts an ignition source, and the vapor plume is within the flammable range, the flame may flash back toward the source of the release. Unprotected people within the cloud may be severely injured. If the velocity of the flame front is great enough, air, products of combustion, and unburned fuel can compress to a point where a vapor cloud explosion could occur. In this case, the deflagration's pressure can also impact persons and property.

Fire Hazards of Hydrogen Gas and Liquid Hydrogen. Hydrogen gas has a flammable range of 4 percent to 75 percent in air by volume. It can be easily ignited and if contained can explode. Hydrogen has a vapor density of 0.07 relative to air, so it will disperse rapidly. Hydrogen has a boiling point of –423°F (–253°C), which means that any liquid release will quickly vaporize. Liquid hydrogen released from a pipe will under many conditions vaporize before contacting the ground resulting in no free-flowing liquid hydrogen. Liquid hydrogen releases may cause oxygen to condense out of the air presenting the additional hazard of an oxygen-enriched environment.

BOILING LIQUID EXPANDING VAPOR EXPLOSIONS

A boiling liquid expanding vapor explosion (BLEVE) is defined as a major container failure, into two or more pieces, at the moment in time when the contained liquid is well above its normal boiling point at atmospheric pressure.[11] Gas and LNG containers are susceptible to BLEVEs. BLEVEs occur when liquids are stored in a container under pressure at a temperature above their boiling points.

LNG and LP-gas both possess high expansion ratios. For instance, 1 ft^3 (0.028 m^3) of LNG expands to 618 ft^3 (17.4 m^3) of natural gas at ambient conditions, and 1 ft^3 (0.028 m^3) of liquid propane expands to approximately 265 ft^3 (7.5 m^3) of propane gas at normal temperature and pressure. Expansion of a liquefied gas increases the pressure on tank walls if pressure relief valves fail to open or if relief valves are incapable of adequately relieving internal tank pressure. A puncture in the tank wall or heating of the container surface due to an exposure or pool fire could cause expansion. As the tank walls' strength decreases and liquefied gas within the tank continues to expand, the tank fails, breaking into two or more pieces. The flammable gas can ignite simultaneously with tank failure.

The insulation of LNG containers that are constructed according to ASME Boiler and Pressure Vessel code helps protect the inner tank from exposure to high temperatures resulting from flame impingement. Storage vessels used at LNG fueling sites are similar to those used for storing cryogenic liquids. LNG containers' outer metal jacket protects an insulating material maintained under a vacuum. This assembly surrounds an inner steel vessel that holds the cryogenic natural gas liquid. This outer jacket and insulation, combined with the liquid's extreme cold, are expected to provide substantial protection from radiant heat exposure due to a pool fire. Fire tests conclude that the pressure relief valves for an uninsulated cryogenic vessel activate within 1 hour. If the tank insulation and vacuum are intact, the relief valve does not actuate for several days.[12]

Additional information on BLEVEs involving LP-gases can be found in Section 6, Chapter 10, "Gases."

HEALTH AND SAFETY CONCERNS

Health Hazards

Health risks of the three alternative fuels discussed in this chapter generally result from two different exposure routes: (1) skin contact and (2) inhalation. Ingestion is usually not a likely route of exposure.

Potential for skin contact with CNG is very low. Almost immediate dispersion results when a container releases CNG stored at pressures in excess of 2400 psi (16,546 kPa). LNG, a cryogenic liquid stored at –260°F (–162°C), can cause burns or frostbite upon contact. Hypothermia can also occur from prolonged exposure to LNG vapor.

Asphyxiation occurs when other gases displace oxygen in the air and the oxygen concentration decreases to less than a tenable level. LNG vapor is not toxic; however, there is potential for lung damage or asphyxiation. Lung damage could occur from prolonged breathing of cold vapors. Neither CNG or LNG has an established time-weighted average because they are simple asphyxiates; LP-gas has a time-weighted average of 1000 ppm. All the gaseous alternative fuels may cause asphyxiation if released in a confined space.

Hydrogen does not present a toxicity hazard. However, liquid hydrogen storage systems operate at extremely low temperatures and present cryogen burn hazards. Also, gaseous hydrogen storage systems operate at extremely high pressures, and the potential energy of these high pressures presents a hazard.

Odorization

Odorization of odorless gas such as natural gas or propane is an important safety precaution. It indicates, by odor, a gas leak or a release event. Natural gas is odorized within the pipeline prior to general distribution. Natural gas is normally odorized at a level allowing detection at 20 to 25 percent of the lower flammable limit of methane. CNG taken from a distribution line and compressed contains the odorants typically added to natural gas. One major difference between CNG and LNG is that LNG has no odor. Consequently, LNG leaks cannot be detected by smell. San Diego Gas and Electric Company developed an odorization technique for LNG in the 1970s. The technique used the same odorants used in natural gas, but blended them with a carrier gas such as liquid propane. A Gas Research Institute study revealed that odorants such as ethyl mercaptan, *i*-propyl mercaptan, and *t*-butyl mercaptan could be used with carrier gases such as liquid propane and *i*-butane to odorize LNG.[13] Although the study indicates viable options for odorization of LNG, NFPA 59A, *Standard for the Production, Storage, and Handling of Liquefied Natural Gas (LNG),* does not require it.

LP-gas is odorized before delivery to a bulk plant.[14] Like natural gas, it is detectable by odor at a concentration in air at less than one-fifth of the lower flammability limit. Typical odorants used include ethyl mercaptan and thiophane.

It is not possible to warn everyone of a gas leak by using odorants. Odorants can fade in transmission lines and containers due to oxidization by oxygen, rust, or iron oxides. Furthermore, olfactory senses diminish with increasing age, allergies, and during smoking and eating.

Hydrogen is typically not odorized. Because hydrogen has a boiling point of –423°F (–253°C) most chemicals would be in the solid phase if mixed with liquid hydrogen. Gaseous hydrogen is often used in fuel cells where the odorants would contaminate the fuel cell catalysts and prevent the fuel cells from functioning. Therefore, odorants are not used in hydrogen. As hydrogen becomes more widely used in fuel cells, there may be odorants developed that would not contaminate the fuel cell. Research is being conducted on this topic.

APPLICABLE NFPA STANDARDS

NFPA standards have been developed for all alternative fuels described in this chapter. NFPA 52, *Vehicular Fuel Systems Code,* 2006 edition, contains requirements for the use of CNG, LNG, and hydrogen. NFPA 57, *Liquefied Natural Gas Vehicular Fuel Systems Code,* has been incorporated into NFPA 52 and no longer exists as an independent document. The 2006 edition of NFPA 52 contains new requirements for both liquefied and gaseous hydrogen. NFPA 58, *Liquefied Petroleum Gas Code,* contains requirements for LP-gas. NFPA 59, *Utility LP-Gas Plant Code,* has requirements for storing and constructing LNG containers. However, the standard was originally written for site-erected LNG containers similar to those found at peak-shaving plants. Conversely, LNG stations normally use shop-constructed containers. Many station designers and operators wanted a separate standard that specifically applies to vehicle fuel systems and LNG dispensing. The National Fire Protection Association responded by developing NFPA 57, which was incorporated into NFPA 52 in 2005.

VEHICLE FUELING STATIONS

There were over 5000 refueling sites in the United States in 2006. The majority of these sites (2771) are for LP-gas refueling (Table 21.4.15). There are 754 sites for CNG refueling, leaving approximately 1500 sites for all other types of alternative fuels. Of these approximately 1500 remaining sites, 37 are for LNG refueling. These sites are both public and private refueling sites, which may skew the distribution toward LP-gas; but even considering this possibility, it is clear that there is much greater access to LP-gas. Note that Alaska and Hawaii do not have CNG refueling facilities and that the majority of states do not have LNG refueling facilities. However, the number of refueling facilities has steadily increased, and if current trends in the increased use of alternative fuel vehicles continue, the number of refueling facilities should also increase.

Compressed Natural Gas Vehicle Fueling Stations

CNG fueling stations can be generally categorized according to the time needed to fuel. The method used depends on the filling time the user desires. Available equipment combinations result in facilities being categorized as either "fast-fill dispensing" or "slow-fill dispensing."

Refueling a standard passenger vehicle at slow-fill CNG stations can commonly take up to 8 hours. These stations connect to the natural gas service line that typically supplies fuel for building heat. CNG slow-filling systems use a small compressor, eliminating the need for high gas flow and large gas supply piping. The small compressor usually combines with the dispensing equipment to form a compact module mounted next to the vehicle's parking space. Typically, no storage containers

are associated with these units, which contributes to longer filling times. Mostly used for overnight fueling, slow-fill units are typically used by fleets of less than 30 vehicles that do not operate continuously. Compact unit design and smaller supply requirement makes slow-fill fueling possible at private residences, depending on local regulations. The installation shown in Figure 21.4.1 uses vehicle refueling appliances (VRAs) to fuel CNG-powered vans overnight. Average fill time for an automobile or van is 4 to 8 hours, depending on the size and number of cylinders.

Fast-fill CNG stations normally fuel a conventional passenger vehicle in less than 5 minutes. Sometimes, fixed storage vessels are used as supply sources and must be transfilled from a high-pressure transport tube trailer that is brought to the station site. More commonly, a connection to the nearest domestic natural gas distribution system supplies the natural gas. A pressure cascade system compresses and dispenses low pressure natural gas (60 to 100 psi [413 to 689 kPa]) at the higher pressures (2500 to 4500 psi [16,536 to 31,005 kPa]) the CNG vehicle requires. These systems can be found at locations typically serving more than 30 vehicles.

CNG Siting Considerations. CNG fueling is performed at public service stations, small private fleet operations, metropolitan mass transit facilities, school districts, cab companies, government agencies, and residences (if local regulations allow). CNG fueling typically is performed outdoors. CNG compression, storage, and dispensing systems should take into consideration setback distances from property lines, on-site adjacent buildings, overhead power lines, nonclassified overhead electrical lighting, and ignition sources. Protective canopies and open structures installed to protect equipment should be of noncombustible construction, with a roof design that ensures adequate ventilation and prohibits pocketing or collection of CNG due to the buoyancy of natural gas. Typical unintentional releases of CNG will be completed in a matter of seconds due to very high compression and storage pressures. The quick release and buoyancy of CNG minimize the potential threat from open-air flammable vapor cloud ignitions. Ignition of leaking high-pressure gas is possible, and the resulting jet fire can extend from 10 to 30 ft (3 to 9 m) in length, depending on the leak's size and CNG pressure. This makes the orientation of storage cylinders and relief valves an important site consideration. With the addition of protective measures and depending on local regulations, CNG fueling can be accomplished indoors. This is a potential consideration when weather- or freeze-protection is needed for the compression, storage, and dispensing systems. Indoor fueling with CNG can only be accomplished inside structures dedicated to this purpose or within rooms or additions provided with at least 2 hour fire-resistive walls as separation from other occupancies. When dispensing CNG indoors, overpressure protection, such as explosion venting, is necessary. Mechanical ventilation that is continuous or activated by a gas detection system must be installed. To allow for delays in the mechanical ventilation startup, the gas detection system should activate ventilation at a level not exceeding 20 percent of the lower flammable limit. An audible alarm should also sound at the 20 percent lower flammability level. Activation of the gas detection system must result in automatic shutdown of compression and dispensing equipment by placement of solenoid switches and automatic shutoff valves. Although not required by NFPA 52, some model building and fire codes may require the installation of an automatic sprinkler system for indoor dispensing and storage of CNG. Local approvals for indoor dispensing may vary, but public structures, such as parking garages, are commonly unacceptable for fueling of any type of conventional or alternative fuel.

FIGURE 21.4.1 Slow-Fill Vehicle Refueling Appliance (Source: Fuelmaker, Inc.)

When considering the siting of CNG fueling stations, the general public is probably most familiar with the hazard potential of natural gas. Their expectation or acceptance of hazard is commonly based on the low pressure natural gas used for home cooking and heating. Mentioning high-pressure natural gas used in CNG fueling is likely to conjure up consequences associated with large-diameter, high-pressure natural gas transmission pipelines. Major CNG fueling facilities that use large-capacity compressors sometimes require the extension of a larger and higher pressure natural gas pipeline. Those who live near large CNG fueling stations may question their safety and acceptability because they fear CNG fueling components and the increased size of natural gas mains in the public right-of-way.

CNG Compressor Components. The very large range of CNG compressors' capacity makes fill time vary. Small, slow-fill units with a compressor capacity of approximately 5 to 10 SCF/min are small enough to fit in the front seat of a car. NFPA 52 defines these compressors as residential refueling appliances or vehicle refueling appliances (see Figure 21.4.1). They generally require only a normal domestic natural gas supply line. Medium-sized, fast-fill compressors typically found at public fueling stations are capable of supplying approximately 1000 SCF/min (28.3 m^3/min). A normal domestic supply line can also supply these medium-sized compressors. Like the slow-fill units, these fast-fill compressor sets are sometimes packaged with other fueling components and are available as portable, premanufactured units that fit in the space required for a passenger vehicle. Large industrial compressors can compress approximately 5000 SCF/

min (142 m^3/min) at about 3600 psi (24,804 kPa) and can fill the space needed to park a bus. Depending on the number of large compressors needed, supply from a 6-in. (152-mm) diameter natural gas pipeline is not uncommon.

Compressors require pressure relief devices set for each stage pressure. A four-stage compressor might have relief valves set for 250, 1250, 1400, and 4150 psi (1724, 8618, 9652, and 28,610 kPa), depending on the compression chamber's size and associated piping into which they are installed. CNG compressors are also required to have automatic shutdown capability in the event of high discharge pressure or low suction pressure. Compressor controls must be manually reset if an automatic shutoff or power failure occurs. Internal combustion engines, modified to operate using natural gas, usually drive compressor sets. NFPA 52 requires the design, construction, and maintenance of these compressor drivers to be in accordance with NFPA 37, *Standard for the Installation and Use of Stationary Combustion Engines and Gas Turbines.*

CNG Storage Components. Pressure vessels are a common method of storing compressed natural gas. NFPA 52 requires pressure vessels to be constructed in accordance with the ASME Boiler and Pressure Vessel Code. Fast-fill dispensing transfers CNG from a bank of pressure vessels to the vehicle in a fairly short time, usually less than 5 minutes. These pressure vessel banks, or cascades, are usually multiple compressed gas cylinders, spherical vessels, or horizontal tubes. Normally, three pressure banks are involved in a cascade system (Figure 21.4.2). To "top off" a vehicle container, dispensing begins from a storage vessel having lower pressure until pressure equalizes, then automatic controls switch to a vessel of higher storage pressure. This automatic switching between cascade banks continues sequentially until vehicle fueling is complete. Subsequent vehicles can be filled until cascade pressure drops too low. Then the system automatically switches to the compressor. This, however, increases fill time, so the capacity of storage containers at a site usually reflects the number of vehicles to be served.

Bulk CNG storage is infrequently required when obtaining an on-site natural gas supply to compress is not possible or when the economics of installation does not justify the cost of a compressor. Bulk storage is usually accomplished by transporting gas compressed at another site, then transfilling from the transport tube trailer into pressure vessels. Bulk vessels do not draw down at the same rate when fueling a vehicle, but their automated systems operate like the cascade system. Bulk compressed gas is usually dispensed from at least three vessels (see Figure 21.4.2).

CNG cascade and bulk storage vessels must be adequately supported on no more than two longitudinal points and should be adequately protected from vehicle impact. A check valve should be installed so that backpressure cannot bleed back to the supply, and adequate pressure-relief devices must be installed in each vessel. The pressure-relief devices should be vertically vented and protected against weather. Pressure gauges installed on each vessel or pressure bank determine the fullness of a storage vessel. Sometimes, outlets for storage vessels are fitted with excess flow valves. These devices restrict flow from the vessel if the tubing or piping leaks. A check-type valve closes when flow exceeds that rated for the piping system. Usually, carbon or stainless steel tubing and piping connect the cascade or bulk vessels, and approved flexible metallic hose is installed for expansion, contraction, jarring, vibration, and settling where necessary.

CNG Dispenser Components. Dispensing equipment can look like conventional gasoline dispensing equipment, or it can simply be a hose and nozzle rated for high-pressure service and mounted on a post (Figure 21.4.3). Fuel dispensers should be provided with protection from vehicle impact, using islands, pipe bollards, or other appropriate designs.

If located at a public service station, the dispenser usually measures "equivalent gallons" of fuel; otherwise, the unit of measure varies depending on the owner's needs or local weights and measures standards. Underground piping usually connects

FIGURE 21.4.2 Pressure Vessels for Storing Compressed Natural Gas

FIGURE 21.4.3 CNG Dispensers

CNG dispensers to the storage and compression systems. Just as at a conventional service station, multiple CNG dispensers are not typically installed on one supply line. Instead, each has individual, dedicated piping from the storage or supply.

CNG dispensing systems require electronic or pneumatic controls that sense vehicle container fill pressure and automatically stop the flow. Settings for these controls are based on outside temperature. In addition, an emergency shutdown device commonly installed at the storage and compressor activates if there is a problem at the dispenser. Even so, a "quarter turn" manual shutoff valve is located at the dispenser just upstream from the dispensing hose and its required breakaway device. The hose breakaway device, located outside the dispenser end, closes if a vehicle moves away from the dispenser without breaking the vehicle fueling connection. CNG breakaway devices release and seal at approximately 44 lb (22 kg) of force from any direction.

The CNG fueling hose must be rated for the system's service pressures. Like the flammable liquids dispensing hose, the CNG hose must be nonconductive. A significant feature of the CNG fueling hose is the inclusion of a second hose, usually designed as integral to the supply hose. When fueling is complete, this second hose collects natural gas from the vehicle fueling connection and supply hose. Some dispensing units vent the hose automatically; others require a manual valve to accomplish this venting. In either case, the vehicle connection does not release until the connection and hose is depressurized. After CNG fueling is complete, vented gas returns to the dispenser and ultimately to storage or an approved vent stack, depending on local requirements. Typical CNG fueling hose is easy to handle and is approximately ½ to ¾ in. (1.27 to 1.91 cm) in diameter. CNG dispensing hose cannot be more than 25 ft (7.6 m) long and must be supported aboveground, usually by a retractable cord like those used on conventional fuel dispensers.

The CNG dispensing nozzle that connects the fueling hose to the vehicle is similar to a typical quick-connect coupling used on compressed air hoses, except it includes breakaway protection. The vehicle fueling receptacle, fuel control valve, and dispenser nozzle are designed in accordance with ANSI/American Gas Association NGV 1, *Basic Requirements for Compressed Natural Gas Vehicle Fueling Connection Devices.*[15] The NGV 1 standard includes requirements for the vehicle fueling receptacle, the dispenser nozzles, and the fuel control valve installed at the dispenser. Depending on the component's style, devices are rated for service pressure between 2400 and 3600 psig. The NGV 1 standard defines three types of nozzles:

- Type 1 nozzles use an integral valve operating mechanism that vents the gas between the vehicle's fill line check valve and the nozzle inlet valve and then disconnects the nozzle from the vehicle (Figure 21.4.4). CNG nozzles are similar to quick-connect couplings used on compressed air hoses. The Type 1 nozzle shown in Figure 21.4.4 has an integral valve that vents the gas between the vehicle's fill-line check valve and nozzle inlet before it can be disconnected from the vehicle.
- Type 2 nozzles use an external valve that must be vented before disconnection.

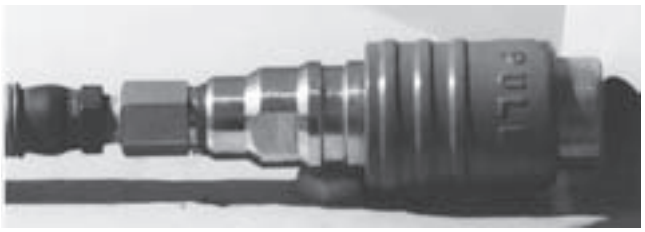

FIGURE 21.4.4 CNG Nozzle

- Type 3 nozzles use controls that automatically depressurize the fill line upon dispenser shutdown. They are normally found on vehicle refueling appliances or residential refueling appliances.

Each type must be designed so that the fueling system is depressurized before the nozzle can be removed.

Liquefied Natural Gas Vehicle Fueling Stations

LNG fueling stations can be characterized according to the method used for obtaining liquid transfer pressure. Some use gravity available from a vertical bulk storage vessel to fill a smaller transfer vessel at 75 to 100 psi (517 to 689 kPa). A portion of the LNG passes through a vaporizer and back into the smaller transfer vessel to warm the liquid. The 618:1 expansion ratio of the LNG in the smaller vessel increases the pressure to as much as 230 psi (1586 kPa) to force liquid into the LNG vehicle. Transfer rates of 40 to 50 gal/min (0.15 to 0.19 m^3/min) are not uncommon.

The other common type of LNG fueling station uses a centrifugal cryogenic pump supplied from a vertical or horizontal bulk LNG storage vessel. Centrifugal cryogenic pumps typically provide LNG fueling rates of 30 to 50 gal/min (0.11 to 0.19 m^3/min), depending on the LNG vehicle tank pressure required. The net positive suction head that the centrifugal pump requires is important. Some installations experience cavitation and poor performance when storage design does not provide enough suction head. Fueling stations that use underground LNG bulk storage vessels are available but not as common. Underground installations use a slow-action, positive-displacement pump that lifts LNG about 25 ft (7.6 m), provides 30 to 50 gal (0.11 to 0.19 m^3/min) of liquid per minute, and delivers at pressures as high as 200 psi (1379 kPa).[16] LNG fueling facilities that use cryogenic pumps typically operate on electricity.

LNG fueling facilities can also be designed to supply CNG vehicles. LNG fueling stations normally create some vapor due to external heat absorption of the stored LNG, priming of pumps, and temperature equalization of equipment. In addition to normal vaporization, LNG is sent to a vaporizer to create gas specifically for fueling CNG vehicles. Under some conditions, LNG to CNG fuel supply or liquefied-compressed natural gas (LCNG) may be cheaper than CNG supplied from domestic natural gas lines. Facilities that use vapor expansion for LNG fueling pressure provide a compressor and cascade system to fuel CNG vehicles. Systems with high-pressure LNG pumps combine LNG pump capacity and gas expansion, through the

vaporizer, to fill the CNG cascade storage. The CNG must be odorized with an odor potent enough to be detected to down to a concentration in air of not over one-fifth of the lower limit of flammability.

LNG Siting Considerations. LNG vehicle fueling is typically associated with large fleet operations in heavily populated urban areas. These include such facilities as mass transit, cab companies, and government agencies. Some rural fleets that use large vehicles, such as mining operations or transport trucking, have also converted to LNG use. Because a significant number of fleet vehicles are necessary for LNG fueling to be economical, self-serve general public vehicle fueling with LNG is not expected to become commonplace.[12] In addition, indoor fueling with LNG is not typically performed. However, it has been proposed that this activity be limited to the use of less than 125 gal (0.47 m^3) containers when necessary gas detection, ventilation, fire protective, and building construction features are provided.

NFPA 57 sets distances from impoundment areas to building and property lines. These distances are based on the container volume and range from 0 for containers of 0.5 m^3 or less to 23 m for containers of 114–265 m^3. This range of 0.5–265 m^3 should include most LNG storage containers. Additionally, there are minimum distances between storage containers set in NFPA 57; these distances range from 0 for containers 0.5 m^3 or less to one-fourth of the diameter of adjacent container(s) for containers ranging from 114 to 265 m^3. There are also requirements for container seismic design that specify the horizontal and vertical forces that shop-built ASME containers must meet based on the amount of seismic activity at the location where the container is to be installed.

Normally buoyant, natural gas vaporizing from a supercooled liquid state remains initially heavier than air. While cool, the natural gas forms a vapor cloud that follows the ground surface until it heats sufficiently to regain its lighter-than-air characteristics. In addition to separation, site consideration should include containment of the fueling facility. Containment helps limit the surface area of an LNG spill, reduces the spill vaporization rate, and thereby reduces the distance a potential vapor cloud travels before becoming buoyant. Separation and containment are important requirements, particularly when locating an LNG fueling facility near other land uses that are densely populated or provide potential ignition sources.

LNG Storage Components. LNG storage and use is not something that very many communities have experienced. Members of the general public who are presently familiar with LNG facilities usually live in areas that have bulk LNG supply for domestic natural gas distribution or power plant peak shaving needs. Cryogenic gas storage and liquid transfer have a long history, but bulk storage and dispensing of LNG vehicle fueling is a relatively new use of an adapted technology. Compared with the other types of alternative fuels, LNG use in private vehicles does not seem to be as well demonstrated. This could result in hesitation to accept the additional hazards associated with LNG storage and vehicle fueling in densely populated urban areas or the costs associated with LNG systems versus CNG systems.

LNG is normally transported from a liquefaction plant to the fueling facility by cryogenic bulk transport trailers. Transfilling may occur at night because LNG-fueled fleets need to be filled before business hours. The number of vehicles to be filled and the capacity of on-site storage dictate the frequency of LNG transport and transfilling. Bulk LNG at typical fueling sites is stored in containers having a total capacity of approximately 15,000 gal (57 m^3). This quantity allows unloading of one transport that usually carries 11,000 to 13,000 gal (42 to 49 m^3) (Figure 21.4.5). Depending on delivery schedules and demand, more than one container might be located at a fueling site. Containers can be horizontal or vertical, depending on owner preference, aesthetics, and available space.

Siting of containers should be based on the requirements of NFPA 59A. Transfer of LNG from the supply truck trailer to bulk storage is accomplished by increasing the trailer's normal storage pressure of 10 psi (70 kPa) to approximately 40 to 50 psi (276 to 345 kPa). If a vertical bulk storage vessel is used, transfer pressure may be as high as 250 psi (1724 kPa). This is accomplished by boiling off some LNG in an auxiliary line and allowing it back into the trailer. A small amount of LNG may leak out of the hose connection to the bulk vessel because of the temperature difference between the inside and outside of the fueling connection. LNG bulk storage containers have liquid level gauges and a high liquid level alarm or indicator that warns the operator to stop filling the bulk vessel. When transfer is complete, a pump on the supply truck transfers any LNG remaining

FIGURE 21.4.5 A 13,500 gal (51 m^3) LNG Container Used for Vehicle Refueling

in the hose to the storage vessel. During transfer, a pressure differential of at least 15 psi is maintained between the transport trailer and the bulk storage vessel. In the event of a backfill condition, a backflow check valve is required on the transfer fill piping of an LNG bulk storage vessel.

LNG spill containment should include the following requirements:

- Impounding area that has the volumetric capacity to hold the greatest volume of LNG that could be discharged into the area during a 10 minute release from any single accidental leakage source
- Measures to prevent any release of LNG from the plant property and for surface water drainage
- Provisions to clear rain or other water from the impounding area
- Separating the point of transfer from the nearest important building not associated with the LNG facility by 25 ft (7.6 m)
- Selecting a design and materials appropriate for LNG
- Operating instructions identifying the location and operation of emergency controls

The use of insulated materials considerably reduces vapor dispersion distances. The containment system's design and the type of insulating material used can reduce the vaporization rate as much as 30 percent.[17] Equipment within the containment should be limited to LNG-related apparatus. CNG equipment such as compressors, vaporizers, and CNG storage cylinders should not be located within the LNG secondary containment, due to potential fire exposure and damage from high pressure.

Pressure-relief valves must be designed with a capacity to not only vent vaporized natural gas adequately if fire exposure occurs but also include capacity for the flow of liquid in the event an overfill of the bulk storage occurs. Pressure-relief valves are typically located in the storage vessel, the insulation space of the vessel, and any insulated piping that can be isolated between two block valves. Typically, a system of air-operated valves controls the flow of liquid for vehicle fueling. Air supply lines for the flow control valves commonly consist of low-melt-point plastic tubing. If exposed to fire, these air supply lines will melt and cause the valves to shut in a fail-safe manner.

LNG Dispenser Components. Dispensers available for LNG fueling can look like conventional fuel dispensers. Typically they do not. Instead they are an assembly of a cryogenic coupling nozzle, insulated cryogenic hose, shutoff valves, and panel or pole mounted gauges. Sometimes the fueling hose attaches to a rotating arm that supports the hose as it is attached to the vehicle. If not, a retractable stainless steel cable supports the cryogenic hose. LNG fueling hoses are insulated and can be 3 to 4 in. (7.6 to 10.2 cm) in diameter. They are fitted with a large cryogenic coupling, about 1 in. (2.5 cm) in diameter. Compared to conventional fuel hoses and nozzles, this assembly can be cumbersome.

A shutoff valve is attached on the open end of the cryogenic hose, just before the LNG coupling that connects to the vehicle. This coupling includes an interlock device that does not allow release during transfer. LNG couplings operate like sexless fittings commonly used on fire hose. A manual emergency shutoff valve is placed in the transfer system, near the connection to supply piping at the storage vessel. This manual shutoff valve must be readily accessible by the operator. Bleed or vent connections incorporated into the coupling let dispenser hoses be drained, depressurized, and sometimes purged with nitrogen. These connections usually drain to a vaporizer, and natural gas either vents or is transferred to a CNG fueling process. LNG dispensing units may have electronic level sensors that automatically activate the dispensing shutoff valve. More often, a level gauge provided on the vehicle requires the operator to measure the vehicle tank level and then manually stop dispensing. Even with these controls, providing drainage should be considered so that accidental LNG spills drain into the storage vessel secondary containment.

Liquefied Petroleum Gas Fueling Stations

Types of LP-Gas Fueling Stations. LP-gas used for vehicle fueling is typically propane. Propane has a long history of use in industrial applications and predominately rural areas as a home-and-business heating fuel. Although most domestic propane heating appliances use vapor as fuel, vehicle fueling transfers propane in liquid form. The equipment needed has been used for many years at bulk plant facilities for transfer to bobtail propane delivery trucks and for container filling. This equipment has also been extensively used for forklift truck fueling at manufacturing and storage occupancies.

Historically, propane vehicle fueling in the United States has been predominantly at bulk plant locations or with the other traditional propane supply services. Some consider LP-gas vehicle fueling the least complicated of the three alternative fuels discussed in this chapter. The mechanics of supplying liquefied gases for fueling vehicles does not vary significantly from the processes used for supplying LP-gas for heating. LP-gas at vehicle fueling locations is typically moved to the fueling site by highway transport truck and then transfilled into the bulk fueling storage container.

There are three common ways to transfer LP-gas in the liquid phase: (1) by use of an LP-gas pump, (2) by gravity, and (3) by use of a compressor. Using LP-gas pumps to transfer liquid is the most common method. This is because of the flexibility afforded by not having a required tank elevation or hazards associated with vessel pressurization. LP-gas pumping has been used extensively to fill LP-gas bobtail delivery trucks from bulk storage vessels. The same pump technology has been adapted for use in fueling vehicles with propane. Positive displacement pumps, such as sliding vane, gear pumps, or centrifugal pumps, are common with the pump discharge pressure limited to a maximum of 350 psig (2412 kPag). Electricity usually powers the LP-gas pumps used at vehicle fueling stations.

LP-gas vehicle fueling facilities can use horizontal, vertical, or, sometimes, underground pressure vessels. Vehicle fueling at LP-gas bulk storage operations is typically in horizontal pressure vessels. LP-gas vehicle fueling at locations with space limitations sometimes uses vertical pressure vessels. Underground pressure vessels dedicated for LP-gas vehicle fueling are not as common because of additional cost, maintenance respon-

sibilities associated with corrosion protection, and, sometimes, prohibitive soil conditions.

LP-Gas Siting Considerations. Vehicle fueling with LP-gas should be limited to outdoors. The liquid–vapor expansion ratio of propane is approximately 270:1,[14] so an unintended liquid discharge releases a greater quantity of vapor than does a leak from the LP-gas vessel's vapor space. In addition, vapor release from emergency relief valves due to unintended container overfilling makes LP-gas vehicle fueling hard to justify as an enclosed, indoor activity. Even outdoors, propane tends to form a vapor cloud that, under the right conditions, can travel downwind at flammable concentrations until it encounters an ignition source. This is because LP-gas has a vapor density approximately 1.5 times that of air. Less common, but possible, is an LP-gas container BLEVE incident initiated by an emergency relief device failure or rapid container exposure to intense radiant heat.

Setback distances from adjoining property lines and adjacent buildings should be evaluated not only for building exposure from leaks at the LP-gas fueling station but also for building fire exposure on the fueling station. Considering mutual exposure is sometimes complicated. Many published setback requirements intend to prevent smaller, more common LP-gas vapor releases from reaching an ignition source. These distances also provide space to buy time for implementing emergency activities such as applying water to a propane pressure vessel to protect it from an adjacent fire's radiating heat. Typically these distances offer protection for releases, such as those from emergency relief valves, that result from container overfilling. A large, continuous liquid leak from a damaged or malfunctioning container connection, transfer piping, or pump casing can produce more serious vapor cloud, BLEVE, and shrapnel hazards. The hazards associated with these situations exceed the largest setback distances specified for LP-gas applications. The setback distances given in NFPA 58 should be considered minimum requirements to reduce risk. These distances should not be treated as safe distances that would eliminate all risk or eliminate the effect of all types of hazardous events associated with LP storage and transfer operations.

Historically, the location of LP-gas applications has been predominantly in rural or suburban areas, or in commercial or industrial areas. In these locations, hazards are commensurate with other hazardous operations and exposure to the public has been limited accordingly.[18] The addition of LP-gas vehicle fueling stations to heavily populated urban areas offers LP-gas suppliers new markets, sometimes near congested residential areas that historically supported conventional public fueling stations. Additional setbacks and protective equipment should be considered in these situations. These help limit urban public exposure to a risk level enjoyed before the alternative fuels market expanded. NFPA 58 gives a set of alternative provisions for the installation of American Society of Mechanical Engineers (ASME) containers, which includes additional safety requirements that allow for setback distance reductions. These provisions would allow the installation of ASME containers at locations, such as conventional refueling facilities, without increasing the risk that these installations create. These additional safety measures include low emission transfer and automatic shutdown of all primary valves in the event of a fire or hose pull-away. Figure 21.4.6 shows a fueling facility that stores and dispenses gasoline, CNG, and LP-gas in an urban area. A release or fire from such an aboveground fueling facility would impact surrounding fire exposures, the general public, and emergency responders.

LP-Gas Storage Components. LP-gas vehicle fueling has typically been accomplished at bulk storage facilities where large volumes are stored in horizontal pressure vessels. With LP-gas vehicle fueling increasing at existing industrial and commercial fleet sites, limited available land area has made the use of vertical pressure vessels more common. The size of pressure vessel used for storage varies because some installations are not dedicated solely to LP-gas vehicle fueling. Typically, installations dedicated for public vehicle fueling use storage pressure vessels having a water capacity of 1000 to 2000 gal (3.8 to 7.6 m^3).

These storage vessels must meet standards addressed in the *ASME Boiler and Pressure Vessel Code*[19] or the API-ASME *Code for Unfired Pressure Vessels for Petroleum Liquids and Gases.*[20] LP-gas pressure vessels must meet design or service pressures, which depend on the vapor pressure of the LP-gas stored. Propane storage vessels used for fueling require a minimum design pressure of 250 psig (1724 kPa). Structural support for LP-gas storage vessels containing propane can vary from

FIGURE 21.4.6 Fueling Facility Storing and Dispensing Gasoline, CNG, and LP-Gas in Densely Populated and Congested Urban Area

concrete saddles on horizontal vessels to structural metal supports protected with a fire-resistive coating on vertical tanks. LP-gas fueling vessels should be permanently fastened to paved surfaces or concrete pads, adequately protected from vehicle impact, and protected from tampering by chain-link fencing. Secondary containment is not provided at LP-gas vehicle fueling facilities because when spilled or released, nonrefrigerated liquid propane immediately vaporizes.

Bobtail tanker trucks with a capacity of 2000 to 4000 gal (7.6 to 15.2 m^3) most commonly supply LP-gas vehicle fueling stations. The operator transfers liquid by a pump mounted on the transport vehicle. A transfer hose connected to the pump discharge is attached to a threaded fill pipe connection located a short distance away from the storage vessel. This fill pipe allows the operator to top fill the fueling station storage container without having to climb on top. NFPA 58 has setback requirements for various types of exposures from the point of transfer if that point is not located on the container. For bulk LP-gas storage, transport hose connections at the fill pipe include breakaway protection. At bulk plants, bulkhead devices provide this protection with cable-activated or pneumatic emergency shutoff valves. On smaller vessels dedicated for LP-gas vehicle fueling, these are not typical. Instead, their design usually incorporates a breakaway valve in the vessel fill piping. In addition, a required backflow check valve at the inlet to the storage vessel prevents pressurized contents from flowing from the fill connection if the piping is damaged.

Filling the storage vessel proceeds until the operator notes that the liquid level has reached the maximum allowed. Several options exist for monitoring when the storage vessel is full. Using a fixed maximum liquid level gauge is a popular method. A No. 54 drill hole bleed valve in this device connects to an internal dip tube. When vessel filling is to begin, the valve is opened and normally vents invisible vapor. The operator notes refrigerated air moisture through the bleed valve when vaporizing liquid reaches the predetermined interior dip tube height. The operator then stops the liquid transfer. Variable liquid level gauges, such as a slip tube or rotary tube, operate similarly but indicate liquid height on a scale that the operator reads to determine when the vessel is properly filled.

Emergency shutoff valves are required at LP-gas vehicle fueling facilities. These consist of emergency devices associated with dispensing from storage into the vehicle. Manual shutoff valves, excess flow check valves, backflow check valves, and quick closing internal valves can be used at liquid bypass, vapor recycle, liquid withdrawal, and equalizing connections. Storage vessel discharge connections located at the bottom of the vessel can be provided with shear protection in the event the discharge piping is damaged. To protect the vessel against significant fire exposure in the event of a leak, a fusible link shutoff valve is commonly installed at the vessel liquid opening, usually in conjunction with an excess flow check valve.

The excess flow check valve for discharge from the vessel is usually installed internal to the vessel; some valves are manufactured to be installed in-line. A spring normally holds excess flow check valves open. The valves close automatically when the device's rated liquid flow is exceeded. Excess flow check valves operate only if a break in the vessel discharge line is sufficiently large for flow to exceed the rated valve setting. Pump bypass liquid lines and vapor equalization lines, commonly connected to LP-gas storage, also have excess flow check valves.

LP-gas storage vessels used for vehicle fueling must have one or more pressure relief devices installed in their vapor space. ASME vessels having a water capacity greater than 1200 gal (4.5 m^3) must have spring-loaded pressure-relief valves that directly communicate with the vessel vapor space. These self-actuated relief valves help to limit the accidental release of LP-gas because they normally close when excess pressure is relieved. Other devices, such as frangible or rupture disks, let the entire contents of the pressure vessel discharge and, therefore, are not used in LP-gas pressure vessels. In addition to spring-loaded relief valves, fusible plugs not exceeding ¼ in. (0.6 cm) diameter may be installed in pressure vessels with a water capacity lower than 1200 gal (4.5 m^3).

LP-Gas Dispenser Components. LP-gas dispensing devices typically include a meter, vapor separator, hydrostatic relief valves, check valve, solenoid valve, pressure differential valve, and manual shutoff valves. As with the other types of alternative fuels, dispensers can be the simple assemblies mounted on a post that are common at fleet operations or the manufactured dispensing units for public fueling locations. Manufactured dispensing units can look like those used for conventional gasoline or diesel fueling. Excess flow check valves in a shear plate are generally installed below the dispensing unit and function like shear valves under conventional flammable liquid fuel dispensers.

LP-gas dispensers can fill at a maximum rate of approximately 18 gal/min (0.07 m^3/min).[21] Pursuant to NFPA 30A, *Code for Motor Fuel Dispensing Facilities and Repair Garages,* LP-gas dispensers should be located at least 20 ft (6.1 m) from gasoline or diesel dispensers. LP-gas fuel hoses must be fitted with a listed emergency breakaway device to prevent propane releases in the event a driver pulls away while the fueling hose is still connected. The LP-gas vehicle fueling hose, commonly known as "wet" hose, is required to be continuously marked "LP-GAS," "Propane," and "350 PSI WORKING PRESSURE." Fueling hose typically connects to the vehicle via a U.S. standard 1¾ in. (4.5 cm) acme-threaded connection. These connectors are designed with a mechanism that prohibits liquid flow unless connected to a vehicle. A "quarter turn" valve located before the threaded connection controls flow. Flow control valves are available with a lever action similar to conventional gasoline-dispensing nozzles. The main difference is that LP-gas lever valves do not presently shut off automatically when the liquid level is full. Instead, an outage gauge or outage vent valve is located on the vehicle, near the hose connection.

The vehicle outage gauge operates like bulk vessel liquid level gauges. When the vehicle tank is approximately 80 percent full, a small amount of liquid propane is released through the outage vent. The operator recognizes that the vehicle container is full and manually disengages the dispensing flow valve. This venting to atmosphere at each refueling has been recognized as a potential problem. Automatic shutoff devices, such as a float valve inside the vehicle tank, are available, and computer-controlled overfill systems are being developed. When per-

fected, these systems might be required on all LP-gas vehicles or dispensers.

VEHICLE COMPONENTS, DESIGN, AND OPERATION

The appearance and shape of alternative-fueled vehicles are the same as conventional-fueled vehicles. In many cases, they are conventional-fueled vehicles that have been retrofitted to operate with alternative fuels. Several vehicle manufacturers are developing alternative-fueled versions of their popular conventionally fueled models. How the fuel is carried and consumed differs in the vehicles. Although vehicle storage containers and delivery systems differ for each type of fuel, the concept is the same for all hydrocarbon alternative fuels. CNG, LNG, and LP-gas vehicles store and consume a mixture of flammable gas. Understanding fuel storage and consumption is important from the perspectives of the vehicle's operator, the individual fueling the vehicle, and the emergency responder.

There are two types of alternative-fueled vehicles: (1) those converted from another fuel, called bi-fueled conversions, and (2) those designed to be exclusively powered by CNG, LNG, or LP-gas. Bi-fuel converted vehicles may operate on natural gas or propane and a conventional fuel, such as gasoline or diesel, because the liquid fuel system remains intact. CNG-, LNG-, or LP-gas-fueled vehicles can cost more than conventionally fueled vehicles because of the vehicle fuel tank expense.

Compressed Natural Gas Vehicles

CNG vehicles include conventional passenger vehicles, light- and medium-duty trucks, and heavy-chassis vehicles such as transit buses. CNG vehicles store natural gas compressed at pressures of 2500 to 4000 psig (17,235 to 27,576 kPa) in compressed gas cylinders equipped with a pressure relief device, a filling connection, and a shutoff valve. The vehicle fuel container connects to either a manifold or single fuel line equipped with a manual shutoff valve. Natural gas is dispensed to the engine via a pressure regulator that reduces the gas to the service pressure the engine uses. After its pressure is reduced, the gas enters a gas-air mixer to produce a flammable mixture that is injected into the internal combustion engine.

NFPA 52 applies to the design and installation of CNG fuel systems on all types of vehicles and their fuel dispensing systems. The standard's scope includes the CNG element of bi-fueled vehicles and vehicles originally manufactured to operate using CNG. Fuel is delivered from a CNG dispenser through its nozzle and introduced into the vehicle's container through the vehicle fueling receptacle. The attachment is like a typical quick-connect coupling used on compressed air hoses. Vehicle fueling receptacles are designed in accordance with ANSI/American Gas Association NGV 1.

CNG Fuel Containers. CNG fuel containers are designed to store compressed methane gas at high pressures. The gas is stored in a compressed state to increase the quantity that can be stored on board the vehicle, thus increasing the vehicle's driving range. American Natural Standards Institute/American Gas Association NGV2, *Basic Requirements for Compressed Natural Gas Vehicle Fuel Containers,*[22] addresses the design and construction of CNG fuel containers. NGV2 containers have service pressures between 2400 and 4350 psi (16,546 and 29,989 kPa) at 70°F (21°C), capacities not greater than 35.4 ft^3, and a service life of 15 years. NGV2 containers are either constructed of metal (NGV2–1), a metal liner reinforced with hoop-wrapped (NGV2–2) or full-wrapped (NGV2–3) resin-impregnated continuous filament, or a full-wrapped continuous filament with a nonmetallic liner (NGV2–4). All construction materials must be capable of operating throughout a temperature range of –40 to 180°F (–40 to 82°C). Containers installed in vehicles require identification using a label that reads "CNG ONLY." This label is required to prevent the installation of cylinders not designed for CNG service.

CNG vehicle fuel containers are subject to nondestructive pressure and leak tests. To achieve certification, metal containers and liners must successfully pass destructive tests that evaluate the materials yield strength, tensile strength, elongation, and its performance under mechanical impact. Other requirements that must be met include drop, fire exposure, gunfire, gas permeation, pressure cycling, and burst tests. These tests ensure the container maintains its integrity over its service life.

Vehicle containers can be located inside, below, or above the driver or passenger compartment, provided all connections to the container are either external or sealed and vented from the area where the driver or passengers sit. Containers are installed in a location that minimizes the probability of damage resulting from a collision. Neither containers nor container components can be located ahead of the vehicle's front axle or behind its rear bumper.

The mounting mechanism must secure the CNG vehicle fuel container to the vehicle's frame, body, or cargo box to prevent damage resulting from road hazards, container slippage, and loosening or rotating of the container. The method used for mounting the container must withstand a static force of eight times the weight of a fully pressurized cylinder applied in six directions of loading. When subjected to this load test, the container is allowed a maximum displacement of ½ in. (1.3 cm) in any direction of loading. Unless shielded, containers require a minimum 8 in. (20.3 cm) clearance from vehicle exhaust systems. If metallic clamps or clamping bands are used, they cannot be in direct contact with the container. This necessary provision protects the container from exterior corrosion resulting from moisture accumulation or mechanical vibration. To satisfy the requirement, a resilient, water-resistant material is commonly installed between the clamp and the container supports.

CNG Pressure-Relief Devices. Vehicle fuel containers are required to be fitted with one or more pressure-relief devices. Pressure-relief devices protect the container from catastrophic failure due to overpressure resulting from fire exposure.

Pressure-relief devices for CNG cylinders are constructed in accordance with Compressed Gas Association Pamphlet S-1.1, *Pressure Relief Device Standards, Part 1—Cylinders for Compressed Gases.*[23] Pressure-relief devices can be rupture disks, fusible plugs, a combination rupture disk/fusible plug,

or a pressure-relief valve. A rupture disk is the component of a pressure-relief device designed to burst at a predetermined pressure and allow gas to discharge. Rupture disks are preformed metal designed to fail at a particular pressure or temperature. When a rupture disk operates, it vents the entire contents of the container. Rupture disks do not close. Fusible plug devices are also nonreclosing pressure-relief devices designed to function when a plug of fusible material melts at a suitable temperature. Fusible plugs are designed to operate at a nominal yield temperature of either 165°F or 212°F (74°C or 100°C), depending on the material selected.

Pressure-relief valves are safety valves designed to relieve excessive pressure. They reclose and reseal to prevent the further flow of gas from the container after the reseating pressure has been achieved. Pressure-relief devices are installed so the relief device is in direct communication with the fuel. Additionally, a shutoff valve should not be installed between the pressure-relief device and the cylinder, or after the pressure-relief devices.

When containers are installed inside vehicles, such as in the cargo trunk of a passenger car, these are the following requirements concerning how the pressure-relief device is installed and terminated to the vehicle's exterior:

- Installation in the same vehicle compartment of the container
- Termination to the exterior using piping or tubing of at least the same diameter as the pressure-relief device
- Termination of the vent opening so that road debris will not block it
- Enclosure of the container neck and all CNG fittings within a gastight compartment

Valves located at the container and the engine isolate the piping system from the container and the engine. A vehicle manual shutoff valve is also located along the frame rail. These valves are provided for the safety of the vehicle user, persons performing repairs, and emergency responders.

A valve is required for the vehicle container. The container valve can be operated manually or with a normally closed remotely activated shutoff valve. When the container has a remotely activated valve, the valve must be equipped with a means that allows the cylinder to be depressurized. Regardless of the valve type used, authorities having jurisdiction should ensure that personnel performing maintenance activities on CNG vehicles clearly understand the manufacturer's procedures for depressurizing a charged cylinder of CNG. In Texas in March 1993, the Austin Fire Department responded to a fire involving a CNG vehicle. The fire resulted from a mechanic improperly depressurizing the container by not electrically bonding the depressurizing tool to the vehicle frame. The high-pressure discharge of natural gas created a static accumulation and spark that ignited the gas jet, forming a flame jet approximately 15 ft (4.6 m) long, as witnessed by arriving fire fighters. Although the fire did not result in any fire fighter or civilian injuries, the vehicle of fire origin was destroyed and an exposed vehicle suffered damage from the thermal flux of the flame jet.[24]

A second valve is required between the engine and the fuel cylinder that permits fire fighters and repair personnel to isolate the containers from the remainder of the fuel system. This manual shutoff valve must be installed in an accessible location and can have no more than a 90° rotation from open to closed position. Labels or stencils stating "MANUAL SHUTOFF VALVE" identify the valve location. The manual shutoff valve requires protection from vibration and road hazards (Figure 21.4.7).

CNG Piping. Finally, a third valve is required in the fuel system that automatically prevents the flow of CNG when the engine is not running but the ignition switch is in the "ON" position. This ensures that methane does not flow during repairs while the vehicle's electrical system is energized.

Piping is used in a CNG fueling system because it offers a reliable, safe, and affordable method of moving high-pressure gas from the container to the engine. Normally, rigid or flexible stainless steel fuel lines connect the fuel containers, engine, and vehicle fueling receptacle. The use of certain materials for CNG piping service is prohibited: plastic piping and fittings for high-pressure service and galvanized piping and fittings. Even so, other considerations, such as temperature and vibration, must be taken into account.

Piping installed on vehicles is subjected to a fairly rigorous service life. As a result, the piping installed between the container and the secondary shutoff valve located along the vehicle's frame must capably withstand a hydrostatic pressure of at least four times the rated service pressure without structural failure. This generally results in only stainless steel tubing being used for CNG vehicle fuel lines.

Pipe connections can be welded, mechanically bent, or mechanically connected. When piping or tubing is threaded, the pipe sealing material must be impervious to natural gas and be applied to all male pipe threads before assembly. When mechanical joints or connections are used, joints must be located in an accessible location. Pipe routing must consider the effects of vibration, corrosion, damage from road objects and collisions, and normal service life wear and tear. Piping routed through engine compartment fire walls or other vehicle panels requires protection from abrasive wear through the use of grommets or other acceptable means.

When the engine requires fuel, the gas leaves the storage containers and flows to a high-pressure regulator. The gas pressure from the fuel container reduces to an intermediate pressure. As the gas expands from a fuel container pressure of 2500 to 4000 psig (17,235 to 27,576 kPa) to the intermediate pressure of 120 to 300 psig (827 to 2068 kPa), its temperature drops by

FIGURE 21.4.7 A Typical Label Identifying the Location of the Manual Shutoff Valve Between the Fuel Containers and Engine, as Required by NFPA 52

as much as 100°F (38°C). If the gas contains too much moisture, it can freeze and damage the fuel system and engine. Also, cold gas can harden pipe seals in the fuel system and result in leaks. For these reasons, most CNG vehicles have pressure regulators heated by engine coolant.

From the high-pressure regulator, the methane gas flows toward the engine through another line to the low-pressure regulator. Located in the engine compartment, the low-pressure regulator reduces gas pressure to approximately 100 psi (689 kPa). Engine coolant does not normally heat this regulator because the refrigeration effect is negligible. From the low-pressure regulator the gas flows to the engine, entering the fuel injectors and the cylinder's combustion chamber.

Liquefied Natural Gas Vehicles

LNG vehicles can be used for such applications as midsize and heavy-duty truck chassis vehicles, such as refuse trucks and transit vehicles. However, LNG is also a viable fuel for railroad locomotives and marine vessels. LNG vehicle fuel systems have several components, such as a pressure regulator and gas-air mixer, that are like those on CNG vehicles. Because engines cannot consume cryogenic fluids, the liquid must be converted to gas, which requires a heat exchanger.

NFPA 57 applies to the design and installation of LNG fuel systems on vehicles and their fuel-dispensing systems. The standard scope includes the CNG element of bi-fueled vehicles and vehicles originally manufactured to operate using LNG. Vehicles fueled by LNG have components designed to operate at temperatures and pressures encountered in cryogenic service. These components are on the system's liquid side. Major components on the cryogenic side of the fuel system include the vehicle's LNG storage tank and fuel lines. When LNG vaporizes into a gas, its components are designed for compressed gas service. Major components on the vapor phase side of the system include the heat exchanger and pressure regulator.

LNG Fuel Containers. LNG vehicle containers commonly use a vacuum-jacketed Dewar-type design, based on the Dewar flask. This double-walled vessel has reflective surfaces on the container's exterior where vacuum is maintained between the two walls. This helps prevent the LNG loss when the container and liquid become warm. An important consideration in LNG vehicle containers' design is hold time. Hold time is the length of time a vehicle can remain unused until pressure in its tank builds to a point that it must be vented. Hold time depends on the liquid/vapor ratio in the tank, as well as the tank's construction. The liquid/vapor ratio depends on the amount of tank ullage. Space is always required to allow for vaporization and liquid expansion that occurs as temperature and pressure increase. The ullage is typically 5 to 10 percent of the vehicle's tank volume. Ullage is necessary in the event the tank reaches a vent pressure. When the pressure-relief valve functions to relieve pressure, gas, not LNG, is discharged.[25]

LNG vehicle fuel containers are constructed with an inner tank and outer tank. The inner tank is normally constructed of stainless steel. Because it serves as a cryogenic pressure vessel, the inner tank's design meets Section VIII, Division 1 of the *ASME Boiler and Pressure Vessel Code* or U.S. DOT regulations 49 CFR 178, for example, DOT 4L tank. It normally contains a baffle and method of indicating the level of liquid in the container. The outer tank is constructed of either stainless or carbon steel. The inner tank connects to the outer tank with supports designed to minimize heat conduction but maintain the container's structural integrity. To minimize radiation heat transfer, insulation consisting of multiple layers of aluminum/polyester film separated by nylon netting is placed in the container's interstice. A vacuum drawn in the interstice minimizes the effect of convective heat transfer. Common LNG vehicle containers are cylindrically shaped with elliptical heads. The structural integrity of an LNG vehicle fuel container during normal operation and under fire or other abnormal stress is analyzed in the tank design. The structural integrity of the LNG container must be evaluated against vibration, acceleration, and shock loads to determine crashworthiness.

LNG vehicle fuel containers are required to have identification features for individuals performing repairs and emergency responders. With the exception of openings for pressure relief or liquid gauging, all openings are designated as to whether they open into the vapor or liquid space. The total volume of the container is identified, and signs indicate that the container can only be used for LNG service. Valves to control liquid and vapor flow must be readily accessible and operable without the use of tools.

Location of the LNG storage container on a vehicle is an important consideration. Containers should not be located ahead of the vehicle's front axle, beyond its rear bumper, or on its roof. Containers may be installed in the interior of vehicles, provided the compartment is not in direct communication with the driver, passenger, or any space containing radio transmitters or spark-producing equipment. This can be accomplished by providing gastight enclosures over the equipment and venting the enclosure outside the vehicle. When LNG is not odorized, a continuous monitoring methane gas detection system is required in the compartment holding the container. The detection system should be designed to sound an alarm when the atmosphere in the compartment exceeds 20 percent of the lower flammable limit for methane. The gas detection system is not required to stop the flow of fuel or turn off the engine's ignition.

LNG Pressure-Relief Devices. LNG storage containers require pressure-relief devices. Most vehicle containers are equipped with pressure-relief valves and rupture disks. Pressure-relief valves relieve the pressure that develops during the LNG hold time in the container. If the pressure-relief device fails, pressure increases until the rupture disk fails. The burst pressure of the disk is higher than the relief valve setting but lower than the container's design pressure. Unlike conventional relief valves, rupture disks are not designed to close. If a rupture disk operates, LNG vapor is released until the tank is empty. If the vehicle is involved in an incident in which the container is overturned and the rupture disk operates, LNG discharges from the pressure-relief opening.

LNG Heat Exchanger and Piping. LNG must be converted from liquid to gas for proper combustion in reciprocating

engines. A heat exchanger performs the phase change. Commonly called a vaporizer, the heat exchanger raises the temperature of LNG vapors so that the phase change from liquid methane to methane gas is efficient. A commonly used heat-transfer medium is engine coolant recirculated between the heat exchanger and the engine's radiator. At maximum fuel flow rate, the heat exchanger must have the capacity to completely vaporize the LNG. In addition, it must heat the gas to the appropriate temperature before the gas enters the fuel regulator. Identifying the maximum allowable working pressure for heat exchangers is a necessity to protect the device against possible overpressurization resulting from the installation of an improperly sized relief device.

From an emergency response perspective, the heat exchanger is the component in the fuel system dividing the cryogenic side and the vapor phase, or noncryogenic side. A pressure regulator ahead of the heat exchanger controls the pressure of gas consumed at the mixer or carburetor.

Piping transfers LNG from the vehicle container's liquid withdrawal connection, through the heat exchanger and pressure regulator, to the carburetor or fuel injector. As LNG travels from the fuel container through the fuel line to the heat exchanger, it begins to warm, causing condensation on exterior surfaces. Most fuel lines are insulated to retard heat loss. Piping designed for LNG vehicles is required to withstand pressure of at least twice the container's maximum allowable working pressure. Typical construction materials for piping include stainless steel, brass, and copper that are fitted using threaded, welded, or brazed joints. Where valves are arranged such that LNG could be trapped between them, a pressure-relief device must be installed in the pipe section to relieve any excess pressure the warm LNG causes.

Liquefied Petroleum Gas Vehicles

LP-gas vehicles include industrial trucks, farm equipment, and vehicles ranging in size from automobiles to heavy-duty trucks. LP-gas has the longest history of all the alternative fuels. Propane used to heat rural homes has also been readily available on the farm for use as a vehicle fuel. According to the DOE's *Transportation Energy Data Book* (Edition 20-2000), approximately 270,000 vehicles in North America are fueled using LP-gas (see Table 21.4.1). This figure does not include off-road vehicles; including these vehicles would increase this number significantly.

LP-gas vehicles normally use propane, a flammable, liquefied petroleum gas stored at pressures of approximately 120 to 200 psig (827 to 1379 kPa), depending on its specific gravity and storage temperature. The vehicle container connects to either a manifold or single fuel line that dispenses propane to the engine via expansion of the liquefied gas. The gas enters a propane carburetor and produces a flammable mixture that is injected into the engine's combustion chamber.

NFPA 58 applies to the design, installation, and maintenance of LP-gas fuel systems on all vehicles and fuel dispensing systems. NFPA 58 covers the installation of fuel systems supplying engines used to propel vehicles such as passenger cars, taxicabs, multipurpose passenger vehicles, buses, recreational vehicles, trucks (including tractors, tractor semitrailer units, and truck trains), and farm appliances.

LP-Gas Containers. NFPA 58 regulates the design, fabrication, and construction of LP-gas containers designed for installation on vehicles. LP-gas vehicle fuel containers must meet either the requirements of *ASME Boiler and Pressure Vessel Code,* Section VIII, Division 1, "Rules for Construction of Unfired Pressure Vessels," or U.S. DOT requirements. Normally, pressure vessels used for LP-gas service have a minimum design pressure of 250 psig (1724 kPa), based on NFPA 58 and ASME requirements for gases with a vapor pressure of 215 psig (1482 kPa) at 100°F (38°C). However, when the pressure vessel is intended for installation on a motor vehicle, such as an automobile or bus, the minimum design pressure for the container increases to 312.5 psig (2154 kPa). The higher design pressure ensures that the pressure-relief device has an increased operating setting because the container may be subjected to operating temperatures not normally found at stationary LP-gas installations. In addition, premature operation of a relief valve on, for example, a school bus filled with children introduces a variety of concerns to vehicle operators and emergency responders. Establishing a higher starting pressure for opening a relief valve reduces the probability of premature LP-gas release.

Particular attention must be paid to the location of vehicle LP-gas containers. Containers must be located to minimize the possibility of damage to them and their fittings. Suitable locations may include the trunk of a passenger car, directly attached to the frame of a vehicle, or in the cargo box of a pickup truck. Containers should be installed in a location to minimize damage resulting from a collision. Containers and their components cannot be located ahead of the vehicle's front axle, behind its rear bumper, or on its roof.

A container installed inside a vehicle should be installed so that the driver or passengers are not exposed to any release of LP-gas, nor should it be within any space containing radio transmitters or other spark-producing equipment. NFPA addresses the three following options to satisfy this concern:

1. Locate the container and its appurtenances outside the passenger compartment.
2. Completely enclose the container appurtenances in a gastight enclosure or housing.
3. Store the container and its appurtenances in the trunk of an automobile and seal the compartment to form a separation from the passenger carrying space.

The size of the container on vehicles is also limited. Vehicles designed to transport passengers, such as buses or automobiles, are limited to an aggregate of not more than 200 gal (0.75 m^3) water capacity, or approximately 160 gal (0.6 m^3) of LP-gas. Vehicles not designed to carry passengers, such as farm machinery or mail trucks, may have an aggregate 300 gal (1.1 m^3) water capacity of volume, or approximately 240 gal (0.9 m^3) of LP-gas. In both instances, more than one tank can be used and manifolded, but the total volume cannot exceed the aggregate quantity.

A method of preventing the overfilling of vehicle LP-gas containers is required. Overfilled containers can be hazardous

when liquid LP-gas expands to the point where the containers become liquid-full, causing the pressure-relief valve to open and discharge LP-gas. To minimize the hazard, containers manufactured after January 1, 1984, and installed in vehicles must be equipped with a device that prevents overfilling. Listed stop fill valves designed to satisfy this requirement are available. Other means, such as a solenoid valve, may be used.[26]

LP-Gas Pressure-Relief Devices. Vehicle LP-gas fuel containers require a method of relieving excess pressure resulting from an external heat source. Spring-loaded pressure-relief devices accomplish this. The relief valve is recessed or flush with the surface of the pressure vessel. For ASME containers, the relief valve is normally designed to meet the requirements of Underwriter Laboratories Standard 132, *Safety Relief Valves for Anhydrous Ammonia and LP-Gas,*[27] Section UG-125 of the *ASME Boiler Pressure Vessel Code,* or other standards acceptable to the authority having jurisdiction. DOT containers require spring-loaded pressure-relief valves in accordance with CGA Pamphlet S-1.1. NFPA 58 prohibits the use of relief devices that use fusible plugs because the vehicle container can be subjected to considerable heat while garaged or in use.

LP-gas pressure-relief devices must be installed in direct communication with the vapor space of the vehicle fuel container. The relief device must also be located at the container's uppermost point. When this is not possible, the device should be internally piped to the uppermost practical point in the container's vapor space. Because propane has an approximate expansion ratio of 1:260, any liquid discharge from a relief device results in the development of a gas vapor cloud. The requirement for locating the relief valve at either the uppermost point of the container or the vapor space is based on experience with relief valves located at or directly above the 80 percent liquid level, in which the relief valve sometimes discharged liquid LP-gas. When the container is installed inside the vehicle, its discharge outlet must terminate outside the vehicle. It must also be directed so that it does not directly impinge on the vehicle fuel containers, the exhaust system, or any other part of the vehicle; it cannot be directed into the passenger compartment.

A manual shutoff valve is required for LP-gas vehicle fuel containers. This valve has an additional protective feature known as the internal excess flow check valve. It closes and stops the flow of gas from the container in the event the shutoff valve is sheared or broken off the container. The excess flow check valve does not operate if the shutoff valve is only partially damaged. Also, the valve does not stop the flow of LP-gas if a fuel pipe leaks downstream of the valve. Manual shutoff valves are normally installed at the container's liquid and vapor openings. These valves must also be readily accessible so they can be shut off using tools or other means.

LP-Gas Piping. The construction materials for piping, hose, and fittings used to connect the fuel container to the vaporizer and carburetion equipment are the same as for fixed installations. Piping must be corrosion-resistant or protected against corrosive action, free of leaks, and securely mounted on the vehicle. Any fuel piping that passes through a vehicle's floor must be installed so that the pipe is beneath or adjacent to the container and connections are outside the vehicle. Hydrostatic relief valves are required between any section of pipe or hose in which LP-gas could be isolated between shutoff valves. Carburetion equipment for LP-gas vehicles is designed to complete the phase change of propane from liquefied phase to gas phase. Equipment is required to be listed for vehicle service and should be acceptable to the authority having jurisdiction. Carburetion equipment is normally rated with a design pressure of 250 psig (1724 kPa), although operating pressures are normally limited to 125 to 250 psig (862 to 1724 kPa). Like CNG and LNG fuel systems, LP-gas fuel systems require an automatic shutoff valve provided as close as practical to the inlet of the pressure regulator. The valve prevents the flow of fuel to the carburetor when the engine is not running but the ignition switch is in the "ON" position. Pressure-relief requirements for carburetion equipment are the same as for containers installed on vehicles: relief devices must be spring-loaded pressure-relief valves; fusible plugs are not acceptable.

Hydrogen-Fueled Vehicles

Hydrogen-fueled vehicles are addressed in Section 21, Chapter 5, "Fuel Cell Vehicles." Most of these vehicles are fuel cell powered, where the hydrogen acts as a fuel for the fuel cell. However, there are some internal combustion engine vehicles that run on hydrogen. These vehicles present hazards that are similar to those presented by CNG vehicles. In Section 21, Chapter 5, the section on physical properties and fire hazards explains some of the differences between the behavior of CNG and hydrogen and will help in understanding how the gases would behave in an accident.

EMERGENCY RESPONSE TO ALTERNATIVE FUEL INCIDENTS

Highway operation of vehicles that use CNG, LNG, and LP-gas is increasingly common. Fire fighters must be prepared to respond to incidents involving the release of these alternative fuels. Emergency response to a vehicle or fueling station releasing alternative fuel requires an understanding of the fuel's hazards, release mechanisms, methods available to safely stop the release, and, in the event an ignition source is introduced, how to safely and effectively initiate a successful fire attack. Three plausible scenarios for emergencies involving the release of alternative fuels are as follows:

1. The vehicle is being fueled.
2. The vehicle is involved in an accident.
3. The vehicle is under repair.

Identifying Alternative Fuel Vehicles

Components of alternative fuel vehicles are normally protected and hidden from view to protect these components in an accident. Fire fighters approaching alternative-fueled vehicles cannot usually distinguish these vehicles from those fueled with gasoline or diesel. Fortunately, measures have been taken to identify these vehicles to responding fire fighters.

All three NFPA standards require that vehicles be identified with a weather-resistant, diamond-shaped label on the exterior vertical surface on the lower right rear of the vehicle (Figure 21.4.8). Most labels are placed on the trunk lid or rear cowl; they cannot be affixed to the bumper because they may be covered by bumper stickers or damaged in minor vehicle accidents. For CNG vehicles, NFPA 52 requires white or silver letters "CNG" on a blue background. NFPA 58 and NFPA 57 require white or silver letters "propane" and "LNG," respectively, on a blue background. The retroreflective labels are visible at night or in fog.

Response to Vehicle Fires and Accidents

Many variables outside fire fighters' control impact how an emergency response will be handled. It is important to understand that alternative fuels have somewhat predictable characteristics when released to the atmosphere, and all the alternative fuels are flammable gases at normal temperatures and pressures. These facts, along with an understanding of the basics of fireground safety, will result in the safe conclusion of an incident.

Apparatus should be placed upwind of a vehicle on fire or involved in an incident. If the vehicle is LNG fueled, the apparatus should be located away from the path of flowing LNG. However, this is not as critical as wind direction because flammable LNG or LP-gas vapors can travel significant distances downwind. LNG vapors will eventually become positively buoyant. Conversely, LP-gas vapors always remain heavier than air due to the molecular weight of the gas. Fire fighters should also recognize that LNG is normally unodorized, but LP-gas is odorized.

Fire fighters should accurately assess the scene before initiating a fire attack. Maintaining an adequate distance, fire fighters should walk completely around the vehicle, observing it and paying special attention to the right rear so they can identify the fuel used. Fire fighters should look for the blue or black retroreflective diamond that identifies which fuel is used.

FIGURE 21.4.8 Diamond-Shaped Label That Identifies the Fuel Used by the Vehicle

For CNG and LP-gas vehicles, water from attack streams can be used to control fire and enhance vapor dispersion. However, for LNG releases, applying water from fire streams greatly increases the vaporization rate for a pool of liquid methane. Fire fighters should attack LNG fires with potassium bicarbonate, ammonium phosphate, or sodium bicarbonate dry chemical fire extinguishers until they confirm that the fire does not involve fuel.

Regardless of the fuel, the primary concern at vehicle crash sites is to ensure the safety of fire fighters and civilians. The strategy is to control or stop the release of fuel and eliminate ignition sources. If a vehicle fuel release has been ignited, stopping the release of additional fuel, if possible, is critical before further fire-fighting activities are undertaken.

The fuel systems for CNG, LNG, and LP-gas can be stabilized by closing the primary shutoff valve at the storage containers. CNG vehicles normally have a second fuel isolation valve installed along the frame rail. NFPA 52 requires a method of identifying this valve's location. All alternative fuel containers are required to vent outside the vehicle. The fire fighter assigned the task of closing the primary valve should also locate and inspect the tank vent line to ensure that it is not blocked.

Closing the primary valve may require the operation of the tank vent. Before fire fighters attempt to isolate the fuel supply on LNG vehicles, they should check the vehicle's on-board gas detection system to determine if fuel is leaking. Because a collision could damage this system, fire fighters should also survey the vehicle and accident scene using gas detection equipment. After checking the vehicle and scene for leaks, fire fighters can proceed to close the liquid product valve. LNG containers have two valves, one for liquid product and the other for the tank vent. The vent line should not be closed because it lets the LNG vehicle container vent gas if tank pressure increases, as it does in a fire. If labels are missing or obscured, fire fighters can always locate the liquid valve because it will be covered with ice and frost formed from moisture in the atmosphere. The vent valve will not be covered with ice or frost.

Hydrogen Fueling Facilities

Hydrogen fueling systems (Figure 21.4.9) typically do not have feed lines from off-site storage but employ on-site storage. Because of the low density of hydrogen gas, hydrogen is often stored as a cryogenic fluid. Hydrogen systems may also have vaporizers to convert the liquid hydrogen to gaseous hydrogen. Additionally, hydrogen fueling systems operate at higher pressures than natural gas fueling systems. Natural gas systems operate in the 3000 to 4000 psi (20,684 to 25,579 kPa) range as compared to hydrogen systems that may reach pressures of 10,000 psi (68,948 kPa). The reason for this difference is that the low density of hydrogen gas means that higher vehicle tank pressures are required to store enough fuel on the vehicle to give it a practical driving range.

Response to Vehicle Fueling Stations

Response considerations for fueling stations are the same as those for vehicles. The difference between the fueling station and vehicle is the amount of fuel stored at the site and the types of safety features.

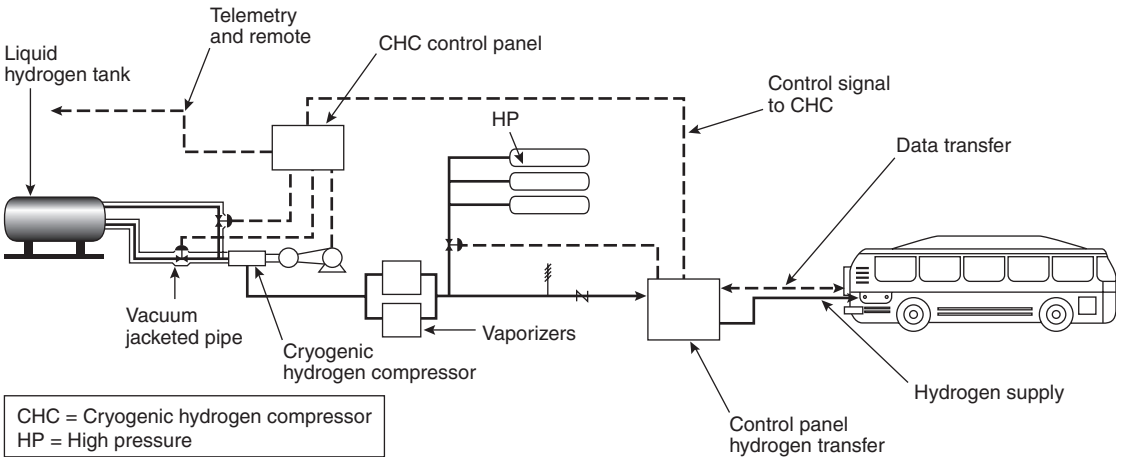

FIGURE 21.4.9 Compressed Hydrogen Gas Fueling System.

Fire fighters who might conceivably respond to a vehicle fueling station should prepare a written plan documenting how to manage and control the response to the facility in the event of a fire or fuel release. The pre-incident plan should consider points of access, required and available water supply, capabilities of fire department resources and personnel, buildings that could be exposed, safe evacuation of occupants, the location of fuel delivery valves and the method of closing them, and safety features or controls provided. The evaluation should also consider probable and worst-case event scenarios. For example, the overfilling of an LP-gas container or the operation of a relief valve on a pressure vessel storing compressed methane are not uncommon and will probably occur over the life of a facility. Conversely, worst-case scenarios can include a catastrophic container failure or a BLEVE. Although catastrophic incidents are rare, such an event can occur. Its consequences to the public and fire fighters must be considered before any response to the fueling station. Where available, fire fighters should consider using a vapor dispersion model such as CHARM (Chemical Hazard Airborne Release Model) to determine the anticipated size and boundary of the exclusion zones. Another resource is CAMEO (Computer-Aided Management of Emergency Operations). This software and supporting information is available at EPA's Chemical Emergency Preparedness and Prevention Office website (http://www.epa.gov/ceppo). CAMEO also has a specific support group website: http://www.CAMEOSupport.com.

The EPA's various guidance documents developed for implementing the Risk Management Program Rule can be used to give estimates of potentially affected areas resulting from an incident. Many of these documents are available through the EPA website, http://www.epa.gov.

All vehicle fueling stations require emergency shutoff devices. These can be simple electrical kill switches or valves designed with integral fusible-links that close if subjected to flame impingement or thermal flux. These devices' location and method of operation should be known and understood. LNG facilities normally require a gas detection system because of the lack of odorant. The gas detection system features and its sequence of operation should be included in the pre-incident plan.

Facility management should be cognizant of the hazards of the alternative fuel stored and should develop its own plan in the event of a release or fire. Further, the fire department and facility management should work jointly to prepare and communicate the pre-incident plan, so realistic action plans can be formulated and the consequences of probable and worst-case events are understood.

SUMMARY

The use of alternative fuels for vehicles has been increasing in the United States, as part of an effort to reduce air pollution and dependence on foreign oil. Compressed natural gas (CNG), liquefied natural gas (LNG), and liquefied petroleum gas (LP-gas) are the most commonly used alternative fuels in the United States. There is significant interest in using hydrogen as fuel for fuel cell powered vehicles. Although relatively few hydrogen-powered vehicles have been produced, there has been a good deal of development and research work done by automobile manufacturers, the U.S. Department of Energy, and other organizations that would play a role in the implementation of a hydrogen energy infrastructure. Hazards associated with these fuels are determined by their physical and chemical properties as well as by time-dependent conditions, the fuel system design, and the quality of the fuel system's manufacture and installation. NFPA codes and standards form the basis of many safety requirements concerning vehicle fueling, fuel storage, and vehicle fuel systems. Fire fighters must be prepared to respond to a vehicle or fueling station releasing alternative fuel and must have an understanding of the fuel's hazards, release mechanisms, ways to stop the release, and methods of conducting a successful fire attack if necessary.

Chapter Contents

Advantages of Fuel Cell Vehicles
Description of Fuel Cell Vehicles
Fuel Cell Systems
Electric Drive Systems
Compressed Hydrogen Storage Systems
Hydrogen System Safety
Postcrash Considerations
Fuel Cell Organizations and Initiatives

Key Terms

auxiliary power unit (APU), bus (transit), compressed hydrogen, electric drive system, fault management, fuel cell, fuel cell vehicle, hybrid car, hydrogen, hydrogen fueling station

The world's leading automakers, fuel cell developers, material and component suppliers, national laboratories, and universities are in a race to bring fuel cell vehicles (FCVs) to the marketplace. FCVs offer an alternative to the internal combustion engine that promises to increase efficiency, lower emissions, and reduce our dependency on foreign oil. The goal is to meet these objectives without compromising the vehicle performance, cost, and safety that consumers have come to expect.

Many of the leaders in fuel cell vehicle development are members of the U.S. Fuel Cell Council. The U.S. Fuel Cell Council is dedicated to being "the voice of the fuel cell industry" and its membership contributed to this chapter. The Transportation Working Group includes producers of fuel cells and equipment, automakers, hydrogen suppliers, and government entities and national laboratories that are actively developing FCVs and the infrastructure to fuel and maintain these vehicles.

FCVs are already on the road in demonstration programs in California and throughout the nation. The California Fuel Cell Partnership estimates that its members will have approximately 300 fuel cell cars and buses operating in demonstrations in the state by 2007. To support these demonstration vehicles, a number of hydrogen fuel stations have been installed in Northern and Southern California, and the state has launched the California Hydrogen Highway Network to help expand fuel stations to support more hydrogen vehicles. Other projects are proceeding in Michigan, Connecticut, New York, Florida, and Washington, DC.

This chapter describes current fuel cell vehicles and operating features being developed to facilitate commercialization and acceptance by the general public and regulatory authorities.

For related topics, see Section 21, Chapter 1, "Passenger Vehicle Fires"; Chapter 2, "Fire Safety in Commercial Vehicles"; and Chapter 4, "Vehicle Fueling Using Gaseous Fuels."

ADVANTAGES OF FUEL CELL VEHICLES

Operating fuel cell vehicles results in a number of advantages for the country. These advantages include but are not limited to reduced emissions and energy independence and diversity.

Emissions

Hydrogen-fueled FCVs are true "zero emissions vehicles." The exhaust is only steam. The EPA and the California Air Resource Board have already certified Honda's FCX as a zero emitting vehicle (ZEV). There are emissions associated with producing the hydrogen, but typical feed stocks being considered for producing the hydrogen would yield emissions that are extremely low in comparison to internal combustion engines (ICEs).

Glenn W. Scheffler has a B.S. in aerospace engineering from Pennsylvania State University and an M.S. in mechanical engineering from the University of Connecticut and has 36 years' experience in the fields of fuel cells and hydrogen. He is chairman of the SAE Fuel Cell Vehicles (FCV) Safety Working Group, vice-chairman of the FCV Standards Committee, chairman of the US-TAG for ISO TC22/SC21 for Electric (and Fuel Cell) Vehicles, and a member of the Hydrogen Industry Panel on Codes (HIPOC).

William P. Collins has a B.S. in mechanical engineering from the University of Connecticut and an M.S. in management from Rensselaer Polytechnic Institute and has 26 years' experience in the fields of power generation, fuel cells, and hydrogen. He is a member of the SAE Fuel Cell Vehicles Standards Committee, the NFPA Electrical Generating Committee, the ASME B31.12 working group, and the US-TAG for ISO TC197.

Energy Independence and Diversity

After a century of continuous improvements, the internal combustion engine still converts on average only about 16 percent of the energy in gasoline to turn the car's wheels. FCVs can achieve energy efficiencies of over 50 percent. Given this significant improvement in energy efficiency, FCVs offer higher mileage and substantial reductions in greenhouse gas emissions and other monitored pollutants.

Additionally, hydrogen can be generated from a number of domestic sources, helping the United States to reduce its dependence on foreign energy. Fueling vehicles with hydrogen also offers the possibility of using renewable energy sources to produce transportation fuel.

DESCRIPTION OF FUEL CELL VEHICLES

The "heart" of the FCV is the fuel cell. Fuel cells are electrochemical devices similar to a battery except that, rather than consuming chemical energy that has been stored with the battery, the fuel cell uses a supply of hydrogen to produce electric power on an ongoing basis.

Hydrogen Storage and Supply

FCV developers are considering several methods to store and supply hydrogen to fuel cells. Examples of methods to store hydrogen are as follows:

- Compressed hydrogen gas
- Liquefied hydrogen
- Hydrogen stored in reversible metal hydrides
- Hydrogen as a chemical hydride

Alternatively, hydrogen (or a hydrogen-rich gas) can be generated on board the vehicles from hydrocarbon fuels and alcohol within fuel-processing systems. Although all of these methods of storing and supplying hydrogen have been demonstrated in FCVs, most FCVs currently utilize compressed hydrogen gas that is stored at high pressure in containers on the vehicle.

For an FCV to be propelled, the electrical power produced by the fuel cell needs to be converted to mechanical energy through traction motors that, in turn, drive the wheels. In its simplest form, the electric drive system has (1) a power control to translate driver "throttle input" into modulated electric power from the fuel cell to the drive motors and (2) electric drive motors for vehicle propulsion.

An example of a typical FCV with compressed hydrogen storage to supply hydrogen to the fuel cells, fuel cells to convert the chemical energy of hydrogen into electric power, and an electric drive system (including a power control and motors) to propel the vehicle is shown in Figure 21.5.1.

In general practice, many current FCVs use a hybrid electric architecture that also includes regenerative braking to recover motive energy from the vehicle during braking and batteries or ultracapacitors to store the energy for future use. The hybrid architecture increases efficiency (i.e., raises mileage) and can improve vehicle response and acceleration.

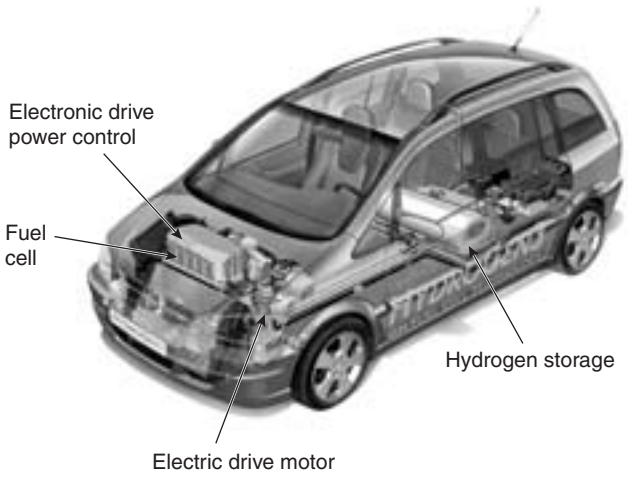

FIGURE 21.5.1 Typical Fuel Cell Vehicle (FCV) (Courtesy of General Motors Corporation)

In addition to propelling the vehicle, fuel cells typically provide electric power for vehicle auxiliary and ancillary systems, such as radios and air conditioners. On many FCVs, auxiliary and ancillary power is supplied by conventional 12 volt batteries or tapped off the fuel cell or electric drive bus; but, in some cases, dedicated power is provided from a separate fuel cell, called an auxiliary power unit (APU) (Figure 21.5.2). The typical power rating of an APU is between 3 and 10 kW.

Fuel cell vehicles are being developed by manufacturers throughout the world. FCVs range from 40 ft (12.2 m) transit buses down to motor scooters and fork trucks. Examples of buses and cars being developed by major vehicle manufacturers are provided in the following sections, along with a discussion of the design practices being employed for basic vehicle safety.

FIGURE 21.5.2 APU in Trunk of Passenger Vehicle (Courtesy of UTC Power)

Buses

Transit buses are widely viewed as a good early market for commercializing fuel cell vehicles. Many advantages have been identified regarding the use of transit buses as fuel cell platforms. Examples are as follows:

- Transit buses have well-defined duty cycles, centralized fueling and maintenance infrastructure, and dedicated maintenance personnel.
- Transit buses are large, providing ample room to install the fuel cell and related components.
- Many older diesel transit buses are noisy and polluting, providing fuel cells with an opportunity to make significant performance improvements.
- Transit agencies are subsidized by the government, thus helping to defray most of the risks and costs of technology development.
- Transit buses are highly visible in the community, providing an excellent showcase for fuel cells.

As a result, governments in North America, Europe, and Asia are supporting many demonstrations of fuel cell buses, causing the number of fuel cell buses to grow at an almost exponential pace (Figures 21.5.3 and 21.5.4).

Cars

A number of domestic car companies are actively developing FCVs. GM's HydroGen3 fuel cell minivan established a long distance driving record in 2004 by traveling 6200 miles from Norway to Portugal and is in service in Japan, California, and Washington, DC (Figure 21.5.5). Ford's Focus vehicles are used in California, Michigan, Florida, Canada, and Germany. DaimlerChrysler's A-class F-cells are in service in Germany, Singapore, Japan, and the United States (Figure 21.5.6).

Major Asian car companies are also very active. Honda's FCX is being used in demonstration programs in New York,

FIGURE 21.5.6 DaimlerChrysler FCV (Courtesy of DaimlerChrysler)

Nevada, California, and Japan. The company is also developing hydrogen fueling stations at customer sites. Toyota's Fuel Cell Hybrid Vehicle (FCHV) is in use in Japan and California (Figure 21.5.7). Nissan has X-Trail Fuel Cell Vehicles operating with both UTC Fuel Cells and Nissan stacks (Figure 21.5.8). Hyundai has introduced an improved version of its Tucson Fuel Cell Vehicle (FCV) using an advanced UTC Fuel Cells stack (Figure 21.5.9).

Most other automakers are also involved in public road tests with their fuel cell prototypes. For example, Mazda's Premacy FC-EV has undergone public road testing in Japan since 2001. Volkswagen's HyPower prototype has completed testing in cold temperatures and high altitudes in the Swiss Alps. The Mitsubishi FCV, based on the Grandis minivan, has been approved for road trials by Japan's Minister of Land, Infrastructure and Development. Suzuki's wagon R-FCV began Japanese road trials in 2005.

Design for Safety

The automotive industry is applying design practices developed over the past 100 years to ensure that FCV development and commercialization is successful and safe. Under normal and anticipated driving and vehicle scenarios, the vehicle and associated subsystems are designed with the objective that foreseeable single-point hardware or software failures do not result in an unreasonable safety risk to any person or uncontrolled vehicle behavior. This, in part, dictates the use of redundant safety features. Where this is not possible, a high safety factor is necessary to provide reasonable assurance that a component, such as a pressure vessel, will not fail.

A standard automotive industry approach to identifying and managing safety risks, particularly in new technologies and designs for higher volume products, is the use of a failure modes and effects analysis (FMEA).[1]

Hazardous conditions often depend on several conditions existing simultaneously. Prudent design, focused on the separation of hazards, prevents hazardous conditions from arising. Isolation and separation of hazards are approaches used to prevent cascading of failures and preclude unwanted or unexpected interactions.

Fail-safe design is a key philosophical approach. With regard to FCVs, automatic electrical disconnects should open and fuel shutoffs should close when de-energized. Utilizing this design philosophy, any interruption of this control signal (whether caused by accident, equipment failure, or human error) will cause isolation of electrical or fuel sources and minimize exposure of occupants, repair personnel, and emergency responders to hazards.

Fault Management

Faults that could result in a hazardous situation are detected and mitigated by control systems on the vehicle. When necessary, a staged warning and shutdown procedure is implemented to shut off the supply of fuel and open the electrical circuits to mitigate potential hazards. A staged warning and shutdown system is used when loss of vehicle power due to an automatic shutdown may, in itself, lead to a hazardous operating condition. In order

to ensure the safety of the driver and the passengers in the vehicle, the sequence and rate of actions depends on the operating state of the vehicle.[2]

A main switch function is usually provided in demonstration vehicles so that the operator can disconnect all vehicle power sources by electrically isolating both poles of a fuel cell stack module, traction battery, and other high voltage sources (if equipped). This main switch, such as a conventional ignition switch, should be easily accessible and activated by the operator.

Typically, when the vehicle is involved in a crash detected by the crash sensors, the fuel is automatically shut off and the electrical system is disconnected. Additionally, to provide protection against electric shock by emergency responders, vehicles are designed to maintain proper electrical isolation following accidents.[3]

FUEL CELL SYSTEMS

In 1839, British scientist Sir William Robert Grove discovered that hydrogen and oxygen could be combined to produce water and an electric current. Fredrick Ostwald helped provide the theoretical foundations of fuel cells in the 1880s and was also able to experimentally determine the roles played by the different parts of Grove's fuel cell. In the late 1950s, Francis Bacon's research team developed a more advanced fuel cell. This design was used for NASA's Apollo moon missions and Skylab programs. Fuel cells also provide electrical power for space applications on board NASA's space shuttle orbiter. Today, fuel cell technology is being brought back to earth to power everything from cars and buses, to homes and businesses, and even cellular phones and laptop computers.

Fuel Cell Operation

Although there are several different types of fuel cells based on the type or state of the electrolyte used within the cell, almost all prototype fuel cell cars and buses use proton exchange membrane (PEM) fuel cells. Each PEM fuel cell is a thin wafer with a catalyst-coated membrane resembling a plastic film that is enclosed in electrically conducting graphite or metal plates (Figure 21.5.10). One side of the membrane acts as an anode and is fed hydrogen gas. The other side of the membrane serves as the cathode and is bathed in air to provide oxygen. At the anode, a catalytic reaction takes place with the hydrogen atoms releasing their electrons and becoming hydrogen ions (protons). The protons are transported through the membrane to reach the cathode. Another catalytic reaction takes place on the cathode where the protons combine with oxygen and electrons to produce water. The electric circuit is completed by connecting the cathode and anode to a load so that the electrons released from the anode can flow through the load to the cathode.

Fuel Cell Stack

In order to meet vehicular requirements, fuel cells are assembled in stacks to generate sufficient power and voltage for the electric drive system (Figure 21.5.11). Fuel cell stacks with electric capacities between 50 to 150 kilowatts are powering prototype passenger cars, minivans, sport utility vehicles, and transit buses. Tremendous improvements in stack efficiency, as well as weight and size reductions, have been achieved in recent years, but more remains to be done to make fuel cells affordable.

Balance of Plant

The fuel cell stack is just one component of the overall fuel cell system. The remainder of the fuel cell system, known as the "balance of plant," performs the following basic functions:

- Delivery of the hydrogen to the fuel cell stack and discharge of exhaust
- Delivery of fresh air to the cathodes of the cell stack
- Management of the fuel cell stack temperature and water

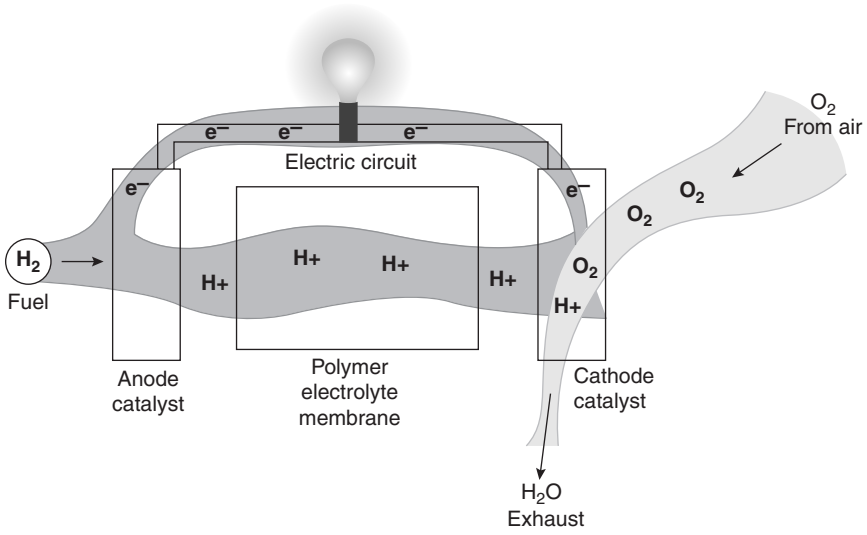

FIGURE 21.5.10 Operation of a PEM Cell (Courtesy of the U.S. Fuel Cell Council)

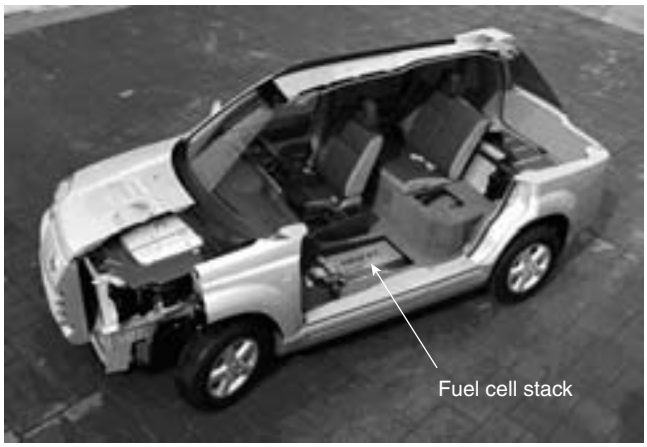

FIGURE 21.5.11 Fuel Cell Stack Installed in a Vehicle (Courtesy Nissan Motor Company)

To meet these functions, the balance of plant typically requires pumps, blowers or compressors, fans, heat exchangers, filters, and control valves. In many cases, standard off-the-shelf components are not suitable and specialized components must be designed and manufactured. Additionally, since many components in the balance of plant require electric power, the balance of plant often includes power conditioners to adjust fuel cell output power to an appropriate level for the component (Figures 21.5.12 and 21.5.13).

ELECTRIC DRIVE SYSTEMS

Operation of Electric Drive System

As described earlier in the chapter, the electric drive system converts the electric power from the fuel cell (and battery or ultracapacitor, if hybrid) into traction power for the FCV. Key functional elements of the system are shown in Figure 21.5.14 and described as follows:

1. The power control translates driver "throttle input" into modulated electric power from the fuel cell to the drive motors.
2. Electric drive motors convert the electric power into vehicle propulsion.
3. Batteries, ultracapacitors, or other methods of energy storage allow energy from regenerative braking to be captured for reuse and can provide improved vehicle response in hybrids.

A simplified electrical schematic is shown in Figure 21.5.15. The power control meets the driver's "throttle" request by varying the power from the fuel cell and the energy storage (if the vehicle is a hybrid) to meet in the propulsion requirement of the electric drive motor. Depending on the type of electric drive motor, the power control may also have to adjust the voltage level or convert the current from dc to ac. Additionally, in hybrid configurations, the power control also manages the recharge of the energy storage (i.e., batteries, ultracapacitors, or other devices) for optimum efficiency and performance of the vehicle.

Electrical Safety Elements

Typical voltages of the electric drive system range from 300 to 600 volts. Since the electrical system of a fuel cell vehicle is

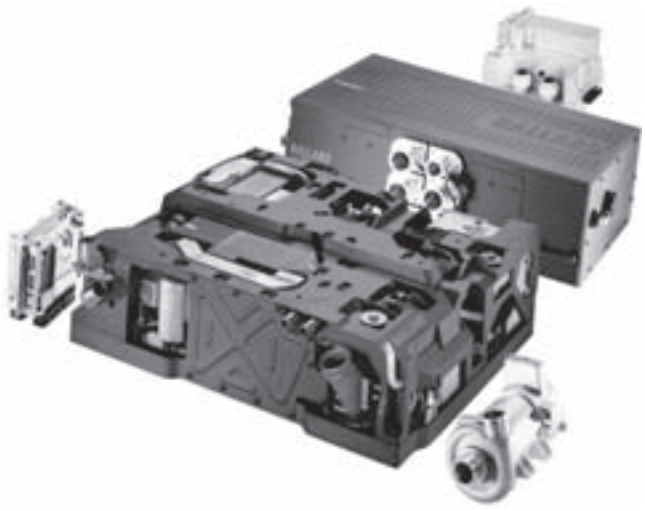

FIGURE 21.5.12 NuCellSys HY-80 Engine with Ballard Fuel Cell (Courtesy of Ballard)

FIGURE 21.5.13 PureMotion™ Fuel Cell Power Plant Installed in a Van Hool Bus (Courtesy of UTC Power)

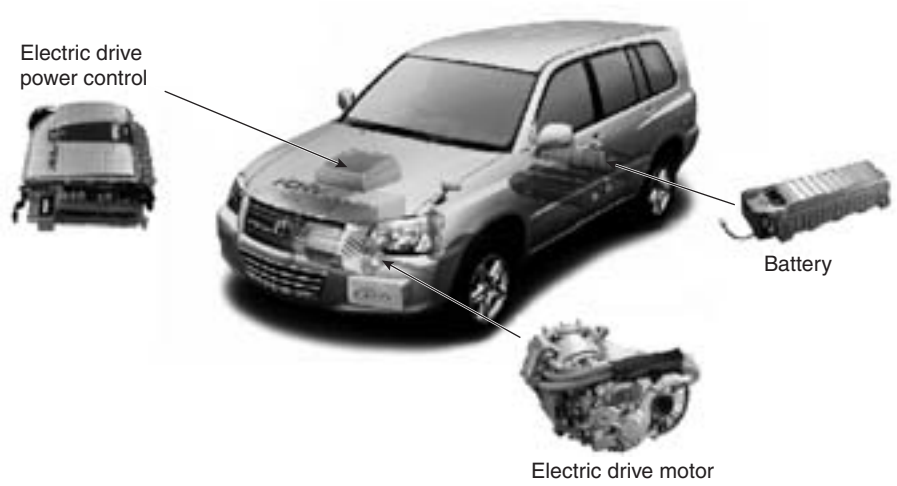

FIGURE 21.5.14 Key Components of the Electric Drive System in an FCV (Courtesy Toyota Motor Company)

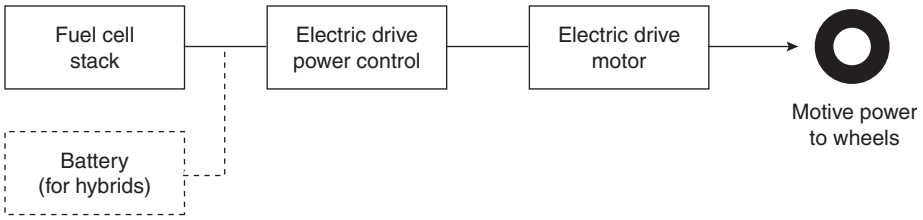

FIGURE 21.5.15 Simplified Schematic of the Electric Drive System

very similar to other electrical and hybrid vehicles, FCVs rely heavily on existing approaches from electric vehicles and hybrids to minimize hazards to vehicle occupants, repair workers, and emergency responders. Key elements of electrical safety include the following:

- *High voltage dielectric withstand capability.* Each high voltage system should demonstrate adequate dielectric strength of harnesses, bus bars, and connectors such that there is no indication of a dielectric breakdown or flashover after the application of voltage.[2,4]
- *Access to live parts.* An interlock, special fasteners, or other means should be provided on covers that are intended to prevent access to live parts with hazardous voltage.[2]
- *Electrical isolation.* Unlike low voltage circuits in vehicles that are bonded (or grounded) to the chassis of the vehicle, high voltage systems in current electric and hybrid vehicles as well as FCVs are isolated from the chassis. By so doing, the high voltage circuit can be touched in any single location without receiving an electric shock. This feature provides a second layer of protection in case the primary measures to prevent access to live parts are compromised by accident or repair activity.[2,3]
- *Fusing/overcurrent protection.* Like low voltage systems in vehicles, the high voltage system should be designed to prevent excessive current due to shorts or malfunctions from causing overheating and fires.[2,5]
- *High voltage wire identification.* High voltage cables and harnesses are visually identified with a permanent orange covering material (Figure 21.5.16).[2,6]
- *Labeling.* Hazardous voltage equipment or compartments containing hazardous voltage equipment should be identified

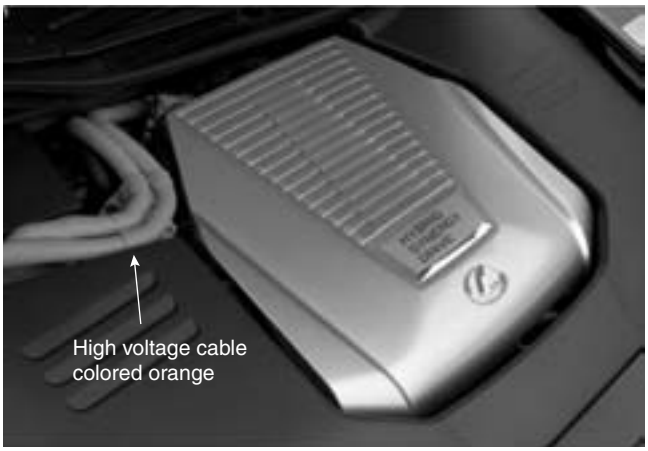

FIGURE 21.5.16 High Voltage Cable Identification as Shown Under the Hood of a Production Gasoline Hybrid Vehicle (Courtesy of Toyota Motor Company)

using the high voltage symbol, as shown in Figure 21.5.17, using black on a yellow background.[2,7]

- *Automatic disconnects.* An automatic disconnect function should provide a means of electrically isolating both poles of a fuel cell stack module, a traction battery, and other high voltage sources (if equipped) from external circuitry or components. This function would be activated by either the main switch or as an automatic triggering protection.[2]
- *Manual disconnects.* A means should be provided to disconnect both poles or de-energize the fuel cell module, a traction battery, and other high voltage sources (if equipped) from external circuitry or components. This function would be used for vehicle assembly, service, and maintenance operations.[2]

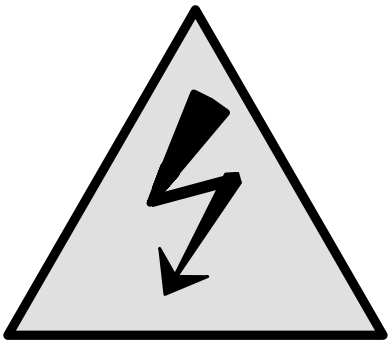

FIGURE 21.5.17 High Voltage Symbol

COMPRESSED HYDROGEN STORAGE SYSTEMS

Compressed hydrogen storage is the most common type of hydrogen storage on current FCVs. The technical challenge with compressed hydrogen is to store enough hydrogen on board the vehicle to achieve reasonable range between fuel refills. A typical FCV requires about 6 kg of hydrogen. To achieve this amount of hydrogen gas storage, manufacturers are increasing the storage pressures from the present level of 350 to 700 bar (5000 to 10,000 psig). Figure 21.5.18 illustrates a compressed hydrogen container installed on an FCV. A simplified process schematic for a compressed hydrogen system is shown in Figure 21.5.19.

FIGURE 21.5.18 Compressed Hydrogen Container in FCV (Courtesy of Toyota)

Functions and Features

Key functions and features of the compressed hydrogen storage system are as follows:

1. A filling receptacle on the vehicle is used to connect to the filling station. The receptacle (such as an SAE J2600 design[8]) typically has a check valve function built into the

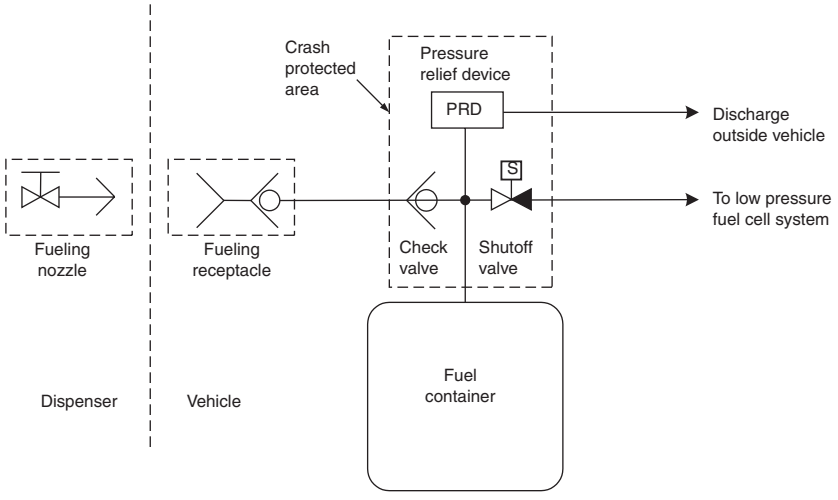

FIGURE 21.5.19 Compressed Hydrogen Storage System Process on FCVs

receptacle to prevent backflow leakage when the fill nozzle is disconnected. Additionally, there usually is a redundant check on the line between the nozzle and tank to meet design for safety requirements.
2. One or more containers on the vehicle store compressed hydrogen for use by the fuel cell.
3. Shutoff valves and pressure regulators are used to control the delivery of hydrogen to the fuel cells, as is done today with compressed natural gas vehicles.
4. One or more pressure relief devices (PRDs) are utilized to prevent tank burst in case the compressed hydrogen system is exposed to a fire due to an accident or other fault.

Safety Measures

The SAE is leading a cross-industry team of engineers from automotive, fuel cell, container, and component manufacturers, including technical experts from CSA (originally, Canadian Standards Organizations). The objective of this activity is to ensure the integrity of the hydrogen storage and fuel systems on the FCVs as well as other hydrogen vehicles that deliver hydrogen or hydrogen-rich gas to internal combustion engines. Guidance will be provided with regard to proper design and material selection. Systems-level, performance-based tests are being developed to demonstrate system integrity for normal operation and during fault management. The aim is to provide real-world system safety guidance while still facilitating rapid technology advances by the industry.

SAE recommendations for fuel cell and hydrogen vehicle safety are built on the excellent safety record for existing fuels. For example, labeling is very important for identifying unique items that are not on conventional vehicles and require special handling or awareness. Natural gas vehicles have historically been identified with a blue diamond with a "CNG" to convey to emergency responders and others that the fuel system on the vehicle is compressed natural gas. Based on the similarities to a natural gas fuel system, SAE has recommended vehicles with hydrogen fuel utilize a similar blue diamond. The difference with hydrogen vehicles would be that the diamond would indicate compressed hydrogen or another method used to store the hydrogen.

HYDROGEN SYSTEM SAFETY

Hydrogen is as safe as, if not safer than, other conventional fuels on the market today.[9] Experience has shown that hydrogen can be safely produced and transported; it has been in mass production and transportation for over 50 years in the United States. Ford Motor Company examined this issue under contract to the Department of Energy (DOE) and concluded in 1997 that "overall, [they] judge the safety of a hydrogen fuel cell vehicle system to be potentially better than the demonstrated safety record of gasoline or propane, and equal to or better than that of natural gas." A Norwegian study in 2002 reached a similar conclusion: "There are no technical or safety barriers that prevent the use of hydrogen for fuel in the transportation sector or as a medium for the storage and transportation of energy. It is possible to manufacture and utilize hydrogen just as safely as with today's gasoline systems."[10]

The automobile industry and government agencies have decades of experience in designing and testing for the safe use of fuels in motor vehicles. Fuels used in automobiles contain energy in a concentrated form. This same characteristic is why fuels must be handled appropriately. The past 100 years of experience with automobile fuels such as gasoline, diesel, and natural gas can be used and expanded upon for hydrogen as an automobile fuel.

The compressed hydrogen systems benefit from experience with compressed natural gas (CNG) and are designed to contain hydrogen and not burst. SAE is working to define performance-based standards for hydrogen systems designed to meet customer demand and use profiles of passenger and fleet vehicles.

Safety Measures

In the event that a leak does occur from the hydrogen system, SAE[2] has defined requirements to ensure that unintended hydrogen discharges do not cause a hazard within the vehicles. Discharges to any compartments within the vehicle that contain or may contain ignition sources are rendered nonflammable and the atmosphere in the passenger compartment is to be maintained nonhazardous through the use of active or passive barriers, dilution of potentially flammable gases, or the use of recombiners to eliminate flammable gases by catalytic reaction. If a leak is detected that exceeds the ability of these countermeasures to appropriately mitigate, then a staged warning and shutdown is executed following the guidance discussed in an earlier section (entitled "Fault Management") in this chapter.

Finally, vehicles are designed to protect the compressed hydrogen system during a crash. Typically, if a crash occurs, the hydrogen shutoff valves at the containers are closed to isolate the system, leaving only a small amount of hydrogen downstream of the shutoff valves as a minimal risk, given that the energy content is typically less than that in fuel lines on conventional gasoline vehicles. If the vehicle is exposed to a fire following the crash, pressure relief devices (PRDs) will thermally activate to release hydrogen and prevent a burst of the container.

Management of Discharges from FCVs

Successful commercialization of fuel cell and hydrogen vehicles requires that these vehicles be used in a manner consistent with current gasoline, internal combustion engine (ICE) vehicles. To achieve this objective, SAE[2] has defined recommended practices such that hydrogen vents, purges, leaks, and exhausts during operating and nonoperating states are consistent with usage in residential garages and commercial structures as well as general use outdoors and that safety is comparable to that presented by leaks and ruptures of fuel lines in present gasoline vehicles. To ensure that discharges are nonhazardous, the discharge is examined in two regions:

1. The local region where the discharge from the vehicle initially mixes with surrounding air
2. The atmosphere surrounding the vehicle after dispersal of the discharge

The local region where the discharges from the vehicle mix with the surrounding air should be locally unignitible at all times.

Discharges may be managed through dilution of potentially flammable gases, use of recombiners to eliminate flammable gases by catalytic reaction, or adjustment of process controls within the fuel cell or vehicle systems.

Hydrogen is potentially flammable in a gas mixture with oxygen and nitrogen (the primary constituents of air) when the concentration of hydrogen exceeds 4 percent (by volume) and the concentration of oxygen exceeds 5 percent (by volume). As shown in Figure 21.5.20, hydrogen discharges may or may not pass through regions of potential flammability during dispersal into the surrounding atmosphere, depending on the local concentration of hydrogen and oxygen concentration as the discharge mixes with the surrounding air. The situation is illustrated by two cases in Figure 21.5.20:

1. In the first case (indicated by the dotted line), the initial concentration of hydrogen is diluted to 5 percent with inerts before discharge. The discharge is always nonflammable as it mixes with surrounding air because the hydrogen concentration falls below 4 percent before the oxygen concentration reaches 5 percent.
2. In the second case (indicated by the dashed line), the initial hydrogen content is 100 percent at the point of discharge and a potentially flammable mixture is formed as the hydrogen mixes with surrounding air.

There is empirical evidence that discharges may not be ignitable even though the local concentration passes through the region of potential flammability. This is because the lower flammability limit (LFL) of hydrogen (4% in air) is based on testing a uniform mixture of gas in a quiescent state,[11] which is inconsistent with the mixing that occurs in the local region of discharge from the vehicle. Testing has shown that flow conditions and mixing during dispersal can actually suppress ignition and that hydrogen concentrations above 8 percent are typically required to ignite discharges.[12] A test method is being developed by the SAE to explore the areas of potential flammability (if they exist) with an ignition source. The objective of the test is to determine if there is a release of energy or the propagation of combustion into a standing flame that could represent a hazard to people or property. The local area of the discharge can therefore be demonstrated to be nonhazardous.

In order to complete the evaluation of hydrogen discharges from the vehicle, it is also necessary to look beyond the local region of discharge and evaluate the condition of the general atmosphere surrounding the vehicle. An approach was defined by the SAE[2] for assessing discharges when vehicles are being parked in residential garages[13] and being operated in mechanically ventilated commercial structures,[14] as well as when being operated out-of-doors.[15] The approach uses a combination of analysis and test for vehicle manufacturers to verify that the atmosphere surrounding the vehicle remains unclassified (see Article 500 of NFPA 70, *National Electric Code*®) and is therefore nonhazardous. By so doing, FCVs can be used and stored in the same manner as current gasoline-ICE-powered vehicles without modification to building codes.

Hydrogen Quality and Odorants

FCVs currently require a clean grade of hydrogen as a fuel. The industry is looking at a quality level that allows less than 1000 ppm of impurities. This is being done for several reasons. One reason is that a clean grade of fuel minimizes the buildup of noncondensable, nonhydrogen constituents. This buildup could reduce the operating efficiency of the fuel cell systems and result

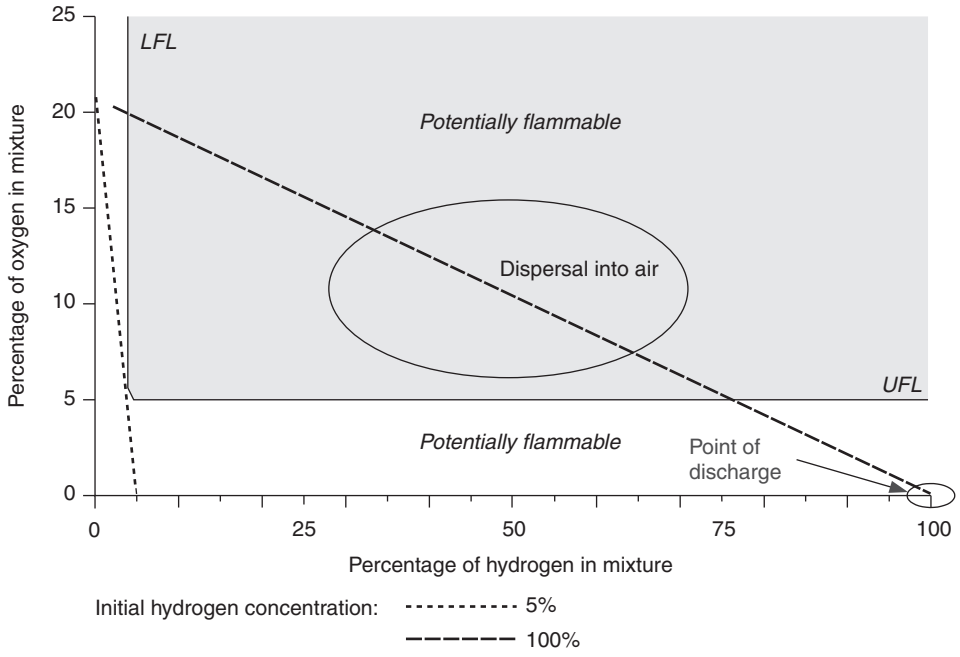

FIGURE 21.5.20 Potential Flammability of Hydrogen Discharges

in increased venting of hydrogen and these noncondensables. This venting would present additional emissions of flammable gases, which would have to be mitigated. Another reason is that some impurities are detrimental to both fuel cell components and fuel storage media. The removal of these impurities on the vehicle will add weight and cost to the vehicle, increase vehicle maintenance costs, and, in some cases, may not be technically practical.

Some parties have suggested odorizing the hydrogen fuel. Although this "low tech" approach has been used for nearly a century with natural gas, it is inconsistent with FCVs because fuel cells do not benignly consume (i.e., burn) the odorant as do internal combustion vehicles. The odorant either adversely reacts with components of the FCV or passes through the fuel cell system. If the odorant reacts with the system, the life and durability of the components will be severely limited. If it passes through the fuel cell system, it is concentrated by up to 500 times the original concentration in the hydrogen supply. This means that detection of a leak would be masked by the highly concentrated (and objectionable) odors emanating from the exhaust pipe.

Finally, the use of an odorant may be inconsistent with common types of hydrogen storage such as liquefied hydrogen and metal hydrides. With liquid hydrogen, for example, all compounds with the exception of helium are separated as solids at liquid hydrogen temperatures. This means that hydrogen could leak out of a containment system but the odorant would be retained inside the system, leaving the leaking gas not odorized and therefore not detected.

For these reasons, current FCVs are designed to operate with odorant-free fuel. As with a number of natural gas vehicle applications, if hydrogen is to be supplied to a filling station by pipeline, the fuel should be deodorized (if an odorant is present) before dispensing at the fueling station to hydrogen vehicles.

Vehicle Fueling

The commercialization of hydrogen fuel cell vehicles raises a "chicken-and-the-egg" question: Which comes first, mass-produced fuel cell vehicles or the hydrogen fueling infrastructure necessary to operate them? With a growing number of hydrogen fuel cell vehicles hitting public roads, the answer to this question may be getting clearer.

It is true that a supporting infrastructure for hydrogen fuel cell vehicles will be needed to make them practical. A fully integrated, fully deployed infrastructure is not, however, needed all at once. State and regional infrastructures are already planned and being developed. Recent examples include the California Hydrogen Highway and hydrogen station plans in the states of Florida and New York. Similar regional efforts are currently under way in Canada, Norway, Singapore, Germany, Japan, and other countries.[16]

These early hydrogen stations (Figures 21.5.21 and 21.5.22) serve to provide a limited infrastructure for fuel cell vehicle demonstrations and some commercial sales arrangements and also serve to research and demonstrate the various ways in which hydrogen can be produced and stored. The California Hydrogen Highway Plan serves to establish a baseline

FIGURE 21.5.21 Hydrogen Fueling Station in Oakland, California (Courtesy of Chevron)

FIGURE 21.5.22 Hydrogen Fueling Station in Washington, DC (Courtesy of General Motors)

network of hydrogen fueling and electrical generating stations along California's interstate highways by 2010. The hydrogen from these fueling stations will be from various sources, including renewables, such as renewable methanol and ethanol, and nonrenewables, such as natural gas.

In today's society, the use of gasoline as an automobile fuel has become so common that the safe handling of the fuel is practically engrained into the culture of users. While refueling their vehicles, users are aware of the precautions and operate in a certain manner, such as not running their vehicle and not smoking. Users often take for granted that fuel distribution systems have built-in safety features. For example, the prevention of static electricity is designed into both the vehicle and the refueling station[2,17] (see NFPA 77, *Recommended Practice on Static Electricity*). Vehicles are designed to maintain a conductive path from the fueling neck to the tires. The refueling station is designed in a manner that a conductive path exists from the

tire contact surface to the fueling nozzle. The result is a bonding and grounding path that prevents sparks that could ignite gasoline during filling. The countermeasures developed for gasoline fueling have been adapted to hydrogen fueling.

FCVs and other hydrogen vehicles will also depend on the filling station and dispenser to provide the following additional protective measures during vehicle filling[18] (see also NFPA 52, *Vehicular Fuel Systems Code*):

- Overpressure protection of the hydrogen storage system on the vehicle by relief valves on the filling station set to 1.38 times the nominal working pressure (service pressure)
- Provision for leak detection
- Emergency shutoff of hydrogen if a fault is detected
- Breakaway protection if the vehicle moves before the fueling nozzle is disconnected

Vehicle Maintenance and Service

Existing model building codes already address requirements for facilities conducting repairs on vehicles (NFPA 30A, *Code for Motor Fuel Dispensing Facilities and Repair Garages*). These requirements are adequate for FCVs, as long as work on the hydrogen storage system is not being conducted.

Additional countermeasures should be considered for areas conducting work on the hydrogen storage systems. For example, a vent system will probably be required to defuel (depressurize and purge) the hydrogen storage system on the vehicle before major repairs are conducted. Additionally, requirements for ventilation, gas and fire detection, electrical classification, HVAC interconnection with other areas of the building, and fire rating of interior walls and doors should be considered, following standard practices for hydrogen systems[19] (see also NFPA 52).

POSTCRASH CONSIDERATIONS

Fuel cells vehicles will be expected to have crashworthiness that is equivalent to or better than current motor vehicles, and the SAE Fuel Cell Standards Committee is developing standards that will allow vehicle manufacturers to evaluate their designs and demonstrate that expectations are fulfilled. In this regard, there are two keys to FCV safety following a crash.

The first postcrash consideration is that occupants or emergency responders must not be exposed to electrical shock hazards. The SAE Fuel Cell Committee has updated SAE J1766 for electrical safety following a crash to account for the unique characteristics of fuel cells and modern hybrid electric drive trains. High voltage electrical circuits are to be discharged or appropriately isolated from ground such that circuits can be touched without receiving a harmful shock.[3]

The second postcrash consideration is that the hydrogen fuel needs to be contained. Crash standards for both gasoline and compressed natural gas (CNG) vehicles were reviewed by the SAE Fuel Cell Standards Committee, and an approach was defined to demonstrate that compressed hydrogen systems will retain their contents and thereby minimize exposure to potentially hazardous events.[2]

Additionally, the fuel system needs to protect against secondary events (such as fire from another vehicle) following the accident. CNG vehicles use pressure-relief devices (PRDs) to vent gas in the event of a fire. By so doing, the fuel tanks can be depressurized by venting fuel, and a potentially hazardous event, such as a container burst, can be avoided. Fuel cell vehicle manufacturers have already adopted this practice, and the SAE Fuel Cell Standards Committee is addressing postcrash situations as part of new standards being developed.

FUEL CELL ORGANIZATIONS AND INITIATIVES

U.S. Fuel Cell Council

The U.S. Fuel Cell Council is the industry association of the fuel cell industry. The council's membership includes producers of all types of fuel cells, major suppliers, automakers, universities, fuel cell customers, hydrogen suppliers, government entities and national laboratories, and other associations. Formed in 1998, the U.S. Fuel Cell Council provides its members with an opportunity to develop industrywide policies and procedures, work with codes and standards developers, conduct education and marketing activities for the fuel cell industry, and collaborate on a wide range of technical subjects.

The U.S. Fuel Cell Council is dedicated to commercializing fuel cell technology. Members of the U.S. Fuel Cell Council are spending their own resources to achieve this goal and are also partnering with government initiatives.

Fuel Cell Initiatives

Two high profile examples of government initiatives are the FreedomCAR Partnership and the California Fuel Cell Partnership (CAFCP).

FreedomCAR Partnership. The FreedomCAR Partnership is a collaboration between the U.S. Department of Energy (DOE), the United States Council for Automotive Research (USCAR), and five large energy providers. The goal of this organization is "the development of emission- and petroleum-free cars and light trucks." The focus is on the high-risk research needed to develop the necessary technologies, such as fuel cells and advanced hybrid propulsion systems, to provide a full range of affordable cars and light trucks that are free of harmful emissions and that do not sacrifice freedom of mobility and freedom of vehicle choice. The FreedomCAR Partnership is not designed to produce any particular vehicle, but rather to accelerate the adoption of advanced automotive technologies. The program has established technology goals to be reached by 2010 in order to target areas for research and development.

California Fuel Cell Partnership (CAFCP). The California Fuel Cell Partnership (CaFCP) is a unique collaboration of auto manufacturers, energy companies, fuel cell technology companies, and government agencies. This organization is demonstrating hydrogen vehicle technology that could move the world toward practical and affordable environmental solutions.

In addition to demonstrating fuel cell vehicles, the CaFCP is examining fuel infrastructure issues and beginning to prepare the California market for this new technology.

Three California transit agencies have a few demonstration sites: Sunline Transit Agency in Coachella Valley, Santa Clara Valley Transportation Authority in Silicon Valley, and AC Transit in Northeast San Francisco Bay. In addition, Santa Clara VTA and AC Transit opened hydrogen fueling stations for their fleets in 2005. For more information see http://www.cafcp.org.

SUMMARY

Fuel cell vehicles (FCVs) are being developed in response to the worldwide need to lower emissions and decrease dependence on oil. A risk-based approach has been used to identify both electrical and fuel system hazards on FCVs, and approaches to mitigate these hazards have been and are being developed based on past automotive experience and sound engineering practice. Overall, a philosophy of mitigating credible single-point failures was utilized as a minimum standard.

Because the electrical system of a fuel cell vehicle is very similar to that of other electrical and hybrid vehicles, the practices and requirements rely heavily on previously published work in these areas. Correspondingly, hydrogen requirements are based on previous experience with gasoline and compressed natural gas (CNG) internal combustion vehicles with appropriate adjustments and expansions for fuel cell propulsion. The overall objective is to establish recommended practices such that FCVs can be used and stored in the same manner as conventional gasoline, internal combustion vehicles while still facilitating rapid advances by the industry.

Overview of Recreational Vehicles
Recreational Vehicle Development and Use
Development of Recreational Vehicle Standards
Recreational Vehicle Fire and Life Safety

Key Terms

motor home, recreational vehicle, towable

Recreational vehicles (RVs) have been around since the beginning of motorized travel in the early 1900s. RVs are available in several styles, types, and sizes to offer people of all ages the opportunity to camp and travel to points of interest or special events and otherwise enjoy the great outdoors. Today nearly 8 million U.S. households own at least one RV—a 15 percent increase over the 4 years from 2001 to 2005 and a 58 percent rise since 1980, according to the 2003 edition of *Industry Profile: RVIA Year End Report.* One in twelve U.S. vehicle-owning households now owns at least one RV.[1]

This chapter discusses the types of recreational vehicles and their features, the development and use of RVs, the development of RV standards, the fire and life safety issues associated with RVs, their fire safety record, and the oversight programs that are in place to assist RV industry manufacturers in the safe production of these vehicles for recreation, travel, and seasonal use.

For related topics, see Section 21, Chapter 1, "Passenger Vehicle Fires"; and Section 21, Chapter 4, "Vehicle Fueling Using Gaseous Fuels."

OVERVIEW OF RECREATIONAL VEHICLES

Recreational Vehicle Defined

Based on the NFPA 1192, *Standard on Recreational Vehicles,* definition as refined by the Recreation Vehicle Industry Association (RVIA), a recreation vehicle (RV) is defined as a vehicle that combines transportation and temporary living quarters for travel, recreation, and camping. RVs may have their own motor power (as in the case of motor homes), may be mounted (as are truck campers), or may be towed by another vehicle (as are travel, fifth-wheel, and folding camping trailers). Not included in the RV definition are conversion vehicles, off-road vehicles, emergency living units, and manufactured housing for long-term residence (i.e., park trailers and mobile homes).

Types of Recreational Vehicles

The two main categories of RVs are *motor homes* (motorized RVs) and *towables* (RVs towed behind the family car, van, or pickup).[2]

Motor Homes. A motor home is a vehicle built on or as an integral part of a self-propelled motor vehicle chassis. It may provide kitchen, sleeping, and bathroom facilities, and it may be equipped with the ability to store and carry fresh water and sewage. Type A motor homes (Figure 21.6.1) are generally the largest, where the driving compartment is built by the RV manufacturer; Type B motor homes (Figure 21.6.2), or van campers, are the smallest and are built on vehicles where the chassis manufacturer provides the driving compartment and the entire exterior shell; and Type C motor homes have the driving compartment provided by the chassis manufacturer (Figure 21.6.3) and generally fall in between these two in size (see Table 21.6.1).

Bruce A. Hopkins is the vice-president of standards and education for the Recreation Vehicle Industry Association (RVIA) in Reston, Virginia. Mr. Hopkins has worked in the area of RV standards for 34 years, 28 of these with RVIA. He has been directly associated with the RV industry for over 40 years.

FIGURE 21.6.1 Type A Motor Homes—Generic Model and Actual Example (Source: Courtesy of RVIA)

FIGURE 21.6.2 Type B Motor Homes—Generic Model and Actual Example (Source: Courtesy of RVIA)

FIGURE 21.6.3 Type C Motor Homes—Generic Model and Actual Example (Source: Courtesy of RVIA)

Towables. A towable RV is designed to be towed by a motorized vehicle (e.g., auto, van, or pickup truck) and of such size and weight as not to require a special highway movement permit. It does not require permanent on-site hook-up. Types of towable RVs are conventional travel trailers (Figure 21.6.4), sports utility RVs (Figure 21.6.5), travel trailers with expandable ends (Figure 21.6.6), fifth-wheel travel trailers (Figure 21.6.7), folding camping trailers (Figure 21.6.8), and truck campers (Figure 21.6.9).

Construction Techniques

RVs are manufactured on production lines similar to that of the automobile industry, but only a few RV manufacturers use fully automated assembly lines. In a typical RV manufacturing facility, the vehicles are generally pushed manually along the assembly line. The stations within a typical production line might include chassis, floors, interior walls, cabinetry, roofs and exterior coverings, installation of electrical/plumbing/propane-

TABLE 21.6.1 Recreational Vehicle Types and Features

Type	*Features*	*Sleeps*	*Price Range*
Motor home—Type A	• Constructed on a specially designed motor vehicle chassis • Kitchen, sleeping, bathroom, living facilities accessible from driver's area	2–6	$76,275–$1,350,000
Motor home—Type B (or van camper)	• Referred to as a "van camper" • Panel-type truck with kitchen, sleeping, and/or bathroom facilities • Freshwater storage, city water hook-up, and top extension for more head room	2–4	$41,000–$72,660
Motor home—Type C	• Constructed on automotive manufacture van frame with attached cab • Kitchen, sleeping, bathroom facilities • Living area behind and above cab	6–10	$48,450–$298,910
Towable—conventional travel trailer	• Towable by car, van, or pickup • Kitchen, sleeping, bathroom, dining, living facilities • 12–35 ft (3.66–10.67 m) long	4–8	$8,085–$79,510
Towable—sport utility RV	• Built-in "garage" for cycles, ATVs, other sports equipment	Up to 8	$21,000–$58,000
Towable—travel trailer with expandable ends	• Built for "fresh air" experience • Folds for lightweight towing	Up to 8	$9,000–$18,000
Towable—fifth-wheel travel trailer	• Equipped same as conventional travel trailer • Raised forward section, allowing bilevel floor plan • Towable by vehicle equipped with fifth-wheel hitch	Up to 8	$10,870–$120,350
Towable—folding camping trailer	• Lightweight with collapsible sides • Towable by family vehicle (even some compacts) • Kitchen, sleeping, dining, (often) bathroom facilities	Up to 8	$4,380–$12,800
Towable—truck camper	• Loaded onto bed or chassis of truck • Most with kitchen, sleeping, dining, bathroom facilities	2–6	$4,580–$22,590

fuel systems, installation of appliances or furniture, final finish, and testing.

RECREATIONAL VEHICLE DEVELOPMENT AND USE

History

Early Years. The recreational vehicle industry developed and grew from its early roots in camping, hunting, and other outdoor activities.[3] Tents, provisions, and cooking and sleeping equipment were loaded and pulled around the countryside on wagons, carts, and other conveyances long before the advent of the automobile.

The development of the automobile in the years around 1900 greatly increased the range of these campers and vagabonds, and mechanical power made it easier for them to take more supplies and comforts along on their adventures. Early "auto campers" simply piled their tents, equipment, and supplies in and on their vehicles. Later, they attached carts and trailers to the cars, increasing carrying capacity greatly. The earliest trailers were often modified horse-drawn carts with wooden cartwheels. The cartwheels were shortly replaced with heavier auto-type wheels. This relative ease of travel, with all the needed camping supplies, brought about the beginnings of what is now recognized as the RV industry and its related lifestyle.

In the early 1910s, trailers were being built not only to transport camping supplies and equipment, but to also be used as "house trailers," or mobile cabins. These earliest units, mostly homemade or custom built by local handymen or carriage makers, allowed for the storage of provisions, preparation of meals, and comfortable and relatively "bug-proof" sleeping. "Living rooms" and most daytime activities were relegated to the great outdoors.

From the mid-1910s to the mid-1920s, individual builders were creating one-of-a-kind "house cars" by motorizing their camping vehicles. Some were permanently built on auto or truck chassis; others were bolt-on structures added to a rigid frame and could be removed and exchanged. It is estimated that 15 million campers and RVers were on the nation's roads in 1922. In 1926, the Chenango Camp Trailer Co. introduced the first

FIGURE 21.6.4 Conventional Travel Trailers—Generic Model and Actual Example (Source: Courtesy of RVIA)

FIGURE 21.6.8 Folding Camping Trailers—Generic Model and Actual Example (Source: Courtesy of RVIA)

FIGURE 21.6.9 Truck Campers—Generic Model and Actual Example (Source: Courtesy of RVIA)

assembly-line-produced travel vehicle, a fold-up tent trailer. A few other manufacturers followed, offering multiple units for sale, and the rush was on.

The rapid growth in numbers of these early "auto campers" and their demands for safe and scenic places to camp and enjoy the outdoors were a primary motivation for the development and early growth of the U.S. National Park system in the early 1920s. City- and county-operated camping sites were also becoming popular in the early 1920s as communities began to realize that the travelers, in most cases, brought money with them and would spend it with local businesses.

The economic disaster of the 1929 stock market crash slowed the rise of the new industry, but not for long. By the mid-1930s, one manufacturer, The Covered Wagon Company of Mt. Clemons, Michigan, was building 40 to 50 units per 8-hour shift from a single factory. Industry production records indicate that, in 1936, one-sixth of the nation's total recorded trailer production came from that single Detroit area factory.

By 1939, there were well over 100 manufacturing companies and an even larger body of suppliers and parts distributors active in the rapidly growing trailer coach industry. Associations of manufacturers were becoming organized, and national and international organizations of trailer owners were proving to be very popular.

The earliest activity of NFPA in the field of mobile homes and recreational vehicles was the formation of the NFPA Committee on Trailers and Trailer Camps in 1937. The first standard was adopted in 1940 and revised in 1952.

Local and national retail and wholesale trailer shows were being organized. The Tin Can Tourists of the World, organized in 1919, had become by far the largest of the consumer groups, with hundreds of thousands of members from the United States and Canada. In 1936 a Tin Can Tourists rally recorded well over 1000 units and nearly 3000 participants in attendance and hosted one of the first large retail shows.

World War II to the Present. World War II caused a second major pause in the dynamic growth of the RV industry, primarily due to very strict material rationing and the conscription of many potential customers and workers. Some manufacturers converted their production to various war-related items and others produced units as temporary housing for workers at war production facilities and military bases. The late 1940s and early 1950s saw a great burst of technological advances and living comforts for trailers, such as portable propane or butane cylinders, allowing gas stoves and heaters to replace liquid-fueled models, on-board refrigeration replacing ice boxes for food preservation, hot and cold running water, as well as on-board

toilets, showers, and 110-volt generators. With this growth came concerns regarding the safe installation of living systems, such as plumbing, LP-gas, and electrical. In the late 1950s, California introduced RV safety standards for the living systems and initiated a state-sponsored oversight program to ensure compliance. Many other Western states followed suit, often creating similar criteria, yet different enough to make manufacturing for multiple markets difficult.

Continued growth in the 1960s brought hundreds of new companies (many of today's industry giants) into the industry, as the baby boomers began to grow up and look for inexpensive recreational opportunities for their young families. In 1963, the Mobile Homes Manufacturers Association and the Trailer Coach Association worked together to create the *American Standard Installations of Plumbing, Heating and Electrical Systems in Travel Trailers* (A119.2–1963).

The growth of the RV industry, up to this point mostly trailer-based, was further enhanced with the advent and availability of affordable, assembly-line-produced motor homes. The development of modern pickup trucks also enabled the creation and popularization of the slide-in pickup carried campers and related Type C motor homes, which today are built mostly on van chassis rather than the original pickup truck chassis.

In the late 1960s, recognizing that these new motorized type products, different from travel trailers, were not included in the safety standards (A119.2-1963), the Mobile Homes Manufacturers Association, the National Fire Protection Association, the Recreational Vehicle Institute, and the Trailer Coach Association jointly sponsored the development of ANSI A119.2 and NFPA 501C, *A Standard for Recreational Vehicles,* 1970 edition. This standard also covered installation of plumbing, heating, and electrical systems. Additionally, definitions were added to clearly identify the product types known today as motor homes, travel trailers, camping trailers, and truck campers. This standard also assisted in defining the separation between mobile homes and recreational vehicles.

That 1960s boom in RV industry growth and the dramatic explosion of affordable motorized units was again nearly destroyed by the embargo-based fuel shortages and astronomically high interest rates of the 1970s, when almost half of the industry manufacturers either went out of business or merged into some of today's industry giants. Through the 1970s, the lifestyle was still primarily referred to as *camping,* and the rigs, whether motorized or towed, continued to be identified as *campers,* as they had been for over 50 years.

In the early 1980s, another dynamic change brought complete livability to the units. Many people with little interest in purely camping and nature-based outdoor activities became attracted to longer and larger rigs with living room space and the availability of features such as couches, recliners, TV, VCR, air-conditioning, and other homelike comforts. The lifestyle known today as RVing began to partially replace camping as the travel attraction, with many retirees and some families with itinerant-type jobs selling their real estate–based homes and residing full time on the road. Destination-oriented trips and not just family jaunts to favorite campsites became popular. This alteration in comforts and conveniences made the growth in popularity of "full-timing" possible. This change also forced the evaluation of fire safety standards developed in the late 1970s and adopted for the first time in the NFPA 501C and ANSI A119.2, *Standard for Recreational Vehicles,* in 1982. These requirements addressed interior finish, textile and film material flammability, exit facilities, fire detection equipment, and smoke alarms.

From the 1930s through the 1950s and into the early1960s, unit lengths were usually less than 20 ft (6.1 m) with 12 to 15 ft (3.66 to 4.57 m) long units very common. Most of the motorized as well as the towable units of the 1960s were less than 25 ft (7.62 m) long. With the improvement of both vehicles and highways, unit length began to grow through the 1970s, with RVs evolving into the common 30 to 40 ft (9.14 to 12.19 m) long units of today. It was this increase in length that allowed the addition of more homelike features to today's RVs.

Early unit pricing varied as widely as do prices today. Entry-level towable trailers in the Depression days of the 1930s were primarily sold in the $250 to $400 range with luxury trailers ranging as high as $1000. At the same time, luxury fifth-wheel rigs (which were often sold with a matching tow vehicle included) and "land yacht" motorized "house cars" up to 35 ft (10.67 m) long were being sold for $25,000 and up.

Today's RV lifestyle has come a long way from its earliest roots in the camping activities of the horse-and-buggy days and the early auto campers through the trailerites and Tin Can Tourists of the 1920s, 1930s, and 1940s. The medium-sized campers of the 1950s and 1960s began the move to modern conveniences and comforts, but the upsizing of vehicles and the resulting larger units of the 1970s and 1980s allowed campers to become RVers and made today's luxury RV lifestyle possible. This has attracted a completely new group of participants whose primary interest is not in camping and basic wilderness outdoor activities, but who enjoy the many benefits of self-contained travel both temporarily and full time.

From 1987 to 2005, NFPA 501C and ANSI A119.2 were updated every 3 years in an effort to harmonize safety and technology. Most of the changes through the mid-1990s were minor revisions and definitional improvements but also included substantive changes, such as requirements for increased exit sizes, requirements for carbon monoxide and LP-gas detectors, and provisions for RVs used for transporting or storing internal combustion vehicles. In 2005, NFPA 501c and ANSI A119.2 were combined to become NFPA 1192, *Standard on Recreational Vehicles.*

RV Ownership

U.S. ownership of RVs has reached record levels, according to a 2005 University of Michigan study.[4] Nearly one in twelve U.S. vehicle-owning households now owns an RV, almost 8 million households, or, as mentioned earlier, a 15 percent increase from 2001 to 2005 and a 58 percent gain from 1980 through 2005. The number of RV deliveries is also increasing, as seen in Table 21.6.2.[5]

Approximately 8.2 million RVs are on the nation's roads. RVIA, the national trade association for RV manufacturers and their component suppliers, estimates there are as many as 30 million RV enthusiasts, including RV renters, nationwide.

TABLE 21.6.2 Recreational Vehicle Shipment Totals, 1994–2006

Year	*Shipment*
1994	259,200
1995	247,000
1996	247,500
1997	254,500
1998	292,700
1999	321,200
2000	300,100
2001	256,800
2002	311,000
2003	320,800
2004	370,100
2005	384,400
2006	390,500

DEVELOPMENT OF RECREATIONAL VEHICLE STANDARDS

Early NFPA RV Standards

The earliest activity of NFPA in the field of mobile homes and recreational vehicles was the formation of an NFPA Committee on Trailers and Trailer Camps in 1937. Its first standard, adopted in 1939, established a general overall outline of regulations for trailer camps. This edition was supplanted by the 1940 *Standard for Trailer Coaches and Trailer Coach Camps,* which expanded the requirements and addressed trailer vehicle construction, safety features pertaining to trailers in transit, and the regulation of trailers while not in transit. The standard, which applied to trailer coaches used as living quarters or for sleeping purposes, defined *trailer coach* as any structure intended for human habitation, mounted on wheels, and capable of being moved from place to place.

In 1952 the standard was revised into two parts and renamed *Standard for Fire Prevention and Fire Protection in Trailer Coaches and Trailer Courts.* Part A of this revised standard applied to trailer coaches intended for use as living quarters or for sleeping purposes. This part of the standard extended to awnings, porches, lean-tos, or other structures and equipment of a portable character designed to be carried in, on, or with the trailer and installed, assembled, or erected as appurtenances to the trailer when parked. Any structures built permanently in place in conjunction with a trailer were not considered as part of the trailer but considered as buildings and subject to the provisions of the building codes or other requirements.

Part B applied to trailer courts accommodating or providing a parking space for more than one trailer coach used for living or sleeping purposes. This part was limited to provisions affecting fire protection and prevention and was intended to be supplemented by municipal sanitary and public health codes. In addition, the standard recognized that local building codes were to be enforced if the wheels of a trailer were removed, if a trailer was permanently blocked up, or if the space beneath it was enclosed.

In 1960 NFPA approved a revised version of the standard, dividing it into two separate standards. NFPA 501A, *Standard for Fire Protection in Trailer Courts,* consisting of Chapters 10 through 19 of the 1952 standard, covered trailer courts intended to accommodate trailers designed (or intended) for living quarters. In 1961 NFPA 501B, *Standard for Fire Prevention and Fire Protection in Mobile Homes and Travel Trailers,* consisting of Chapters 1 through 9 of the original 1952 standard, was finalized.

In the early 1960s the Mobile Homes Manufacturers Association (MHMA) and the Trailer Coach Association (TCA) prepared, under the aegis of the American Standards Association (now American National Standards Institute, or ANSI), two standards that were subsequently approved as the *American Standard Installations of Plumbing, Heating and Electrical Systems in Travel Trailers* (A119.2–1963) and *Standard for Fire Prevention and Fire Protection in Mobile Homes and Travel Trailers* (A119.1–1963). In 1969 the Recreational Vehicle Institute (RVI) was added to the MHMA, NFPA, and TCA as a fourth cosponsor of the project. The first *Standard for Recreational Vehicles* developed under the consolidated efforts of NFPA, MHMA, TCA, and RVI was approved by NFPA in 1970 and by ANSI in 1971. This standard replaced ASA Standard A119.2–1963. In 1975 the MHMA and the TCA merged to become the Manufactured Housing Institute. Also in 1975 the Recreational Vehicle Institute absorbed the Recreational Vehicle Division of the Trailer Coach Association and was redesignated the Recreation Vehicle Industry Association.

This time period also saw the publication of two other NFPA standards: NFPA 501C, *Standard for Recreational Vehicles Installation of Plumbing, Heating and Electrical Systems,* and NFPA 501D, *Electrical Standard for Recreational Vehicle Parks.* Under various formats and titles, subsequent editions of the NFPA 501 series were published from 1972 through 1977, with only minor changes.

After 1977 NFPA withdrew as a cosponsor of the existing ANSI project and established its own ANSI-approved project, covering only the subject of fire safety for recreational vehicles. This committee, charged with developing a standard for fire safety for recreational vehicles and recreational vehicle parks, produced and revised three standards through the 1980s: NFPA 501A, *Standard for Fire Safety Criteria for Manufactured Home Installations, Sites, and Communities;* NFPA 501C, *Standard on Recreational Vehicles;* and NFPA 501D, *Standard for Recreational Vehicle Parks and Campgrounds.* These standards excluded all sections of the previous editions not considered within the committee scope, primarily plumbing and sanitary issues.

The standards continued through the 1990, 1993, and 1996 editions with only minor changes, including the size of alternate exits, clothes dryers, LP-gas detectors, and the expansion of provisions for recreational vehicles used for transporting or storing vehicles with internal combustion engines.

NFPA 1192, *Standard of Recreational Vehicles,* and NFPA 1194, *Standard for Recreational Vehicle Parks and Campgrounds*

In 1999 NFPA 501C was renumbered as NFPA 1192, *Standard on Recreational Vehicles,* and the requirements on LP-gas containers and connectors were updated. Changes also included modifications to requirements for exit facilities and special transportation provisions. Similarly, NFPA 501D was renumbered as NFPA 1194, *Standard for Recreational Vehicle Parks and Campgrounds.* NFPA 501A continues, most recently updated in 2005.

In 2002 there was a major editorial reorganization of both NFPA 1194 and NFPA 1192 in accordance with the NFPA *Manual of Style,* 2002 edition. Other changes occurred in the language of caution and warning labels.

In 2005 NFPA and RVIA once again merged the requirements from ANSI A119.2 into NFPA 1192, and ANSI A119.2 was no longer published. NFPA 1192 now contains minimum requirements for the installation of plumbing, fuel burning, electrical, and other safety-related systems in recreational vehicles. Technical changes to the standard include clarification of requirements for location and securing of propane containers, requirements for high-pressure piping, revision of requirements for fuel tank installation, and the inclusion of requirements for automatic generator starting systems.

NFPA 1192 Requirements. The following partial table of contents of NFPA 1192 shows the scope of this standard, which covers the fire and life safety criteria for recreational vehicles:

Chapter 4 General Requirements

4.1.1 Differing Standards
4.1.2 U.S. Federal Regulations
4.1.3 Exterior Labels
4.1.4 Electrical Requirements

Chapter 5 Fuel Systems and Equipment

5.1 Quality of Design and Installation
5.2 Propane Systems
5.3 Propane Piping Systems
5.4 Fuel-Burning Appliances
5.5 Venting, Ventilation, and Combustion Air
5.6 Marking Appliances (Installation and Operation Features)
5.7 Circulating Air Systems for Heating (Other Than Automotive Type)
5.8 Air Conditioning (Other Than Automotive Type)
5.9 Consumer Information
5.10 Gasoline or Diesel Fuel Systems
5.11 Propane Vehicle Propulsion Engine Installations

Chapter 6 Fire and Life Safety Provisions

6.1 Interior Finish and Textile or Film Materials
6.2 Recreational Vehicle Exit Facilities
6.3 Fire Detection Equipment
6.4 Other Considerations
6.5 Automatic Generator Starting System (AGS) Requirements

Chapter 7 Plumbing Systems

7.1 Plumbing System
7.2 Plumbing Fixtures
7.3 Water Distribution Systems
7.4 Drainage Systems
7.5 Waste Holding Tanks
7.6 Vents and Venting
7.7 Plumbing System Tests

NFPA 1194 Requirements. NFPA 1194, *Standard for Recreational Vehicle Parks and Campgrounds,* provides minimum construction requirements for safety and health for occupants using facilities supplied by recreational vehicle parks and campgrounds that offer temporary living sites for use by recreational vehicles, recreational park trailers, and other camping units. The following partial table of contents of NFPA 1194 shows the scope of this standard:

Chapter 4 General Requirements

4.1 Differing Standards
4.2 U.S. Federal Regulations
4.3 Electrical Requirements
4.4 Wildland/Urban Interface Areas
4.5 Recreational Park Trailers

Chapter 5 General Design Criteria for Recreational Vehicle Parks and Campgrounds

5.1 Park Design and Construction
5.2 Recreational Vehicle Site
5.3 Recreational Park Trailer Site
5.4 Camping Unit Site

Chapter 6 Fire Safety

6.1 Fire Detection and Alarm Services
6.2 Fire Safety Rules and Regulations for Recreational Vehicle Parks and Campgrounds—Posting of Emergency Information

Chapter 7 Environmental Health and Sanitation

7.1 General
7.2 Potable Water Supply and Distribution
7.3 Potable Water Connections at Individual Sites
7.4 Drinking Fountains
7.5 Sanitary Conveniences
7.6 Number, Location, and Arrangement of Toilets, Urinals, and Lavatories
7.7 Showers
7.8 Sewerage Facilities
7.9 Sanitary Disposal Stations
7.10 Potable Water Supply Stations
7.11 Refuse Disposal

RECREATIONAL VEHICLE FIRE AND LIFE SAFETY

Safety and Fire Data

As the industry has matured, so have its safety efforts. Over the years, RV safety has expanded. Interiors now have fire retardant

requirements, fire extinguishers, propane detectors, CO detectors, and smoke alarms. The exit facilities have increased in size and their markings have improved to help occupants exit RVs in dangerous situations.

Fire and Life Safety Issues

Reasons for Decrease in Fatalities. Why deaths in RVs due to fire decreased between 1993 and 2002 is difficult to determine because records are limited and also because the manner of classifying vehicles in police accident reports is inconsistent. RVs are sometimes reported as mobile homes or manufactured homes, and motor homes and trailers are often referred to by brand names, such as Airstreams or Winnebagos, regardless of whether they are towable or motorized RVs. Also, other vehicles such as all-terrain vehicles and dune buggies are reported and documented as RVs, skewing the data available. All these reporting variables prevent the emergence of a true picture of how RVs perform over a specific period of time and of which factors affect the data.

RV Standard Changes Affecting Fire Safety Results. Some changes to the RV standards, beginning with the 1993 edition of NFPA 501C, that could be credited for enhanced fire and life safety resulting in fewer deaths by fire might include the following:

- The provisions for portable fire extinguishers mandated a size increase from 4B:C to 5B:C for towable RVs and later added the requirement for motorized RVs to have a 10B:C fire extinguisher.
- Carbon monoxide detectors were required in all RVs equipped with an internal combustion engine or designed with features to accommodate future installation of an internal combustion engine.
- Propane detectors were required in all RVs equipped with propane appliances and 120 volt ac systems.
- Emergency exit openings were increased in size and exit markings were added.
- Propane containers were required to be shielded from exhaust components and other high-heat sources.
- RVs designed for the transportation of internal combustion engine–type vehicles inside the RV required the transport area to have ventilation and vaportight separation from the living area, as well as requiring consumer information to be provided for guidance relating to fire and life safety.
- Low-voltage wire was required to have a minimum insulation rating of 90°C for interior applications and 125°C in an engine area.
- 30 A power supply assemblies were limited to a maximum of five branch circuits.
- RVs were required to have listed low-voltage lighting fixtures to reduce heat buildup at their mounting surfaces.
- Receptacles serving countertops with sinks were required to be provided with ground-fault circuit interrupter (GFCI) protection.
- RVs were limited to only one power supply assembly instead of two.

RV Manufacturer Compliance with Codes and Standards

The Recreation Vehicle Industry Association (RVIA), the national trade association representing more than 550 manufacturers and component suppliers that produce approximately 98 percent of all RVs and conversion vehicles manufactured in the United States, is headquartered in Reston, Virginia. Consumers shopping for an RV often look for the RVIA seal prominently displayed on the exterior of an RV. The seal means the manufacturer certifies compliance with more than 500 electrical, plumbing, heating, and fire and life safety requirements established under NFPA 1192. The oval-shaped RVIA seal comes in three colors, depending on RV type:

- Gold ovals with the word "MOTORHOME" for all Type A, B, and C motor homes
- Silver ovals with the words "TRAVEL TRAILER • FIFTH-WHEEL" for all conventional, hybrid, and fifth-wheel travel trailers
- White ovals with the words "TRUCK CAMPER • FOLDING CAMPING TRAILER" for all truck campers and folding camping trailers

As a condition of membership, all RVIA member manufacturers are subject to periodic, unannounced plant inspections by RVIA representatives to audit these member manufacturers' pledge to comply with NFPA 1192. Members who fail to maintain acceptable levels of compliance can be expelled from the association, thereby losing the right to display RVIA seals on their products.[6]

In addition to RVIA's oversight, which helps the manufacturers build safe RVs, the manufacturers must comply with the standards and regulations established by the U.S. Department of Transportation and with a variety of state regulations. All programs, both state and federal, are self-certification programs. There is no oversight by an outside agency to ensure compliance. However, compliance is of paramount importance to the manufacturer. Manufacturers are required by law to notify the government of all safety-related defects. Most safety-related defects require the manufacturer to conduct a recall campaign to fix the failed part or system. The federal government imposes the same program requirements on RV manufacturers as they do on the automotive industry.[6]

SUMMARY

Recreational vehicles (RVs) have been around since the beginning of motorized travel in the early 1900s. RVs, which are defined as vehicles that combine transportation and temporary living quarters for travel, recreation, and camping, may have their own motor power, as in the case of motor homes; be mounted, as in the case of truck campers; or be towable, as in the case of travel, fifth-wheel, and folding camping trailers. Discussed in this chapter are the types of recreational vehicles and their features; the historical development and use of RVs; and the development of the two main RV standards, NFPA 1192 and NFPA 1194. The chapter concludes with a discussion of the fire and life safety issues of RVs and the oversight programs that are in

place to assist RV industry manufacturers in the safe production of RVs for recreation, travel, and seasonal use.

Chapter 7

Fixed Guideway Transit and Light Rail Systems

Revised by
Tom Peacock

Chapter Contents

System Characteristics
Underground Trainways
Underground Stations
Surface-Level and Elevated Transit Systems

Key Terms

elevated transit system, fixed guideway transit system, King's Cross Station fire, passenger rail system, point of safety, rail car, traction power, transit vehicle, underground (transit) station, underground (transit) system

The environment of a transit and passenger rail system (the system) lends itself to peculiar and difficult fire safety problems. Large numbers of people who move through these subterranean enclosures and elevated structures compound the life safety dangers. Fires within subways—such as the 1987 fire at King's Cross Station in London in which 31 people died—have attracted international attention over the years due to the danger facing passengers who must evacuate trains through smoke-filled trainways and other emergency exitways. Figure 21.7.1 illustrates the King's Cross fire.

Among the causes of fire in a system can be mechanical failure of undercar components, high-energy electrical short circuits, accumulation of combustible debris along the trainways and within vent shafts, accumulation of road film and oils on the transit vehicle underside, combustible materials in car components, combustible construction of trainways including crossties, and hazards associated with the human factor, such as criminal or terrorist acts.

This chapter covers areas in a transit system requiring special attention, including underground trainways, underground stations, and surface-level and elevated transit systems.

For related topics, see Section 21, Chapter 8, "Rail Transportation Systems."

SYSTEM CHARACTERISTICS

Although underground and elevated trainways and underground stations pose the most serious threat to transit users from fire, certain basic considerations must be recognized throughout the system.

Traction Power

Traction power provides the electrical energy needed to run trains and may be carried throughout the system by means of a third rail or overhead contact system and is typically a nominal 600 to 750 V dc. For transit systems with traction power provided by a third rail, a coverboard of electrical insulating material is often installed throughout the system to prevent people from inadvertently coming in contact with the energized rail. The coverboard should be strong enough to hold a 250 lb (113 kg) weight. Warning signs should be affixed to the coverboard in any area accessible to the public.

Disconnect switches should be located strategically throughout the system so traction power can be removed as quickly as possible under emergency conditions. Otherwise, alternative prompt and reliable means for disconnecting power should be provided.

Tom Peacock has graduate engineering degrees from the University of Maryland and Johns Hopkins University as well as 35 years of professional engineering experience. He previously headed the Federal Railroad Administration's Motive Power and Equipment group and currently serves as the director of operations and technical services for the American Public Transportation Association. He also heads the American Public Transportation Association's Transit Standards Program.

FIGURE 21.7.1 Remains of Booking Hall After Fire at King's Cross Underground Station

Egress from Stations

When determining required exit capacity, future occupancy needs must be considered. After a station has been constructed, it becomes very difficult, if not impossible, to place additional stairs or escalators where they best serve the public. Complying with required exit width may present major difficulty to designers. NFPA *101*®, *Life Safety Code*® as modified by NFPA 130, *Standard for Fixed Guideway Transit and Passenger Rail Systems,* contains basic requirements.

To establish required exit widths for any structure, it is first necessary to determine occupancy classification. For example, the State of California, other jurisdictions, and NFPA *101* determined that places where people await transportation should be classified as assembly occupancies. Effective June 1983, however, NFPA 130 established requirements for life and fire safety in system stations, trainways, vehicles, and outdoor vehicle maintenance areas. The dynamic exiting concept in NFPA 130 determines occupancy based on estimated numbers of patrons waiting in stations and alighting from trains. NFPA 130 considers only those stations accommodating passengers and employees of the system and incidental occupancies. Where large numbers of people other than transit patrons are involved, such as where stations are incorporated into shopping malls, sports facilities, or other occupancies, NFPA *101* sets exit requirements.

Because transit systems are designed to move people rapidly, most new systems have installed escalators as the primary means to enter and exit stations. Escalators that are designed to be reversible, depending on commute conditions, are acceptable as emergency exits. However, escalators should not account for more than the number of units of exit at any one level that are specified by NFPA 130.

When escalators are designed as required exits, their usability in evacuating a station under emergency conditions must be seriously studied. For example, provisions must be made to stop all platform-bound escalators so that they can be used as egress. Reversible escalators should be set to run in the exit direction. NFPA 130 contains requirements for methods of stopping escalators in a manner that prevents injuries to patrons.

In many instances, escalators penetrate two or more floor levels to access the intended platform. This can pose special design problems because many designers prefer to maintain an open environment throughout a station complex. Vertical penetration of more than one floor without enclosures has been accomplished in some systems by increasing other fire protection components.

Exit Barriers

Stations contain two basic areas to separate those individuals who have paid their fare from those who have not. These are commonly referred to as "paid areas" and "free areas." Patrons in the free area can move directly to the outside without encountering barriers. Patrons within the paid area may go through fare barriers to access the free area. During emergency evacuation, either all fare barriers should open automatically, allowing patrons to evacuate the station rapidly, or specially designed access gates should be installed for the same purpose. With increased emphasis being directed to patrons with disabilities, access gates become more useful in basic station design.

Procedures and methods that allow operators to quickly control or limit the number of patrons allowed into a station in the event of a delay or a malfunction are most important. A public address system that notifies and advises patrons during an emergency or a malfunction is also considered essential.

Grills or steel doors completely close off many stations after normal revenue hours. Installing small doors in the grills can provide easy access for fire department personnel, as well as serve as an acceptable means of exit for any employees who may be working in the station.

Emergency Procedures

Due to the variety of hazards involved in a fixed guideway transit and passenger rail system, local fire authorities must establish a direct line of communication with the system's top management. Good inspection techniques must be developed, and coordinated emergency response procedures planned. Access points to all parts of the system must be pinpointed, and engine and truck company response patterns tailored to meet special access problems. Information regarding the system, such as floor plans, electrification, vehicle design, structures, fire protection systems, and communications, is needed to plan emergency procedures properly. Specially developed map books, known as "Fire Maps," for fire department use have proven valuable. A wise course for a fire department is to assign one command officer the responsibility of coordinating all emergency activities required to protect against fires on rapid transit trains, on the right of way, and adjacent to the right of way.

Communication must also extend in the other direction. Fires and other emergencies in adjacent properties may require modified transit operation. In downtown areas, fire suppression activities in nearby buildings can cause water drainage into subways, or flammable liquid spills can endanger below-grade stations. Elevated structures can block fire department access to adjacent buildings. The American Public Transportation Association, RT-S-OP-007-0 Standard for Rail Transit System Emer-

gency Management provides detailed guidance to rail transit systems on planning for emergency preparedness.

Transit and Passenger Rail Vehicle

The construction and use of the transit vehicle (the rail car) has received a great deal of attention regarding fire and life safety. With a reasonable degree of attention, all elements of the transit system—trainway, stations, wayside equipment, and maintenance facilities—can be designed with an acceptable level of fire protection. Construction materials and methods can provide a noncombustible, if not fire-resistive, profile. These elements are static, and many solutions for achieving a degree of fire resistance are already in use in related structures, such as buildings and bridges, and in support subsystems, such as elevators, escalators, and electrical and mechanical systems.

Because of performance and comfort considerations, the modern rail car has made extensive use of manufactured materials. The rail car includes many attractive and serviceable plastics, such as foams, fibers, and other synthetic materials. These are often quite combustible and may emit toxic combustion products while burning. These problems are not unique to the transit and passenger rail car. Combustible plastics are used in passenger compartments of other modes of transportation, including aircraft, buses, and the family car. However, transit vehicles can accommodate several thousand people—far more than even a jumbo jet—and this therefore presents the potential for great loss of life.

Much attention must be focused on the materials and finishes of every item that goes into each car, including insulation for propulsion motors and other electrical wiring. The rail car is typically a source of toxic smoke generated by, and fuel contributed to, a fire.

Therefore, the rail car is a primary concern in a fire and life safety program for a transit system. Unfortunately, many existing fire test methods used to measure performance of materials in fire test conditions have proven inadequate in predicting actual fire performance. NFPA 130 contains a table of required specific test methods and tests to be used for transit rail car materials. This table is based on a guideline for grantees developed by the Federal Transit Administration. The Federal Railroad Administration has incorporated a version of this table into the federal regulations that applies to commuter rail cars. The NFPA 130 requirements and the Federal Railroad Administration requirements are slightly different.

Considering all this, the complete fire hazard assessment for new or retrofitted cars should include fire propagation resistance, smoke emission, ease of ignition, and heat and smoke release rate. The cars' total combustible loading should be limited to as low a value as possible. Existing tests, such as those in NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials;* NFPA 251, *Standard Methods of Tests of Fire Resistance of Building Construction and Materials;* ASTM E162; ASTM E84; and others can be used if results are interpreted in relation to the transit environment. With the sponsorship of the Volpe Transportation System, the National Institute of Standards and Technology is developing tests to better predict the performance of materials when subjected to elevated temperatures, especially with respect to the release of toxic products.

UNDERGROUND TRAINWAYS

Fires within the confines of an underground system, especially those in trainways, are among the most difficult to extinguish because fire fighters have limited room in which to operate. Access points for fire personnel, emergency exit locations for passengers, availability of water supply, and ventilation capabilities are among the fundamentals that must be considered in providing adequate safeguards for passengers and facilities for fire fighters responding to emergencies.

A direct liaison between system operating authorities and fire officials is essential to keep emergency forces apprised of current conditions in underground installations. Floor plans of stations and subways must be reviewed continually. Fire protection included in the original system design may have changed, thus requiring fire-fighting plans to be updated.

Ventilation

Ventilation of underground trainways in emergencies is of primary importance. The removal of smoke during fires must be seriously studied. Several commercially developed computer programs are available to model various smoke removal scenarios. Exiting schemes that allow passengers to exit rapidly into fresh air must also be developed. Some systems have installed fully reversible fans within vent shafts. They move large quantities of air by intake or exhaust, and thus purge smoke from the trainway in a predetermined direction so passengers can evacuate to the nearest station or exit. Ventilation shafts and fans are often placed at each end of an underground station and, in some instances, between stations. When vertical shafts are included in the ventilation construction, the possibility of flammable liquid spills entering the shaft at street level must be considered. Shafts should terminate in roadways only when absolutely no other alternative exists. Adequate sumps equipped with flammable vapor detectors must be developed to retain such spills. Ventilation equipment installed within shafts and fan rooms should meet requirements for expected fire exposure.

Transit systems need to develop safeguards to ensure that central control operators responsible for implementing fire emergency ventilation scenarios receive the correct initial information. Implementing the wrong scenario could move smoke to where the people are rather than away from them, resulting in disaster.

Access/Egress

Walkways. Primary consideration must be given to evacuation of large numbers of passengers to a point of safety if a train stopped between stations must be evacuated. A "point of safety" could be a station platform or direct access to the open air through vertical exitways. Some older systems evacuate passengers by having them descend from the train to the walkway, and then walk until they reach a vertical exit or station platform. In newer systems, passengers evacuate the rail car to a walkway

constructed alongside the rail car opposite the third-rail power source (Figure 21.7.2). This arrangement lets passengers step directly from the train to the walkway.

For trainways separated by noncombustible walls and fire doors, the walkway system also provides easy access to a train on the opposite trainway and an acceptable horizontal exit path that remains relatively free of smoke and heat. Obviously, adequate underground trainway lighting must be provided to allow safe evacuation.

Many systems currently operate underground on trainways completely separated from each other by noncombustible walls and fire doors (Figure 21.7.3). As previously mentioned, this concept provides a refuge for passengers, as long as adequate train control and planning is practiced. Separation walls should have no less than a 2 hour fire resistance rating, and openings in them should be protected by 1½ hour fire doors. Openings through the wall, protected by fire doors, can provide an acceptable horizontal exit path from the trainway on which an accident has occurred to the other trainway, which remains relatively free of smoke and heat. Cross-passageways between trainways can be used in lieu of emergency exit stairways to the surface. When used, cross-passageways should not be farther than 800 ft (244 m) apart. Hardware normally used in the installation of fire doors and frames has been found inadequate for the pressures generated by a train moving through the trainway and for the damp environment found in trainways. Special study and consideration must be given to the type of door, frame, hinges, locking device, and method of securing the frame to the opening. Sliding fire doors with counterweights require special attention.

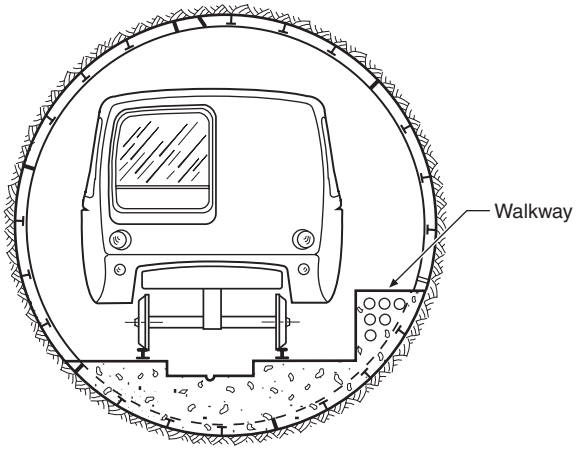

FIGURE 21.7.2 Sectional View of a Single-Tube Subway Tunnel, Showing Location of Emergency Passenger Walkway to Floor of the Car

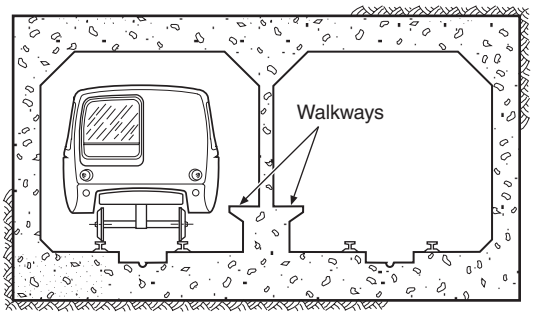

FIGURE 21.7.3 Sectional View of a Subway Tunnel Having Trainways Separated from Each Other by a Noncombustible Wall

Emergency Exits. Several factors must be considered to determine exit requirements from an underground subway system, including the following:

- Train length
- Depth of trainway below grade
- Accessibility to exit at grade
- Accessibility to exit at trainway
- Time and distance needed for people to exit to surface
- Available ventilation and controls
- Access to trainway for fire service

Due to transit systems' ability to control smoke using sophisticated ventilation systems, and since unlimited vertical shafts are impractical, NFPA 130 allows emergency exit shafts to be placed so that maximum travel distance does not exceed 1250 ft (381 m) in tunnels. The intent and basics of NFPA *101,* as modified by NFPA 130, should be followed in designing exit stairs. Hatches can be used at the surface, if there are provisions to prevent obstructions that would keep them from opening in an emergency.

Internally illuminated exit signs with two power supply sources should be installed at the trainway level to direct passengers, and emergency lighting should be provided within the exit enclosure.

Communication

Probably one of the most serious problems encountered during underground emergencies involves communications. Emergency telephones normally are identified throughout the underground system by a distinctive light: in most systems blue lights designate emergency phone locations. Communication from the trainway directly to a central control room is accomplished merely by picking up the phone.

Blue-light stations identifying the location of emergency telephones can also serve multiple purposes. For example, on the San Francisco Bay Area Rapid Transit (BART) System headquartered in Oakland, California, blue-light stations include a third-rail or power-disconnect button, a 110 V outlet, and a 20 lb (9 kg) multipurpose dry chemical extinguisher. Stations are spotted throughout the underground system at 1000 ft (30 m) intervals or in line of sight, whichever is shorter.

Communication (particularly radio communication) in an underground system is sometimes very difficult. Many newer subway systems have installed equipment to let fire department radios be used in underground stations and tunnels. Where this capability does not exist, fire authorities should make every ef-

fort to test their communication systems under actual conditions throughout the subway system. Consideration should be given to using hard-wired communication systems that may already exist. Portable radios or emergency phones with a direct line to the transit system's central headquarters or to train radios are both useful. Every system should have a radio network providing two-way communication connecting personnel on trains and other vehicles anywhere in the system.

During emergencies, radio frequencies and telephone lines quickly become overwhelmed. Portable hardwire telephones, dedicated to fire department use, should be available for point-to-point communications.

Fire Protection in Underground Trainways

A principal fire protection device in systems is the standpipe hose system. NFPA 14, *Standard for the Installation of Standpipe and Hose Systems,* provides good guidance for installations, and Class I or Class III service should be specified.

Standpipes. Standpipes should be located in stations and throughout the underground trainway system. Standpipes in tunnels should be at least 4 in. (101.6 mm) in diameter or sized by hydraulic calculations, and may be of the dry type. Generally speaking, local fire authorities determine locations of standpipe outlets, with consideration given to fire department access at tunnel level, available vertical access shafts for emergency forces, available street access to the fire department, and siamese connections at grade level.

Some systems require that dry standpipe outlets be no more than 200 ft (61 m) apart throughout the underground. Others have determined that maximum separation distances of 300, 400, and 500 ft (91, 122, and 152 m) are acceptable.

Some systems place bins or boxes containing 2½ in. (64 mm) hose near dry standpipe outlets and leave inspection and testing of such hose to system personnel. Fire authorities operating under this principle should seriously consider assigning personnel to witness hose inspections and required waterflow testing. Other systems and fire departments have agreed to only place hose and appliances in lockers at the base of access shafts. In areas where local fire authorities wish to use their own hose, provisions must be made to transport hose and other equipment to a fire site or to store necessary equipment in tunnels and stations.

Special Apparatus. In lieu of supplying the fire hose required at standpipe stations, some systems have taken innovative measures to ensure that hose is available when needed. BART, for example, with approval of fire authorities, removed all fire hose from its subway system, except the 1½ in. (38 mm) hose located within stations. In turn, BART provided five fully equipped, specially designed fire engines capable of traveling by street or rail to previously designated rendezvous points. The responding fire department then boards the apparatus and goes to the fire or emergency location within the underground. Each piece of apparatus includes, as part of its inventory, 1200 ft (366 m) of 2½ in. (64 mm) hose and 400 ft (122 m) of 1½ in. (38 mm) hose, as well as nozzles, a portable emergency generator, a power saw, a cutting torch, extension cords, floodlights, demand breathing apparatus, lifelines, miscellaneous tools, a high-expansion foam unit and nozzle, a 300 gal (1136 L) water tank, and a small pressure pump.

A more practical solution is manual pushcarts, designed to run on rails and stored in stations. These carts range from small commercially available maintenance carts to specially designed folding multilevel carts constructed using lightweight alloys. These pushcarts can also be used to evacuate stretcher cases.

Fire Department Operational Plans. Fire departments that respond to emergencies in underground systems must be extremely familiar with the layout, access, exit, communications, ventilation, and other special factors that must be part of an operational plan for both the fire department and the system. Such plans must be reviewed and practiced regularly, and all fire department members and system employees must be trained to respond appropriately to incidents.

Every fire fighter entering an underground system to fight a fire must have self-contained breathing apparatus (SCBA) to meet the requirements of NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program.* One challenge facing the fire department is how to maintain an adequate supply of replacement air cylinders for members working below grade level. This may require long-duration breathing apparatus and trucks to refill or deliver quantities of SCBA air cylinders.

Fire Extinguishers. Fire extinguishers should be placed on board each car. In addition, fire extinguishers should be placed near fixed equipment throughout the underground system where ignition sources and/or combustibles exist. Locations should include electrical equipment, sumps, ventilation equipment, and so on. If the blue-light or the emergency station is suitably located, one or the other would be a preferred place for extinguishers. The size and type of exposure expected dictates the extinguisher's size and type.

Drainage. Adequate drainage of water accumulated during a fire requires careful consideration. Fire authorities should be made aware of the underground system's drainage capabilities and recognize that large amounts of water could seriously impair other required rescue operations. When fighting structural fires at street level near station entrances or street ventilation grills, fire officers should alert transit system officials that water intrusion into their system may be expected and take steps to prevent water intrusion using tarps.

UNDERGROUND STATIONS

Design and Construction of Underground Stations

Underground stations should be constructed of minimum approved noncombustible materials—that is, Type I, Type II, or combinations thereof—as outlined in NFPA 220, *Standard on Types of Building Construction.* Many modern systems use reinforced concrete construction for the station's outer shell and protected steel beams, girders, and columns within the shell.

This results in a structure with a very substantial fire-resistive capability.

Very few major fires have occurred within stations. A notable exception is the King's Cross Station fire, which occurred in London, England, on November 18, 1987.[1] Thirty patrons and one fire fighter were killed in that fire. Among the many possible causes of station fires are poor housekeeping or electrical fires in escalator machine rooms.

A significant fuel source at stations, other than the trains, is the concessions. Small concessions that sell newspapers and magazines normally have a low-risk classification, whereas major concessions, such as restaurants or theaters, have a high potential risk classification for smoke and heat development.

Newspaper and magazine concessions should be limited in size and must not block required exits. Automatic sprinkler protection should be installed to protect concession areas. Possible future expansion of the area should be considered in designing the fire protection system.

Station public areas should be separated from nontransit areas with a fire barrier having at least a 3 hour fire rating. Major concessions or openings from public areas of the station into existing commercial structures should be protected by fire door assemblies having a 1½ hour fire protection rating. Even if the system owns the commercial activity and the station, good separation between the two areas is needed. Fire barriers can be established by installing fire doors or automatic fire extinguishing systems to prevent fire and smoke spread from the commercial occupancy into the station or from the station into the commercial occupancy. Before making any opening into a station, existing conditions on both sides of the proposed opening must be reviewed carefully so that an effective fire protection plan can be developed.

Fire Protection for Underground Stations

An underground station may be compared to a multiple-basement structure, except that a station generally has a very low fire-loading factor when compared to that of a commercial basement. Because of the substantial cost of code-compliant fire protection and transit car design, these may be good applications for performance-based design, in which tests and calculations are used to show that innovative approaches and designs meet the intent of the code, if not the letter of the code. In late 2001, ASTM adopted a guide for fire hazard assessment of rail cars as a step in the direction of supporting performance-based innovation.

Automatic Sprinkler Systems. All areas in stations that are used for concessions, storage, and fare collection, and other similar areas with combustible loadings, as well as the steel truss area of all escalators in a single-entry station, should be protected by automatic sprinklers equipped with flow alarms and supervision. Trainways are excluded. NFPA 13, *Standard for the Installation of Sprinkler Systems,* should be used. Other approved fire extinguishing systems, such as clean agent extinguishing systems in train control rooms, could also be used in lieu of the automatic sprinkler system, but only with the approval of the authority having jurisdiction (AHJ).

Deluge Systems. In the event of a fire in undercar equipment, train operators are instructed to bring trains to stations for passenger evacuation whenever possible. Some newer systems have opted for undercar deluge systems. These systems consist of fixed piping connected to a water supply, with open sprinklers located between rails. They are activated manually from the station attendant's booth or at the ends of the platform.

An alternative is an overcar deluge system designed to create a water curtain between a burning train and the platform. The system can be activated automatically by heat detectors in the trainway or manually as described previously. Examples of both types of installations are found in the Baltimore Metro System.

Emergency Communications. Underground stations typically do not have traditional fire alarm systems with pull stations and bells. Instead, the public address system alerts and directs passengers in the event of an emergency. Passengers can report emergencies through emergency voice alarm reporting devices located on the platform and throughout the station. Emergency communication systems must conform to *NFPA 72®*, *National Fire Alarm Code®*.

Fire Detection Systems. All nonpublic areas commonly classified as support or ancillary areas, if not protected by an automatic fire suppression system, should be fully protected by a fire detection system conforming to *NFPA 72.* Listed smoke alarms are preferable, although rate-of-rise detectors may be used if authorized by the concerned fire authority.

It is good practice to provide supervision for all fire detection and automatic fire suppression systems. Supervisory signals should be received at the system's command center and annunciated by zone at the station agent's booth or kiosk.

Wet Standpipes. Where separate standpipe and automatic sprinkler systems are provided, wet standpipes usually are supplied by a piping system that is separate and distinct from that used for automatic sprinkler systems. Fire department siamese connections, properly labeled and installed at grade level, let the fire department supply additional water to either system.

Fire hose cabinets may contain 1½ in. (38 mm) and 2½ in. (64 mm) control valves, as recommended in NFPA 14. A maximum of 100 ft (30 m) of attached 1½ in. (38 mm) hose with nozzle and/or 2½ in. (64 mm) hose and a spanner wrench may be stored in cabinets for use by the fire department at the discretion of the local AHJ. A suitable fire extinguisher may also be placed in the cabinet. To reduce pilferage of fire equipment, cabinets should be locked and a breakaway glass panel installed to allow ready access under emergency conditions. Some systems have installed intrusion alarms, which send a signal to the station agent if a fire hose cabinet has been opened.

SURFACE-LEVEL AND ELEVATED TRANSIT SYSTEMS

Generally, combating fires in transit systems at or above grade is no more difficult than fighting any other type of fire at grade.

Primary consideration must always be given to the traction power. Even when assured that the power has been shut off, fire department personnel should operate under the assumption that the third rail or overhead wire is still energized.

Although fires in trains on surface track or elevated trainways present a less serious exposure to the public, design must address certain basic considerations, such as means of egress along elevated trainways. As always, communication is paramount in any emergency operation. The ability to direct emergency forces to the scene of an incident and to place the system in a safe condition for egress is necessary for patrons and emergency personnel.

Access to a trainway also may require special provisions. Locating trainways in a joint corridor with a railroad or freeway may limit access for long distances of the trainway. Trainways extending from population centers through undeveloped areas sometimes extend where surface roads and water mains do not exist. Trainways in congested areas, trainways elevated to unusual heights, and trainways in other sections not accessible to emergency vehicles or paramedic units could create other problems. Trainway construction can also cause problems of fire exposure and access to adjacent structures. For example, an elevated trainway above existing city streets and adjacent to existing buildings can interfere with fire department operations at those buildings.

Similar problems can exist at stations. However, permanent exits provide both passenger evacuation and emergency personnel access. Recent systems have incorporated stations in the lower elevations of high-rise buildings or within mall complexes that have divergent occupancies. In these cases, detailed plans for coordination and compatible design are necessary.

Stations that can be considered to be buildings would normally be reviewed through normal code procedures. If a transit system passes through more than one jurisdiction, particularly if different basic codes apply, development of a common set of requirements is desirable to achieve uniformity throughout the system.

Most existing building codes do not usually address the subject of trainways, however. The exception is NFPA *101*. Items that should be considered during a plan review of a guideway include the following:

1. Designated location markers to provide a response location for fire personnel
2. Locations where overhead trainways may intersect with known street locations
3. Egress gates allowing passengers to exit the system under authorized employee supervision
4. Available wayside communications allowing the fire department to communicate directly with the system's command center
5. Locations of substations, switching stations, gap breaker stations, or other major electrical installations of concern to local fire authorities

SUMMARY

Fire protection of fixed guideway transit and passenger rail systems is similar to fire protection of other occupancies in many respects. Prevention of ignition is of paramount importance, as are safe evacuation of occupants and the safety of responding fire fighters. However, the unique characteristics of fixed guideway transit and passenger rail systems are more challenging, particularly in underground trainways and stations.

Chapter 8

Rail Transportation Systems

Revised by
Charles J. Wright

Chapter Contents

Overview
Railroad Operations and Facilities
Hazardous Materials Transported by Rail
Safety on Railroad Property
Passenger Transportation
Motive Power
Freight Cars and Equipment
Rail Tank Cars
Intermodal Tank Containers

Key Terms

freight car, hazardous material, intermodal tank, locomotive, passenger train, rail transportation, railroad, refrigerator car, right-of-way, rolling equipment, rolling stock, tank car

The rail industry as a whole considers safety a top priority. The federal government, through the Federal Railroad Administration (FRA) and the Federal Transit Administration (FTA), provides the basis of regulation, which may be enforced by either FRA inspectors or state inspectors using federal guidelines. Design standards and recommended practices for new or rehabilitated railroad infrastructure are prepared and maintained by organizations such as the Association of American Railroads (AAR), the American Railway Engineering and Maintenance of Way Association, and the American Public Transportation Association (APTA). In some instances, the Code of Federal Regulations (CFR) references these standards and in other cases it cites them as guidelines and encourages compliance as a condition of accepting capital grant money. The codes and standards of the NFPA are often incorporated by reference or serve as a design and/or maintenance basis for the safe and efficient operation of railroad properties. Railroad systems are classified into two broad groups. The first group consists of systems that operate on the general railway system of the United States. These systems are regulated by the FRA and include the freight carriers, intercity rail services (Amtrak), and commuter rail systems. The second group is the rapid transit and light rail (trolley) lines in metropolitan areas not connected to the general railway system. These systems are regulated by state and local bodies with FTA oversight.

This chapter addresses the first group of rail systems only and introduces the reader to physical aspects of the rail transportation industry. It identifies different types of rail rolling equipment used by North American railroads, both freight and passenger, and discusses fire hazards associated with them. It also identifies fire problems involving rights-of-way and specialized railroad facilities and presents safety precautions, both general and situation specific, that all persons should follow while on railroad properties or near rail activities. The chapter generally discusses the rail transportation of hazardous materials. It also discusses in detail the transportation of hazardous materials in rail tank cars and in intermodal tank containers and describes emergency response capabilities of the rail industry.

The business of rail transportation touches on a wide variety of topics. Most chapters in this handbook provide useful assistance in dealing with at least some aspect of the industry. However, the reader is specifically referred to these chapters for discussions of related topics:

Section 13, Chapter 6, "Public Fire Protection and Hazmat Management"; Section 13, Chapter 8, "Managing the Response to Hazardous Material Incidents"; and Section 21, Chapter 7, "Fixed Guideway Transit and Light Rail Systems."

OVERVIEW

Rail Transportation Systems

Rail Transportation Systems, a membership section of the National Fire Protection Association, was organized in 1963 as the Railroad section. It is dedicated to promoting interest in, and improving the methods of, fire prevention and protection in the railroad industry and to encouraging proper safeguards and recommended practices against fire through the interchange of ideas and

Charles J. Wright is manager of hazardous materials training at the Union Pacific Railroad in Omaha, Nebraska.

experience. The Rail Transportation System annual meeting is held each May in connection with the NFPA Annual World Fire Safety Congress and Exposition. This event provides an excellent forum for the exchange of ideas between the fire service and railroad fire safety specialists.

Terminology

Two important rail transportation terms are used in this chapter. *Rolling equipment,* or *rolling stock,* is an all-inclusive term that includes locomotives, freight cars of all types, cabooses, and on-rail track maintenance (maintenance-of-way) equipment. *Right-of-way* refers to the (usually) continuous strip of land on which tracks are laid and trains operate. Right-of-way also technically refers to the contiguous property areas on which shops, offices, switching yards, and other railroad facilities and activities are located or take place. The rail transportation company usually owns and maintains the right-of-way.

U.S. Freight and Commuter Railroads

According to the AAR,[1] the more than 562 freight railroads operating today in Canada, Mexico, and the United States are vital to North America's economic health. They form a seamless integrated system that provides the world's most efficient and cost-effective freight service. North American railroads operate over 140,806 (2005 data) miles of track and earn $42 billion in annual revenues.

Also, according to the AAR,[1] U.S. freight railroads fall into one of several classifications. *Class I* railroads, which comprise the largest classification, are those with operating revenue of at least $319.3 million in 2005. Currently there are seven Class I railroads. *Regional* railroads, of which there were 30 in 2005, are line-haul railroads that operate at least 350 miles of road and/or earn revenue between $40 million and the Class I threshold. *Local* railroads include freight railroads that are neither Class I nor regional; they operate less than 350 miles of road and earn less than $40 million. In 2005, there were 320 local railroads.

According to the APTA,[2] there are 20 commuter rail passenger systems associated with various transportation agencies in the United States. In addition, Amtrak provides intercity service.

Railroad Fire Losses

Since their inception, railroads have been associated with fires. Steam engines powered the earliest locomotives; burning wood made the steam. Engine exhaust sparks commonly ignited nearby dry vegetation. A published account of the first passenger train trip in the United States describes how these sparks ignited passengers' clothing and parasols. In the period from 1994 to 1998, rail vehicle fires that were reported to U.S. local fire departments averaged 650 per year, with associated losses of 6 civilian deaths, 12 civilian injuries, and $221.0 million in direct property damage per year.[3]

The rail transportation industry has fire risks primarily in the following three separate areas:

1. The company's fixed physical plant, which ranges from high-rise offices to locomotive heavy repair shops to diesel fuel storage and dispensing facilities
2. Fires on trains, involving locomotives, rolling stock, passengers, or cargo
3. Fires caused by trains or right-of-way maintenance activities that cause damage to railroad property or to adjacent, privately owned properties; railroads are unique in that they typically operate over a continuous right-of-way that they both own and maintain

Tank Car and Intermodal Tank Container Fire Hazards

Fire hazards of tank cars and intermodal tank containers are minimal unless a car is damaged in an accident. If a fire does occur, it is essential to learn the contents of the car or the container before attempting to fight the fire. A tank car or a container exposed to radiant energy from a fire, particularly direct flame impingement, should be approached cautiously. If a commodity absorbs too much heat, vapor pressure can build up and cause the pressure relief device to operate or the tank to rupture. If any of the commodity is released, personnel should be prepared to deal with corrosive, toxic, or otherwise harmful effects. Direct contact with vapors discharged from tank cars or containers under emergency conditions should be avoided, unless appropriate protective clothing and self-contained breathing apparatus are worn.

RAILROAD OPERATIONS AND FACILITIES

Technological Advances

Today, on all but the smallest of railroads, trains are dispatched from remote dispatching centers. On several of the largest railroads, one central dispatching center controls all trains on the entire system. Crews on the trains follow explicit instructions at all times and are in continual radio and electronic contact with a dispatcher. Some locomotives have full-time computer contact both with the dispatcher and with their company's central computer system. One railroad tracks its trains' locations by satellite.

Advances in electronics and their increased use permit other railroad operational efficiencies as well. One or more locomotives (the "locomotive consist") at the front of the train still pull most trains, but it is now practical in certain circumstances to place locomotives at the end of a train or at intervals throughout the train, providing important operational and control efficiencies. However, with such advances come potential problems: a train is no longer the predictable entity it used to be. The emergency responder faces more uncertainties as well as genuine benefits: advanced computer systems have made a tremendous amount of information on a train's cargo, its proper handling, and emergency response protocols instantly available even at remote locations. Thus, it is now more imperative than ever for nonrailroaders involved in rail transportation activities or responses to communicate with, and to coordinate their activities with, proper railroad officials.

Miscellaneous Railroad Facilities

Many railroad facilities are similar to industrial facilities with familiar hazards. However, other facilities are unique to the railroad industry, such as diesel locomotive running repair and heavy repair shops, freight car repair shops, paint shops, and locomotive fueling facilities. Hazards associated with a diesel locomotive repair shop include cutting, welding, poor housekeeping, and fuel leakage.

Fueling facilities need particular protection, not only because of the economic value of the systems and of the stored fuel but also because of the value of locomotives and the cost of interruption of service. Fuel pump houses should be of noncombustible construction and, preferably, equipped with automatic fire protection and with light fixtures and devices suitable for hazardous locations. Because leakage is a prime hazard, careful housekeeping and preventive maintenance are essential. Portable and wheeled dry chemical fire extinguishers should be located throughout the fueling area. It is most desirable to have a high-volume water supply nearby.

Other facilities are critical to railroad operation and, if involved in fire, could stop the movement of trains in a given territory. These facilities include computer centers, microwave communications facilities, centralized train control equipment, and the many support elements in classification yards. Private detection and protection systems should protect these facilities. Typical fire suppression systems range from sprinklers to carbon dioxide and other clean-agent designs. Nearby adequate water and hydrant systems are essential.

Bridges and Trestles

Fire prevention is the key to continued operation of bridges and trestles. Regular maintenance should be done to provide and maintain a 25 to 50 ft (7.5 to 15 m) clearance between combustible structures and nearby vegetation. Susceptibility to fire damage can be reduced by treating the structure with a fire retardant and by providing water barrels, fire detection systems, standby pipe and hose systems, and guard service.

At some particularly valuable and critical bridges, fireboats and water buckets that can be attached to helicopters have been provided, and noncombustible bridge segments have been constructed at regular intervals to limit damage should fire occur. Most railroads have been replacing combustible bridges and other track structures with noncombustible construction at every opportunity, thus reducing their exposure to fire-related losses.

Exposure Risks for Rail Equipment

Exposure fires that destroy loaded and unloaded freight equipment underscore the need for close analysis of terminal fire hazards. These fires can start both on and off railroad property. When classification or switching yards are designed, adequate fire protection, both private and public, should be a prime consideration.

Lack of nearby fire mains and hydrants can contribute to fire loss in large yards. In a major incident, fire-fighting activities should be confined to containment and protection of exposed property. A prefire plan should map fire mains and hydrants both in and near the yard, because protection in the yard may be rendered useless or inaccessible during a major event.

Railroad sidings present a similar exposure hazard, particularly at grain elevators, lumber yards, flammable liquid or LP-gas unloading facilities, and similar industrial properties.

Railroad Communications

Communication with railroads today is simple, effective, and very necessary. On most railroads, a call to any office can be quickly connected to any other, including dispatching centers, maintenance crews, railroad emergency response teams, and, often, even the train itself. Similarly, the crew on a train can immediately notify dispatchers of an emergency on or off railroad property and advise in detail as events unfold. Dispatchers are specially trained to make appropriate emergency contacts both inside and outside of their company. See the next section, "Hazardous Materials Transported by Rail," for information on railroad emergency response capabilities. Most railroads currently have a single telephone number to a central location for emergency situations. Personnel at these locations make notifications and provide appropriate information as necessary.

HAZARDOUS MATERIALS TRANSPORTED BY RAIL

Hazardous material shipments are strictly regulated by the U.S. Department of Transportation (DOT) through the Pipeline and Hazardous Materials Safety Administration (PHMSA). The FRA enforces these regulations.

Statistical Overview of Hazardous Shipments

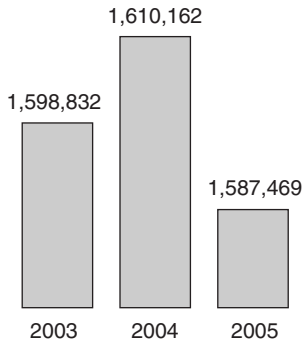
The Bureau of Explosives[4] reports that in 2005 U.S. and Canadian railroads originated 1,587,469 hazardous material shipments. During rail transportation 859 nonaccidental and 27 accidental releases (U.S. only) of hazardous materials occurred for a total of 886 releases of hazardous materials for the year. Figure 21.8.1 shows AAR/Bureau of Explosives' depiction of the total numbers of hazardous material shipments for 3 years (2003 to 2005).[4] Table 21.8.1 shows a summary of hazardous material shipments by hazard class.[4]

It is interesting to note that in 2005, 25 commodities accounted for approximately 93 percent of all the hazardous material that was shipped by rail (Table 21.8.2).[4]

Emergency Response

With the increased danger associated with emergencies involving hazardous materials, shippers, carriers, and local, state, and federal agencies, that is, fire, police, health, and environmental agencies, respond. The immediate purpose of the response is to minimize harm that would otherwise occur: death, injury, property damage, environmental damage, and system disruption. To accomplish this task, responders must identify hazardous materials involved in the emergency.

Sources for detecting the presence of hazardous materials include placards, markings, and shipping papers. Placards may



Note: The Bureau of Explosives' report breaks down these shipments by hazard class as follows: railroads transport hazardous materials in various types of rail cars, such as tank cars, covered hoppers, gondolas, box cars, and trailers and/or containers on flat cars (TOFC/COFC). The majority (85% in 2005) of rail shipments of hazardous materials move in tank cars.

FIGURE 21.8.1 Hazardous Material Shipments for the United States and Canada, 2003–2005

TABLE 21.8.1 Hazardous Material Shipments by Hazard Class for U.S. Originations, 2005

Hazard Class and Divisions	*All Rail HM Shipments*	*Tank Car HM Shipments*
Class 1 (explosives)	478	3
Division 2.1 (flammable gases)	229,355	229,132
Division 2.2 (nonflammable gases)	76,447	76,211
Division 2.3 (poison gases)	47,321	47,301
Class 3 (flammable liquids)	378,902	375,342
Combustible liquids	66,674	64,686
Division 4.1 (flammable solids)	22,407	22,307
Division 4.2 (spontaneously combustible)	1,482	1,293
Division 4.3 (dangerous when wet)	3,399	590
Division 5.1 (oxidizers)	50,329	15,448
Division 5.2 (organic peroxides)	6	0
Division 6.1 (poisonous materials)	31,615	31,037
Class 7 (radioactive materials)	11,074	0
Class 8 (corrosive materials)	278,763	276,772
Class 9	202,522	168,931
Mixed freight all kinds	139,103	660

be affixed to both sides and both ends of the rail car, trailer, or container. They alert response personnel to a hazardous material's presence and indicate the hazard class. The DOT identification number, which also may be found on both ends and both sides of the rail car, trailer, or container, will cross-reference the specific material involved, along with emergency response information. Another marking, the name of the contents, may be stenciled on the sides of the rail car, trailer, or container. Due to the orientation of the cars, placards and markings may not be visible in some emergencies. Because of the nature of the emergency, it may not be prudent to approach the car closely enough to read the placards and markings. Aided vision (binoculars, etc.) may be helpful in some cases. See the sections "Tank Car Markings" and "Tank Container Markings" for more information.

Shipping Papers

Rail cars, trailers, or containers transporting hazardous materials must be documented on shipping papers. Therefore, shipping papers are primary safety instruments in rail transportation for recognizing and identifying hazardous materials. The typical shipping paper for a train movement is a train consist or train list. This document lists the location of each rail car, trailer, or container in the train, including the location of each hazardous material in the train. The train consist/train list also includes emergency response information for each hazardous material on the train. It indicates the contents of each car, including the hazardous material shipments. Shipping papers may differ slightly among railroads; therefore, response personnel should be familiar with the railroads that move through their jurisdiction.

Shipping Paper Contents. The rail shipping paper typically includes the following entries: proper shipping name, hazard class, identification number, packing group, quantity, and hazardous material response codes (previously the 49 series Standard Transportation Commodity Code [STCC]). A 24 hour emergency response telephone number and detailed emergency response information are included with the shipping papers.

Shipping Paper Location. Shipping papers are available from the conductor on the train crew on-site or from the train dispatcher. Although traditionally found on the caboose, the conductor will be found in the lead locomotive of trains without cabooses. However, in an emergency involving hazardous material, the conductor and the rest of the train crew are likely to move to a safe location at least one-half mile upwind, uphill, or upstream of the problem.

Shipping Papers in Rescue Efforts. Upon notification of an accident or other occurrence involving rail equipment, response personnel should take the following actions:

1. Contact the responsible railroad. The telephone number should be identified in preemergency planning activities. Obtain a copy of the shipping papers and emergency response information, whether hard copy or from the railroad verbally.
2. Obtain as much information about the incident as is available: identify hazardous materials involved by name, DOT

TABLE 21.8.2 Top 25 Hazardous Materials in Rail Transportation, 2005

Rank	*Class*	*Commodity Name*	*Shipments*
1	2.1	Butane; liquefied petroleum gas; petroleum gases, liquefied; propylene; LP-gas; propane; isobutane; isobutylene; LP-gas (butylene/isobutane); LP-gas (butane/butylene); isopentane	166,310
2		Freight all kinds—hazardous materials	139,104
3	9	Elevated temperature liquid, N.O.S.	90,832
4	8	Sodium hydroxide solution (caustic soda)	82,892
5	8	Sulfuric acid	58,576
6	3	Alcohols, N.O.S.	75,057
7	4.1/9	Molten sulfur	62,261
8	3/CL	Diesel fuel	55,850
9	3/CL	Flammable liquid, N.O.S.	54,766
10	2.2	Anhydrous ammonia	52,634
11	3	Gasoline	47,362
12	2.3	Chlorine	36,475
13	3/CL	Fuel oil	31,452
14	8	Phosphoric acid	30,745
15	2.1	Vinyl chloride, stabilized	27,499
16	9	Environmentally hazardous substances, liquid, N.O.S.	26,182
17	3	Methanol (methyl alcohol)	22,641
18	9	Environmentally hazardous substances, solid, N.O.S.	22,401
19	8	Hydrochloric acid	22,154
20	2.2	Carbon dioxide, refrigerated liquid	20,245
21	5.1	Ammonium nitrate fertilizers	17,631
22	3	Styrene monomer, inhibited	17,279
23	2.1	Propylene	16,800
24	6.1	Petroleum distillates, N.O.S.	14,138
25	5.1	Sodium chlorate	14,043

identification number, or placard applied; determine the types of containers involved; determine the topography, bodies of water, population density, and so forth; obtain specific emergency location and best avenues of approach; ascertain whether any injuries have occurred; and determine when the emergency occurred.

3. Upon arrival at the scene, establish contact with the senior railroad official or representative before attempting to deal with the emergency.
4. Initiate command and control activities, including protecting yourself and others, initiating an incident command system, controlling access to the site, and making appropriate notifications.

In addition to the railroads, other organizations that can provide rail-oriented assistance include the following:

- AAR Bureau of Explosives (BOE)—BOE personnel will respond to major rail emergencies involving hazardous materials on request, typically from a railroad
- Carrier emergency response teams

Some carriers have developed emergency response capabilities to handle emergencies involving hazardous materials. Such teams are equipped with specialized tools and equipment to repair leaks and even transfer contents of damaged tank cars. For example, Union Pacific Railroad has two transfer vehicles equipped with tools and equipment to perform product removal activities as necessary (Figure 21.8.2).

Many rail carriers prepare guides and recommendations for handling rail emergencies involving hazardous materials and make them available to local emergency response agencies along their right-of-way. Railroads also present various training programs to local response agencies and assist at various local, state, and national fire school programs.

SAFETY ON RAILROAD PROPERTY

All who visit rail transportation properties under emergency or routine conditions need to exercise particular caution. The hazards are many and unfamiliar. The potential consequences are severe.

Taking Precautions

Always assume the tracks are "live"—expect a train to appear from either direction at any time. Rails are slippery—always

FIGURE 21.8.2 Union Pacific Railroad Transfer Vehicle Performing Multiple Liquid Transfers at an Incident

step over, not on, a rail, after first making sure the way is clear.

More and more often, a person at a distant dispatching center electrically operates track switches, the devices that physically move the rails and route a train from one track to another. Unlike the person who once stood near the switch and manually operated it, a remote operator cannot see the switch and is unaware of activities in its vicinity. Keep feet, hands, and equipment away from the moveable switch components.

Do not block tracks or place items across them without positive assurance from the railroad that all trains in the area have been stopped. Even then, minimize exposure to trains and clear the tracks as soon as practical. Hose lines laid across a railroad track can be cut by a passing train.

Until the railroad has given positive assurance that all trains in the area have been stopped, do not work around tracks or place equipment on or near tracks, until flaggers with red flags (in daylight) or red fusees (in darkness) have been deployed a minimum of 1½ miles (2.4 km) down the track in each direction. Where trains may be moving rapidly, an additional flagger should be placed a mile farther away in each direction. Fast-moving trains, freight or passenger, take at least that long to stop.

Rail emergencies on bridges and in tunnels with multiple tracks pose special hazards to the responder, as there usually is no work space except on tracks. Until positive assurance is received that all train activity in the area has stopped, there is no safe workplace for emergency activities and equipment and no safe haven for workers should a train appear on an adjacent track.

The railroad should be contacted at first opportunity whenever emergency activities occur on its property. This not only helps to maximize responder safety but it also activates the railroad's considerable emergency response capacity. Maintaining regular contact with each rail transportation entity in their area ensures that emergency responders are fully aware of the transportation company's emergency response resources that are available to them.

Self-Propelled Fire-Fighting and Derrick Equipment

Most carriers are well prepared to clear derailments and rerail freight equipment with their own forces or by standing arrangements with specialty contractors. They use lifting equipment with capacities ranging from 150 to 250 tons (136 to 227 metric tons). These may be mounted on a work train that also may carry water cars and fire pumps powered by the train air line or powered independently by an internal combustion engine. It is increasingly common to find wreck-clearing equipment with rubber tires or crawler tracks transported to the scene by highway. Carrier equipment usually includes fire hoses, nozzles, foam extinguishing compound, play pipes, and a quantity of extinguishers.

Work trains are especially valuable in incidents that occur in remote and inaccessible areas. Fire-fighting needs for such emergencies can be handled by driving a fire department pumper onto a flat car and taking it to the emergency by train.

Some railroads have self-propelled fire-fighting cars that can be used independently of the work train. The availability of such fire-fighting equipment is often overlooked in preemergency planning.

Rights-of-Way

A difficult problem is the right-of-way fire, or fire on railroad land adjacent to the roadbed. These fires can spread off railroad property. Such fires have occurred since the first days of railroading, but this risk has been greatly reduced by improved railroad equipment, controlled burning, chemical control of vegetation, and installation of fire breaks. Cooperation with the USDA Forest Service has led to development of spark arresters, spark arrester exhaust manifolds, and sparkless brake shoes. Planned vegetation, planting the right-of-way with fire-resistive vegetation, is a practice that, if properly maintained, can further reduce these fires.

PASSENGER TRANSPORTATION

Safety Precautions for Passenger Equipment

It is advisable to be aware of the following safety precautions, which are typically employed on passenger trains:

1. Passenger trains, including commuter trains, typically use 480 V ac power generated from a locomotive or a power car for onboard electrical systems, including heating, air conditioning, lighting, and food service. Generally, cables located beneath and between rail cars on both sides transmit this power. In an emergency situation, these cables may be damaged or loosened. Never attempt to disconnect any cables without assistance from the train crew. Never open any empty electrical receptacle until assured that the 480 V ac system has been deenergized. Contacts in the receptacle can be energized without the presence of cables and can produce an arc that can result in serious injury or death. Typically, 480 V ac systems are stepped down by transformers located under the car to provide 220/110 V ac power for onboard electrical equipment. Some electrical components use capaci-

tors, which store residual electrical energy for a time after the system has been shut down.

2. Typical passenger trains employ a 72 V dc emergency battery backup system for operation of lighting, electric doors, and public address systems when the 480 V ac power is lost. These batteries, typically nickel-cadmium and generally located under the car, can present a hazardous materials danger if damaged in an accident. In addition, train cars may be connected by 72 V dc jumper cables for public address and other systems. These cables must be approached with the same caution as 480 V ac cables.

3. Typical passenger trains also employ a pressurized air system, up to 140 psi (965 kPa), for operation of brakes, doors, and lavatories. Compressors in locomotives or power cars provide air pressure, and most passenger cars are equipped with at least one pressurized air reservoir. Some passenger cars ride on air-pressurized bellows instead of springs for improved passenger comfort. Emergency response personnel should be aware of the air pressure hazard and remain clear of any components where they hear the sound of leaking air, until assured that the system has been depressurized.

Passenger Equipment

Modern cars are constructed of steel and aluminum. Materials used for the interiors of today's passenger coaches, diners, and sleeping cars are, at the least, tested to the performance criteria outlined in Table 8.4.1 in NFPA 130, *Standard for Fixed Guideway Transit and Passenger Rail Systems.* Interiors designed to these criteria should show limited fire involvement when exposed to fire. Causes of fires on passenger trains include smoking materials, arson, and mechanical or electrical problems with equipment. However, extensive fire involvement can occur when cars have been exposed to an external fire source such as a flammable liquids fire. In diners, hazards include those inherent in stationary restaurants, such as grease and exhaust system fires. These, plus air-conditioning and heating systems, must be properly safeguarded, and regular preventive maintenance is essential.

Amtrak Trains

Amtrak sleeping cars are equipped with smoke detection systems that, when activated, shut down the HVAC system, sound an alarm within the car, and provide evacuation instructions to the car's passengers.

Amtrak high-speed trains operate along the Northeast Corridor from Washington, DC, to Boston, Massachusetts. These electric-powered trains operate as fixed train sets in which the individual cars are not typically separated. Each train set has a power car at each end. These train sets have some unique fire protection system features, such as the following:

- A deluge sprinkler system in the machine space of the locomotive, which is supplied with water through fire department connections located on each side of the unit
- A gaseous fire suppression system in some electric cabinets in the machine space, which is activated by a heat detection system connected to a control/releasing panel located in the cab of the engine
- On some units, an engineer's escape hatch in the roof of the cab of the power car; if the hatch is not present, there will be a marked "soft" spot in the roof of the cab
- The absence of drop steps on the passenger cars, which are present in older Amtrak cars; folding ladders are used for passenger evacuation, located in a marked compartment near each exit door
- A folded evacuation ramp stored beneath the train; the train crew is trained in the deployment of this ramp
- Every window in the car usable for evacuation; note that these windows are very heavy and care should be used when they are removed
- Presence of a marked "soft" spot located in the center of the roof of each passenger car; typical fire-fighting cutting equipment can be used to remove this soft spot to gain access to the car's interior

Emergency Response Efforts

Modern rail passenger equipment is designed to withstand the tremendous physical forces that would occur in a collision. This construction defeats typical rescue or forcible entry tools. Rescue and fire-fighting operations should be conducted through a car's doors and windows. The windows in passenger equipment generally are made of polycarbonate material that is far stronger and more flexible than safety glass—it cannot be smashed with an axe. Attempts to break windows can result in tool rebound, which can cause serious injury to the rescuer. Windows can be removed from inside or outside cars following the procedures given on labels or placards generally found adjacent to the windows.

Emergency response personnel must always assume that other trains are operating nearby. Modern passenger trains typically operate at up to 79 mph (127 kph) in most areas of the United States. In the Northeast Corridor, from Washington, DC, to Boston, trains operate at up to 125 mph (201 kph), with Amtrak's high-speed train operating at up to 150 mph (241 kph). The emergency stopping distance of a train traveling at 79 mph (127 kph) is approximately 1½ miles (2.4 km) after brakes are applied; at 125 mph (201 kph), it is 2½ miles (4 km); at 150 mph (241 kph), it is 3 to 3½ miles (4.8 to 5.6 km).

Emergency responders must protect the scene by providing flagging protection on the track in both directions from the incident at a distance of 1½ to 2 miles (2.4 to 3.2 km). In the high-speed corridor, this distance should be increased to 2½ to 3 miles (4 to 4.8 km). Flagging protection should be maintained until positive assurance has been received that the system operator or dispatcher knows that emergency response personnel are on the right-of-way and that other rail traffic has been notified. Even with these assurances, it is recommended that flagging protection be maintained for the event's duration.

Because of the weight and size of railroad passenger cars, stabilization in a derailment cannot be obtained using the highway-grade cribbing materials, portable rachet pullers, or air bags that emergency response personnel typically carry. It is strongly recommended that damaged or derailed cars be stabilized by using railroad ties (readily available at most derailment sites) or other suitably heavy-duty materials.

Most cars in a passenger train are those owned by the train's operator, usually Amtrak. Occasionally, however, privately owned passenger cars are attached to the train. Although most commercial passenger cars use electrical power for onboard lighting, food service, door operation, and heating/air-conditioning systems, privately owned passenger cars may employ liquefied petroleum gas (LP-gas) or diesel fuel for heating, cooking, or a generator system as an auxiliary power source. For this reason, responders must be prepared for such materials when dealing with a privately owned passenger car.

Rail transportation companies typically provide training for emergency response personnel on the proper procedures for dealing with a rail incident. Emergency responders with rail operations in their area should make certain that they take full advantage of the rail operators' training resources.

MOTIVE POWER

Diesel Electric Locomotives

What is generally referred to as a diesel locomotive is actually a diesel electric locomotive (Figure 21.8.3). The power is developed by the diesel engine, which drives a main traction generator (or alternator on ac locomotives). The output of this generator or alternator is then transmitted to the traction motors, which are mounted under the locomotive in massive frames called trucks and geared to the axles and wheels. The traction motors actually drive the locomotive. The numerous support systems of a locomotive include a battery that provides power to start the diesel engine, an auxiliary generator or alternator that charges the battery and supplies low-voltage current for control and lighting circuits, and an auxiliary alternator, mounted integrally with the main traction generator or alternator that furnishes field current for the main alternator and power for the radiator cooling fan motors and for a blower motor, which cleans the inertial carbody filters.

Main line locomotives have a normal service life of more than 30 years. Thousands of units still in service have operated far longer. Locomotives in main line service on a major railroad will average between 150,000 and 250,000 miles (241,403 and 402,338 km) per year.

The diesel electric locomotive is an enclosed, self-contained piece of equipment. Fire prevention in the engine room is almost exclusively limited to housekeeping and maintenance, which includes stopping and repairing fuel oil, lubricant oil, or exhaust leaks and ensuring that debris and products of leakage do not accumulate. Improved carbody filtration, through the development of self-cleaning inertial-type carbody filters and carbody pressurization, has also helped to improve engine room safety in modern diesel electric locomotives.

Improvements to electrical cabinets on newer locomotives include the use of fire-retardant wire and cable insulation and the practice of ventilating electrical cabinets with filtered air. This ventilation prevents flammable gases from collecting and keeps dirt out of the electrical cabinet. Other improvements include better wiring techniques, increased use of circuit breakers and fuses, and the pressurization of electrical cabinets. Design improvements, particularly in the extensive use of electronics throughout the locomotive, have also reduced fire hazards.

Fire protection for diesel locomotives includes the following:

Hot Engine Protection. To protect against excessive temperatures in the engine cooling system and hot engine oil, devices are installed to prevent excessive heat buildup in the engine and supporting systems.

Engine Crankcase Protection. This device is designed to detect a dangerous buildup of pressure in the engine and to shut down the engine when necessary.

High-Voltage Ground Protection. If a high-voltage fault develops on the locomotive and goes to ground, the ground relay detects the fault and disconnects the electrical load to the locomotive.

Emergency Fuel Cutoff Switches. In an emergency, the fuel supply to the engine can be stopped by pressing any one of three emergency fuel cutoff buttons. Two buttons are located on the

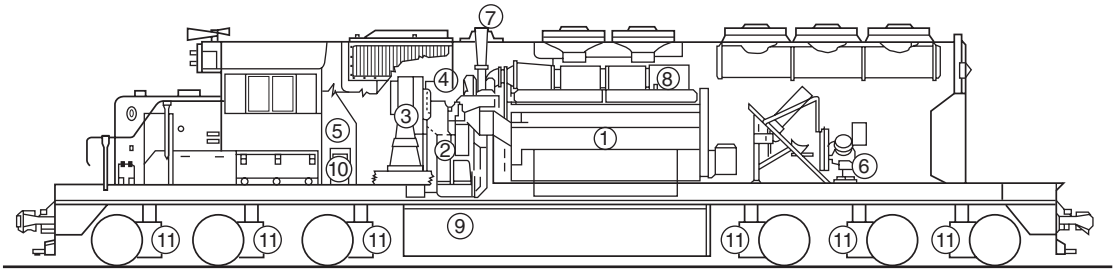

FIGURE 21.8.3 Diesel Electric Locomotive Showing the Location of Principal Components of the Power System

underframe near the fuel filler, one on either side of the locomotive, and a third is found on the engine control panel in the cab.

Main Battery Knife Switch. This large, single-throw knife switch is located in the engine cab at the lower portion of the fuse panel. It connects the battery to the locomotive low-voltage system.

Personnel Protection from High Voltage. Modern locomotives have their high-voltage electric componentry isolated in a labeled panel. This panel has interlocks and other design features to ensure that opening the panel door automatically de-energizes the electric components. Older units may not have this feature, however, so extreme caution is advised when working around locomotive electrical systems.

Portable Fire Protection Equipment. Each diesel electric locomotive is equipped with portable fire extinguisher protection, generally ordinary dry chemical. The quantity and type depend on the size of the locomotive and its use in yard, local, or main line service.

Preventive Maintenance and Inspections. Diesel electric locomotives are inspected, tested, and serviced on a regular schedule, based on life expectancy of component parts, empirical failure data, and Federal Railroad Administration (FRA) regulations.

Alternative Fuel Locomotives

The vast majority of locomotives operate on diesel fuel. The railroad industry is, after the federal government in the United States, the country's largest user of diesel fuel. Locomotive fuel is a significant element of a railroad's operating costs. Efforts are ongoing to reduce these costs, both the cost of the fuel itself as well as its storage, handling, and dispensing costs.

One railroad is now extending the range of some of its long-distance trains by placing a tank car of diesel fuel in its locomotive consist. This practice also permits the train to take on large quantities of fuel where the price is lowest. The larger quantity of locomotive fuel potentially involved in a train collision or derailment should be recognized by the fire community.

A few railroads are experimenting with liquefied natural gas (LNG) as a locomotive fuel. A handful of experimental units are in use on selected assignments. Some LNG locomotives designed only for use in switching yards use a relatively low-powered, spark-ignition engine that permits LNG to be the only fuel on board.

Other experimental LNG locomotives are high-horsepower units intended for long-distance hauling. They use engines with traditional diesel-type, compression-ignition technology. These units require that a percentage of diesel fuel be mixed with the LNG primary fuel to achieve combustion, so both diesel and LNG fuels are found on board. At present there is no uniformity of application: some units use high-pressure LNG technology; others use low-pressure designs.

Refueling arrangements for LNG units are also in the experimental stage. Installations and practices vary widely, both within a single railroad and between different companies. Some locations have fixed LNG fueling facilities operated by railroad personnel. At other locations fueling may be by a vendor's crew and tank truck.

The LNG-powered locomotive consists for long-distance service in use or contemplated now have this basic similarity: all have two high-horsepower locomotives with an LNG fuel tank car, or tender, between them. Equipment is well protected from all known hazards, including break-apart. The LNG in the tender is not considered to be in commerce; therefore, the LNG-containing tender is not subject to the DOT regulations and does not need to be placarded. All experimental locomotives and locomotive consists, along with LNG fueling operations, can be expected to be well marked.

Electric Locomotives

Electric locomotives today are used almost exclusively on passenger trains in major metropolitan areas.

Figure 21.8.4 illustrates the general arrangement of an electric locomotive. This particular unit can deliver 5100 hp (3.8 MW) at the rail and operates on 25,000 or 50,000 V alternating

⑪ Roof hatch

FIGURE 21.8.4 Electric Locomotive Showing the Location of Some Essential Pieces of Apparatus

current from an overhead wire. Because the electric locomotive derives its power from an electrical circuit, it is necessary to deenergize the circuit to extinguish any electrical fire safely.

Emergency Stop Buttons. These buttons, one on each side of the locomotive under the operator's cab, can be reached from the ground. Pushing either button trips the vacuum circuit breaker on the roofs of all locomotives in the consist and removes the power.

Manual Pantograph Grounding Switch. Usually located in the right rear of the locomotive, this switch grounds the pantograph before personnel perform maintenance or climb to the roof through the rear hatch. Grounding the pantograph (catenary), which is described in special instructions, varies depending on locomotive type and the overhead system employed. Fire fighters should obtain this information from railroad officials and include it in prefire plans.

Emergency Shutdown Switch. This switch, located on the master control housing, is used in emergencies to remove power from the locomotive during single-unit operation or to remove power from all units of the consist during multiple operation.

Electric locomotives, by their very nature, operate with voltages considerably higher than diesel locomotives. Modern electric locomotives have vacuum breakers that trip in cycles, thereby considerably reducing short circuits that could cause fires on older motive power.

Preventive Maintenance. Preventive maintenance is mandatory to preclude downtime caused by fire or equipment failure. Electrical circuits are tested for grounds or other defects when equipment is at major shops or at intervals of no more than 3 months. All tests and scheduled maintenance are performed in compliance with U.S. DOT rules, as a minimum.

Portable Fire Protection Equipment. Electric locomotives are equipped with portable fire extinguishers. Gaseous extinguishers are normally located in each cab and in the equipment compartment. The number of onboard extinguishers varies with equipment type and company policy. To minimize damage to delicate equipment found on electric locomotives, every effort should be made to use a gaseous agent to extinguish a fire.

Safety Precautions. Certain precautions must be observed when boarding an electric locomotive in an emergency, such as the following:

1. Never climb on top of any railroad equipment under an overhead catenary system until obtaining positive assurance that the wires have been deenergized and that locomotive grounding switches are engaged. Failure to follow this procedure can result in severe burns and even electrocution.

2. It is imperative that all persons on or near electric locomotives be aware of hazards associated with the high voltages involved. Electricity supplied by the overhead catenary system is typically 11,000 V ac and from the third rail, 600 V dc. Voltages within locomotive electrical cabinets are 600 V dc and 480 V ac. If the catenary wire falls on the train body, it energizes the entire train with high voltage. Do not assume that safety features on the power system or locomotive have functioned and deenergized the circuits. Make certain the power is off or use suitable precautions.

3. Unless human life is threatened, no fire-fighting activity should be undertaken on an electric locomotive until the catenary power has been removed and the overhead wire grounded by a qualified electric traction (ET) representative from the railroad. If action is required before an ET representative arrives, consult the train crew's conductor or engineer. These individuals are trained in the proper procedures to lower and secure the pantograph and to ground the electrical equipment.

4. Never enter any high-voltage compartment when the locomotive is energized.

5. Never touch motors, switches, protective barriers, or other electrical apparatus without knowing their exact purpose and function.

6. To protect against serious or fatal personal injury, be sure the pantograph is actually latched down before opening the roof hatch.

FREIGHT CARS AND EQUIPMENT

Freight cars account for the largest share of rail vehicle fires (Table 21.8.3). Major causes of fire in freight equipment, including motive equipment, are collision/derailment, suspected arson, electrical, brake shoe sparks or overheated brakes, welding and cutting, hot journals, and heating appliances. Tables 21.8.4 to 21.8.6 provide additional information on leading causes of rail vehicle fires.

Design advances and preventive maintenance are keys to reducing or eliminating fires caused by brake shoe sparks, exhaust sparks, hot journals or "hot boxes," electrical failures, and hot particles emitted from internal combustion engines. Design advances that should lessen the frequency of fires include increased use of turbochargers; renewed attention to the design and maintenance of eductor tubes, long a source of hot carbon particles on turbocharged locomotives; spark retention exhaust manifolds; nonsparking brake shoes; roller bearings; heat detectors, sensors, and indication lamps that supervise electrical circuits and components; and increased use and efficiency of trackside devices to detect overheated journals and dragging equipment.

Cotton bales are shrink-wrapped, which eliminates the need for metal bale bands and virtually eliminates the possibility of cotton bale fires. Bale fires can be caused by friction heat, which results when the bale bands rub against and ignite loose strands of cotton.

Fires resulting from collisions and derailments are a major concern of the railroad industry. To reduce these incidents, operating rules and safety programs are undergoing major revisions. An inventory of all grade crossings is being used by individual states to establish priorities for crossing improvements. This systemized approach to reducing crossing accidents, combined with the Federal Aid Highway Act of 1976 and the "Operation

TABLE 21.8.3 U.S. Rail Vehicle Transport Fire Problem, by Type of Vehicle, 1994–1998 Annual Averages

Vehicle Type	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Property Damage (in Millions of Dollars)*	
Freight, box, or hopper car	220	(33.8%)	0	(0.0%)	0	(0.0%)	2.8	(31.2%)
Locomotive or engine	200	(30.0%)	2	(37.9%)	4	(32.2%)	11.5	(54.7%)
Passenger or diner car	60	(8.6%)	3	(51.7%)	4	(33.9%)	1.2	(5.9%)
Maintenance equipment car	40	(6.2%)	0	(0.0%)	0	(3.4%)	0.5	(2.3%)
Self-powered car, trolley, or rapid-transit car	30	(4.4%)	0	(0.0%)	1	(6.8%)	0.1	(0.5%)
Container or piggyback car	20	(2.6%)	0	(0.0%)	1	(6.8%)	0.1	(0.7%)
Tank car	10	(1.4%)	0	(0.0%)	0	(3.4%)	0.9	(4.4%)
Unclassified or unknown-type rail transport vehicle	90	(13.1%)	1	(10.3%)	2	(13.6%)	3.8	(18.3%)
Total	650	(100.0%)	6	(100.0%)	12	(100.0%)	21.0	(100.0%)

Note: These are fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies. Fires are rounded to the nearest ten, civilian deaths and injuries to the nearest one, and direct property damage to the nearest hundred thousand dollars. Sums may not equal totals due to rounding errors. Property damage figures are not adjusted for inflation. Percentages were calculated on the actual estimates, so two figures with the same rounded-off estimates may have different percentages.

Lifesaver" educational program, is keeping the public alert to the dangers associated with railroad crossings.

Refrigerator Cars

Three types of cars commonly transport perishable and semiperishable commodities that require refrigeration, heater service, or protection from the extremes of heat or cold.

Standard Car. The standard ice car is virtually obsolete as a refrigerator car. Few railroads still furnish ice for shipment in such cars. However, some cars still may be used to keep commodities from freezing. Portable liquid fuel heaters that burn a mixture of methanol and isopropanol can be installed in the end ice bunkers. Alcohol foam is recommended as an extinguishing agent for these fuels because water may be ineffective.

Insulated Bunkerless Car. The insulated bunkerless car is widely used to protect semiperishable commodities such as canned goods, beer, grocery products, and drugs and medicines from extreme heat and cold. These cars provide no refrigeration, but they can be equipped with portable liquid fuel heaters. The heaters are usually suspended by chains from hooks, four per heater, in the ceiling of doorway areas. Heat shields protect the ceiling above each heater.

Refrigerated Car. The mechanically refrigerated car is the most modern and versatile of the freight cars used for perishables (Figure 21.8.5). It provides automatically controlled temperatures from 0 to 70°F (–18 to 21°C). Foamed-in-place polyurethane insulation helps to ensure consistent and dependable car temperatures. A compressor-evaporator is powered by a self-contained diesel-engine generator set located in a separate compartment within the car. The compressor-evaporator also can be powered directly from the alternator output of a diesel electric unit or from any suitable 220-V standby power supply. The fuel tank for the diesel engine is suspended below the car and normally carries 500 to 550 gal (1.9 to 2.1 m^3) of No. 1 or No. 2 diesel fuel oil. Fire fighting can be complicated by burning insulation and by the fact that fire fighters have not learned the location of the diesel engine stop control, which is clearly identified. Fire fighters should wear self-contained breathing apparatus when they enter a burning insulated or refrigerator car.

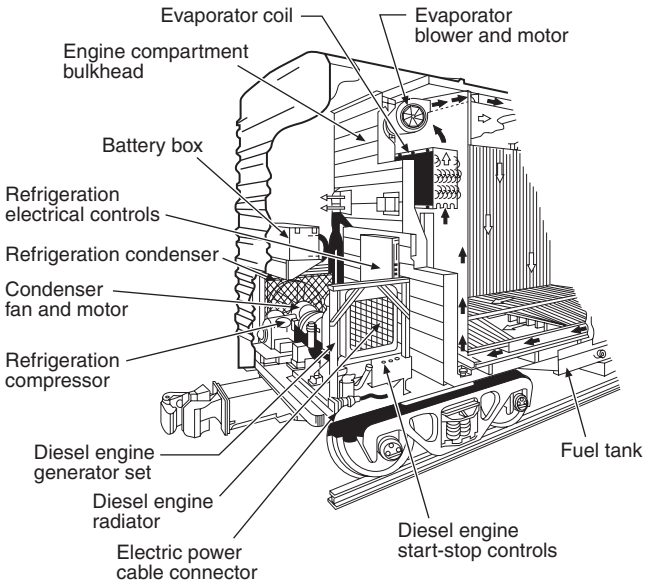

FIGURE 21.8.5 Engine Compartment of a Typical Mechanically Refrigerated Car. Note the start-stop control for the diesel engine at the lower left, mounted on the side of the car.

TABLE 21.8.4 U.S. Rail Transport Vehicle Fires, by Factor Contributing to Ignition Grouping, 1999–2002 Fires Reported to U.S. Fire Departments in NFIRS Version 5.0

Factor Contributing to Ignition	*Percentage of Fires*	*Percentage of Civilian Deaths*	*Percentage of Civilian Injuries*	*Percentage of Direct Property Damage*
Mechanical failure or malfunction	47	0	33	51
Unclassified mechanical failure or malfunction	27	0	0	27
Leak or break	13	0	33	23
Worn out	4	0	0	0
Backfire	2	0	0	0
Manual control failure	1	0	0	0
Misuse of material or product	19	0	0	7
Cutting or welding too close to combustible material	8	0	0	3
Heat source too close to combustible material	5	0	0	2
Abandoned or discarded material or product	2	0	0	0
Unclassified misuse of material or product	1	0	0	0
Flammable liquid used to kindle fire	1	0	0	0
Flammable liquid or gas spilled	1	0	0	1
Electrical failure or malfunction	15	0	67	6
Unclassified electrical failure or malfunction	8	0	0	2
Unspecified short circuit arc	3	0	0	0
Short circuit arc from defective, worn insulation	2	0	0	1
Arc or spark from operating equipment	1	0	0	0
Arc from faulty contact or broken conductor	1	0	67	0
Operational deficiency	7	100	0	7
Collision, knockdown, or overturn	1	100	0	0
Unclassified operational deficiency	1	0	0	1
Failure to clean	1	0	0	3
Overloaded equipment	1	0	0	0
Unattended equipment	1	0	0	2
Equipment not operated properly	1	0	0	0
Fire spread or control	5	0	0	32
Exposure fire	3	0	0	32
Rekindle	1	0	0	0
Unclassified fire spread or control	1	0	0	0
Design, manufacturing, or installation deficiency	2	0	0	0
Design deficiency	1	0	0	0
Manufacturing deficiency	1	0	0	0
Unclassified natural condition	2	0	0	0
Unclassified factor contributed to ignition	7	0	0	3

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. More than one factor contributing to ignition may be entered per incident. Fires in which the factor contributing to ignition was undetermined, not reported, or coded as "none" were allocated proportionally among fires with known factor contributing to ignition. Although this field is not required for fires that were coded as intentionally set or attributed to a cause of "other," the share of incidents with unreported data (fires—17%, deaths—0%, injuries—40%, property damage—54%) or fires with "none" (fires—27%, deaths—0%, injuries—0%, property damage—7%) generally exceeded those for undetermined (fires—11%, deaths—0%, injuries—0%, property damage—9%), suggesting that this type of allocation would be most appropriate.

TABLE 21.8.5 U.S. Rail Transport Vehicle Fires, by Area of Fire Origin, 1999–2002 Fires Annual Averages

Area of Fire Origin	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*	
Engine area, running gear, or wheel area	340	(45%)	0	(0%)	2	(2%)	6.0	(35%)
Cargo or trunk area of vehicle	120	(15%)	0	(0%)	2	(2%)	4.2	(24%)
Unclassified vehicle area	70	(9%)	0	(0%)	1	(1%)	3.1	(18%)
Exterior or exposed surface of vehicle	50	(6%)	0	(0%)	0	(0%)	1.0	(6%)
On or near railroad right-of-way	40	(6%)	0	(0%)	0	(0%)	1.6	(9%)
Operator or passenger area of vehicle	40	(5%)	5	(77%)	75	(95%)	0.5	(3%)
Unclassified area of origin	20	(2%)	0	(0%)	0	(0%)	0.1	(1%)
Separate operator or control area of vehicle	10	(2%)	0	(0%)	0	(0%)	0.0	(0%)
Fuel tank or fuel line	10	(1%)	1	(16%)	0	(0%)	0.1	(1%)
Storage room, area, tank, or bin	10	(1%)	0	(0%)	0	(0%)	0.2	(1%)
On or near highway, parking lot, or street	10	(1%)	0	(0%)	0	(0%)	0.0	(0%)
Unclassified storage area	10	(1%)	0	(0%)	0	(0%)	0.0	(0%)
Other known area	40	(5%)	0	(7%)	0	(0%)	0.4	(2%)
Total	770	(100%)	6	(100%)	79	(100%)	17.4	(100%)

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest ten, civilian deaths and injuries to the nearest one, and direct property damage is rounded to the nearest hundred thousand dollars. Sums may not equal totals due to rounding errors. Property damage figures are not adjusted for inflation. Percentages were calculated on the actual estimates, so two figures with the same rounded-off estimates may have different percentages. Fires in which the area of origin was unknown or not reported were allocated proportionally among fires with known area of origin.

Source: NFIRS and NFPA survey.

Box Cars

The design of all box cars is essentially the same; only the capacity, length, and details of the cars vary. Additions, such as special racks, dunnage devices, and nailable steel floors, are made to prevent vibration damage to the contents of the car without adding combustibility.

Special-Purpose Rail Cars

Equipment used to meet special shipping needs includes articulated cars, multilevel and enclosed cars for automobiles, "high cube" (large-capacity) box cars, 100 ton (90 metric ton) capacity covered hoppers, side-loading "all door" box cars, and aerated cars to handle bulk materials that require pneumatic loading and unloading mechanisms to "inhale" cargo at the loading point and "exhale" it at the destination.

"Intermodal service," in which specially designed flatcars carry loaded cargo containers, intermodal tank containers, or highway-type truck trailers, is an increasingly important part of the rail transportation business. Loaded and sealed, containers and trailers are delivered to the railroad at special intermodal terminals, where they are placed, usually by crane, onto the flatcar. Intermodal cars usually are part of a regular train, but intermodal-only trains are increasingly common. A single intermodal flatcar carrying two trailers, or as many as four cargo containers, usually has a wider variety of cargo than a single box car. Intermodal service also uses articulated cars of various designs and length for transporting containers and trailers.

Cabooses

Once every train had a locomotive at one end and a caboose at the other. The caboose was the traveling office of the conductor, the person in charge of the train, and a rear brakeman. Today, cabooses are a rarity; end-of-train electronic devices have taken over their "train-completion" function. Now only two or three persons riding in the lead locomotive customarily staff long-haul trains. Cabooses today are found only on an occasional branch-line or short-line train.

Cabooses' chief fire hazards are their combustible furnishings and heating systems. Most cabooses are heated with oil or coal. Fires can start because stoves and stovepipes do not have adequate clearances from combustible materials. Fire protection varies from water extinguishers to portable dry chemical extinguishers, although some carriers have discontinued this protection because of continuing problems with extinguisher theft.

RAIL TANK CARS

A tank car is a type of bulk packaging in which the tank is an integral part of a rail transport vehicle. More than 250,000 tank

Source: National estimates based on NFIRS and NFPA survey.

cars transport a diverse range of commodities—both hazardous and nonhazardous—including a variety of compressed and liquefied gases, liquids, and solids. The number and types of materials transported in a tank car depend on the size, construction, fittings, linings, and other physical features of the tank.

When faced with a tank car problem, communicating an accurate, detailed description of its contents, its condition, and other circumstances to tank car specialists not on the scene may be the most beneficial contribution an emergency responder can make. To help provide that information, one must under-

stand tank car construction and features, tank car markings, types of tank cars, and tank car fittings.

Tank Car Construction and Features

Typically, tank cars are enclosed longitudinal cylinders (with or without compartments) with rounded ends called heads. Tank cars may or may not have underframes. If not, the tank must bear the stresses of train movement. Tank cars have railroad running gear and safety appliances. Figure 21.8.6 shows the shape and components of typical tank cars.

Tank cars may have such features as insulation, thermal protection, linings, and claddings. Manufacturers add these features to a basic tank, depending on the physical properties of commodities the tank is to carry. Safety features are applied to tank cars to reduce the potential for a release. Older tank cars have been retrofitted with these newer safety features.

Tank cars are built to mechanical standards common to all rail freight cars. In addition, they must meet the requirements of both the *Hazardous Materials Regulations of the Department of Transportation* (49 CFR, Part 179) and the AAR *Manual of Standards and Recommended Practices, Section C—Part III, Specifications for Tank Cars.* They also meet or exceed the ASME standards for pressure vessels. Builders must obtain design approval from the AAR Tank Car Committee before building a tank car. Transport Canada's *Regulations for the Transportation of Dangerous Commodities by Rail* contains Canadian tank car requirements.

Repairs of tank car tanks requiring welding, riveting, removal of damage, alterations, or conversions must occur only at AAR-certified facilities, using procedures and materials the AAR Tank Car Committee has approved.

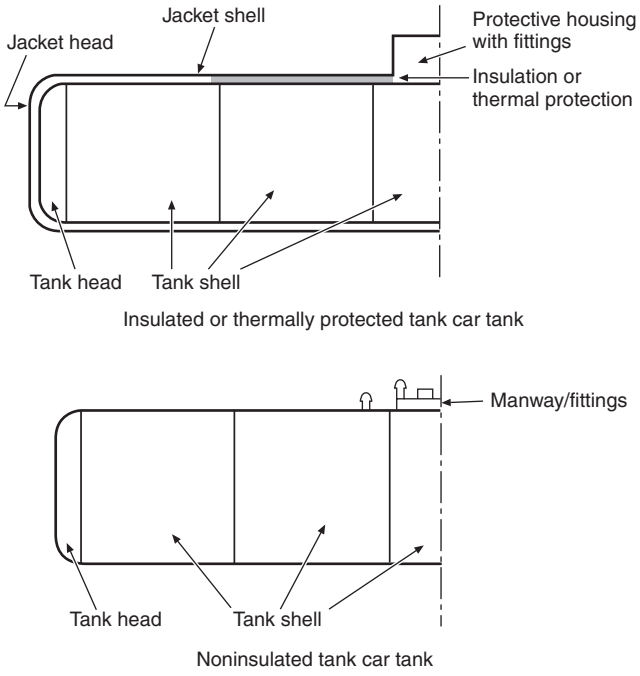

FIGURE 21.8.6 Tank Car Design and Nomenclature

Tank Car Tanks. Each tank car tank consists of a cylindrical shell closed at the ends by heads. The shell is constructed of two to seven rings formed from metal plates. Heads are made from plates pressed into a flanged-and-dished or an ellipsoidal shape; 2 to 1 ellipsoidal heads are the strongest. The rings and heads are fusion-welded together. In some older nonpressure tank cars, the tank parts are riveted together.

The completed tanks are heated to 1100°F (593°C) for 1 hour to relieve metal stresses caused by welding. Representative samples are X-rayed to identify possible flaws in the metal or the welds. Finally, they are hydrostatically tested.

Carbon steel is used in over 90 percent of tank car tanks, with aluminum making up most of the remainder. Stainless steel, referred to in the regulations as alloy steel, is used in a smaller number of cars. Nickel or nickel alloy is used for some tanks in acid or food services. Regulations specify the plate thickness of materials used to construct tank car tanks (Table 21.8.7).

TABLE 21.8.7 Minimum Tank and Jacket Plate Thickness

Minimum Plate Thickness After Forming	*Common Use of Plate Thickness*
Steel	
11 gauge (approximately ⅛ in.), also aluminum	Jacket of insulated tank cars, or jacket for thermally protected cars
7/16 in.	Tank for nonpressure tank cars, outer tank for nonpressure tank within a tank, or shell portion of outer tank for cryogenic liquid tank cars
½ in.	Head puncture resistance (head shield) or head portion of outer tank for cryogenic liquid tank cars
9/16 in.	Tank for steel pressure tank cars with tank test pressures of 200 psi and below
11/16 in.	Tank for steel pressure tank cars with tank test pressures of 300 psi and greater
¾ in.	Tank for steel pressure tank cars in chlorine service
Aluminum	
½ in.	Tank for nonpressure aluminum tank cars
⅝ in.	Tank for aluminum pressure tank cars

Notes:
1. If high-tensile-strength steels are used, plate thickness for pressure tank car tanks may be reduced but in no case should that thickness be less than ½ in.
2. Plate thickness for nonpressure steel tank cars with expansion domes is a function of where the plate is used in the tank and the diameter of the tank. Thickness ranges from ¼ to ½ in. For tank cars built after 1969, minimum plate thickness is 7/16 in., except for tank cars with a diameter of 12 to 122 in. where the thickness is ½ in.
3. For SI units: 1 in. = 2.54 cm; 1 psi = 6.9 kPa.

The capacities of tank car tanks vary from 4000 gal (15 m^3) to approximately 45,000 gal (170 m^3) in jumbo tank cars. Since 1970, however, the maximum capacity of new DOT specification tank cars transporting regulated hazardous materials is limited to 34,500 gal (130 m^3), or not more than 286,000 lb (119,295 kg) gross weight on rail.

Tank car tanks may be divided into as many as six compartments, each of which is actually a separate tank. Compartments may be of different capacities and may transport different commodities (Figure 21.8.7).

Car Structure. The completed tank is mounted on a car structure. The car structure consists of body bolsters attached to a framework (either continuous or stub sill). The framework rests on trucks at each end. The structure of the tank car includes the following components:

1. *Underframe.* Either a continuous underframe in which a one-piece assembly bridges the trucks of a tank car and assumes the draft and buff forces associated with train movement; or stub sill (underframeless), in which a short, longitudinal structural member welded to each end of the tank accommodates the coupler and draft gear assemblies and the attachment of the tank to its trucks
2. *Bolster.* In which a structural crossmember is mounted transversely to cradle the tank; tank cars have two body bolsters, one at each end of the tank
3. *Truck assembly.* Which consists of wheels, axles, sideframes, springs, truck bolster, and center bowl and pin; it supports one end of the car and allows it to be moved on the rail

Car Features. To increase their usefulness for a wide range of materials, tank cars may be equipped with various features, such as insulation, thermal protection, jackets, linings and claddings, and heater coils. These features have the following characteristics:

1. *Insulation.* Insulation is used on some tank cars to moderate the effects of temperature on the cars' contents. Fiberglass or polyurethane foams are the most common insulating materials. However, cork insulates tank cars carrying hydrocyanic acid, and perlite insulates cars transporting refrigerated liquid gases.

2. *Jacket.* Both insulation and jacketed thermal protection are held in place by a jacket, which also keeps out the elements. The jacket is constructed of a minimum of 11 gauge (approximately ⅛ in.) steel and serves as a heat-radiation shield. Metal brackets hold the jacket away from the tank. Jacketed cars can be recognized by a metal protective cover, or flashing, over the body bolster or tank bands; by the flattened appearance of the ends of the tank car; by flat sections on the sides of the car; or by the rough appearance of visible welds, even lap welds, which are generally thinner than the tank weld.

3. *Linings and claddings.* Some tank cars are lined to protect the tank from the corrosive or reactive effects of the contents or to maintain the contents' purity.

   a. Lining materials and coatings are applied after the tank is constructed. Rubber is most commonly used in hazardous materials service, but glass, lead, nickel, polyurethane, polyvinyl chloride, and stainless steel are also used.
   b. Cladding materials are applied to the tank base metal before the plate is formed. Nickel and stainless steel are used as cladding materials.

4. *Heater coils.* Some tank cars are equipped with heater coils, either inside or outside the tank. Steam, water, or hot oil from an external source runs through these coils to heat thick or solidified materials, such as asphalts, fused solids, heavy fuel oils, phenol, metallic sodium, or petroleum waxes to make them flow more easily when unloading. Outlets and inlets for interior heater coils have caps, which are in place when the car is loaded so that any damage to the coils does not release contents. Caps are off when the car is emptied and for cars equipped with external heat coils.

Safety Features

Various safety features have been instituted for tank cars to improve the safety of new and existing cars. The next four paragraphs provide examples of these programs.

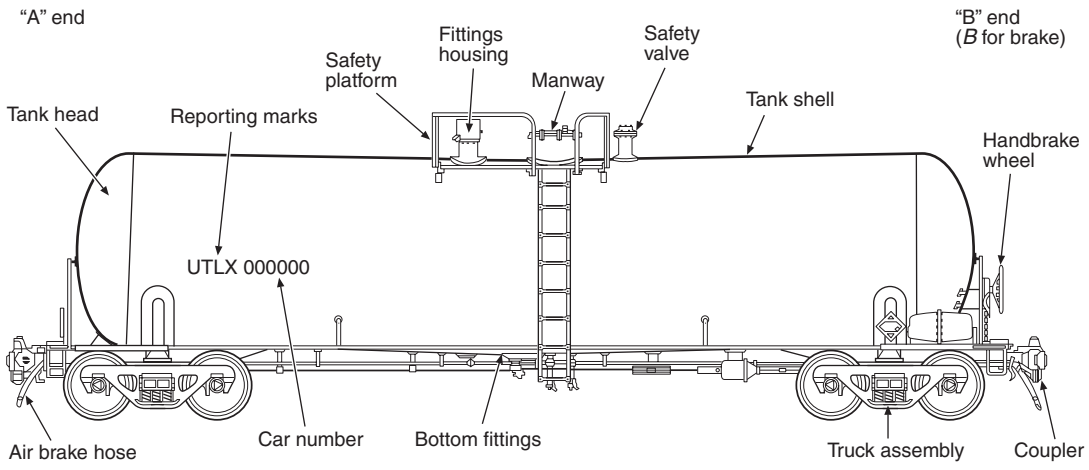

FIGURE 21.8.7 Typical Tank Car Tank with Some Basic Features Identified

Head Puncture Resistance (Head Shields). The head shield is applied to the lower portion of both ends or may cover the entire head to protect it against punctures. Some head shields are built into the jacket, whereas others are visible either as "half head" or trapezoidal-shaped plates of steel mounted on both ends of the tank car. Some head shields cover the entire head of the tank.

Top and Bottom Shelf Couplers. A top and bottom shelf coupler is a type of coupler with a vertical restraint mechanism, top and bottom, to reduce potential coupler disengagement in an accident.

Thermal Protection. Thermal protection, not to be confused with insulation, is used on some tank cars to protect the tank from flame impingement. It is designed to keep tank metal temperatures below 800°F (427°C) for 100 minutes (pool fire impingement) or 30 minutes (torch fire impingement). Thermal protection is used primarily on tank cars transporting liquefied flammable gases and on some nonpressure tank cars, such as the DOT-111J100W4 tank car for ethylene oxide. The following two types of thermal protection are used:

1. Jacketed thermal protection, in which mineral wool or various man-made ceramic fiber blankets are held in place by a metal jacket
2. Sprayed-on thermal protection, in which rough-textured coating sprayed onto the tanks or the jacket in some jacketed cars protects by expanding on exposure to fire

Bottom Discontinuity, or Skid, Protection. Skid protection is a safety device applied to the bottom of tank cars to protect bottom outlets, washouts, and sumps in a derailment.

Tank Car Markings

Various markings found on tank cars include initials, called reporting marks, and tank number; a specification marking; a DOT special permit (previously called an exemption) marking; tank and valve test dates; and tank identification plates.

Initials (Reporting Marks) and Tank Number. The car's initials and number identify the tank car, like any other freight car. The initials and number are found on both sides and both ends of a tank car. As one faces the side of the car, the initials and number are found on the left.

The initials indicate ownership of the car. An "X" as the last initial represents private ownership; that is, the railroad does not own the car. The number following the initials identifies the specific car. Most tank cars are owned by nonrailroad companies.

Using the car's initials and number, shippers, carriers, and emergency response personnel can identify a tank car's contents from the computer or shipping papers. The shipping papers indicate when the contents are hazardous.

Specification Marking. A specification marking identifies the standards to which a tank car is built. The specification marking is stamped into the head of the tank and stenciled on the car's sides. As one faces the side of the car, the specification number is to the right, opposite its initials and number.

The specification marking consists of a two- or three-letter prefix, followed by a series of numerals and/or letters. Specification markings may be as simple as DOT-103 or as detailed as DOT-111A60ALW1. A specification marking does not identify the car's contents but does indicate how the tank car was built. Specification information can be obtained from the railroad's computer using the car's initials and number (Figure 21.8.8).

Two- or three-letter prefixes of the specification marking include the following:

- DOT—Department of Transportation
- AAR—Association of American Railroads
- ICC—Interstate Commerce Commission (authority to DOT in 1966)
- CTC—Canadian Transport Commission
- TC—Transport Canada (replacing CTC)

Class. The *class* is the general designation of a tank car that may include several specifications (see Table 21.8.8). The term *class* designates a group of several specifications (e.g., Class DOT-112). The approving authority prefix and class number together indicate the class.

The specification is the specific designation of a tank car within a class (e.g., Specification DOT-112J340W).

Delimiter Letter. On most nonpressure tank cars, the letter *A* separates the class number from the tank test pressure and has no meaning. However, on pressure tank cars, cryogenic liquid tank cars, and some nonpressure tank cars, the letter indicates

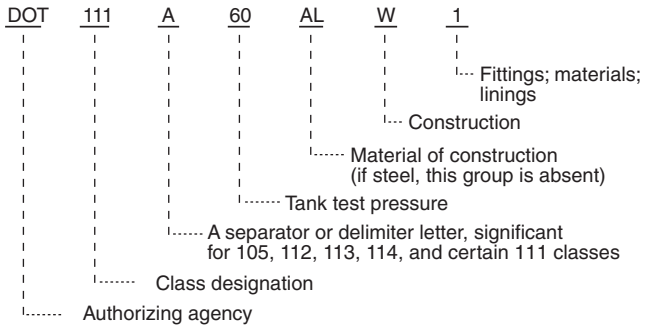

FIGURE 21.8.8 Explanation of Specification Marking

DOT-109

Cryogenic liquid tank car classes
DOT-113 AAR-204

how the car is equipped. The last number following the weld construction designator, if present, identifies special fittings, materials of construction (alloy steel), and linings.

You can get specification information from the railroad, shipper, car owner, or the Association of American Railroads (from the car's certificate of construction) by using the car's initials and number. The specification is the specific designation of a tank car within a class (e.g., Specification DOT-112J340W). The location of a specification marking is shown in Figure 21.8.9.

Capacity Stencil. The volume of the tank car tank, typically in gallons and liters, is stenciled on both ends of the car under the car's initials and number (Figure 21.8.10). The load limit, typically in pounds and kilograms, is stenciled on the sides of the car under the car's initials and number. *Load limit* means the same as *capacity.* Certain tank cars (e.g., DOT-111A100W4) have the water capacity (water weight) of the tank, typically in pounds and kilograms, stenciled on the sides of the tank near the center of the car.

FIGURE 21.8.9 Location of Specification Marking on Tank Cars with Qualification Stencil

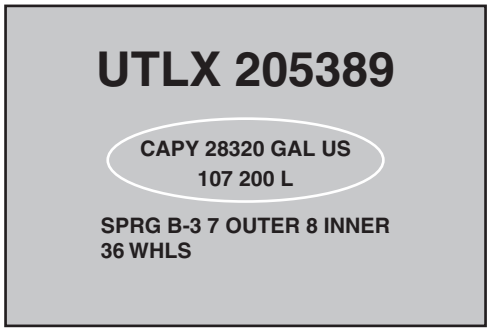

FIGURE 21.8.10 Capacity Stencil Marking Found on Heads of Tank Cars

DOT Special Permit (Previously Exemption) Marking. When special permits (exemptions) from the regulations for packages and containers and the preparation and offering of hazardous materials for shipment are made, the outside of each package must be plainly and durably marked DOT-SP (previously DOT-E) followed by the number assigned, such as DOT-SP8623 (previously DOT-E8623). On portable tanks, cargo tanks, and tank cars, the marking must be in 2 in. (50.8 mm) letters. This SP marking replaces the previously used E marking for an exemption from the regulations.

Tank Car Qualification Stencil. Tank and pressure-relief devices, if installed, have varying retest intervals, depending on the car's specification and/or age. Retest and test due dates must be marked or stenciled on the tank or on a dataplate. Interior coils are also tested (see Figure 21.8.9).

Tank Car Identification Plate. New tank cars will be equipped with two identical stainless steel identification plates. Plates (Figure 21.8.11) are permanently affixed in a visible location to the inboard surfaces of the AR and BL body bolster webs. The information on the dataplate includes the manufacturer, serial number, AAR certificate number, tank specification, shell and head material, insulation material, and date of manufacture.

Tank Car Types

Tank cars are classed according to their construction, features, and fittings. The tank's specification determines the product it may transport.

Nonpressure Tank Cars. Nonpressure tank cars, also known as general-service tank cars or acid-service tank cars, transport a wide variety of hazardous and nonhazardous materials at low pressures. Nonpressure tank cars transport hazardous materials, such as flammable and combustible liquids, flammable solids, oxidizers, organic peroxides and poison, corrosive materials, and molten solids. They also transport nonhazardous materials, such as tallow, clay slurry, corn syrup, and other food products.

Tank test pressures for nonpressure tank cars range from 60 to 100 psi (430 to 689 kPa). Capacities range from 4000 to 45,000 gal (15 to 181 m^3).

Nonpressure tank car tanks are cylindrical with rounded heads. Newer nonpressure tank cars have at least one manway to allow access to the car's interior. Some older nonpressure tank cars have at least one expansion dome with a manway (Figures 21.8.12 and 21.8.13). Fittings for loading and unloading, pressure and/or vacuum relief, gauging, and other purposes are visible at the top and/or bottom of the car.

Nonpressure "Tank-Within-a-Tank" Tank Cars. This nonpressure tank car is built as a tank within a tank. It consists of an inner tank of steel, alloy steel, or aluminum covered with thick insulation and enclosed within an outer tank. This tank car transports temperature-sensitive materials, such as food products.

FIGURE 21.8.11 Tank Identification Plate

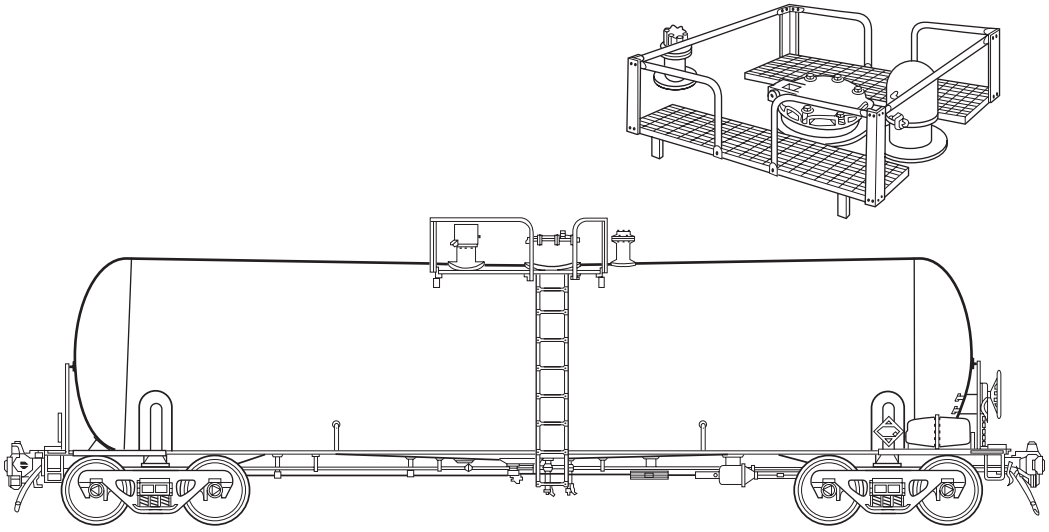

FIGURE 21.8.12 Typical Nonpressure Tank Car (DOT-111)

Tank Train®. The Tank Train is a series of nonpressure tank cars interconnected with flexible hoses that allow the cars to be loaded and unloaded from one end. A spring-loaded butterfly valve arrangement on each car is controlled pneumatically from the loading/unloading point. After loading, hoses are purged of liquid, and valves close automatically, isolating each car. The Tank Train transports hazardous and nonhazardous materials, including gasoline, fuel, oil, caustic soda, and pesticides.

Multicompartmented Nonpressure Tank Cars. Multicompartmented nonpressure tank cars have up to six compartments. Each compartment is considered a separate tank because of its

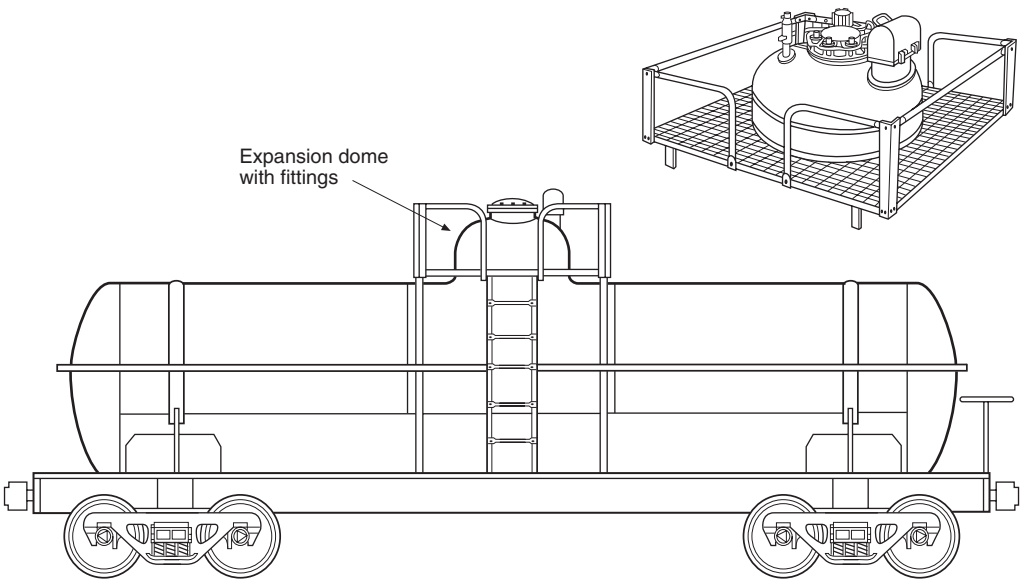

FIGURE 21.8.13 Typical Older-Style Nonpressure Tank Car (DOT-103) with an Expansion Dome

construction. Compartments may be of different capacities and may contain different materials. Each compartment has its own loading and unloading fittings.

Pressure Tank Cars. Pressure tank cars typically transport hazardous materials, including flammable, nonflammable, or poisonous gases at higher pressures. However, pressure tank cars can transport other commodities, depending on the characteristics of the product or the process for loading and unloading the tank. Other products transported in pressure tank cars are ethylene oxide, pyrophoric liquids, sodium metal, motor fuel antiknock compounds, bromine, anhydrous hydrofluoric acid, and acrolein (Figure 21.8.14).

Tank test pressures for these tank cars range from 100 to 600 psi (689 to 4137 kPa). Pressure tank cars range in capacity from 4000 to 45,000 gal (15 to 170 m^3).

Pressure tank cars are cylindrical, noncompartmented steel or aluminum tanks with rounded heads. They are top-loading,

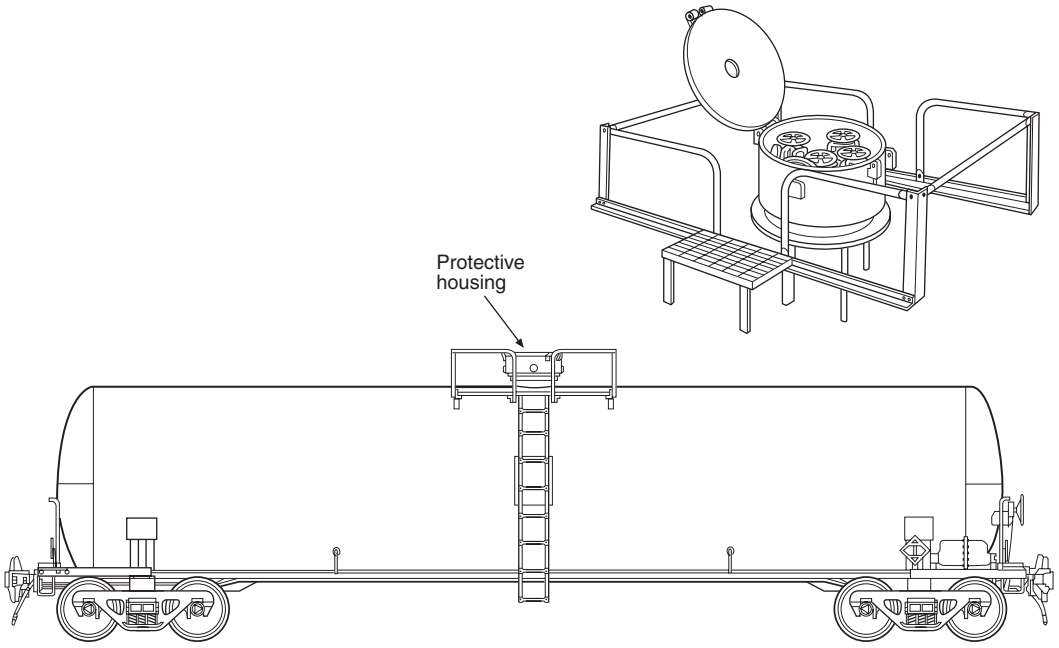

FIGURE 21.8.14 Typical Pressure Tank Car with Protective Housing

with fittings for loading and unloading, pressure relief, and gauging located inside protective housing mounted on a single manway.

Pressure tank cars may be insulated and/or thermally protected. The top two-thirds of pressure tank cars without insulation and without jacketed thermal protection will be painted white or another reflective color.

Cryogenic Tank Cars. Cryogenic tank cars carry low-pressure—usually 25 psi (172 kPa) or lower—cold liquids refrigerated to –155°F (–104°C) and below. Typical contents of these tanks are argon, ethylene, hydrogen, nitrogen, and oxygen (Figure 21.8.15).

Cryogenic tank car tanks (DOT-113) are of the tank-within-a-tank style with an alloy (stainless or nickel) steel inner tank inside an outer tank. The space between the inner tank and the outer tank is filled with insulation and under a vacuum. The combined vacuum and insulation protect the contents for only 30 days, making shipments in these cars time sensitive.

Fittings for loading and unloading, pressure relief, and venting are located in ground-level cabinets at diagonal corners of the car or in the center of one end of the car. Built to tank car specifications, the pneumatically unloaded covered hopper cars are covered hopper cars, which are unloaded through pressure differential, or pneumatics, by applying air pressure. Even though the pressure is used only during unloading, tank test pressures for the car range from 20 to 80 psi (138 to 551 kPa). Dry caustic soda is one commodity transported in this type of car (Figure 21.8.16).

Tank Car Fittings

Numerous fittings used on tank cars allow for loading and unloading and provide for safe transportation of their contents. All fittings are not found on all tank cars. This section addresses tank car fittings for nonpressure and pressure tank cars from a very general standpoint.

Fittings for Loading and Unloading Tank Cars. Various fittings are used to load and unload tank cars, including the following.

Manway. This large opening on top of the tank car allows access to the tank's interior. It is closed either with a permanently mounted cover plate with fittings attached or with a hinged-and-bolted cover opened for loading the car.

Liquid or Vapor Valves. These valves control the passage of liquid or vapor into or out of the tank in pressure tank cars (Figure 21.8.17).

Liquid valves, usually two, are used to load or unload liquids from tank cars. Unloading occurs as a result of pressure generated by the contents or when the tank is pressurized with air, nitrogen, or other gas. An eduction pipe reaches from the liquid valve to the tank's bottom.

One or two vapor valves are used to remove vapor from the tank or to pressurize the tank. On pressure tank cars, they are called vapor valves; on nonpressure tank cars, they are called air inlets or air valves. (Note: Excess flow valves found under various fittings shut when flow exceeds a predetermined amount.)

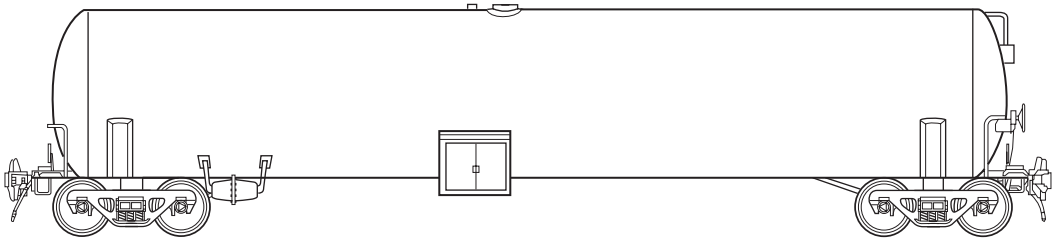

FIGURE 21.8.15 Typical Cryogenic Liquid Tank Car (DOT-113)

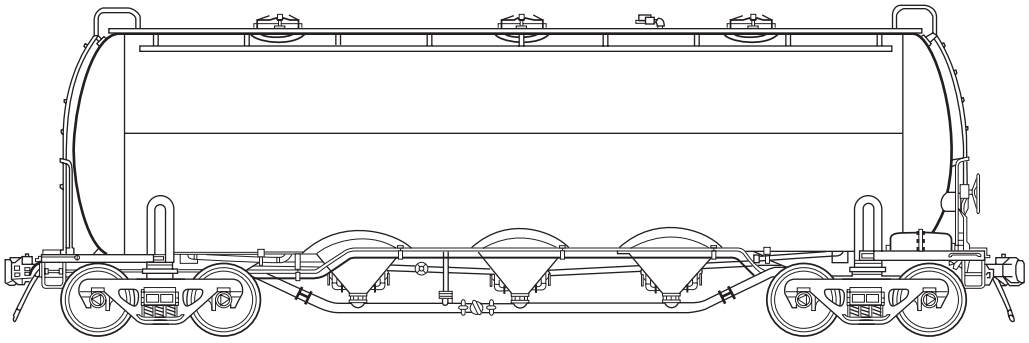

FIGURE 21.8.16 Pneumatically Unloaded Covered Hopper Car

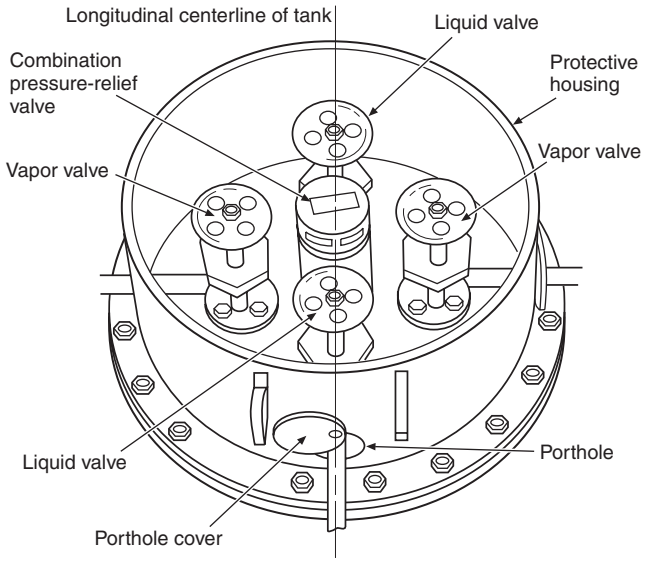

FIGURE 21.8.17 Fitting Arrangement in the Protective Housing on a Liquid Chlorine Tank Car

Bottom Outlet Valves. These valves are used to unload the tank from the bottom. Examples are a plug-type valve operated from the top of the tank, called a "top-operated bottom unloading valve"; a ball-type valve either external to or inside the tank and operated from ground level; or a wafersphere, or butterfly valve, mounted outside the tank.

Pressure-Relief Devices. These devices reduce the buildup of excess internal pressure that commodity vaporization and expansion cause. Pressure-relief valves are set at either 75 percent of the tank's test pressure or 33 percent of the tank's burst pressure.

Pressure-Relief Valve. This relief device has an operating part held closed by one spring or multiple springs. It is designed to open and reclose at predetermined pressures. The device can be mounted with the spring inside or outside the tank. It is typically set to activate when 75 percent of the tank test pressure is reached.

Safety Vent. This device uses a frangible disk, called a rupture disk, that seals the vent opening under normal conditions. The disk is designed to rupture at predetermined pressures and, once ruptured, does not reclose. Rupture disks are made of steel, plastic, rubber, or a combination of metal, plastic, or rubber. Lead is no longer authorized. Relief vents are used on certain nonpressure tank cars. Cars equipped with relief vents will be stenciled "Not for poisonous or flammable liquids."

Combination Pressure-Relief Device. This combination device uses a rupture disk and/or a breaking pin combined with a spring-operated pressure-relief valve.

Fittings for Gauging the Inage and Outage in Tank Cars. Gauging devices are used to determine the amount of lading in a tank. These devices allow one to measure the amount of liquid in the tank, such as liquefied or cryogenic gases (inage), or the amount of vapor space left in the tank (outage). Gauging devices usually measure outage. The following are two types of gauging devices:

1. *Open-type gauging devices.* These devices eject liquid once the liquid level reaches the bottom of a fixed- or adjustable-length tube; they read outage
2. *Closed-type gauging devices.* These devices use a float, coupled with a magnet on a measuring rod or a dial indicator, to show the liquid level of the commodity

Another method of determining the amount of lading in a tank car is to insert a measuring pole while using the appropriate inage/outage tables. Outage is also determined by gauge bars or "T" bars on most nonpressure cars.

Other Fittings. Various other fittings may be found on tank cars.

Sample Line. This device is used to obtain a sample of the commodity without opening the tank.

Thermometer Well. This closed tube, filled with a permanent-type antifreeze, extends into the tank. By inserting a thermometer into the tube, the temperature of the lading inside may be determined.

Bottom Washout. This bolted and flanged opening in the bottom of the tank car is used only when a tank is cleaned. There is no way to control the lading flow once the closure is removed.

Sump. This closed projection in the bottom of the tank allows the liquid eduction pipe to extend slightly below the bottom of the tank to unload the tank more completely.

Vacuum Relief Valve. This valve is designed to prevent excessive internal vacuum buildup (greater than 0.75 psi [5.5 kPa]) negative pressure in some nonpressure tanks. The vacuum relief valve used during unloading opens to admit air when a vacuum occurs and then recloses after normal conditions have been restored.

INTERMODAL TANK CONTAINERS

Since the early 1980s, the use of tank containers throughout the world has increased greatly. Factors accounting for this increase are improved safety, portability, lower transportation costs, and benefits of a multimodal transport system.

Advantages over alternative methods of transport, such as drums, tank trucks, and trailers, include reduction in the amount of handling required, faster transfer at ports and terminals, convenient storage options at the destination, and ready use of conventional container-handling equipment already in place.

Built according to many domestic and international standards, tank containers are used to transport diverse commodities, including an increasing number of hazardous materials.

Problems involving tank containers are best handled by giving an accurate, detailed description of the contents and condition of the tank container, and the circumstances to those with specialized knowledge and skills necessary to help handle the problem.

Tank Container Construction and Features

Tank containers consist of a single metal tank mounted inside a sturdy metal supporting frame. This unique frame structure, built to international standards, makes tank containers multimodal (intermodal). Thus, they are used interchangeably in two or more modes of transport, such as rail, highway, or water. Tank containers may be equipped with a variety of features.

Tank Container Tank. The tank container tank is generally built as a cylinder enclosed at the ends by heads. Other tank shapes—rectangular tanks—and configurations—tube modules—exist but are rare. Tanks with multiple compartments, each built as a separate tank, are also rare. A tank's capacity does not ordinarily exceed 6340 gal (about 24 m^3).

Ninety percent or more of the tanks are built of stainless steel; the rest are constructed of mild steel. Stainless steel is used because it resists cold temperatures. Aluminum and magnesium alloy tanks are available, but they cannot be used in water transport mode.

Minimum head and shell thickness is measured in terms of "equivalent thickness in mild steel" after forming. For steel tanks, the minimum thickness for nonregulated commodities is ¼ in. (6.35 mm). For regulated materials, the minimum thickness is ⅜ in. (9.5 mm). For stainless steel tanks, the minimum thickness for nonregulated materials is slightly less than ⅛ in. (3.2 mm). For regulated commodities, the minimum thickness is just under 3⁄16 in. (4.8 mm).

Most tanks are built according to the pressure-vessel standards of ASME, and the welds are X-rayed. Welds on carbon steel tanks are postweld heat-treated.

Supporting Frame. The supporting frame of a tank container protects the tank and provides for stacking, lifting, and securing the container. It also supports the walkways and ladders. Like other types of freight containers, supporting frames are built to the requirements of the International Standards Organization (ISO).

The most common size of supporting frame is 20 ft (6 m) long, 8 or 8½ ft (2.4 or 2.55 m) wide, and from 8 to 9½ ft (2.4 to 2.85 m) high. Except for the half-height tube modules and some cryogenic tank containers, some of which are 35 ft (10.5 m) long, very few tanks longer than 20 ft (6 m) are used in the United States.

There are two basic supporting frame types: the box type, which encloses the tank in a cagelike framework and the "beam type," which uses frame structures only at the ends of the tank.

Corner Casting. Supporting frames for all intermodal containers, including tank containers, are built with standard corner fittings, called corner castings. They are used to secure the tank and to lift it with standard container-handling equipment. Corner castings must conform to ISO standards. Cast-iron corner castings are prohibited. In an accident where proper lifting devices are not available, the corner castings may be used to lift or move the tank only after consulting the tank's owner or manufacturer.

Features. To increase their use for a wide range of cargoes, tank containers may be equipped with various features, such as linings that protect the tank from the lading, refrigeration units, electrical or steam heating, and insulation to maintain the desired temperature of the contents.

Foamed plastic, both polyurethane and polystyrene, is the predominant insulating material. However, mineral wool and fiberglass are also used. Insulation, generally 3 to 4 in. (76.2 to 101.6 mm) thick, is always covered with a weathertight jacket. Jackets are made of metal, at least 1⁄32 in. (1 mm) thick or of an equivalent thickness of plastic reinforced with either glass or fiber.

Tank Container Markings

Various markings may be found on tank containers, including the tank initials and number, the specification marking, the DOT exemption marking, the AAR 600 marking, the country and size/type markings, the dataplate, and the tank and valve test dates (Figure 21.8.18).

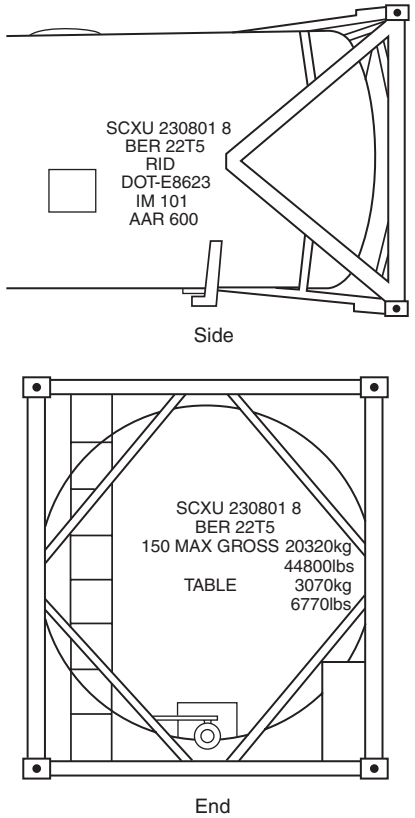

FIGURE 21.8.18 Typical Markings on Tank Containers

Tank Initials and Number. Tank containers must be registered with the International Container Bureau in France. They must be marked with initials, or reporting marks, and with a tank number. The initials indicate the tank's ownership, and the tank number identifies the specific tank.

The initials and tank number are generally on the right side of the tank, as one faces it from either side, and on both ends. They may be displayed either on the tank itself or on the frame.

With this information, shippers, carriers, and emergency response personnel can identify the tank's contents, using shipping papers or computer data. They can then determine if the contents are hazardous.

Specification Marking. The design, construction, and use of tank containers must conform to strict standards and regulations of many agencies, both in the United States and abroad. Markings on the tank container indicate the standards to which the tank was built.

In the United States, tank containers must meet the design, construction, and safety standards set forth by the DOT. Tanks meeting these standards have the specification markings or an exemption number displayed on both sides (generally the tank's initials and number). Examples of specification markings are IM 101 (IMO Type 1), IM 102 (IMO Type 2), and Spec. 51 (IMO Type 5 or IMO Type 7).

DOT Special Permit (Previously Called Exemption) Marking. When DOT grants special permits (previously exemptions) from the regulations governing packages and containers, and the preparation and offering of hazardous materials for shipment, the outside of each package must be plainly and durably marked in 2 in. (50.8 mm) letters and numbers—that is, DOT-SP (previously DOT-E) followed by the number assigned, such as DOT-SP 8623 (previously DOT-E8623).

AAR-600 Marking. For interchange purposes in rail transportation, tank containers should conform to the requirements of Section 600, "Specification for Acceptability of Tank Containers" of the AAR *Manual of Standards and Recommended Practices, Section C—Part III, Specification for Tank Cars.* Tanks meeting these requirements display the AAR 600 markings in 2 in. (50.8 mm) letters on both sides, near the tank's initials and number. The AAR-600 marking identifies tanks that can be used for regulated materials, whereas the AAR-600NR marking identifies tanks that cannot be used for regulated materials.

Country and Size Type Markings. In addition to the initials and number and the specification marking, the tank also displays a country code and a size/type code. When displayed, the two- or three-letter country code indicates the tank's country of registry.

The four-character size/type code follows the country code. Its first two characters (digits) jointly indicate the container's length and height. The second pair of characters (T + a digit) is the type code, which indicates the tank's pressure range.

Dataplate. For further technical, approval, and operational data, dataplates are permanently attached to the tank containers' tanks or frames.

Tank and Valve Test Dates. Tanks and pressure-relief devices, if installed, must have a retest interval not greater than 5 years. Retest and test due dates must be marked or stenciled on the tank or on the dataplate.

General Classes of Tank Containers

Tank containers are classed according to the specification of the tank and fittings. The classification of a tank container determines which products it may carry.

Nonpressure Tank Containers. Also called intermodal portable tanks or IM portable tanks, nonpressure tank containers comprise over 90 percent of the total (Figure 21.8.19). They usually transport liquid and solid materials at maximum allowable working pressures (MAWP) of up to 100 psi (690 kPa). Tanks are tested to at least 1.5 times the MAWP. In the United States, the following two groups of nonpressure tank containers are common:

1. *IM 101 portable tanks.* These tanks are built to withstand MAWP of from 25.4 to 100 psi (175 to 690 kPa). They may transport both nonhazardous and hazardous materials, including toxics, corrosives, and flammables, with flashpoints below 32°F (0°C). Internationally, an IM 101 portable tank is called an IMO type 1 tank container.

2. *IM 102 portable tanks.* These tanks are designed to handle lower MAWP—that is, from 14.5 to 25.4 psi (100 to 175 kPa). They transport materials such as liquor, alcohols, some corrosives, pesticides, insecticides, resins, industrial solvents, and flammables with flashpoints between 32 and 140°F (0 and 60°C). More often they transport various nonregulated materials, such as food-grade commodities. Internationally, an IM 102 tank is called an IMO type 2 tank container.

Pressure Tank Containers. Also known as DOT Spec. 51 portable tanks, these containers are less common in transport. Designed to handle internal pressures ranging from 100 to 500

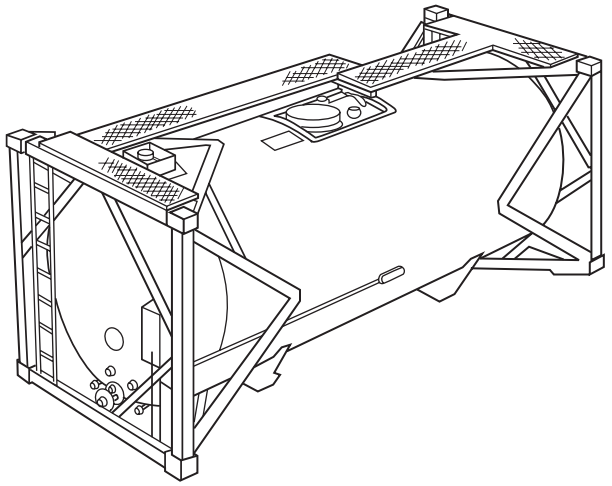

FIGURE 21.8.19 Nonpressure Tank Container

psi (690 to 3450 kPa), they generally transport gases liquefied under pressure, such as LP-gas and anhydrous ammonia. They may also carry liquids, such as motor fuel antiknock compounds or aluminum alkyls. Internationally, they are called IMO type 5 tank containers (Figure 21.8.20).

Specialized Tank Containers. There are several other variations of tank-type containers. Among them are the following:

1. *Cryogenic tank containers.* These containers carry refrigerated liquid gases, such as argon, oxygen, and helium, and are built to DOT Spec. 51 standards. Internationally, they are called IMO type 7 tank containers.
2. *Tube modules.* These containers transport gases in high-pressure 3T cylinders tested to 3000 or 5000 psi (20,700 or 34,500 kPa), permanently mounted within a full or half-height ISO frame (Figure 21.8.21).

Tank Container Fittings

Nonpressure Tank Container Fittings. Various fittings make nonpressure tank containers functional and safe.

Spillbox. On nonpressure tanks, a spillbox encloses the top fittings. It protects the tank's shell from any spillage. Any spilled material, as well as rainwater in the spillbox, drains through an open pipe.

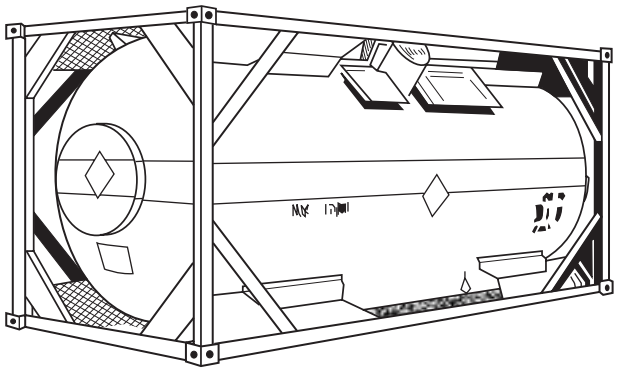

FIGURE 21.8.20 Typical Pressure Tank Container

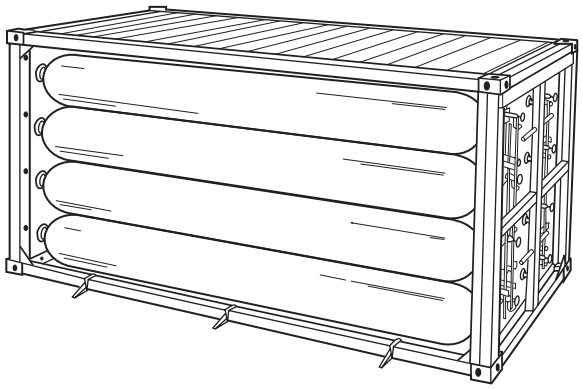

FIGURE 21.8.21 Tube Module

Manhole, Cover, and Dipstick. The manhole, located on the top center of the tank, is secured by six or eight wing nuts on a hinged and bolted lid fitted with a replaceable gasket.

The dipstick may be inside the manhole. Used in conjunction with a calibration chart, known as a strapping chart, it measures the amount of commodity in the tank. For liquids other than compressed gases, a minimum outage of 2 percent of total tank capacity must be provided in rail transportation.

Top-Loading Valves. Top-loading valves attached to a removable eduction pipe—dip leg, dip tube, or siphon tube—run into the tank.

Bottom-Outlet Valves. When tank containers are used for hazardous materials, two externally operated, bottom-outlet valves are required. Connected in series with a replaceable gasket between them, they are located at one end of the tank, the so-called discharge end. A liquidtight closure on the external valve is also required. It may be a blind flange, which is required on international shipments; a screw cap; or a cam-lock cap attached to the external valve. A positive lock is required on the external bottom valve to keep it closed.

In an emergency, the internal valve, or foot valve, can be shut off from a remote location. As one faces the discharge end of the tank, the emergency shutoff is on the right side near the far end.

Air-Line Connection. An air-line connection, located on the tank's top, can be used for pressure unloading, vapor return, and blanketing contents with an inert gas. On occasion, blind flanges may replace the top-loading valve and air-line connection. In this situation, the shipper or supplier of the tank must provide appropriate fittings for loading and unloading.

Pressure/Vacuum Relief Devices. Generally found in pairs on nonpressure tank containers, a combination pressure/vacuum relief device serves dual purposes of protecting the tank from both overpressure and from a vacuum of more than 0.75 psi (5 kPa) negative pressure. In many cases, this relief valve has a rupture, or bursting, disk between the pressure-relief valve spring and the commodity. It protects the spring from the commodity.

Thermometer. Some tanks have a built-in thermometer to measure the temperature of the lading.

Pressure Tank Container Fittings. Like nonpressure tank containers, pressure tank containers are equipped with various fittings to make them functional and safe. A wide variety of fitting arrangements exists for pressure tank containers. Pressure intermodal tanks may have fittings on top, at the end, or on the bottom. Generally, fittings are recessed or enclosed with a cover to protect them from mechanical damage.

Loading/Unloading Valves. Liquid and vapor valves are used to fill and empty the tank. The liquid valve reaches into the lading

by means of an eduction pipe, which may be fitted with an excess-flow check valve. Vapor valves, which also may have an excess-flow check valve, are used to remove vapor from the tank or to pressurize the tank for unloading.

Pressure-Relief Devices. Pressure-relief valves, mounted on top, protect the tank from overpressure under abnormal conditions. In many cases, a rupture disk between the pressure-relief valve spring and the commodity protects the spring from the contents.

Gauging Devices. Gauging devices may be installed to measure how much liquid is in the tank.

Other Fittings. A sample line for sampling the lading and a thermometer well for measuring lading temperature may also be installed.

SUMMARY

Fire hazards in rail transportation systems exist in principally three areas: physical plants, ranging from office buildings to diesel fuel storage and dispensing facilities; trains, involving locomotives, rolling stock, passengers, or cargo; and adjacent, privately owned properties that can be damaged by a train or right-of-way fire. Fire protection for diesel, electrical, and other locomotives and for freight and other types of cars, together with fittings and equipment, includes proper design, preventive maintenance, protective equipment, and safe operations. Identification and proper documentation of the hazardous material are essential. Many rail carriers provide guidelines and training for responding to rail emergencies involving hazardous materials. Fire protection for fueling facilities and other railroad buildings and structures includes noncombustible construction, proper maintenance, fire suppression systems, and adequate water and hydrant systems. Measures that reduce the risk of right-of-way fires include improved railroad equipment, controlled burning, chemical control of vegetation, and installation of fire breaks.

Airport Safety Worldwide
Aircraft Fire Safety
Airport Facilities
Aircraft Maintenance and Servicing

Key Terms

aircraft, aircraft cabin, aircraft fire fighting, aircraft fuel, aircraft loading walkway, aircraft power plant, aircraft rescue, airport terminal building, air transport, aviation fuel, dangerous goods, hangar, hazardous materials, restricted articles

Aviation fire hazards develop from the energy of motion, the conversion of fuel to propulsive power, and the machinery necessary for the creation of a life-supporting environment above the surface of the earth. Complex system safety analysis and procedures are conducted to prevent problems from developing and to limit consequences of failures and mishaps that do occur. Most nations have extensive design, builder, and operator criteria for aircrews and maintenance personnel. A cohesive and comprehensive approach to safety during the operational phase of flight servicing must include training of baggage and cargo handlers, cabin clean-up crews, and customer contact personnel about their role in the safety management system and in response to a major accident or occurrence.

Airborne and ground navigational aids, weather monitoring, air traffic control, runways and overruns, taxiway design, the proper maintenance of such equipment including maintenance of clear approach, departure, and taxi paths are beyond the scope of this chapter.

For related topics, see Section 13, Chapter 7, "Aircraft Rescue and Fire Fighting (ARFF)"; and Section 17, Chapter 6, "Halon and Halon Replacement Agents and Systems."

AIRPORT SAFETY WORLDWIDE

Commercial aircraft internal fire safety features do not vary greatly worldwide since the choice of metals, composites, fuels, and interior furnishings are led by technical considerations and by major manufacturers throughout the world. Because builders must have their products accepted in worldwide markets, the degree of fire safety is uniformly high.

There are diverse approaches to fire safety goals in aviation ground facilities worldwide. In passenger terminals there may be only spot use of fire sprinklers and large areas of low risk may be unsprinklered. Although terminal buildings are rarely over five stories in height (except for towers), restaurant fires and fires in baggage-handling areas have contributed to serious smoke problems in passenger common areas.

For aircraft hangars, the design and construction materials may differ depending on the owner's and user's view of what is at risk: the aircraft or the building. Air-supported unconventional structures have received some attention. Military considerations, however, have brought about reinforced concrete shelters that provide internal aircraft fueling, maintenance, loading facilities, and electronic system testing. Because of the hazards associated with these activities, the hangars are equipped with ultrafast fire detection and suppression systems.

Aircraft loading walkways have been used that feature glass sidewalls. Although aircraft fires, both internal and external to the aircraft, at the loading walkways are rare, such incidents do occur.

Aircraft rescue and fire-fighting strategy and tactics, equipment, and personnel do not vary much from one major airport to another. The International Civil Aviation Organization (ICAO), NATO, and various pilots' unions tend to drive a high degree of competence. As in the United

Captain Brian Boucher is a fire protection engineer and has also been an airline pilot for the past 30 years. He spent 25 years as a municipal structural fire fighter holding the rank of chief of training for 8 years. He has been a member of the NFPA's ARFF Technical Committee for over 20 years and has served as chair for the past 10 years.

States, however, third-tier airports in other countries may depend on local or regional funding mechanisms and this usually translates into less than ideal personnel, equipment, and training. The most common and effective aircraft rescue and firefighting agent in the United States is an aqueous film-forming foam based on military specifications. In much of Europe, however, other formulas are favored.

AIRCRAFT FIRE SAFETY

Fire safety in aircraft starts on the drawing board, and aeronautical engineers bear the brunt of responsibility for fire prevention and control. Aircraft require large quantities of fuel, lubricating oils, hydraulic fluids, and Class A combustibles, which are in proximity to potential ignition sources such as power plants, auxiliary power units, electrical systems, and heaters. Many aircraft carry oxygen systems (liquefied and gaseous), and some use oxidizers for auxiliary power units or are equipped with small rocket units for additional takeoff thrust. Consequently, aircraft fire safety requires skillful blending of reasonable safeguards that are lightweight and do not interfere unduly with the use and mission of the particular aircraft.

Most nations that have a major aircraft production industry also have extensive regulations governing the use and arrangement of the foregoing items, and it is extremely important that the designer be thoroughly versed in the letter and intent of these regulations.

Installed fire detection and extinguishing equipment are normally required for those aircraft areas that possess inherent fire hazards and ignition potentials. Other fire prevention techniques used are the following:

- Compartmentation of fire hazard areas from critical structural components and flight control systems
- Judicious use of other materials that are fire or heat resistive or of very low flammability
- Separations of systems containing flammable fluids from potential ignition sources. For example, all aircraft have fire protection systems in washrooms because of the high risk of passengers smoking and placing their cigareete butts in the garbage. Also, aircraft that fly with only two engines follow the guidelines of Extended Twin Operations (ETOPS). Such aircraft must have fire protection systems that will suppress a fire for a minimum of 60 minutes (up to 207 minutes).

Because fires inflight pose tragic life hazard potentials, inflight fire prevention and control must receive high priority. Fires following impact accidents can result in the loss of many lives. Fires during maintenance can have consequences that range from the obviously disastrous to high monetary loss from small and simple fires. Even a very short fire exposure can result in delamination of honeycomb structures.

In commercial, light general aviation, and military reciprocating engine aircraft, the lightweight structure needed to allow the aircraft to perform its mission also permits impact energy to be transmitted to the aircraft occupants. Thus, more deaths occur due to impact trauma than due to fire.

In large turbine aircraft that operate in a more demanding flight envelope, heavier gauge metals, advanced composite materials, and computer-assisted design techniques strengthen airframe structures. These aircraft structures absorb a greater amount of impact energy, thereby transmitting less of it to the occupants. Subsequently, in accidents involving this type of aircraft, the postaccident fire is a more significant cause of serious injuries or death to the occupants.

As a result of aircraft accident investigations, there has been ongoing research on methods of minimizing aircraft fatalities. Improved seat belt design, heat-resistant evacuation slides, elimination of injury-causing projections, floor mounted emergency lighting systems, fire blocking seat materials and wall furnishings, stronger seats that withstand up to 16 g's, and overhead storage bins are some developments that improve occupants' chances of survival when an aircraft accident occurs.[1]

Many methods are being studied to reduce the hazard of postimpact fires. They include, but are not limited to, the following:

1. Segregating flammable-fluid containers and systems from ignition sources
2. Improving fueling systems and fuel containment methods
3. Reducing the rate of evaporation and the speed of flame spread over the surface of the spilled fuel
4. Improving the materials used for interior decor, insulation, sound attenuation, and cushioning to reduce ease of ignition, flame spread, and smoke and toxic gas generation
5. Compartmentation with lightweight fire walls in the occupied portions of the cabin, blind spaces, lavatories, and trash containers
6. Onboard cabin fire suppression systems using a variety of extinguishing agents
7. Early warning fire/smoke detection systems in occupied portions of the fuselage
8. Inerting fuel tank vapor space to reduce the possibility of explosion from static electrical discharge and lightning strikes. This can be effective in flight but does little to contain the postimpact fire, because the inert atmosphere would be lost almost immediately on impact, with the disruption of the tank structure

See Berg,[2] Diehl,[3] and Murray[4] for related information.

Aircraft Power Plants

Civil aircraft in the United States are subject to extensive federal regulation through the U.S. Department of Transportation (DOT), Federal Aviation Administration (FAA). The Code of Federal Regulations (CFR) Title 14, "Aeronautics and Space," contains the Federal Air Regulations. Other nations have similar requirements. The following list summarizes the regulations that apply to aircraft power plants:

1. All reciprocating engines, auxiliary power units, fuel-burning heaters, or other combustion devices intended for operation in flight must be separated from other areas of the aircraft by fire walls, shrouds, or equivalent means so that no hazardous quantities of air, fluid, or flame can pass from these compartments to other portions of the aircraft. These regulations also

apply to the combustion, turbine, and tailpipe sections of turbine engines. The fire walls and shrouds must be made of a material that withstands heat at least as well as steel. When applied to power plants, the material must perform under the most severe conditions of fire and duration likely to occur in such zones. All openings in fire walls and shrouds must be sealed with close-fitting fire-resistive grommets, bushings, or fittings. In engine nacelles, a fire seal or bulkhead is used to isolate the engine power section and exhaust system. In addition, a main fire wall segregates the complete engine assembly (power section, exhaust system, and accessory section) from the remainder of the nacelle section and, as applicable, the wheel well. In gas turbines, the fire seal or bulkhead separates the combustion, turbine, and tailpipe section from the compressor and accessory section. An additional main fire wall isolates the engine assembly from the support pylon or remainder of the aircraft, as applicable.

2. The cowling and nacelle skin are designed to prevent fire from circumventing the fire seals and main fire walls.

3. Tanks containing a flammable fluid cannot be located in a fire zone except when it can be proved that construction, connecting lines, controls, and shutoff means provide protection equivalent to segregation. A specified air gap is required between flammable fluid tanks and a fire wall, and materials that can absorb flammable fluids are prohibited from the area of the tank or any other system containing flammable fluids.

4. Emergency fuel shutoffs are required for each engine, auxiliary power unit, or combustion heater. The emergency shutoffs must be fire resistive or located so that a fire in any fire zone does not affect their operation. Operation of the emergency shutoff must not affect other emergency functions or the operation of any other engine.

5. Flammable liquid lines in fire zones must be fire resistive and, where required, flexible. This also applies to drain and vent lines for flammable fluids or vapor.

6. Reciprocating and turbine engine air inlets must be arranged to prevent backfire flames from entering the fire zone and designed so discharge from vents and drains cannot enter the air induction system.

7. Exhaust systems must discharge in a safe manner, not expose any portion of a flammable fluid system, and be provided with heat shields wherever they may impinge on other potions of the aircraft.

8. Drains must be provided for all fire zones, with the discharge arranged so that drained fluids will not be reingested into any portion of the aircraft.

Aviation Fuels

The fire hazard properties of aviation fuels are identified according to ease of ignition, flashpoints, flammability limits, distillation range (initial and end boiling point), and electrostatic susceptibility. (Note: Octane rating has no relation to the degree of fire hazard of a fuel.) Table 21.9.1 summarizes characteristics of more common aviation fuels. NFPA 407, *Standard for Aircraft Fuel Servicing,* requires that the same fire safety precautions apply to all types.

The following factors must be considered when evaluating fuel in an operating aircraft and when fuel stored in a tank at a bulk plant is being evaluated:

- Because an aircraft travels at different altitudes and through varying ambient temperatures, conditions of flammability in the tank vapor space can change rapidly. Thus, a fuel type such as

TABLE 21.9.1 Summary Data on the Fire Hazard Properties of Aviation Fuels

Characteristics	*Gasoline AVGAS*	*Kerosene Grades JET A, JET A-1, JP-5, JP-6, and JP-8*	*Blends of Gasoline and Kerosene JET B and JP-4*
Freeze point[a]	–76°F	–40°F to –58°F	–60°F
Vapor pressure[b] (Reid-ASTM D323-58)	5.5 to 7.0 psi	0.1 psi	2.0 to 3.0 psi
Flashpoint[a] (by closed-cup method at sea level)	–50°F	+95°F to +145°F	–10°F to +30°F
Flashpoint[a] (by air saturation method)	–75°F to –85°F	None	–60°F
Flammability limits			
Lower limit	1.4%	0.74%	1.16%
Upper limit	7.6%	5.32%	7.63%
Temp. range for flam. mixtures[a]	–50°F to +30°F	+95°F to +165°F	–10°F to +100°F
Autoignition temperature[a]	+825°F to +960°F	+440°F to +475°F	+470°F to +480°F
Boiling points[a]			
Initial	110°F	325°F	135°F
End	325°F	450°F	485°F
Pool rate of flame spread[c,d]	700–800 fpm	100 fpm (or less)	700–800 fpm

Note: Figures vary for some of these values.
[a] 5⁄9(°F – 32) = °C.
[b] 1 psi = 6.9 kPa.
[c] 1 fpm = 0.3 m/min.
[d] In mist foam, rate of flame spread in all fuels is very rapid.

Jet A—which is normally too lean in a tank vapor space at sea level with a fuel temperature of 70°F (21°C)—can move into the flammable range as the aircraft gains altitude. Other factors contribute to this change, such as aircraft skin heating from air friction, outgassing of dissolved oxygen, and sloshing of the fuel from air turbulence. Figure 21.9.1 illustrates changes in flammability limits of aircraft fuels in tank vapor space due to altitude and temperature changes.

- After an impact when major structural damage occurs to aircraft fuel tanks, the fuel may be released as a mist due to forward momentum, splashing, and wind shearing. Regardless of the type of fuel involved, this mist can ignite easily from disrupted electrical circuits, hot engine surfaces, or ignition sources on the ground. The resulting fireball then acts as the ignition source for other combustibles in the area, including pools of high flashpoint Jet A fuel. In some aircraft crashes where deceleration forces are low, liquid fuel flowing from ruptured fuel tanks or broken fuel lines can be vaporized and ignited by hot engine surfaces, hot brakes, heavy electrical arcs, and so forth.
- Reciprocating engines present a fire hazard for a short period after shutdown. However, turbine engine tailpipe fires are fairly common and in crash situations turbine engines may be an ignition source for many minutes after a nominal "shutdown."

Relative Safety of Jet Fuels. The kerosene-type turbine fuels offer a safety advantage over other types of aviation fuels especially during fueling operations and aircraft fuel system maintenance. Fires are less likely in impact-survivable accidents when the aircraft involved has class Jet A fuel in the tanks. However, once ignition occurs, all fuels exhibit similar behavior, and control measures must be instituted quickly to prevent injury and fatalities.

In some portions of the world, Jet A (kerosene grade) fuel is not readily available, and Jet B (JP-4) is used. Some nations also have reduced the minimum flashpoint of Jet A to increase yield of aviation fuel per barrel; the minimum flashpoint has been in the 80°F (27°C) range. The actual flashpoint has been above 100°F (38°C).

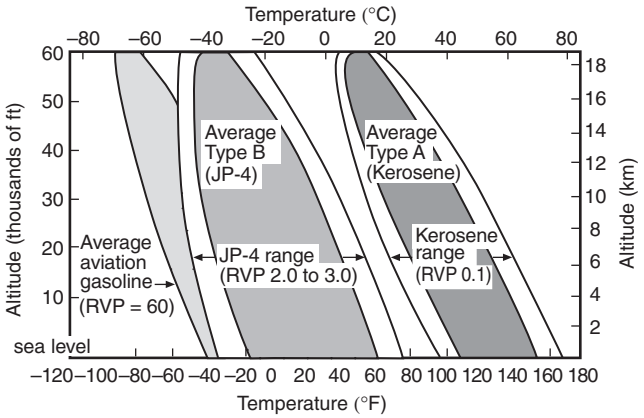

FIGURE 21.9.1 Flammable Ranges of Aviation Gasoline and Jet A (Kerosene) and Jet B (JP-4) Turbine Fuels, Showing Variations with Altitude

Electrostatic Susceptibility and Autoignition. The degree to which a static charge may be acquired by aviation fuels depends on many factors: the amount and type of residual impurities, dissolved water, the linear velocity through piping systems, and the types of filters and water separators used. Jet A and Jet B fuels are better static generators than AVGAS. Although all fuels generate static charges, the electrical conductivity of the fuel directly relates to the speed of charge relaxation (dissipation).

Antistatic additives increase static charge. However, rather than preventing the formation of static charges, they actually increase fuel conductivity, thus considerably shortening relaxation time. The charge generation increases as fuel passes through filter/water separators and other equipment. An unbonded object in the vicinity of the charge generation point before the charge has an opportunity to relax can act as a collector and cause high-energy static discharge.

Although possibly misnamed, antistatic additives have greatly increased the safety of aircraft fueling operations although there are some circumstances that are exceptions (e.g., the unbonded collector in close proximity to the static generation point). Autoignition in fuel cells/tanks can result if the internal fuel pumps run hot and/or dry.

Aircraft Fuel Systems. Most aircraft make extensive use of the internal wing volume to store fuel. In larger aircraft and newer general aviation aircraft, the wing structure is sealed and forms the fuel tank. This is commonly called integral tank, or wet wing, construction. Older and light aircraft may incorporate a flexible bladder to contain the fuel within the wing structure, using the wing structure only for support. Separate metal tanks or fiber-reinforced nonmetallic tanks are not widely used but can be found on aircraft that need extended fuel range when ferrying long distances.

With integral tank construction, and only to a slightly lesser extent with thin-wall bladder tanks, disruption of the wing structure by ground impact or other damage typically results in the release of fuel and potential for ignition. This can occur even though occupied portions of the aircraft may be only slightly damaged. If so, fire becomes a threat to the occupants. Figure 21.9.2 illustrates typical fuel-occupied spaces in a large turbo jet powered aircraft. The reserve tanks and Nos. 1, 2, 3, and 4 are integral tanks in this particular airplane, and the wing center section tank is of the bladder type.

One approach proposed is crash-resistant fuel tank construction with dry break fittings and automatic fuel shutoffs. Although the technology to develop this tank has been highly advanced, it has not been widely adopted due to weight limitations and reduction in volume available for fuel storage in long-range, military, and commercial aircraft. However, certain helicopters operated by the U.S. Army are equipped with such crashworthy fuel systems.

Open-celled plastic foam blocks, cut to fit and placed in the tank, are used on some military aircraft. Although primarily intended for explosion protection after projectile penetration (incendiary bullets, etc.) of the vapor space, they also improve the postcrash fire situation. Tests showed some resulting improvement, but the problems of removal and replacement for tank

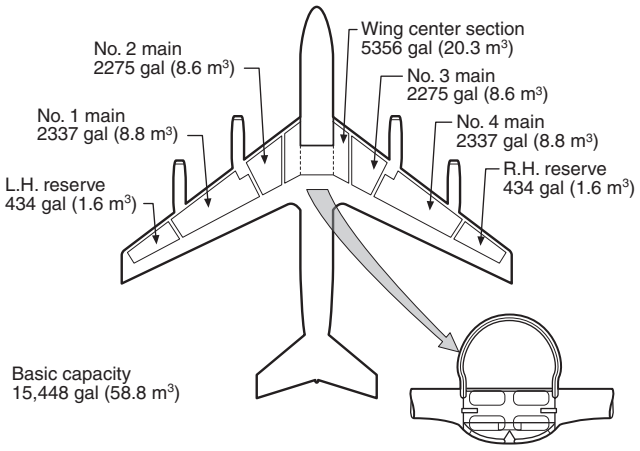

FIGURE 21.9.2 Arrangement of Fuel Tanks in a Typical Turbine-Powered Air Carrier Aircraft

interior maintenance and loss of available fuel volume preclude their use in large, long-range civil and military aircraft.

Aircraft equipped with these foam blocks can have internal fuel tank fires. Foam increases the static charging tendency and/or acts as the unbonded collector. However, the presence of the remaining foam in the tank vapor space prevents further propagation of the fire/explosion.

Many aircraft use the wing center section (where it passes through the fuselage) for additional fuel storage. In some aircraft, such as the Boeing 727 and DC-9, this is an integral tank with a bladder liner. Newer aircraft designs use a double-wall tank of metal with a honeycomb core. Although such tanks are well protected by the center wing section box structure (the heaviest on the aircraft), they directly expose the fuselage interior. To extend normal operating range, some aircraft use fuselage fuel tankage of the double-wall type outside of the wing center section box, and thus are deprived of heavy structural protection. As a reasonable compromise, all fuel tanks (at least those within the fuselage) should be crash-resistant with dry break fittings and automatic shutoff valves.

Certain models of existing aircraft contain fuel tanks well forward or aft in the fuselage. Fuel storage in the horizontal stabilizer and vertical fin is being used on certain aircraft to extend range.

Other Design Considerations

The Federal Air Regulations mention several design principles that affect basic aircraft fire safety and crashworthiness (excluding cabin furnishings and evacuation systems):

1. When the same structure supports fuel tanks and landing gear, shear pins must be incorporated in the landing gear support structure, allowing the gear to be wiped off without applying structural loads to the fuel tanks.
2. The metal aircraft structure must have electrical continuity to prevent accumulation of static electrical charges, particularly in the fuel tank areas. This is extremely important when designing an all-metal aircraft, since the aircraft structure acts as a Faraday Cage, shielding all contents from lightning strikes.
3. Static discharge devices and lightning divertors must be located and installed correctly.
4. Fuel lines supplying rear fuselage-mounted engines must be designed to ensure proper fire resistance and have the flexibility to resist rupture in a crash situation.
5. Fuel lines and main electrical leads must be segregated.
6. Main electrical power cables in the fuselage must be shrouded in fire-resistive flexible conduit.
7. The hydraulic system must be designed properly and use fire-resistive fluids. Such fluids presently in use have autoignition temperatures in excess of 1000°F (538°C) and are only slightly flammable. (Older types of mineral oil-based hydraulic fluids are still widely used, particularly in the military.)

Aircraft Cabin Fires

Cabin fires in flight are infrequent and usually discovered in their incipient stage and rapidly extinguished. The potential life loss, however, is severe if fire progresses beyond the point of control by use of handheld fire extinguishers. The fire reaction of aircraft cabin interior materials, once ignited, is crucial from a life safety viewpoint and can result in severe structural damage or loss of the aircraft, as was the case of Swiss Air 111 over the North Atlantic.

Prior to the mid-1940s, few, if any, regulations concerned the flammability of cabin furnishings. Old aircraft at air shows and in museums show wicker chairs, gauze fabric curtains, and other combustibles. Following World War II, a qualification test was required that involved igniting small horizontally mounted samples by a short exposure to a Bunsen burner flame. If a sample did not continue to burn after removal of the igniting flame, or burned less than a specified distance in the specified time, it was classified as self-extinguishing or slow burning. Although this test procedure was developed for laboratory comparisons, it created a widespread impression in the aviation industry that cabin furnishings were fire resistive. They were not.

In the 1950s and 1960s, research began to improve the fire resistance criteria. Various public and private organizations conducted tests that proved the inadequacies of the existing fire resistance criteria and, further, disclosed the problem of heavy smoke and toxic gas.

In the late 1960s and early 1970s, the fire resistance criteria were upgraded to require a material sample to be self-extinguishing when tested in the vertical position, with exceptions such as floor carpeting. Although flame spread of compliant materials was reduced, there is room for further improvement, and the problem of toxic smoke may need to be addressed directly.

In the late 1970s and early 1980s, researchers developed a method of "fire blocking" aircraft seat cushions. Inserted between the cushion, which is usually made of polyurethane foam and decorative upholstery, this fire-blocking layer is intended to delay or prevent seat cushion involvement in a cabin fire. The FAA now requires all commercial aircraft seat cushions to be fire blocked.

In addition to fire blocking, research is continuing toward the development of an improved, fire-resistant aircraft cabin window material to delay or prevent postimpact fire entry into the fuselage via the windows. These transparencies/windows are complicated design challenges because they must resist heat, cold, vibration, and substantial internal air pressure variations as the aircraft moves from ground level to heights of 40,000 ft (12,500 m) or more.

Many aircraft carry supplemental oxygen for the potential failure of cabin pressurization and in portable cylinders for first-aid purposes. In a crash, localized fire intensification can be expected if the oxygen cylinder fuse plug operates due to fire exposure and releases oxygen in the cabin atmosphere. In addition to potential oxygen release from high-pressure cylinders, some aircraft carry chemical oxygen generators. Improper packaging and transport of such devices in a cargo bay resulted in a disastrous inflight fire over the Florida Everglades.

Possible causes of aircraft cabin fires include the following:

1. Ignition of the cabin interior from a postimpact fuel fire or a fire resulting from a fueling operation malfunction. In such a fire, although the interior materials have a certain fire resistance, heat from the exposing fire overwhelms the materials' resistance.
2. Electrical failure and electrical arcing within concealed spaces, often behind the cabin decorative liner. Such fire can remain undetected for a considerable time period and grow beyond control of handheld fire extinguishers before it is discovered. Flight deck fires (or as often described "smoke in the cockpit") are a threat for several reasons: obscuration of pilot's vision, loss of instrumentation, and incapacitation of the flight deck crew. Radar, radios, life support systems, and motors to operate flight controls require tremendous electrical power. The wiring to serve them is subject to embrittlement, abrasion, vibration, and cracking. Events in the 1990s have resulted in more attention to electrical wiring.
3. Improper use of flammable liquids during cabin cleaning and refurbishing
4. Improper use or disposal of smoking materials (which should decrease due to prevalence of "no smoking" flights). Aircraft lavatories aboard all carriers are now required to be equipped with smoke detectors specifically designed for those areas. In addition to its functional purpose, the requirement deters persons who might wish to smoke in a lavatory. Tampering with or rendering aircraft lavatory smoke detectors inoperational is a serious offense. Figure 21.9.3 shows a UPS DC-8 cargo aircraft that landed successfully in Philadelphia after the pilots reported smoke in the cockpit.

NFPA 424, *Guide for Airport/Community Emergency Planning;* NFPA 415, *Standard on Airport Terminal Buildings, Fueling Ramp Drainage, and Loading Walkways;* and NFPA 402, *Guide for Aircraft Rescue and Fire Fighting Operations,* provide guidance concerning such fires. For more information on aircraft cabin fires and materials for use in aircraft cabins, see Babrauskas[5] and McCaffrey.[6]

FIGURE 21.9.3 Safe Landing of a DC-8 After Report of Cockpit Smoke

Air Transport of Dangerous Goods

Hazardous cargoes (hazardous materials, nuclear materials, and restricted articles) can present a problem to aircraft in flight, on the ground, during ground handling, and in a postcrash situation. This is an international problem, since many shipments cross national boundaries. Many agencies regulate hazardous cargoes, including the U.S. Department of Transportation, the International Air Transport Association, the International Civil Aviation Organization (an agency of the United Nations), and others.

The regulations cover the type of cargo that may be shipped, quantities allowed, packaging method, and aircraft type (passenger or cargo only) in which this material may be carried. Flight crews must be informed of the presence of hazardous cargoes on the manifest and, in some cases, the captain can refuse to carry the material.

If the rules are followed rigidly, there is little hazard to safety of flight or to ground personnel, whether in normal handling or a postcrash situation. Problems arise when the shipper, either in ignorance or in willful contempt of the regulations, misrepresents the contents of the shipment to a carrier or does not package the material adequately to ensure containment during transit.

After several serious crashes in the 1980s and early 1990s, the regulations were revised and further restrictions adopted. Better training is now required for each carrier's receiving agents, standard labels have been adopted, and penalties are assessed against shippers who violate the law. Detailed information regarding the air transport of dangerous goods and a listing of the United Nations warning label system can be found in Appendix B of NFPA 402.

Aircraft Fire Detection and Extinguishing Systems

Fire detection and extinguishing systems are required in certain zones of the aircraft, notably the power plant areas. These systems are defined in design regulations of the nation of aircraft origin.

The systems are similar to those used in ground installations, but there are significant differences. In most aircraft installations, the flight crew manually activates the extinguishing system. The detection system must be very sensitive, very stable (i.e., free of false alarms), and able to withstand extremes of the environment in which it must function—temperature, vibration, high airflows, and structural flexing. The system must also reset automatically to notify the flight crew when the fire has been extinguished, or when the temperature in the protected zone drops below the set point. System response must be within seconds of the beginning of abnormal conditions.

Extinguishing agent hardware must be lightweight, rugged, and, to overcome the high flows of flight, capable of higher rates of agent discharge than would be expected in a similar ground installation.

The most common extinguishing agents used in aircraft are bromotrifluoromethane (Halon 1301) and bromochlorodifluoromethane (Halon 1211). Due to the ozone depletion characteristics of the halogenated hydrocarbons, these chemicals are being phased out in accordance with international treaties. The development of suitable replacement agents is under way. See Section 17, Chapter 6, "Halon and Halon Replacement Agents and Systems." Older aircraft still use carbon dioxide, methyl bromide, and chlorobromomethane. All are somewhat effective on flammable liquid and electrical fires.

Cargo Compartment Fire Detection and Extinguishing Systems. Cargo compartments in passenger aircraft often are equipped with fire detection systems. Air starvation is one of the more common techniques used in fire extinguishment in cargo spaces. Upon actuation of fire detection systems, all ventilation to the compartment is sealed off and the fire is allowed to self-extinguish due to lack of oxygen. Fire extinguishing systems traditionally using Halon 1301 or Halon 1211 will need to switch to treaty-compliant halon alternatives.

Recent regulations have been adopted to improve the fire resistance and fire penetration-resisting capabilities of cargo compartment liners. An upper limit has been placed on the volume of a cargo compartment; above this limit, a fire suppression system must be installed regardless of compartment construction. For more information, see Bennett[7] and Grosshandler.[8]

Figure 21.9.4 shows an electric fire that occurred inflight over Canada. The fire was caused by an electrical arcing of a heater ribbon tape. The aircraft landed safely and ARFF crews quickly extinguished the fire.

Aircraft Hand Fire Extinguishers

The FAA requires portable hand fire extinguishers in all air transport category aircraft. In some smaller general aviation aircraft, they are recommended but not required.

NFPA 408, *Standard for Aircraft Hand Portable Fire Extinguishers,* requires portable hand fire extinguishers on all aircraft and describes the type, quantity, minimum capacity, installation, location, and spacing of the extinguishers.

Although the FAA recognizes carbon dioxide, water, dry chemical, Halon 1211, Halon 1301, and halon combinations, at least two extinguishers installed on large transport aircraft must be of the Halon 1211 or combination Halon 1211/1301 type. Due to environmental problems associated with halogenated agents, their use is prohibited except in specific circumstances.

FIGURE 21.9.4 Results of an In-Flight Electrical Fire

NFPA 408 no longer recognizes carbon dioxide and dry chemical as suitable for use on aircraft. Carbon dioxide is not recognized as suitable for the following reasons:

1. Ineffectiveness on Class A materials
2. Chilling effect of solid carbon dioxide (snow) may damage delicate electronic components
3. Weight of container and agent versus similar agent capacities of the halon type
4. Required dwell time and concentration for Class A fires is not compatible with human life

Dry chemical has long been banned from aircraft in NFPA 408 for the following reasons:

1. Obscuration of the operator's vision, particularly in confined spaces
2. Possibility of an insulating chemical layer forming on delicate electrical contacts, which could affect continued safety in flight
3. Dry chemical can irritate the eyes and mucous membranes even though it is not considered toxic
4. If not immediately cleaned up, certain types of dry chemical can be highly corrosive to aircraft metals

Means of Egress from Aircraft

In aircraft, emergency exit facilities are particularly important because postcrash fire exposure can be severe and safe evacuation time for the occupants is limited.

U.S. Federal Air Regulations set the number of exits required in transport category aircraft, depending on passenger capacity. The manufacturer or operator must demonstrate that evacuating a full load of passengers can be accomplished in 90 seconds or less, with half the available exits inoperative. These simulations require that the test subjects represent an

average passenger load, with certain percentages of able-bodied males and females, elderly, children, and disabled. Tests are accomplished without normal cabin lighting; emergency lighting, however, is functional. The exits to be blocked are not preannounced to crew or occupants.

The simulations have some shortcomings:

1. Smoke, which could obscure emergency lights or exit signs, is not used.
2. The test subjects know this is an emergency exit certification test and will seek any usable exit. (In real life, most passengers may pay little attention to preflight announcements and, consequently, tend to attempt leaving the aircraft by the same door through which they entered.)
3. Again, many test subjects have taken part in previous demonstrations and although there is a required minimum time period since last participation, retain a certain knowledge of "what to do in the test."
4. Actual crash experience has shown considerable obstruction of egress because of failure of overhead storage bins, presence of carry-on luggage, and beverage/food service carts.

Escape Systems and Devices. It is acceptable and permissible to use the normal entrance and passenger service doors as part of the emergency exit system. If the door is power assisted in its normal mode of operation and operates relatively slowly, it is equipped with a high-speed power assist for the emergency mode.

Modern passenger aircraft are equipped with inflatable evacuation slides at all emergency exits that have a normal door sill height that exceeds 5 ft (1.5 m). The distance from door sill to ground level, however, can drastically change in the event of a collapse of the main gear or nose gear. (A deployed slide under these conditions would not provide an effective angle for safe descent.) FAA regulations require the slide to deploy and inflate automatically when an exit door opens in emergency mode. In many instances evacuation slides can also serve as life rafts. Figure 21.9.5 shows evacuation slides used in an emergency passenger evacuation in Lajes, Azores, after an AirBus 330 aircraft ran out of fuel and landed successfully without engines. The 300 passengers sustained only minor injuries.

FIGURE 21.9.5 AirBus 330 That Landed Without Engine Power

The openings designated as emergency exits must be operable from the outside and designed to resist jamming due to fuselage distortion. The slides must deploy properly regardless of wind direction or other influences.

The fire resistance of the slide material used to be very low, and even slight exposure to flame caused deflation of the slide. However, slide material has now been developed that incorporates a reflective coating, reducing the possibility of damage and deflation caused by radiant heat. At present, not all aircraft have been upgraded with this new material.

Emergency escape slides that are enabled during flight operations are deactivated when the aircraft reaches the terminal/parking spot. Consequently these systems are not available for food servicing, cleaning, and toilet service personnel.

Obscuration of exit signs and emergency exit lighting by smoke can seriously impede evacuation of the aircraft. All air transport aircraft are required to have exit signs installed at a lower level and the exit access must be visible from a minimum distance of 35 ft (11 m), assuming a smoke level above the seat back height. In addition, illuminated exit path lights installed in aisle seat armrests or in the floor must be provided.

Aircraft Construction Materials

Aircraft from small personal and business reciprocating engine powered to the largest and fastest of commercial and military jet aircraft use an amazing smorgasbord of metals, organic fibers, gases, and fluids. Metals such as aluminum, magnesium, and titanium can and do burn if heated sufficiently. Composites are used for structural components and for body, wing, and control surfaces. The organic binder and fiber matrix of these metal replacements can fracture under crash conditions and release physiologically dangerous materials to nearby occupants and rescue personnel. Protective clothing and personal breathing equipment should be worn at all times until it can be determined that there is no further risk to rescue personnel.

Pressure hazards range from tires inflated to 250 psi or more to pressure vessels both metal and fiber reinforced plastic wrapped that accumulate pressures of 3000 psi or more. These aspects of aircraft rescue and fire fighting are discussed in NFPA 402.

Aircraft Rescue and Fire Fighting

Aviation fire protection is an enterprise of wide challenge for economic, social, and technical reasons. In aircraft, a firewall can be a thin sheet of metal, an egress path can be an aluminized fabric slide, and survival from fire may be measured in seconds. Generally, survival from fire in exposed intact large aircraft can be as little as 3 minutes. Aluminum skin can burn through in 60 seconds, and windows and insulation may burn through in a few additional seconds. Fortunately, major airfield fires are rare, but it is clear that ready and competent rescue and fire-fighting teams are essential (see NFPA 403, *Standard for Aircraft Rescue*

and Fire-Fighting Services at Airports, and NFPA 405, *Standard for the Recurring Proficiency of Airport Fire Fighters*).

Three distinct types of ground incidents can occur within the flight environment of the aircraft (excluding fires from fueling incidents, malfunction of ground servicing equipment, or fires originating during maintenance procedures).

The first type of ground incident is the high-speed and/or high-angle impact with the ground or other object that results in such structural breakup of the aircraft that survival of the occupants is highly unlikely (i.e., all or nearly all fatalities occur due to impact trauma).

The second incident type involves relatively low-speed and/or shallow ground impact angles. In this type of incident, occupant survival rate can be very high, especially if there is no postcrash fire or if the fire is controlled quickly in the area immediately surrounding the occupied portion of the aircraft.

The third incident type occurs when an aircraft in a landing/takeoff/taxiing mode impacts with another aircraft or other object such as a maintenance vehicle or construction equipment.

Fire can be anticipated in almost all abnormal aircraft landings as well as incidental occurrences such as overheated brakes or undetected fuel leaks. It is essential that airports maintain a well-equipped and trained rescue and fire-fighting capability during all hours that flight operations are in progress. At smaller airports, the response team is often made up of persons having other airport duties such as security, fueling operations, maintenance, or baggage handling. However staffed, personnel need to participate in frequent and meaningful training sessions, be equipped with proper protective gear, and be provided with the means to respond immediately to the scene of any emergency on or adjacent to the airport.

The term *rescue* used in the context of aircraft rescue and fire fighting means the control of life-threatening fire in the critical area during the time necessary for all physically able aircraft occupants to self-evacuate. The continuance of fire control is necessary in order to permit the extrication of those who are severely injured or pinned in the wreckage. Assisted rescue of individuals from small aircraft is often routine; however, in aircraft having a large number of occupants, such assistance is usually not possible in the time available. NFPA 403 mandates that responding units have specialized equipment and manpower for interior fire fighting operating within 5 minutes of notice of an accident.

Survivable accidents tend to occur within a certain area related to the runway centerline and threshold lights. This *critical rescue and fire-fighting access area* (CRFFAA) is clearly defined and illustrated in NFPA 402 (Figure 21.9.6).

To be considered effective, the demonstrated response time of the first responding fire-fighting vehicle to reach any point on the operational runway must be 2 minutes or less, and to any point remaining in the CRFFAA, 2.5 minutes or less. These conditions must be met when flight operations are in progress; however, NFPA 402 recognizes that mitigating circumstances can make it impossible to meet these times.

More accidents tend to occur during inclement weather and this can result in longer response times. In recent years the use of global positioning satellites and forward looking infrared optical devices help locate aircraft more speedily when visibility is poor.

Preplanning for declared emergency landings on airports is extremely important. Prepositioning of personnel and vehicles greatly reduces response time and increases the chance of survival of the aircraft occupants should the landing become a major emergency. Figure 21.9.7 illustrates one system of preplanning for this type of emergency.

Specialized vehicles have been developed that have the ability to transport rescue and fire-fighting personnel, equipment, and extinguishing agents to the scene of aircraft accidents within the required response time despite terrain surface or condition. Detailed information regarding such vehicles is contained in NFPA 414, *Standard for Aircraft Rescue and Fire-Fighting Vehicles.* The number and size of response vehicles and the amounts of extinguishing agents required at a given airport depends on the types of aircraft used and the frequency of air carrier operations.

Part 139 of Title 14 of the Code of Federal Regulations (CFR) contains these minimum levels. In addition, the FAA Advisory Circular 150/5210-6B[9] gives recommended levels of

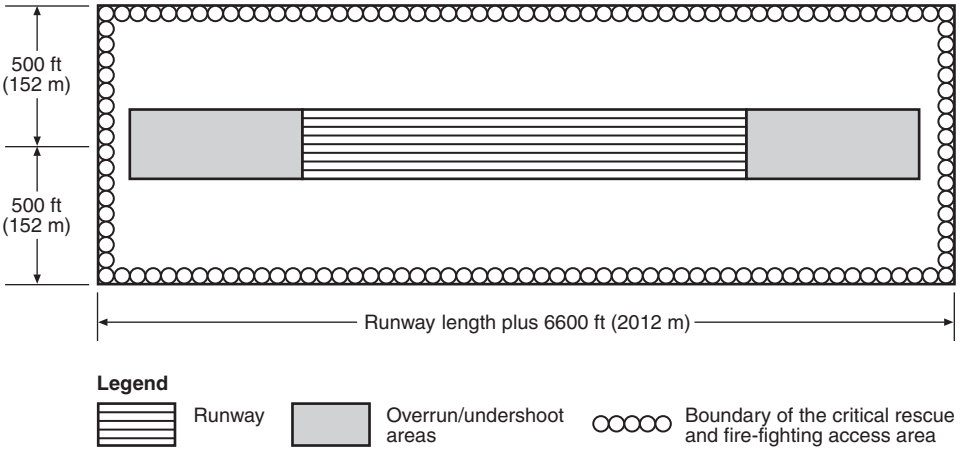

FIGURE 21.9.6 Critical Rescue and Fire-Fighting Access Area (CRFFAA)

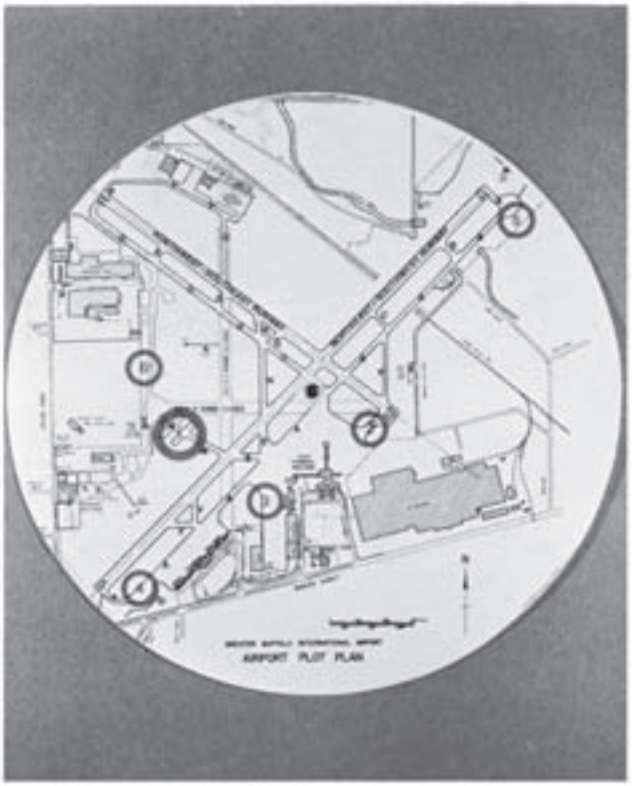

FIGURE 21.9.7 Typical Airport Plot Plan Indicating Preplanned Standby Positions for Rescue and Fire-Fighting (RFF) Vehicle

airport protection that are considerably higher than the minimum levels in Part 139.

Other information on the subject of aircraft rescue and fire-fighting protection is published in NFPA 403 and the International Civil Aviation Organization (ICAO) Annex 14 (Aerodromes) to the Convention on Civil Aviation.

There are interesting similarities of requirements among NFPA, ICAO, and the FAA Advisory Circular 150/5210-6B, as compared to the minimums of CFR Part 139. One major difference among the three is that ICAO and the FAA allow a remission factor so an airport may drop to a lower index if the number of movements (takeoffs and landings) of the largest aircraft to use the airport is below a certain daily or yearly operational level. NFPA does not recognize the remission factor, requiring protection for the largest aircraft that regularly uses the airport, regardless of operational levels.

The term "index" (e.g., l–5, 6, 7–10), as used in the aircraft rescue and fire-fighting context, provides an approximation of the number and size of fire-fighting vehicles required for problems with the larger aircraft using the airport regularly. However, this system (FAA, ICAO, NFPA) does not address the manpower needed to handle the myriad aspects of a rescue/crash response. See NFPA 424 for insight and detail concerning manpower and organizational demands. For a more detailed discussion of aircraft rescue and fire fighting see Section 13, Chapter 7, "Aircraft Rescue and Fire Fighting (ARFF)."

Rescue and Fire-Fighting Personnel, Training, and Safety

After requirements for an airport's rescue and fire-fighting protection have been determined, the next major consideration is the selection of qualified personnel. Airport fire fighters should, at a minimum, meet standards set forth in NFPA 1003, *Standard for Airport Fire Fighter Professional Qualifications.* Candidates should be in top physical condition, and the department should maintain a required physical conditioning program to ensure the best possible performance of its personnel. Physical and mental stresses encountered when dealing with a major aircraft accident can be very demanding, and efficient performance is crucial.

In addition to physical conditioning, frequently scheduled and meaningful training sessions covering all phases of aircraft rescue and fire fighting are extremely important. Such sessions are necessary to maintain a high degree of competence and readiness (see NFPA 405).

Training of attendants proved important in the AirBus 340-300 crash pictured in Figure 21.9.8. Attendants were credited with the successful evacuation of all passengers. The aircraft was consumed by fire.

In addition to the physiological and psychological preparation of responders as individuals, the exercise serves to test communication, command, and control when noise level is high, visibility is poor, and dimensions of the problem may not be fully known.

"Live fire" training using hydrocarbon fuels and other flammable liquids has been suspended at many airports due to local environmental constraints. The FAA, the U.S. military, and private industry are all in the process of developing alternative "live fire" training exercises to duplicate realistic fuel fire atmospheres and at the same time, meet all necessary environmental requirements.

Special aircraft informational charts developed by airframe manufacturers are available to airport fire fighters as well as mutual aid fire departments adjacent to an airport. These charts

FIGURE 21.9.8 Overrun of Toronto, Canada, Runway by AirBus 340-300 in August 2005

indicate locations and operation of emergency exits, areas that normally contain flammable and hazardous materials, oxygen storage, and other pertinent information. Combined with pre-incident planning inspections of aircraft that normally use the airport, periodic review of the charts keeps fire fighters current on pertinent information on various types and models of aircraft. Most airline operators encourage familiarization with their aircraft and schedule tours when flight schedules permit. A variety of aircraft information charts are contained in NFPA 402.

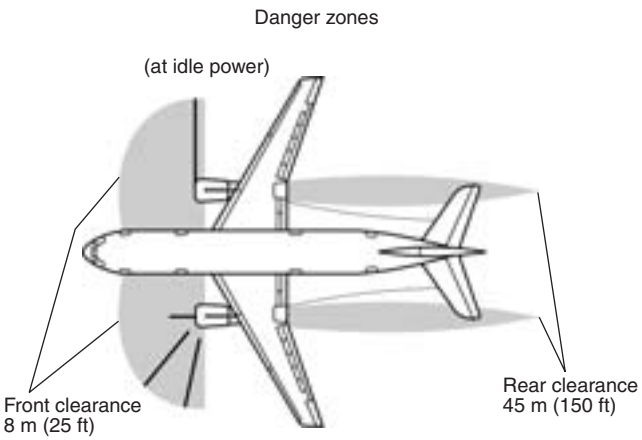
The potential for extreme danger exists anywhere in the vicinity of operating aircraft, especially with regard to rotating propellers and rotors and jet engines. Severe injuries can occur when persons do not remain alert and do not maintain the necessary safe distance. Figure 21.9.9 depicts typical jet engine intake and exhaust danger areas.

Overheated brakes may cause wheel disintegration, control surfaces may deploy unexpectedly, and extremely-high-pressure tanks may rupture under fire conditions. The results of a brake fire and explosion in France can be seen in Figure 21.9.10. The protective fire fighter hoods restrict vision and hearing. NFPA 402 discusses these concerns.

Ground Environment Safety Factors

Serious crashes can occur off the ends of runways due to insufficient clearance from various objects. The problem may be compounded where zoning regulations permit construction in these areas. Dikes, structures supporting navigational aids, and blast fences can be struck by aircraft operating in conditions of poor visibility.

Atmospheric conditions also contribute to serious aircraft incidents. Fog, rain, sleet, and snow all adversely affect runway surfaces, aircraft performance, and visibility from the flight deck. Abnormal wind conditions, particularly the phenomenon called windshear, also can be factors. Normally, unusual atmospheric conditions are handled routinely. When they are involved in combination with other factors, incidents can occur more easily.



Note: Crosswinds will have considerable effect on contours.

FIGURE 21.9.9 Engine Run Dangerous Areas

FIGURE 21.9.10 Brake Fire That Occurred During Certification Testing of an AirBus 340-600

During airport construction and repair, especially on movement areas, presence of construction and resurfacing equipment can be a factor in accidents. Another principal area where incidents can occur is in the overrun portions of runways when aircraft are unable to brake effectively, running off the runway, striking airport boundary fences, or bogging down while traversing unimproved ground surfaces. Unimproved ground surfaces between runways can result in aircraft being inaccessible to fire and rescue equipment, especially equipment not specifically designed for off-highway use.

Heliports present special problems because they are frequently located in congested areas of cities, on roofs of buildings, near hospitals, and on piers adjacent to water. NFPA 418, *Standard for Heliports,* covers landing deck construction, drainage, egress, and fire protection requirements.

Preplanning for Aircraft Incident Emergencies

All commercial airports serving passenger aircraft are required to develop and maintain an emergency plan that can be immediately activated should an aircraft incident occur on or near the airport. The plan needs to be flexible and encompass all aspects of the most difficult anticipated emergencies. All local emergency services, civic organizations, and resources need to be included in the plan. To be effective, a full-scale exercise of the plan should be conducted regularly to test and update its effectiveness.

Both tabletop and full-scale exercises are necessary because of personnel turnover in prime and supporting agencies. Physical changes in and about the airport need to be considered before, during, and after the construction period. Refer to NFPA 424 for further guidance.

Airports located adjacent to large bodies of water must give special consideration to the possibility that an aircraft incident could occur in the water. In these instances, special watercraft equipment dependent on the specific need should be provided. In addition, mutual aid agreements should be established with

all local water rescue resources such as the Coast Guard, Navy, and fireboats.

AIRPORT FACILITIES

Hangars

An aircraft hangar is simply a building built to provide weather protection and shop space during aircraft maintenance and storage. Hangars pose unusual fire protection problems due to their occupancy's special nature. Since removing all fuel from an aircraft before moving it into a hangar is often impractical and economically unsound, potential exists for having large quantities of flammable liquids, mainly aviation fuel, inside the hangar. Quite often, aircraft contained in the hangar, particularly large aircraft, are several times more valuable than the hangar, necessitating some measure of protection for the aircraft as well as the hangar structure.

Aircraft hangars are divided into Types I, II, or III, which roughly correspond to the size and type of aircraft they house and their anticipated fuel loading. NFPA 409, *Standard on Aircraft Hangars,* defines these types and outlines requirements for construction, protection, drainage, fire cutoffs, and other provisions for each type of hangar. Innovative air/steel frame supported tents have been used at a few airfields. Consensus for exact fire protection measures have not been achieved, but it is clear that due to the value of housed aircraft and life hazards, an installed fire protection system will be warranted. Such steel-framed membrane-covered structures are recognized in several building codes.

Fixed hangar fire protection systems of the past provided protection for the hangar structure and consisted mainly of water-type sprinkler systems using the extra-hazard pipe schedule, or hydraulically calculated systems, primarily of the deluge type. In aircraft hangars, these water systems are no longer recognized as viable protection by NFPA 409. With increased size and fuel loading of the aircraft, foam-water deluge sprinkler systems are now common practice. Current designs incorporate foam-producing and oscillating monitor nozzles at (nominal) floor level in conjunction with previously mentioned systems, to provide fire control/extinguishment for the shadow area beneath the wings of large aircraft.

Adequate protection of the hangar structure can be achieved as well as providing increased protection for the aircraft, primarily due to more rapid fire control and/or extinguishment.

In older hangars being modernized, a different technique has more recently been used with the approval of the authority having jurisdiction (AHJ). This technique uses overhead closed-head type sprinkler systems hydraulically designed to deliver a specified minimum water density over a specified area. It is capable of delivering aqueous film-forming foam (AFFF) solution through standard (nonaspirating) sprinklers by using wide-range proportioning devices. Scheffey provides more insight on AFFF in an airport environment.[10]

Primary fire-extinguishing capability affording some degree of aircraft protection is provided by oscillating monitors that completely blanket the floor of the entire hangar with foam within 20 to 30 seconds of actuation.

Whether the foam delivery system is used only for shadow area protection or total floor coverage, foam monitor location, oscillation speed, foam pattern, and nozzle barrel centerline height above the floor are critical. Monitors should be located so that all areas to be covered can be easily reached. Depending on the arc of coverage, no more than 15 seconds should be necessary for a complete cycle. The foam pattern should be dispersed rather than a straight stream. This minimizes turbulence at the point of stream impact with objects or the floor. Figure 21.9.11 shows a typical monitor installation.

Due to hangar sizes or multiple aircraft positions, monitor nozzles can be mounted at the bottom of the roof truss space to provide coverage for these void spaces. Arrangements should be made to exercise and test the oscillating mechanism from the hangar floor or other easily accessible locations (Figure 21.9.12).

The principal means of fire detection for actuation of overhead sprinkler systems in hangars has been rate-of-rise type devices; however, as hangar roof heights have increased to as much as 150 ft (46 m) from the floor to the roof deck, the ability of this type of device to perform within the time required to minimize aircraft damage is limited. In climates with moderate to severe winter conditions, it is difficult to maintain stability of such systems, due to the opening and closing of hangar doors and the installation of high-recovery-rate heating systems, and still maintain the sensitivity necessary for rapid fire detection. Optical-type detectors of ultraviolet/infrared type or dual function can be used for high-speed detection of relatively small fires and actuation of monitor nozzles. Rapid temperature changes do not affect those devices.

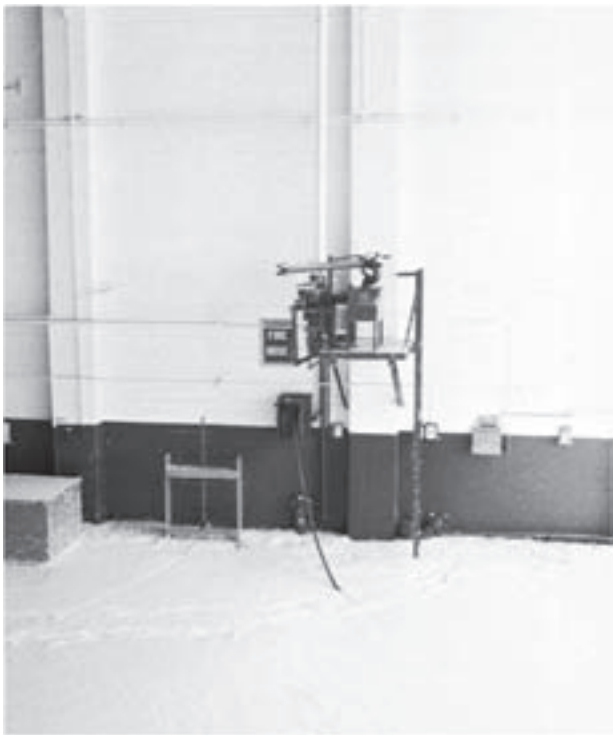


FIGURE 21.9.11 Foam Monitor Nozzle (Source: United Airlines)

FIGURE 21.9.12 Monitor Nozzle Mounted Beneath the Roofwork to Fill Void Areas Unreachable from Monitors Located Near the Walls. Centerline of the barrel is approximately 65 ft (20 m) above the floor. Control valves are located at the floor line along the hangar wall. The small-diameter lines illustrated are for testing and exercising the water-powered oscillating mechanism. (Source: United Airlines)

Care must be taken in selecting the type of detector and control devices for optical detection. They must have demonstrated operational integrity, yet not be overly sensitive and subject to false or unwanted operation. Considerable progress has been made recently in developing optical detection systems that ignore or are insensitive to routine aircraft maintenance procedures involving welding, high-intensity lights, boroscopes, radioisotopes, X-ray inspections, and so on. Whenever an optical system is installed, its sensitivity to fire should be tested. Further, a recording device should be attached to provide a hard-copy record of what detectors "see" during routine aircraft maintenance operations. During the initial period after installation (usually 60 to 90 days), the detection systems should be in the "alarm only" mode and a careful record made of the recording device printout. Aircraft maintenance records can often determine what operation affected the optical detectors.

Floor drainage is another portion of the hangar fire protection system. The drainage system removes excess fire protection water and also removes large quantities of liquid fuel from the fire scene. These systems should be flushed thoroughly with high volumes of water at least annually. Oil/water separators should be meticulously maintained to prevent pollution of lakes and streams and to reduce hazards in the airport drainage system to which the hangar system may be connected.

In recent years environmental concerns have necessitated more restrictions on the disposal of AFFF solution subsequent to discharge. Therefore, new system designs should consider the provision of bypasses and retentional areas for initial and periodic system testing.

Airport Terminal Buildings

Airport terminal buildings include any fully enclosed extensions that function as passenger concourses (sometimes called fingers or piers) and satellite buildings that serve passenger-handling functions. The satellite building may be connected to the main terminal building via tunnels beneath the aircraft operating ramp or via people-mover transit systems operating on a fixed guideway, above or below ground level. Terminals also contain airline-related businesses, such as offices, restaurants, and gift shops. Quaglia and Grubits have discussed the fire safety design of airport terminals.[11]

Special attention is given to airport terminal buildings in NFPA 415. These buildings have a severe fire exposure potential from immediately adjacent aircraft fueling and servicing operations and the high-occupancy (people) load in terminals.

Walls and glass areas of terminal buildings and other airport structures that may be exposed to jet blast or explosion require design for wind loads in excess of that which building codes normally require.

Although NFPA 415 primarily addresses the terminal building interface with the aircraft ramp, a variety of other NFPA codes apply to areas such as restaurants, baggage handling systems, and important electronic and computer installations.

Aircraft Loading Bridges or Walkways

This equipment is frequently installed at the terminal area for passenger convenience and to protect passengers from the weather while they move from the terminal loading gate area to the aircraft. Loading equipment also increases safety by reducing ramp congestion and segregating passengers from the aircraft servicing equipment and personnel.

In the event of fire caused by a fueling malfunction or other reason, a loading bridge or walkway can serve as a means of egress from the aircraft to a safe refuge, for example, the terminal building. Most people naturally tend to exit an area (aircraft or building) the same way they entered. Because the emergency situation requiring evacuation may occur before the preflight safety and evacuation briefing, the loading bridge may be the only means of egress familiar to passengers. For this reason, NFPA 415 requires 5 minutes of safe passage from the aircraft to the terminal. Construction features, special fire protection, or a combination of both may accomplish this. Safe egress must be provided during severe fire exposure to the bridge.

Doors, if any, at the terminal end of the bridge should be equipped with panic hardware and swing in the direction of travel from the aircraft to the terminal. The loading bridge should not be considered part of the terminal egress system, unless a vestibule and stairs conforming to NFPA *101*®, *Life Safety Code*®, are provided at the terminal end, even though auxiliary stairs may be located near the aircraft end. Auxiliary stairs are strictly for the use of aircraft servicing personnel or flight crew.

Training of loading bridge operators in positioning the equipment and obtaining the best possible "seal" with the aircraft in all weather conditions is very important. Unless the bridge and closure curtain are properly positioned and utilized, the integrity of the loading bridge as a means of egress from the aircraft is seriously compromised. The operator must be aware that the closure curtain is a safety item, not merely weather protection.

Since escape slides aboard the aircraft are normally deactivated during the loading, unloading, and maintenance cleanup phases of activity, the loading bridge/walkway is a critical element in the fire safety system. It is essential that this egress path not be blocked by wheelchairs, trash carts, and so on.

Aircraft Fueling Ramp Drainage

The large amounts of combustible/flammable liquids (in the form of fuel) handled on aircraft servicing ramps demand that special attention be paid to the drainage system provided to prevent exposing the terminal or aircraft unnecessarily in the event of unintentional release. NFPA 415 specifies the amount of slope and direction regarding ramp geometry, location of drainage system inlets, water seal traps, and oil/water separators.

AIRCRAFT MAINTENANCE AND SERVICING

Aircraft Maintenance

To keep an aircraft airworthy, every part must be inspected, repaired, or overhauled periodically. The frequency of these procedures varies. Operations may be performed all at once in a single maintenance visit, or as part of a progressive overhaul system where a certain portion of a total overhaul is conducted periodically. In addition, periodic inspections are required between major overhauls to repair minor discrepancies, inspect critical structures, and test various components. Nonroutine maintenance can occur at any time to replace or repair a defective or prematurely failed part.

Many maintenance procedures involve the use of highly flammable solvents, sometimes unstable or toxic chemicals, and personnel entry into integral fuel tanks. When situations such as these occur, special procedures must be developed to ensure the safety of the operation. It is sometimes possible to pressurize equipment housings with shop air, using appropriate power/pressure interlock to prevent penetration of flammable vapors. Localized ventilation and curtailment of operations utilizing flammable or combustible liquids are also helpful. In any event, each potentially hazardous procedure should be developed or reviewed by a person who is thoroughly familiar with the basics of fire safety and aircraft maintenance requirements and procedures. NFPA 410, *Standard on Aircraft Maintenance,* should be used to develop local procedures for the more common hazardous aircraft maintenance operations, such as welding, spray painting, fuel tank ventilation, and so forth.

NFPA 70, *National Electrical Code®*, defines certain areas in hangars and around aircraft as Class I, Group D, Division I or II locations. In this age of sophisticated testing using electronics, eddy currents, X-rays, and so on, it is often impossible to design or obtain equipment listed or approved for these locations. Injuries and fires can occur due to the complexity of aircraft and associated electrical test equipment. Induced current, capacitor-type discharges, errant electromagnetic radiation, and simple poor electrical continuity are some of the electrical fire and safety hazards that can occur during aircraft maintenance. Welding (usually inert gas-shielded arc) is frequently performed on installed engines or aircraft structures.

Testing fuel tanks for system leaks is commonly performed in hangars using high flashpoint Jet A fuel or a special, usually combustible, test fluid. Toward this end, many hangars have a fixed system to load and unload fuel or test fluid. It has also been a practice to park a standard fuel servicing tank truck outside the hangar and run long hoses to the aircraft connection points. This practice is to be discouraged, because the hose is the weak point in any system. Although hoses are necessary for flexible connections, they should be kept as short as possible.

Painting the interior and exterior of aircraft is also accomplished in hangars. Although a few hangars have been constructed specifically for aircraft exterior painting, it is more common to control ignition sources and rely on the sheer volume of the hangar and natural ventilation to dissipate flammable vapors. Latex paints, which contain little, if any, solvent, are being used for aircraft interiors. Interior panel partitions and equipment can be painted in place rather than removed to a standard paint spray booth. Whenever using flammable paints inside an aircraft is necessary, special precautions for ventilation and control of ignition sources must be followed.

Aircraft Fueling

The potential exists for spills and fires each time an aircraft is fueled. Preventing such incidents is aided by reference to NFPA 407, a document accepted worldwide. The standard outlines specific precautions to control the extent of this hazard and gives recommendations on the design of aircraft fueling hose, aircraft fuel servicing tank vehicles, airport fixed fueling systems utilizing fuel hydrants, hydrant vehicles (to connect the fuel hydrant to the aircraft), as well as safety procedures to follow in the event of an accidental spill. A common type of spill is at the aircraft tank vent point, when an aircraft internal shutoff valve fails or closes slowly, allowing an overfill condition to develop.

Aircraft postincident defueling safety is important due to the possibility of injury to technicians, loss of salvage value, and potential environmental impact. Fuel system damage due to impact, inversion, or fire may result in a variety of aircraft balance, wiring, switch, plumbing, pump, tank, or other component irregularities that must be addressed by competent technicians. Only then can restoration of the incident sites be accomplished.

SUMMARY

Civil aircraft in the United States are subject to extensive federal regulation. Aeronautical engineers blend fire prevention and control safeguards with the use and mission of a particular aircraft. Fire detection and extinguishing equipment is normally required for aircraft areas possessing inherent fire hazards and ignition potentials, notably the power plant areas. The extinguishing agents most commonly used in aircraft are Halon 1301 and Halon 1211, although these chemicals are currently being phased out and replacement agents developed. Another key design element is emergency exit facilities, since postcrash fire exposure can be severe and safe evacuation time for the occupants is limited. Aircraft rescue and fire-fighting preplan-

ning for emergency landings is extremely important. Airport facilities, including hangars, terminal buildings, loading bridges, and walkways, all require appropriate safeguards. In addition, special procedures must be developed to ensure the safety of inspection and maintenance operations and aircraft fueling.

According to industry statistics, fires and explosions continue to contribute to the fatalities and injuries experienced in marine vessel casualties. This chapter discusses marine fire hazards on small pleasure craft, small commercial boats, and commercial vessels, as well as the design, construction, and shipboard fire prevention systems normally installed to deal with them. It first covers pleasure and small commercial craft and then devotes the balance of the chapter to large commercial vessels.

Additional information about extinguishing systems suitable for use on vessels is found in the following chapters: Section 16, Chapter 3, "Automatic Sprinkler Systems"; Section 16, Chapter 9, "Water Spray Protection"; Section 17, Chapter 1, "Carbon Dioxide and Application Systems"; Section 17, Chapter 4, "Foam Extinguishing Agents and Systems"; Section 17, Chapter 5, "Fire Extinguisher Use and Maintenance"; and Section 17, Chapter 6, "Halon and Halon Replacement Agents and Systems."

PLEASURE AND SMALL COMMERCIAL BOATS

The latest boating safety statistics from the U.S. Coast Guard (USCG) indicate there are nearly 13 million pleasure and small commercial boats in the United States.[1] Statistics for the 5 year period from 2001 to 2005 show that annually there were approximately 5500 accidents, 700 fatalities, and 3800 injuries involving such boats. The fatality rate for this period is down an average of almost 50 per year (or about 6%) below that for the previous 5 years. The report indicates that approximately 225 fire and explosion accidents caused, on average, about 5 fatalities and 93 injuries per year. These accidents also resulted in a 5 year total property damage of almost $54 million.

The introduction of the 1960 edition of NFPA 302, *Fire Protection Standard for Pleasure and Commercial Motor Craft,* stated, "There are few other uses of petroleum fuels by the public in which the fire and explosion hazards parallel those possible in motor craft." In spite of technical developments since that time, the statement remains true today.

Overview

Boats and vessels of all sizes are constructed to create a form that is closed on the bottom and on all sides. This basic hull form is necessary for the boat to float. In the case of trains, aircraft, and all land vehicles (other than amphibious types), openings can be provided where needed to permit both liquid fuel leakage and heavier-than-air vapors to drain by gravity to the open atmosphere. Gasoline is commonly used for both propulsion engines and for onboard generators, and liquefied petroleum gas (LP-gas) is commonly used for cooking. Any leakage of these fuels and any gas or vapors released as a result of using those fuels is retained inside the hull. The two means of discharging gas and/or vapor "overboard" are (1) the slow process of natural ventilation, which requires airflow over the boat (from boat motion or wind speed), and (2) mechanical ventilation, which is used before starting any engine. Exhaust blowers tend to be effective in only the general area of the exhaust blower pickup. By comparison, automobiles and trucks are normally completely open on the bottom, providing effective ventilation in all areas of the fuel system. Seepage of liquid fuel and vapors can freely drain to the open atmosphere along the road from any point in the system.

Randall Eberly, P.E., is a staff fire protection engineer in the Lifesaving and Fire Safety Standards Division at U.S. Coast Guard Headquarters.

Aircraft, likewise, have drains in their engine nacelles and under their wings, allowing vapors to be dispelled to the atmosphere inflight or on the ground.

Since bottom drains are not possible in a boat, safety on boats depends on a carefully maintained, leak-free fuel system and on ventilation capable of discharging heavier-than-air fuel vapors overboard. When vapors are discharged overboard from lower levels, fresh air is automatically introduced into the hull's upper levels. The fresh air tends to dilute vapors in the upper level. An adequate removal and dilution process keeps the vapor and/or gas mixture below the lower explosive limit.

Consider that 1 oz (0.3 L) of gasoline fuel can create about 11 ft^3 (0.3 m^3) of explosive vapor. Gasoline vapor is approximately four times as heavy as air and tends to sink to the bottom of the bilge. Natural or mechanical ventilation cannot render a boat safe in any reasonable time if any liquid leakage occurs. An operating marine exhaust blower with a pickup duct placed 1 ft (0.3 m) above an open container of gasoline does not materially reduce the time required for the fuel to evaporate. Because an exhaust blower, or any ventilation, does not materially accelerate the fuel's vaporization rate, power ventilation should not be used when liquid fuel is known to be present. Ventilation, in addition to removing some flammable vapors in the duct intake areas, introduces fresh air that can bring an overly rich mixture into the explosive range. Whenever liquid fuel is present, no electrical circuit should be turned on or off. The battery should not be connected or disconnected. An arc can occur when making or breaking a circuit.

Boat Hulls

The hull of a pleasure boat or small commercial vessel must be arranged so that all compartments are as accessible as practicable for inspection and maintenance. Access must always be provided to sea cocks for emergency use. There must be two means of escape from all accommodation spaces in case fire in the engine space or the galley blocks one means of egress. Escape hatches must be unobstructed, readily accessible, and adequately sized and shaped for their designed purposes. Congestion of an engine compartment is unsafe; it may make sea cocks inaccessible and discourages adequate inspection and maintenance of engines and equipment. Adding internal combustion auxiliary machinery increases ventilation requirements.

Engine spaces (for propulsion engines, generators, and other auxiliary engines) must be separated from accommodation spaces by fore, aft, and transverse bulkheads and decks. The separation must serve as an effective fire barrier and minimize the escape of fire-extinguishing media that may be discharged into the space. Unsealed bulkheads with a ¼ in. (6.4 mm) annular space around items penetrating the bulkhead are considered adequate for ignition-protection purposes and for confining fire-extinguishing agents. However, these same bulkheads do not prevent carbon monoxide that may be present in the engine space from passing through the bulkhead to accommodation spaces.

Materials

Boat hulls, bulkheads, and superstructures are constructed of a wide variety of materials, including aluminum, steel, reinforced fiberglass laminates (FRP), and wood. In addition to solid fiberglass laminates, there are fiberglass laminates with balsa wood or plastic honeycomb core materials and wooden structures that have been covered with a fiberglass laminate on both sides, making a sandwich construction. The combustibility, flame spread rate, smoke production, and heat release characteristics of these various flammable materials have not been investigated and classified for use on boats. Thinner outer laminations of cored construction burn through relatively quickly, exposing core materials. Choice of material is determined by boat size, type, intended service, and cost. Horizontal deck surfaces, such as the deck above the engines, are very quickly involved in fire spread because of the low height and small volume of the compartments above which the decks are located. To minimize fire spread, fire-retardant resins and fire-retardant coatings suitable for marine service may be used. Because fire-retardant resins may reduce the structural strength of the laminate in which they are used, changes may be needed to compensate for strength differences. Upholstery and carpeting used in cockpits and accommodation spaces might have high flame spread ratings. The flame spread ratings of all materials and fire-retardant coatings used should be carefully considered. As in engine spaces, ceiling heights in accommodation spaces are low compared to those in buildings, and the height reduction effectively accelerates horizontal flame spread.

Ventilation

Ventilation is defined as the positive changing of air, by natural or mechanical means, within a compartment. Boat ventilation is primarily designed to remove heavier-than-air flammable vapors from the bottom of the compartment. When air is removed from the compartment, fresh air is simultaneously introduced at the upper level. The fresh air dilutes the flammable vapors in the upper levels where the intake ducts terminate.

Natural ventilation's effectiveness depends on outside air velocity and direction. Without wind or boat motion, there is virtually no natural ventilation other than that created by thermal air currents. The most important factors affecting air movement inside a hull are (1) the shape of the boat's superstructure (cabin or, in small open boats, the windshield), (2) the location of the boat cabin or windshield, and (3) the type and location of the ventilation fittings. With a bow wind, a boat cabin's shape makes it function like a ventilating clam shell, reducing pressure under the cabin. In runabouts, pressure is reduced behind the windshield. Reduced pressure results in an airflow to that area. For maximum ventilation efficiency, the engine space airflow that ventilating fittings create should be used to reinforce the airflow the cabin creates. Neither natural nor power ventilation effectively removes the hazard of vapors created by the presence of liquid gasoline because flammable vapors can be generated faster than they can be removed. Airflow created by the ventilating system only slightly affects the time necessary to evaporate liquid gasoline. Therefore, in the presence of liquid gasoline leakage, introducing fresh air by operating blowers may create, rather than eliminate, an explosive mixture. The boat's blowers should not be used.

Ventilation in an engine space plays an important role in controlling heat levels in that space. Ventilation for temperature

control depends on natural airflow into the engine space when the boat is under way and on the efficiency of external ventilating fittings and ducts. These fittings and ducts must be large enough to supply the air required for the engines. The compartment pressure depression must be measured with all engines operating at full power. Exhaust blowers are not used to control temperature or to supply air to the compartment. The engines operate with block temperatures of about 140 to 180°F (60 to 80°C). Because of anticipated high engine room temperatures, electrical conductors are derated in those spaces.

Of all cooking fuels, LP-gas creates the greatest ventilation problem because the gas is approximately 1.6 the density of air. It tends to sink and must be removed with positive ventilation.

Ventilation and Carbon Monoxide

Carbon monoxide (CO) is a flammable, gaseous poison having the same vapor density as that of air. Large quantities of CO are produced as a component of gasoline engine exhausts and, to a lesser degree, from diesel exhausts. Cooking appliances produce smaller quantities. This gas must be kept out of accommodation spaces to the greatest degree possible. Control of CO depends on awareness of the following basic factors:

1. The separation of the engine exhaust system discharge fittings from ventilation system fittings, scuppers, drains, and any other openings into the hull is vital to prevent the gas from reentering the boat. The direction and velocity of airflow over the boat must be considered. It affects the flow of air into and from all the ventilation intakes and exhausts.
2. It is not possible to prevent CO gas from reentering the boat under some operating conditions. One common condition, for instance, would be when a boat is operated at slow speed with a following wind. The operator must recognize and avoid these conditions.
3. Even engine room bulkheads that meet the ignition protection requirements of USCG regulation 33 CFR 183.410 do not effectively prevent CO gas from moving from the engine space into accommodation spaces.
4. A CO detector can help warn the boater of the presence of CO. CO is a flammable gas, but its greatest danger is that it combines with blood hemoglobin in the same manner as oxygen. CO is the leading cause of gas poisoning deaths in the United States.
5. In 2000, the USCG became aware of another dangerous condition involving CO on recreational boats. On boats with gasoline-powered generators and transom exhaust ports, lethal concentrations of CO have been documented and pose a threat to any swimmers using stern swimming platforms. The Coast Guard issued an advisory and the National Marine Manufacturers Association (NMMA) distributed a safety pamphlet on the hazard.

Lightning Protection

Lightning hits many boats every year. USCG statistics consistently show that people killed by lightning on boats are usually in small open motorboats, not sailboats. Even if a sailboat does not have a complete lightning system, its metallic mast inherently serves as the major down conductor. It tends to conduct the lightning past the occupants.

The probability of a lightning strike on a boat varies with geographic location and season. Lightning protection can be provided on a boat that has a conductive mast with a conductivity equal to a No. 4 AWG conductor and enough height that an imaginary line drawn at a 45 degree angle from its tip does not intersect any part of the boat. A pointed lightning rod should be installed at the tip. The mast's base must be connected vertically and as directly as possible to an external grounding plate or grounding strip, located below the lightning mast. An external rectangular (1 ft^2 [0.09 m^2] or larger) grounding plate or an external horizontal grounding strip of the same approximate area may be used, running fore and aft from below the lightning mast to a position aft below the engine(s). Large metallic masses, such as metallic guard rails, engines, and tanks near the lightning ground conductor, should be connected to the grounding strip to prevent side flashes. If the mast being used is stepped on deck, the connection between the mast and the external grounding plate or strip should be made with a No. 4 AWG conductor or two parallel No. 6 conductors routed on both sides of an opening. The normal horizontal electrical system bonding conductor in a boat may be connected to a lightning conductor system, but should not be relied on as a lightning conductor. To be effective, lightning conductors must provide an essentially vertical path to the ground plate or strip.

Figures 21.10.1 through 21.10.4 show normal boat lightning protection systems. Spiral wrapped radio transmitter antennas will not function as lightning masts, but steel antennas may help, provided the antennas' coils are bypassed with a lightning arrester. If an external grounding strip is used, as illustrated in Figure 21.10.2, the sharp edges of the grounding strip should not be rounded. In both sailing auxiliaries and cruising power boats, the external grounding strip most effectively connects items in the boat to the ground without long horizontal conductors inside the boat. The mast and bow rails can be connected to the forward end, and the engine and back stay (sailboats) to the aft end of the strip. In larger boats it is difficult to avoid installing a number of horizontal lightning conductors to connect large metal masses to the system. Instead, an equalization bus may be installed inside the boat parallel to the external lightning grounding strip. The internal equalization bus and external grounding strip are interconnected at the forward and aft ends and must be connected to the lightning ground system. They must never be connected so that they become part of the main down conductor. If a seacock or through-hull fitting carries the full lightning current, any water in the seacock turns to steam instantaneously, breaking the fittings and possibly sinking the boat.

Occasionally, a sailboat's aluminum mast hits an overhead power line, and the question arises whether masts or sections of masts should be made of a nonconductive material to avoid such accidents. The answer is that a boat's lightning system should be maintained.

Engines

Liquid-Cooled Engine. Liquid-cooled marine gasoline and diesel engines may be cooled directly by seawater or with fresh water using a raw water-cooled heat exchanger. Liquid-cooled

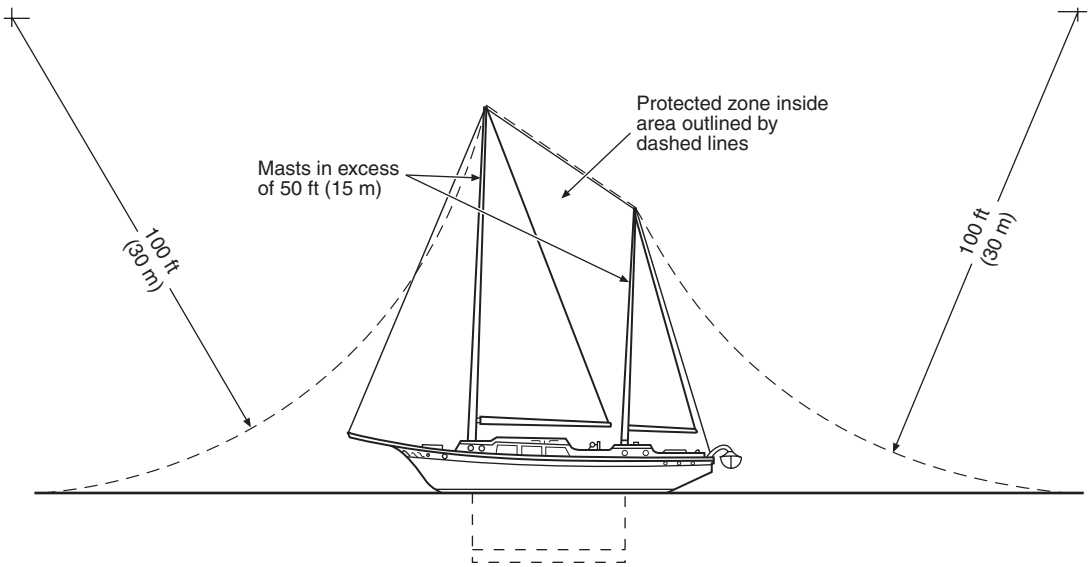

FIGURE 21.10.1 Proper Lightning Protection for a Boat with Masts More Than 50 ft (15 m) Above the Water. Protection is based on a lightning striking distance of 100 ft (30 m).

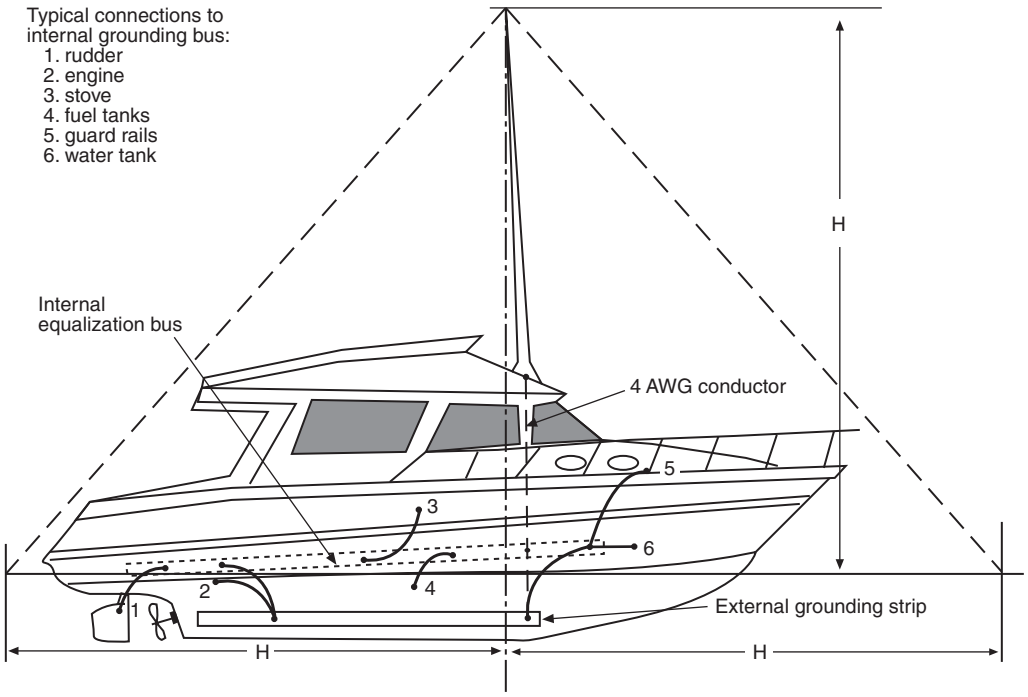

FIGURE 21.10.2 Boat with Mast Not More Than 50 ft (15 m) Connected to External Ground Strip, with Optional Equalization Bus

engines use water-jacketed blocks, heads, and exhaust manifolds. A self-priming, engine-driven pump circulates the cooling water. In a raw water-cooled engine, water circulates through the engine and then discharges into the exhaust pipe to create a raw water-cooled exhaust. The water discharges into the exhaust pipe through a water-jacketed riser at the engine. The riser's design prevents water from backing up into the engine through the exhaust manifold. Fresh water-cooled engines using a heat exchanger require two separate water pumps. One pump recirculates the fresh cooling water through the engine, and the second circulates water through the heat exchanger and provides raw water for the water-cooled exhaust. Fresh water-cooled

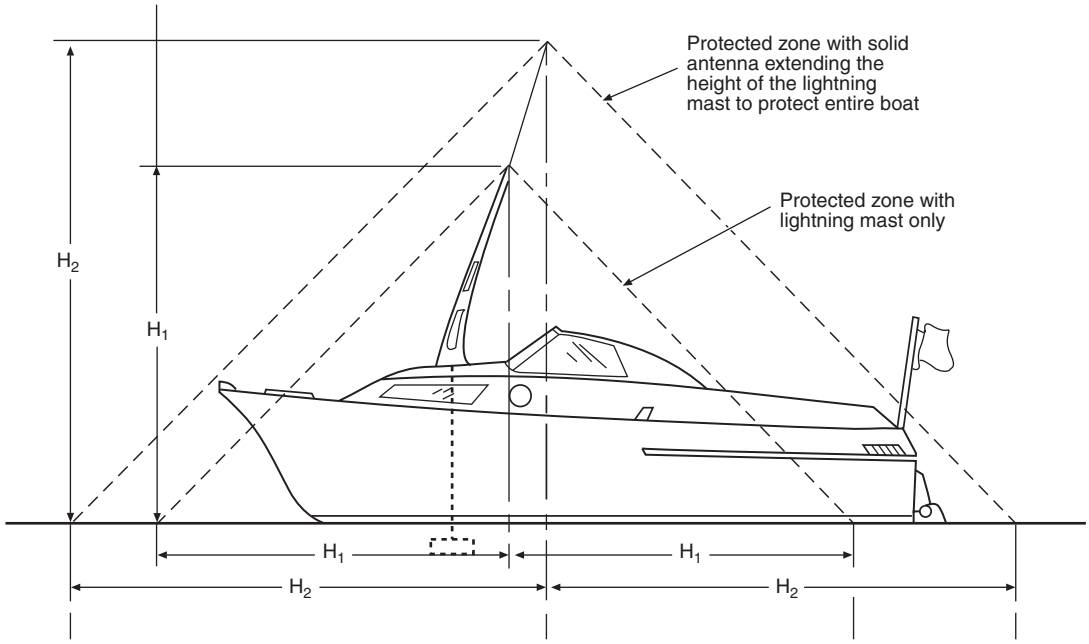

FIGURE 21.10.3 Proper Lightning Protection for a Small Sailboat with a Mast Not More Than 50 ft (15 m) Above the Water

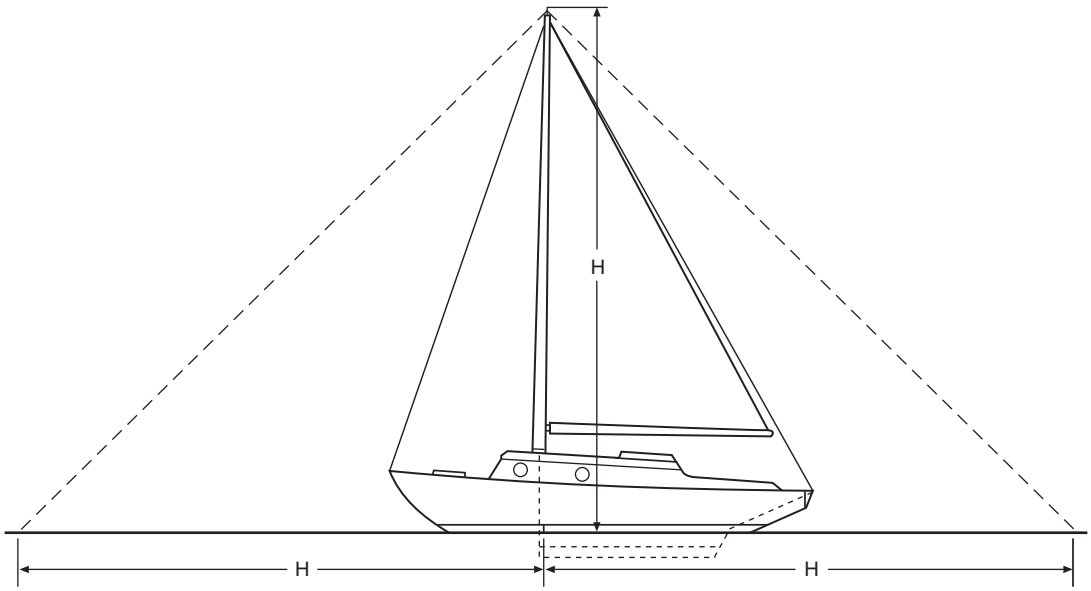

FIGURE 21.10.4 Proper Lightning Protection for a Boat with a Mast Not More Than 50 ft (15 m) Above the Water

engines can operate efficiently at approximately 180°F (82°C), whereas raw water-cooled engines, using seawater, must operate less efficiently at 140°F (60°C). The lower temperature prevents excessive salt precipitation in the block, manifold, and head of the engine. Raw water-cooled engines and engines using a heat exchanger can overheat if the pump fails or the water intake becomes blocked. Means to indicate loss of engine cooling water must be provided at all helm positions for propulsion engines. Nonpropulsion engines must automatically shut down with the loss of lubricating oil pressure, excessive engine temperature, and excess heat in the exhaust system.

Air-cooled engines are not recommended. However, if they are used in an enclosed space, a separate air duct must be provided for effective cooling. Because these ducts are large, they

must be located to minimize the intake of excessive seawater, which could affect boat stability. A device must be provided to warn of excessive temperatures.

Fuel Injection. Technical advancement in automotive and marine engines has caused rapid replacement of carburetion with fuel injection. The more efficient fuel injection systems eliminate boilover and float-leakage problems of carburetors but are still subject to rap or lock. However, injection systems with return fuel lines present a major hazard not encountered in carburetor engines. Fuel injection gasoline engines and diesel engines may use a return fuel line that is warm and under pressure. In comparison, fuel in the distribution line from the fuel tank to the engine operates at reduced pressure, minimizing the hazard. When the engine is not running and the distribution line is at a reduced pressure, a pinhole may not leak any fuel at all. When the engine is running, a pinhole leak in the return line will tend to spray fuel, creating an immediate hazard. Consider that the return line can totally fail and not affect engine operation. The operator may be unaware of fuel spilling into the bilge unless there is an operating vapor detector. The fuel line requirements remain the same for distribution and return lines.

Backfire flame arresters are still required to meet the same requirements, but they no longer require a USCG approval number. Diaphragm fuel pumps must be designed and installed to prevent the release of fuel to the bilge in case of diaphragm failure. All electrical equipment in the engine space must be ignition protected.

Ignition Protection

All ac and dc electrical equipment in a gasoline engine space and any space with fuel line fittings must be ignition protected. Ignition-protected equipment has the same performance objective as hazardous location (explosionproof) equipment on shore and on commercial vessels. However, the requirements for ignition protection are less stringent and do not require hazardous location wiring. Accident statistics indicate that ignition protection has effectively reduced explosions in boats. Unfortunately, investigations of fire and explosion accidents have revealed that ignition-protected equipment is frequently replaced with non-ignition-protected equipment, eliminating the protection originally provided.

To eliminate the need for ignition-protected equipment in accommodation spaces, a bulkhead must separate the engine space from accommodation spaces. The bulkhead must be watertight for 12 in. (30.5 cm) or one-third the bulkhead height, whichever is less. Above that level the annular space around anything passing through the bulkhead (wires, cables, ducts, etc.) must not exceed ¼ in. (6.3 mm).

Fuel Systems

In aircraft and land vehicles, gravity drains liquid leakage, thereby preventing accumulation; this is not possible in a boat. Because both liquid fuel leakage and fuel vapors accumulate in a boat, fuel system components' design must resist vibration and shock failure, corrosion, and chemical deterioration. The system must be designed, installed, and maintained so as to be liquidtight and vaportight to the hull interior at all times. All fuel system parts should be capable of withstanding exposure to free-burning gasoline for 2.5 minutes without fuel leakage. Hose used instead of copper tubing must be USCG Type A1 or A2 fire-resistant hose. (Fire-resistant fuel distribution lines, however, are not required if less than 5 oz [150 mL] of fuel will leak when the distribution line is cut at the lowest point.) When fire resistance is not required, a USCG Type B1 or B2 hose can be used. Metallic fuel fill fittings must be electrically bonded to the engine negative terminal to dissipate static electrical charges. Fill hoses must be double-clamped.

Diesel fuel systems and gasoline fuel injection systems require the installation of efficient fuel filters and water separators to prevent dirt and water from reaching the fuel injector pump. Diesel and some gasoline fuel injector systems have pressurized return lines to the tank that must meet the same requirements as the fuel distribution line to the engine. Heated return fuel will gradually raise the temperature of the fuel in the tank. At normal temperatures, diesel fuel does not vaporize and create an explosive fuel air mixture, but diesel fuel has a greater tendency to accumulate in the bilges and create a fire hazard. Pressurized gasoline lines create an immediate hazard at any leakage level.

Appliances

Open flame appliances must be designed specifically for marine use and be installed to minimize personal and physical hazards. They must also be designed for attended use. The manufacturer must furnish printed instructions for their proper installation, operation, and maintenance. Portable devices and any device that cannot be secured in position when in use or stored are not permitted. A durable and permanently legible instruction sign describing safe operation and maintenance must be provided. The sign should be installed on or adjacent to the appliance where it can be quickly read. Air consumption and exhaust product venting from galley stoves and other appliances must be considered in the design and layout of compartments where they are installed. Lack of permanently open vents to supply air to the appliances can result in oxygen depletion in the compartment. Exposed materials around galley stoves and other heat-producing appliances must have a flame spread index (rating) of less than 75. Fabrics must not be used within 39 in. (1 m) of a galley stove.

Pilot lights and other automatic igniters are prohibited unless they are used in sealed combustion chamber type devices with outside air supply and exhaust discharge. Gas-fueled appliances must be equipped with flame failure devices to prevent gas flow if the flame is extinguished. Unattended devices, such as water heaters, refrigerators, and cabin heaters, cannot have automatic ignition unless they are of the sealed combustion chamber type, with the internal flame completely separated from accommodation spaces. Open flame water heaters and refrigerators are not permitted because they could be left on during fueling and because undetected leaks could occur in the fuel system. Gasoline is not permitted for use as a galley fuel.

Coal, charcoal, and wood-burning stoves must be installed on a hollow tile base or mounted on a noncombustible base with a clearance of 5 in. (13 cm) between the stove bottom and any

deck. The deck must be sheathed with a noncombustible material. The sides and back of a stove must have a clearance of not less than 9 in. (23 cm) and must have a flame spread index of not more than 75.

Liquefied Petroleum Gas and Compressed Natural Gas Systems

The properties of both liquefied petroleum gas (LP-gas) and compressed natural gas (CNG) must be understood to ensure their safe use. Both are frequently used in the galley for cooking and are popular because they do not require priming like pressure alcohol stoves. At ambient temperatures, LP-gas can be liquefied at well under 250 psig (1724 kPa), the rated pressure of an LP-gas cylinder. CNG does not liquefy at ambient temperatures and is stored in cylinders under a pressure of about 2000 psig (13,790 kPa). LP-gas is a two-phase (liquid/vapor) fuel with a higher calorific value than CNG. LP-gas, when released as a gas, has approximately 1.6 times the density of air, and tends to sink to a boat's bilges. CNG is released as a lighter-than-air gas and tends to collect at the top of a compartment if not vented. When confined to a space, the gases will fill that space in a short time through diffusion. Diffusion and convection cause the gases to pass through and over bulkheads in all directions. An odorant added to both gases facilitates detection. A pressure regulator lowers the stored pressure of both gases to a system working pressure. LP-gas, normally stored at a pressure of 150 psig (1034.35 kPa) or less, is delivered to the appliance at approximately 14 in. (36 cm) water column, or about 0.735 psig (5.0 kPa gauge). CNG is reduced to about 6 in. (15 cm) water column, or about 0.22 psig (1.5 kPa gauge) at the appliance.

NFPA 302 permits LP-gas and CNG containers and regulators to be located on an open deck or on a cabin top in a housing, open at the top and bottom so escaping gas does not reenter the hull or accumulate in a cockpit or any enclosed space. The housing must protect the valves and the regulator assembly from mechanical damage. If not located on an upper deck or cabin top, the LP-gas containers and regulator assemblies must be located in a vaportight locker. The locker must be located above the waterline, be vaportight to the hull interior, be provided with a latched gasketed cover, and be vented overboard. It must be located so that when the cover is open, escaping vapor does not flow to the bilges, machinery spaces, accommodation spaces, or other enclosed spaces. Normal locations are along the side of the cabin in a molded-in locker or in an open cockpit in a vaportight locker. LP-gas lockers are vented with a ½ in. (13 mm) line led overboard with traps. The locker vent discharge must be separated from any hull opening and from any exhaust discharge fittings. Because CNG is lighter than air, CNG lockers must be vented with a ½ in. (13 mm) vent to the open atmosphere at a level above the cylinders and regulator assembly. CNG tanks, like LP-gas tanks, may be installed on an open deck, in a vaportight locker with an overboard vent or in a compartment that has no openings to an engine space above the level of the regulator. Engine room bulkheads that meet the ignition-protection requirements are not vaportight and therefore might communicate with other spaces.

Low-pressure distribution lines from the system regulator assembly to an appliance may be either copper tubing or hose. Copper tubing can be used with LP-gas without a problem, but copper tubing used with CNG must be internally tinned. LP-gas hose with permanently attached fittings must meet the requirements of UL Standard 21. CNG hose must meet the requirements of NFPA 52, *Vehicular Fuel Systems Code.* Distribution lines must be installed in continuous lengths from the regulator assembly to the appliance. The only exception is the installation of a flexible hose connection between copper tubing or copper piping and a gimbaled appliance.

Standards prohibit the use of pilot lights or other automatic ignition forms on gas-consuming appliances, but do permit a flame control for an oven in use. The flame control must be off when the oven control is off. All gas-fueled appliances must have a flame failure control to prevent gas flow if the flame is extinguished. Stoves with gas containers having less than 8 oz (0.24 L) of fuel are exempt from this requirement.

LP-gas or CNG systems installed in accordance with NFPA 302 can be simply, quickly, and positively checked for leakage in about 10 minutes. The method, which requires a pressure gauge, should be used frequently. The standard leakage check should be done after the system has been serviced, after the containers have been changed, and after any storm or grounding that might affect the system. NFPA 302 recommends that the check be done at the start of any cruise or voyage during which the system will or may be used. The standard specifies the following procedure:

- With the appliance valves closed and all other valves open, note the pressure on the gauge.
- Close the container valve.
- Observe the pressure to ensure that it remains constant for at least 10 minutes.
- If pressure drops, locate leakage by applying a soapy water solution at all connections.
- Repeat test for each container in multicontainer systems.
- *Never use flame to check for leaks.*
- *Never use soap containing ammonia.*

Electrical Systems Under 50 V

A boat's low-voltage dc system is intended to be a two-wire system with insulated conductors running parallel to each other to and from the power source, to each item of electrical equipment. The two-wire system minimizes the creation of magnetic fields that can affect the compass and other magnetically sensitive equipment and also minimizes the chances for stray dc current flow between metallic underwater components. Negative ground has been adopted as standard for dc systems, and the engine negative terminal is established as the single point for the dc system ground. When stray dc current flows between any two metallic components in contact with an electrolyte, such as seawater, the more positive (anodic) metal suffers accelerated corrosion. The more negative (cathodic) metal tends to be protected. Making the engine's lower unit or propeller and shaft purposely more negative or cathodic protects them and any other metallic objects connected to the same ground from accelerated corrosion due to stray currents. Although a true two-wire system

would best serve the boating industry, most marine engines use converted automotive single-wire components. The automotive industry uses a common chassis ground return system so that all engine-mounted components have a negative conductor grounded to the frame. Because of the engine, the two-wire dc system on a boat is something of a compromise: mostly a two-wire system, it remains a single-wire system at and near the engine. The single-wire system has been extended off the engine by permitting an accessory negative bus for accessories near the engine. Accessories connected to a panelboard may have their negative conductors connected to the accessory bus near the engine, instead of the panelboard negative terminal strip. Whenever the system becomes a single-wire system and the feed and return conductors are not run in a pair, a magnetic loop forms. Standards do permit a completely ungrounded system, provided the engine's electrical components are all ungrounded.

Even though the engine's system is single wire, metal hulls and boat bonding systems must never be used as ground return paths. The boat bonding system—used to connect the non-current-carrying metal housing of dc equipment to the engine negative terminal—serves three functions:

1. Because the non-current-carrying parts of dc electrical equipment are connected to the engine negative terminal, stray current leaking from this equipment returns to the engine negative terminal (and battery negative) on the bonding conductor inside the hull. Electrical flow inside the hull minimizes current flow outside the hull between metallic appendages that would result in stray current corrosion of the equipment. A stray current leak of less than an ampere through a 1 in. (2.5 cm) through-hull fitting can destroy the fitting and sink the boat in 3 days.
2. A boat bonding system may be interconnected with and become part of the lightning protection system. When used in the lightning protection system to interconnect large metallic objects, the conductor size must be at least a No. 6 AWG conductor.
3. The bonding system conductor connects underwater metallic hardware to a galvanic anode (zinc) for galvanic protection.

If a boat has two or more propulsion engines and more than one battery bank, its engine blocks must be interconnected with two conductors capable of carrying the cranking current of the largest engine. The conductors prevent heavy damaging stray current corrosion due to current flow between propellers and shafts or outdrives when cranking one engine from the battery of another. Positive interconnection of all engines also prevents a current path through metallic fuel lines and control cables.

All dc conductors in the boat, except cranking motor conductors, require overcurrent protection at the power source for any circuit, generally within 7 in. (17.8 cm) of the source. USCG regulations and NFPA 302 permit a wire that is directly attached to the battery to be 72 in. (1.8 m) long without overcurrent protection. Using this exception is not recommended. NFPA 302 specifically requires the underground battery charger leads to be protected at the battery point of connection to the dc system. Under the regulations and NFPA 302, it is also possible to extend an unprotected sheathed wire's length from 7 in. (17.8 cm) to 40 in. (101.6 cm). The exception is used between the engine cranking motor solenoid hot terminal and the engine circuit breaker to position the circuit breaker high on the engine.

Boats have a special problem because many dc motors used on boats have no internal thermal protectors and by design cannot have the equivalent impedance protection. Lacking internal protection against overload, branch-circuit breakers or fuses must protect these motor-operated devices (pumps, blowers, etc.) against a "locked-rotor" condition. A locked-rotor condition exists if the pump becomes jammed and cannot turn. The motor manufacturer cannot easily specify the branch-overcurrent protection because it depends on the total wire length in that branch circuit.

Electrical Systems over 50 V

Three different sources may power the 120/240 V ac electrical system on a boat: (1) shore power, (2) an onboard ac generator, or (3) an onboard dc to ac inverter. Using shore power invites a special problem because the ac grounded neutral conductor is grounded to the earth on shore, but must never be grounded on the boat. When powered from shore, ac leakage currents return to the earth ground on shore. In contrast, both the onboard ac generators and the onboard inverters are grounded on the boat so that all leakage current remains on the boat. When two or all three sources of ac power are available, a switching arrangement must be provided to prevent any two sources of power from feeding the same circuit at the same time. This switch must disconnect one ac power source before connecting the circuits to another power source.

As on shore, under NFPA 70, *National Electrical Code®*, a green grounding-wire system keeps the non-current-carrying housings of ac appliances and ac equipment at ground potential to prevent electrical shock. When ac current is from an ac generator or an inverter on the boat, the green grounding-wire connects to the generator or inverter ground on the boat. With shore power, the green ac grounding-wire to the boat engine's negative terminal connects the underwater hardware of the boat (propellers, shaft, outdrivers, etc.) to other boats or any grounded metal on shore. Accordingly, aluminum- and steel-hulled boats and boats with aluminum outboard engines or aluminum stern drives suffer accelerated corrosion when connected to more noble metals (cathodic materials) on other boats or the dock. The interconnection with other boats or the dock can result in severe continuous galvanic corrosion of the anodic metals. This interboat corrosion could be stopped by not connecting the green grounding-wire to the boat engines, but any ac leakage on the boat can charge the surrounding water, electrocuting any swimmer near the boat. The solution requires the installation of a marine "galvanic isolator" or the installation of an isolation transformer in accordance with NFPA 302. The galvanic isolator is a device installed in series with the green grounding-wire on the boat. The device blocks the flow of dc galvanic currents while permitting the flow of ac current in the grounding conductor. The galvanic isolator must be sized to carry the system's full current because if it fails, the green grounding-wire stops working.

Fire Extinguishers

Testing laboratories normally evaluate the fire extinguishment potentials of portable fire extinguishers. The USCG also classifies portable fire extinguishers based on the Underwriters Laboratories Inc. classification of fires, but uses a different method to indicate extinguishment potential. Table 21.10.1 lists these designations.

PLEASURE AND SMALL COMMERCIAL BOAT OPERATIONS

General Maintenance

Operation and maintenance of pleasure and small commercial boats rely on general good housekeeping practices. Safety requires periodic inspection and maintenance of all equipment. When checks are conducted, unprotected electric lights should not be taken into areas of possible vapor accumulation from gasoline or liquids used for cleaning. The following, and other inspections and tests, are needed:

1. *Rags.* Clean rags should be kept in covered metal containers. Dirty waste and rags should be kept in separate covered metal containers. These should be disposed of each time the boat is docked.
2. *Fuel system.* The entire fuel system, from the fuel tank to the engine, must be visually examined periodically. The fuel tank should be checked to determine whether it shows any evidence of corrosion or leakage. Once a year the entire system should be pressure checked at 3 psi (20.7 kPa). The fuel hoses should be checked to determine that the connections (fittings and clamps, etc.) are tight and that hoses show no signs of deteriorating or cracking. The fuel pump should be checked to determine that it is a marine type, with a hose back to the intake manifold or carburetor in case of diaphragm failure. Fuel filters should be checked to determine that they are clean and not leaking. Used gaskets should be replaced with appropriate new ones whenever a fuel filter is cleaned.
3. *Detectors.* All detectors must be checked to determine whether they are working.
4. *Exhaust blowers.* Ventilating ducts should be checked to determine that they are installed without excessive bends and are neither kinked nor torn. Overcurrent protection should be checked to determine that it includes locked-rotor protection.
5. *Ignition protection.* All electrical equipment in the engine space and any space with fuel line fittings should be checked to determine that it is ignition protected. Replacement with automotive parts eliminates such protection.
6. *Painting.* When interior areas are repainted, fire-retardant paints should be used.

Proper maintenance and sensible fuel system operation, used together with ignition-protected electrical equipment, are probably a boat owner's most important fire prevention duties.

Fueling

Utmost care must be exercised during fueling operations. The following are general guidelines to be observed during fueling operations:

1. Fueling should not be undertaken at night, except under well-lighted conditions.
2. Smoking must be forbidden on board the boat and in the area of the fuel pumps and hose.

TABLE 21.10.1 Number and Distribution of Fire Extinguishers

Boat Type	*No. of Extinguishers*	*Minimum ANSI/UL Rating*[a,b]	*Minimum USCG Rating*[c]	*Location*
Open boats under 16 ft (4.8 m) with fiberglass or metal hulls and a light load of flammable Class A materials	1	5 B:C	B-1	Steering position
Open boats under 16 ft (4.8 m)	1	1A: 10B:C	B-1	Steering position
Boats 16 ft (4.8 m) up to, but not including, 26 ft (8 m)	2	1A: 10B:C	B-1	Steering position and galley, when on board, or cockpit
Open boats 16 ft (4.8 m) up to, but not including, 26 ft (8 m)	2	1A: 10B:C	B-1	Steering position and galley or cockpit
Boats 26 ft (8 m) up to, but not including, 40 ft (12 m)	3	1A: 10B:C	B-1	Outside engine compartment, steering position, and near galley or passenger cockpit
Boats 40 ft (12 m) up to, but not including, 65 ft (20 m)	4	1A: 10B:C	B-1	Outside engine compartment, steering position, crew quarters, and galley, when on board, or cockpit

[a]If a discharge port is installed, a USCG Type B-1 portable fire extinguisher might not be adequate.
[b]Extinguishers intended for machinery space protection are not required to have a Class A rating.
[c]Boats under 26 ft (8 m) in length without enclosed accommodation spaces or enclosed galleys shall be permitted to be equipped with a bucket with attached lanyard in lieu of Class A-rated portable fire extinguishers.

3. Before opening fuel tanks,
   a. Shut down all engines, motors, and fans
   b. Extinguish all open flames
   c. Close all ports, windows, doors, and hatches
   d. Determine the quantity of fuel to be taken aboard before fueling operations start
   e. Point out to the fuel attendant the correct deck fuel fitting for each tank
4. The fuel delivery nozzle must be in contact with the fuel fill deck fitting before fuel delivery begins. This contact should be maintained continuously until flow has stopped. Static discharge is a serious hazard if this rule is not followed. The fuel-fill fitting must be of a material that conducts electricity and must be electrically connected to the engine's negative terminal to ground the static charge.
5. Fuel tanks should never be completely filled because fuel expands. A minimum of 5 percent tank space must be allowed for expansion.
6. After fuel flow stops,
   a. Tightly secure the fill fitting cap
   b. Completely wipe up spillage
   c. Ventilate all spaces and check for gasoline vapors before starting any engine or operating any appliance

Storage Between Voyages

Before storing a boat, even for a short time period, several precautionary actions should be taken. The entire vessel should be thoroughly inspected. All combustible trash and rags should be removed, as well as any paint or other flammable liquids. Bilges should be inspected and pumped dry. All underwater hardware, including propellers, outdrives, rudders, through-hull fittings, and the hull should be checked and necessary repairs made. All seacocks should be checked and operated to make sure they can operate in an emergency. Liquid level of batteries and specific gravity of battery cells should be checked. If possible, lockers and bilge hatches should be secured in a partially open position to ventilate the spaces.

COMMERCIAL VESSELS

Code of Federal Regulations (CFR)

Ships and offshore marine structures present a wide range of potential fire risks that could threaten the safety of the public and our environment. The U.S. Congress has assigned the task of developing and instituting marine fire protection regulations to the United States Coast Guard, through the various laws governing marine inspection in the United States Code (USC). These laws delegate the authority to enforce all applicable federal laws on the high seas and on the waters subject to the jurisdiction of the United States for the safety of life and property. They are enforced through the application of detailed technical regulations for fire-fighting equipment and other precautionary measures guarding against fire, including the number, type, size, capacity, details of construction, methods of operation, stowage, maintenance, and drills and exercises necessary to assure proper functioning of the fire protection measures. The fire protection regulations are listed in the *Code of Federal Regulations* (CFR) under Title 46, *Shipping*. The regulations are further broken down into the various parts of Title 46, which address the different types of vessels and the types of fire hazards related to their normal operation. The transportation of hazardous materials on ships, or dangerous goods as they are called internationally, is regulated by the U.S. Department of Transportation (DOT) rules in Title 49 of the CFR Parts 171–180, *Hazardous Materials Regulations,* and by the Coast Guard at Title 46, Parts 147–148, *Dangerous Cargoes,* and Parts 150–154, *Certain Bulk Dangerous Cargoes.*

The regulations covering U.S. flag commercial vessels are contained in the following parts of the *Code of Federal Regulations:*

46 CFR Parts 24–28, *Uninspected Vessels*
46 CFR Parts 30–40, *Tank Vessels*
46 CFR Parts 70–80, *Passenger Vessels*
46 CFR Parts 90–105, *Cargo and Miscellaneous Vessels*
46 CFR Parts 107–109, *Mobile Offshore Drilling Units*
46 CFR Parts 114–122, *Small Passenger Vessels Carrying More Than 150 Passengers or with Overnight Accommodations for More Than 49 Passengers*
46 CFR Parts 125–134, *Offshore Supply Vessels*
46 CFR Parts 166–169, *Nautical Schools*
46 CFR Parts 175–185, *Small Passenger Vessels (under 100 gross tons)*
46 CFR Parts 188–196, *Oceanographic Research Vessels*

International Ship Fire Safety Requirements

The United States is a signatory nation to the International Convention for the Safety of Life at Sea treaty (SOLAS), which establishes regulations for fire protection on vessels that engage in international voyages to countries outside of the United States. The SOLAS convention is maintained by the International Maritime Organization (IMO), a specialized agency of the United Nations headquartered in London, England. IMO is the repository of all treaties dealing with commercial vessel safety, and has developed mandatory requirements as well as recommended codes and standards of practice relating to specialized maritime subjects. Under the terms of the SOLAS convention, all signatory countries are obligated to accept a SOLAS safety certificate, issued by another member country, as evidence of a ship's compliance with the convention. The use of mutually accepted safety certificates ensures a minimum level of safety and permits ships to operate freely between nations. The SOLAS regulations are sometimes written in very general terms to allow the use of equipment that is commonly accepted and approved by one member state, but which may be unfamiliar in other geographic locations. In some cases, SOLAS wording is intentionally vague, resulting from an inability to reach international agreement on more precise terms. As a result, there may be different interpretations between the member states regarding the SOLAS regulations. The convention has provisions permitting the countries where ships call to perform additional inspections, if needed, to ensure compliance with SOLAS. These inspections are called port state inspec-

tions, whereas those conducted by the ship's country of registry are called flag state inspections.

The Coast Guard regulations contained in the CFR are consistent with many of the SOLAS requirements, except that the CFR lifesaving and fire protection equipment and material requirements are much more detailed. Historically, SOLAS did not contain any type approval or testing requirements for the required fire protection measures, relying instead on nationally accepted procedures of the flag states. In 1998, a new Fire Test Procedures (FTP) Code was adopted that lists mandatory testing procedures for structural fire protection measures.

U.S. flag ships that engage only in domestic routes do not need to comply with the SOLAS requirements. Vessels that engage in international trade, however, must comply with SOLAS.

The SOLAS convention currently in effect is SOLAS 1974, as amended. This convention became effective for ships built after May 25, 1980, and has been amended several times since it was accepted. The large number of unrelated amendments and interpretations to SOLAS following its adoption made the convention difficult to apply. The International Maritime Organization, therefore, decided to perform a comprehensive review of the fire protection regulations in SOLAS and to update and reorganize the document to make it more user friendly. This updated version was adopted in the 2000 SOLAS amendments.

The update included several key changes. It incorporated the existing amendments and interpretations directly into the text of the Convention and included a new performance-based option. It was also decided that the fire extinguishing and fire detection system design and installation requirements in SOLAS should be removed from the convention and placed into a new mandatory standard called the International Code for Fire Safety Systems (FSS Code). Finally, new requirements were introduced for the carriage of emergency escape breathing devices (EEBDs), supplemental local application fire-fighting systems for the protection of high-hazard areas within machinery spaces, and a new Part E which contains requirements for the operational readiness of fire protection systems.

The performance-based option required changes to the Chapter II-2 regulations to include defined fire safety objectives and functional requirements within each regulation. In addition, a new regulation II-2/17 was developed to provide a methodology for approving alternate design and arrangements. Thus, owner/operators have the option of specifying ships that comply with either the prescriptive criteria listed in SOLAS, or specifying ships with performance-based designs that are demonstrated to achieve the stated fire safety objectives.

United States Domestic Ship Fire Safety Requirements

The fire safety regulations for vessels in domestic U.S. service are based on the principle of passive fire safety. Noncombustible fire boundaries and limited use of combustible materials are intended to limit fires to their space of origin. The different vessel regulations in the CFR are intended to provide a consistent level of fire protection safety to the many types of vessels common to the maritime industry. Ships may travel on different routes, have more passengers, engage in operations with varying levels of risk, or carry cargoes of varying fire hazard. The regulations, therefore, look at each class of ships separately, considering key fire protection and life safety risk factors. The regulations are based on many years of operating experience, compliance with international requirements, and lessons learned from casualty investigations.

The following service-related factors have been considered in the development of the vessel regulations:

- Relative size of the vessel
- Quantity, stowage arrangement, fire risk, and packaging of the cargoes carried
- Level of protection offered by the vessel's hull in collisions and groundings
- Number of passengers carried
- Length of a typical voyage
- Ship's means of propulsion and fuel type
- Route the ship will follow, as affected by weather issues and day or night operations

The following general vessel descriptions are provided to clarify the application of the regulations.

Uninspected Vessels. Uninspected vessels are generally smaller ships, such as tugboats, charter fishing boats, motorboats, or recreational boats (Figure 21.10.5). The fire risks are limited because the vessels carry limited cargoes, are limited in size, and carry only a small number of passengers. Vessels that are under 100 gross tons and carry less than six passengers for hire fit into this category. 46 CFR 28 contains regulations that specifically apply to commercial fishing, fish processing, and fish tender vessels. These vessels not only catch fish but may also include large refrigerated storage holds and processing facilities to cut, package, and flash-freeze the fish while at sea.

Tank Vessels. Tank vessels are vessels and barges that are designed to carry bulk liquid cargoes, mainly liquid petroleum products, that are usually flammable or combustible in nature. Because of the quantity and hazard of the cargoes carried, this class of vessels is subject to significant fire safety requirements, both in their design and operation. Tank vessels also include ships that carry hazardous chemicals and pressurized

FIGURE 21.10.5 Uninspected Tugboat Towing an Open Hopper Type Barge

or liquefied gases. Liquefied natural gas (LNG) or liquefied propane gas (LP-gas) carriers are included in this category.

Passenger Vessels. Passenger vessels are vessels that carry passengers for hire. Passengers for hire are defined as passengers who have either paid fares or contributed other consideration, as a condition of carriage on the vessel, whether directly or indirectly flowing to the owner, charterer, operator, agent, or any other person having an interest in the vessel. Passenger vessels may be further divided into five distinct classes:

1. *Uninspected passenger vessels less than 100 gross tons carrying 6 or fewer passengers.* Charter sailing vessels, charter fishing boats, and small water taxis are in this category.
2. *Uninspected passenger vessels more than 100 gross tons carrying 12 or fewer passengers.* Large luxury charter yachts are the best-known representatives of this class of vessels.
3. *Small passenger vessels less than 100 gross tons carrying more than 6 passengers.* Examples of this class include inflatable dive boats, passenger submarines, small ferries, dinner and tour boats, charter fishing headboats, and various types of sailing vessels. These vessels are also called "T boats," because their regulations are found in Subchapter T of 46 CFR.
4. *Small passenger vessels less than 100 gross tons carrying more than 150 daytime passengers or more than 49 overnight.* Typical examples include larger dinner cruise boats, casino vessels, and ferries. With their regulations located in Subchapter K of 46 CFR, these vessels are also called "K boats."
5. *Passenger vessels more than 100 gross tons carrying more than 12 passengers.* Examples of these type vessels are very large casino vessels and riverboats, as well as large oceangoing cruise ships. The regulations for these vessels are in Subchapter H of 46 CFR.

The majority of the passenger vessels in U.S. domestic service are Subchapter T and K boats. (Note that Subchapter T and K vessels that engage in international service must also comply with SOLAS.) Large oceangoing cruise ships are Subchapter H vessels if they are U.S. flag vessels. The majority of cruise ships are not U.S. flag vessels. They are foreign flag ships subject to the SOLAS regulations and U.S. port state inspection.

Cargo and Miscellaneous Vessels. Cargo and miscellaneous vessels are ships designed to carry general freight for hire, either in bulk, breakbulk, or containerized form. Breakbulk cargo is a nautical term that refers to cargoes that are baled, palletized, or placed in packaging for shipment and are consigned by various owners for delivery to different purchasers, yet are stowed in a common hold for shipment. Bulk cargoes are those that are loaded in loose condition, such as ores, grains, and coal. Breakbulk cargoes are loaded into the ship's holds by cranes, whereas bulk cargoes are usually loaded into the holds using conveyor belts, blowers, or grab buckets. This vessel category also includes container ships carrying multimodal freight containers that can be loaded directly onto railcars or truck chassis to continue their voyage. Vehicles carried as cargo can be driven on and off specialized cargo ships known as roll-on/roll-off or just ro-ro ships.

Mobile Offshore Drilling Units (MODUs). MODUs are special marine vessels designed for exploratory drilling operations on the ocean subfloor for possible offshore oil and gas well locations. These units must be mobile, because they are moved from site to site to look for new resources. Once a well is drilled and found to be satisfactory, a production platform is constructed at the site. Production platforms routinely pump thousands of barrels of oil daily, whereas MODUs only find productive well sites. The production platforms are thus exposed to greater fire risks. Production platforms are either connected to a pipeline through which oil is pumped to a refinery, or the oil is stored on the platform until it can be loaded onto a tank ship to be taken to the refinery terminal. Among the common types of MODUs are the following:

- *Jackup rigs:* These are mobile drilling rigs that float, so they can be moved or towed into position. A jackup rig has a series of self-elevating legs that are lowered to the seafloor to anchor the unit and lift the drilling platform out of the water. These rigs are generally used where the water depth is less than 400 ft (122 m).
- *Submersible rigs:* These are mobile drilling rigs that can be moved or towed into position. The rig has a hull that allows the unit to float. When the rig is in position, the lower section of the hull is flooded, causing it to settle onto the seabed, but keeping the work platform above the water. Submersibles provide very stable drilling platforms, but can only be used in limited water depths.
- *Semisubmersible rigs:* These are similar to submersible units; however, when the hull is flooded, the rig does not settle on the seabed, but floats beneath the surface of the water, keeping the working platform above the water. These types of rigs can be used in very deep water, as their submerged section assists in stabilizing the rig in heavy seas.
- *Drilling ships and barges:* These rigs are easily moved, as they are designed with similar hull shapes as oceangoing vessels. They are used to drill wells in remote locations. The limitation of these rigs is their lack of stability in very rough weather. They are, therefore, mainly used in locations where calm seas are enjoyed most of the time.

There are several types of production platforms in use, depending primarily on the water depth at the well site and the distance to the refinery:

- *Rigid steel platforms:* These are rigid platforms with a tubular steel foundation or jacket that is supported on piles driven into the seabed. The steel jacket is usually so large that it is towed to the site in a horizontal position and partially flooded to tip it into a vertical position and lower it onto the pilings. The crew quarters, the drilling rig, and all support equipment are then put on a platform positioned at the top of the jacket.
- *Rigid concrete platforms:* These are rigid platforms that resemble steel platforms, except the platform is supported

on large hollow concrete caissons. The entire rig is constructed and towed to the site, and then the caissons are flooded to anchor the unit to the seabed. Because of the tremendous weight of the concrete caissons, the rig does not have to be attached to the bottom with pilings. The hollow caissons are used to store the oil until it can be offloaded into tankers for delivery to the refinery. Because of their weight, these platforms are very stable in rough seas and are common in the North Sea.

- *Tension leg platforms:* Rigid platforms are limited in application to water depths less than roughly 1000 ft (305 m). For deeper water, a type of production rig called a tension leg platform (TLP) is used. Resembling semisubmersible drilling rigs, TLPs are moved into location and are then anchored to the seabed with tensioned steel tubes or cables. The working platform floats on the surface but is stabilized by the steel tensioning apparatus.
- *SPAR platforms:* Designed for very deep waters, SPAR platforms consist of a large cylindrical tube that floats vertically, anchored to the seafloor. Water ballast in the lower end of the tube keeps the SPAR deep in the water for stability in adverse sea conditions. The end of the cylinder above the water supports production and accommodation facilities. Newer SPARs are large enough to also accommodate a drilling rig for drilling new wells. Oil and gas processed on the SPAR are pumped into an underwater pipeline system.
- *Single point buoy mooring system (SPBM):* In locations in which a pipeline from the well to a refinery is neither economical nor practical to construct, a special mooring system can be built to allow oil tankers to load oil directly from the wells or from an underwater pipeline system serving several wells. A piping riser is constructed from the ocean floor to a mooring buoy that floats on the surface of the water. The oil tankers tie up to this buoy using a single line from the bow of the ship, hence the name. Some buoy systems also have a permanently attached tanker that is used for oil storage. These facilities are called floating production, storage, and offloading (FPSO) systems.

Offshore Supply Vessels. Offshore supply vessels are small cargo ships specifically designed to carry equipment, supplies, and workers to and from oil production platforms and drilling rigs. Special regulations were developed because these vessels are part cargo ship, part tanker, and part passenger ship, and they generally travel in limited geographic regions. The regulations were adapted to the specialized service of these vessels.

Nautical School Ships. Nautical school ships are training vessels used by merchant marine academies to provide their students with actual maritime operating experience. Although nautical school ships may be designed as cargo ships, they are provided with additional safety measures because the students carried on board are not licensed mariners, and there are generally more students on board than would be expected on a typical merchant ship.

Oceanographic Research Vessels. Oceanographic research vessels are vessels that are similar to small passenger vessels that have onboard laboratories to conduct research of water quality, marine life, or environmental science. The accommodation areas on these type ships are typically larger than those on board cargo vessels, because they need sufficient berthing capacity for the normal ship's crew plus the scientific complement. The laboratory areas are required to be separated from the accommodation areas by fire-rated bulkhead and decks, since flammable and combustible liquids may be used for the experiments.

MARINE FIRE PROTECTION CONSIDERATIONS

The application of fire protection engineering principles to ships and offshore marine structures is based on much of the technology used for the protection of buildings, warehouses, industrial plants, tank farms, and similar shoreside installations. Because the design and operating environment of ships are quite different from that of buildings, the basic fire protection principles have been adapted to suit the different marine-related circumstances.

Layout and Configuration

The basic layout and configuration of ships must be different from that of buildings because of their movement and the effects of the wind and wave forces they must endure. Ships cannot easily be designed with numerous deck levels without affecting their stability or their natural ability to remain upright. Similar to a building, a resting ship floating in calm water is subject to only the vertical force of the ship's weight acting through its center of gravity in a downward direction and the upward force of the water's buoyancy. Buildings, however, are designed as nonmoving structures, able to resist wind and weather forces without movement. Ships float and are propelled through the water. The directional forces caused by ships' engines and the wind and waves causes them to roll and pitch in the water. If more deck levels are added to a ship, its center of gravity is raised upward. The center of gravity is the chief force that keeps the ship in an upright position, and if the center of gravity is located too high on the vessel relative to its center of buoyancy, its righting ability is limited. Ships must be built in a horizontal rather than a vertical aspect because of this.

Multistory buildings have a similar footprint on each floor, which simplifies the design and layout of sprinkler and detection system devices. This common arrangement also greatly simplifies the arrangement of fire barriers and the means of egress. The main fire subdivisions in buildings are formed by the floor/ceiling assemblies, which prevent vertical fire spread. In contrast, the decks of a ship may vary considerably in shape and configuration on each level. The deck construction prevents vertical fire spread, but additional fire barriers must be provided to limit horizontal fire spread. The decks on some passenger vessels can be over 200 m in length. Horizontal fire barriers are only seen in very large buildings where the floor area exceeds that allowed by the building codes. The regulations for passenger ships require a 1-hour-rated fire barrier every 40 m fore and aft to subdivide them into fire areas called main vertical zones (MVZs).

Construction Materials and Design

The materials and design of fire barriers used in shipboard construction are quite different from those in buildings. The origin of modern shipboard fire barrier design can be traced to 1934, when the U.S. passenger ship *Morro Castle* burned off the coast of New Jersey, taking 124 lives. The combustible wooden construction and open stairways were determined to be the cause of the rapid fire spread throughout the vessel.[2] Outrage over this massive loss of life prompted the U.S. Senate Committee on Commerce to create a special Subcommittee on Fireproofing and Fire Prevention to develop recommendations for enhanced fire protection measures aboard ships.

The subcommittee procured a surplus ship, the *S.S. Nantasket,* from the Maritime Administration's reserve fleet moored on Virginia's James River and used it for a series of full-scale fire tests. Conducted in 1936, these tests showed the superior performance of steel bulkheads insulated with asbestos blanket insulation and joinerwork bulkheads constructed of noncombustible asbestos cement board panels.[2] The testing program also compared the temperatures developed in the full-scale *S.S. Nantasket* fires to those developed in the ASTM Standard E119 laboratory furnace to determine how other construction materials might be accepted.

At the conclusion of the *S.S. Nantasket* test series, the subcommittee report to Congress recommended the use of only noncombustible materials of construction.[2] The nearly exclusive use of noncombustible materials for shipboard fire protection has resulted in the development of methods and materials that are unique to ships. Although there have been many advances in the materials used for shipboard construction, the requirement for noncombustible materials remains the cornerstone of the structural fire protection system.

The majority of modern ships are constructed of steel. The regulations have, therefore, only needed to address one type of construction. Thus, they do not prescribe height and area limitations based on the type of construction, as is customary with the various building codes. Recent trends in construction methods are advancing the use of aluminum and composite materials for shipbuilding; however, the regulations have not fully recognized these materials, except in the development of the IMO High Speed Craft Code. This code was developed for the construction of lightweight high-speed vessels that cannot be constructed of steel without affecting their performance. These ships use lighter weight materials of construction such as aluminum alloys and fiberglass composites.

Fire Extinguishing and Fire Detection Systems Design

The design of fire extinguishing and fire detection systems on board ships also merits special consideration. Fire protection systems installed on board seagoing ships are more susceptible to environmental and operationally induced failures than those installed in buildings because of their continual exposure to salt water, humidity, shock, and vibration.

Because ships are moving structures, the installed equipment is regularly exposed to the vessel's motions and opposing wind and wave forces. Wiring connections may come loose from the constant vibration, so ring type connectors are used instead of spade connectors. Wiring nuts and solid conductor wiring, commonly used in building fire alarm systems, are not acceptable on ships because exposure of these components to vibration may result in circuit failure. Vibration is also a concern for the mounting brackets and equipment used to secure high-pressure cylinders employed in fire-extinguishing systems and portable fire extinguishers. The cylinders must be properly mounted to prevent vibration from causing damage to them or from causing their inadvertent operation.

The quality of the water supply used for fire protection is another matter that affects shipboard systems. Most ships sail in salt water. Those that do not, sail in river water that contains mud, sediment, and debris. Both fresh and salt water may contain biological organisms such as barnacles, Asiatic clams, or Zebra mussels. The fire main and sprinkler system suction arrangements must be designed with positive features to prevent clogging from these contaminants. Moreover, shipboard automatic sprinkler systems must be kept charged with potable fresh water to avoid marine growth in their branch lines. A very limited onboard fresh water supply is provided that automatically switches to a seawater pump during a fire to provide sufficient duration for the sprinkler protection.

The use of common shoreside materials such as anodized aluminum for fire hose couplings and nozzles is not realistic on ships because of corrosion-related failures. Fire-fighting equipment made from brass, bronze, or galvanized steel must be used to prevent corrosion problems. Stainless steel can be used in some applications, except that stainless steel fire extinguisher shells cannot be used on board ships because of their history of stress-corrosion cracking when exposed to saltwater environments.

Oceangoing ships can regularly be miles from the nearest port of refuge. It is essential that the installed fire protection equipment is rugged and reliable. Ships cannot depend on fire-fighting aid from a local fire department, so they must carry their own equipment and trained fire fighters. Fire-fighting tactics on ships are quite different from those used to attack fires in buildings. Ships are compartmentalized by steel bulkheads and decks. The fire brigade cannot ventilate a space before entering it by cutting openings in the overhead. The fire fighters entering confined areas may therefore be exposed to temperature extremes. As previously noted, stability is a significant concern, and the unlimited application of fire-fighting water on the upper decks must be controlled to keep the ship upright. This is compounded by the inability to readily drain water out of fire-affected compartments because floor drains and exterior doorways are not always available. Accumulated water can threaten the stability of the ship, so bilge pumps need to be operating when a significant amount of water has been used in fire-fighting efforts.

Evacuation

The evacuation of passenger ships is much more complex than the evacuation of a building. Ships have emergency evacuation components that are rarely, if ever, used for normal building occupancy. Passengers normally board cruise ships in port via

gangways that connect the dock to the main deck of the ship. The capacity and configuration of the ship's main access corridors and stairways are planned to facilitate passenger movement across the gangways.

If a fire occurs while the vessel is in port, the gangways can be used for emergency evacuation of the ship. If a fire occurs at sea, the paths to the dock are no longer available, and the only means available to evacuate the ship are the survival craft (lifeboats, inflatable life rafts, etc.). The egress paths to the survival craft are through totally different routes from those used to board the ship.

Because passenger ships have multiple types of occupancies, emergency evacuations are further complicated by the possibility of two distinct initial passenger distribution conditions. The daytime condition considers that most of the passengers will be distributed throughout the public assembly spaces such as the restaurants, lounges, and theaters. During the nighttime condition the majority of the passengers are expected to be in their staterooms asleep. This variation is similar to that expected in a large shoreside hotel; however, unlike a hotel, passenger ships do not have direct exits on the ground floor to evacuate the public spaces. Passengers exiting from the public spaces to the open deck may have to reenter the ship to travel to the survival craft. For either the daytime or the nighttime condition, the passengers must assemble and move to the survival craft, which may be located several decks above the public spaces. On many ships, an emergency evacuation requires the passengers to ascend stairways. This action may seem foreign to many passengers, who are accustomed to exiting buildings by descending the exit stairways.

Ships are considered their own best lifeboat and are only evacuated if it appears that sinking is imminent. Evacuation procedures initially move passengers from the fire-affected spaces on the ship to areas of safe refuge called assembly stations. These are usually areas where there is ready access to the survival craft. When the passengers ultimately discharge from the exit system on board the ship, they are not at a safe location. Passenger ship exit systems discharge to the assembly stations, and if necessary, the occupants are put into the survival craft and lowered to the water (Figure 21.10.6). Depending on the weather, time of year, and location, the sea could be a much more hazardous environment than the ship. Thus, evacuation of a ship is only done when the ship is in peril. Shipboard evacuations must be possible in adverse sea states, with ship movements and even the possibility that one side of the ship might be inaccessible (due to listing or rolling to one side, for example).

Regulatory Review

Ships may be subject to regulatory review by different authorities having jurisdiction (AHJ) throughout their lifetime. Owners of vessels on international voyages must have their ship design and operation approved by the maritime authority of the country where the ship is registered (flag state), which is primarily responsible for ensuring that the ship meets international standards. Authorities of the countries to which the ship sails have the right to examine the ship to confirm compliance with international standards (port state control). This sometimes results in difficulty dealing with differing interpretations of the same regulations. Even ships limited to U.S. domestic service come under the jurisdiction of different Coast Guard authorities when they change their home port. Different local conditions and interpretations can mean that some aspect of ship design or operation acceptable in one port will not be acceptable in another. This is not the case for buildings, which are usually within the same jurisdiction for the life of the building.

FIGURE 21.10.6 Enclosed Survival Craft Being Launched

The ship's crew can also include residents of many different countries, who may not all speak or understand the language of the flag state. Some ships may also be built in shipyards located outside of the flag state. For these reasons, there may be significant language issues to overcome in order to ensure that the entire crew understands the emergency procedures to follow in a fire emergency. The crew may also need supplemental training in the operation and maintenance of the installed fire protection equipment to ensure that it is properly serviced and remains operable at all times.

MARINE FIRE HAZARDS

General Fire Hazard Analysis

The general fire hazards on board ships can be analyzed looking at the three major occupancies common to all ships: (1) the engine room, which contains the propulsion machinery and auxiliary equipment; (2) the cargo holds or cargo tanks depending on the service of the vessel; and (3) the accommodation and service areas where the crew and/or passengers are berthed.

The U.S. Coast Guard maintains a database that is used to track casualty information relating to accidents investigated by the Coast Guard.[3] The database has been in use since 1985 and is useful to show trends in fire-related casualties. From an overall fire damage perspective, roughly 60 percent of all shipboard fires occur in the engine room. The remaining 40 percent of the total number of fires are split evenly between the cargo area and the accommodation area.

Engine Rooms. The engine rooms on modern ships usually have one or more large diesel engines and related auxiliary equipment for the propulsion of the ship. Some vessels may also have steam boilers for propulsion or auxiliary purposes. Engineering support systems include electrical generators and

distribution systems, hydraulic systems, ventilation systems, and lubricating oil systems. The diesel engines are supplied with fuel from small capacity day tanks located in the engine room, which are filled by fuel pumps that take suction from large fuel storage tanks located outside the engine room. Casualty data shows that the majority of engine room fires are caused by broken fuel or lube oil lines spraying onto hot surfaces such as exhaust manifolds, turbochargers, or engine casings.[3] The next most likely engine room fire cause is attributable to shipboard electrical systems, usually a short circuit or failure of an electrical component or device. Although not seen as frequently, engine crankcase, clutch, and turbocharger explosions may occur, usually due to wear on the equipment. Human error is also a noted contributor to engine room fires, primarily cutting and welding operations that are not safely performed.[3]

Cargo Holds. The cargo holds on general cargo ships and container ships are nothing more than a series of large separated warehouse spaces. These ships could be used to transport general cargo in packages, multimodal containers, or portable tanks; vehicles; or flammable liquids or gases. Vehicle carrier holds are similar to general cargo holds except that they may have internal elevators or power-operated doors and may run the entire length of the vessel without subdivision. The vehicles carried may have gasoline in their tanks, which requires the cargo hold electrical system to be suitable for use in hazardous atmospheres. Bulk liquid cargo tanks on tank vessels are used to carry a variety of flammable and combustible liquids and are segregated from the accommodations areas aft where sources of ignition could be present. Electrical shorts and sparking are listed as the most frequently identified fire cause of shipboard cargo areas, followed by cutting and welding, contact with hot surfaces, human error/discarded cigarettes, static electricity/lightning, explosions, and chemical reactions.[3]

Accommodation and Service Areas. Shipboard accommodation and service areas include the staterooms and berthing areas, galleys, mess rooms, pantries, ship's offices, laundry facilities, navigating bridge, and radio room. The fire hazards in these areas are typical for light or ordinary hazard occupancies. Casualty statistics[3] show the leading causes of fires in these areas to be electrical in nature, followed by galley and cooking fires, human error/cigarettes, cutting and welding, portable heaters, and contact with hot surfaces.

Detailed Fire Hazard Analysis

Engine Rooms. Shipboard engine rooms or machinery spaces typically occupy the aft (rear) section of the ship up to the main deck, with the machinery space casing extending up through the accommodation area to the top of the vessel. The casing is a narrowing vertical trunk, similar to a pipe chase, which contains the engine exhaust pipes and ventilation equipment. A typical engine room has multiple levels separated only by steel gratings and ladders. The engineer's control room and various workshops could also be included within the engine room boundaries. Engine rooms are separated from the remainder of the ship by steel bulkheads and decks, with all openings and penetrations sealed to prevent the migration of hydrocarbon vapors to adjacent occupied areas.

The primary fire hazard in the engine room is the fuel oil used to supply the engines or boilers. This is usually marine diesel fuel, which is similar to # 2 fuel oil, or it may be a heavy oil called bunker C, which is similar to # 6 fuel oil. If heavy fuel oils are used, they must be heated in order to be transferred. Fuel and lube oil systems are the principal causes of fires in shipboard engine rooms.[3] Failures may occur in the fuel line piping and fittings from the continual exposure to vibration or because components were replaced with substandard parts not qualified for the intended service. Many ships are also fitted with duplex fuel strainers, which have two separate filter chambers that allow the crew to manually switch between them to clear the operating filter without stopping the engines. A significant number of fires occur in these filters because they are normally operated while the fuel system is under pressure.[4] Most ships will also have one or more day tanks that feed fuel to the engine room under a gravity head.

If an engine room fire occurs, the fuel in the tanks could continue to leak into the engine room until the tanks are empty. Because of this, fuel lines have remotely operated shutoff valves to allow the fuel tanks to be isolated from outside the engine room in the event of a fire. Beginning in 2002, the SOLAS convention required additional fuel system safeguards on new vessels. Specifically, all high-pressure fuel piping is required to be double jacketed, and any fuel lines that could spray onto hot surfaces must be suitably shielded or guarded.

Engine crankcase explosions are another recognized fire source in shipboard machinery spaces.[5] These explosions can occur when the engine's piston rings or related components become worn and allow fuel oil to be forced from the combustion chambers into the crankcase. Rigorous maintenance programs to replace worn equipment are the most effective way to prevent crankcase explosions. Pressure-relief vents are also provided on engine blocks to mitigate the effects of explosions. Recent advancements in oil mist detection technology show promise in their use for recognizing component wear before an explosion occurs.[5]

Because of the fire hazards inherent to engine rooms, the Coast Guard regulations require them to be protected by a total flooding carbon dioxide or clean agent fire-extinguishing system. Detection systems are not required except when the engine room is automated and when engineers are not continually present. The extinguishing systems are required to have a manual means of release to guard against unintentional discharges. The inadvertent discharge of an automatic engine room extinguishing system will cause the engines to shut down, leading to the loss of propulsion and steering. This could place a moving vessel in an extremely dangerous situation, depending on its location.

The SOLAS regulations allow the use of water spray or high-expansion foam protection for engine rooms in lieu of a total flooding gaseous system; however, these types of systems are currently not accepted for use aboard U.S. flag vessels. Water mist systems are the only water-based system accepted by the Coast Guard for the total flooding protection of engine rooms. Type approval for total flooding systems is based on IMO MSC/

Circ. 1165, *Revised Guidelines for the Approval of Equivalent Water-Based Fire-Extinguishing Systems for Machinery Spaces and Cargo Pump-Rooms.*

Galleys. Ships' galleys are similar to commercial restaurant kitchens. As a result they are vulnerable to the same fire hazards (Figure 21.10.7). Ship galley fires are often attributable to the buildup of grease in the galley hood and exhaust ducts, or from malfunctions in the cooking appliances themselves. Galley range tops and cooking appliances are designed with battens or guardrails to keep the cookware in place on the burners when the ship is in motion. The restraints prevent personnel injury and also guard against the heated cookware contacting adjacent combustibles. Galleys on domestic passenger vessels are required to have either a dry chemical or wet chemical extinguishing system for the protection of the hood. SOLAS vessels must have a fixed means of extinguishing a fire in the galley exhaust duct. On all vessels, the galley exhaust ducts must be separated from adjacent combustibles; however, fires still occur because crew members improperly store trash and other combustibles in void spaces or in lockers adjacent to the galley exhaust ducts.

Breakbulk General Cargo. Breakbulk cargo consists of general commodities in separate packaging that is stowed in a hold and tracked by separate bills of lading, as opposed to bulk cargoes such as coal or gain. Cargo holds designed for the carriage of breakbulk general cargoes typically comprise three or more levels: a lower hold, a 'tween deck, and an upper 'tween deck. 'Tween deck is a nautical term referring to the mezzanine levels between the bottom and top of a hold. Each cargo hold level has a fixed peripheral area, called the wing area, while the center area of the hold is open and is covered by removable hatch covers to allow vertical loading of the cargo by overhead cranes. The cargo is normally loaded into the center of each level by cranes, and then the stevedores move the cargo into the wing areas with forklifts until the hold is completely filled. The only other access to the holds is through small manholes and ladders. Breakbulk cargo is not loaded with any access aisles or storage racks in order to maximize the ship's carrying capacity. The cargo pile height is usually near the overhead, and may range from 10 to 20 ft (3 to 6 m) in height on each deck. At sea, the cargo holds are rarely accessed.

FIGURE 21.10.7 Typical Galley on Board a Large Passenger Ship

Many ships also have provisions for on-deck stowage, which is generally reserved for hazardous materials or bulky items. The materials carried on cargo ships are as varied as those in any general storage warehouse and routinely include hazardous chemicals, explosives, oxidizers, and flammable liquids and gases. The segregation and stowage of incompatible materials must be carefully controlled to minimize the risks of fire or explosion. The U.S. Department of Transportation (DOT) regulations in Title 49 of the Code of Federal Regulations and the IMO International Maritime Dangerous Goods (IMDG) Code provide highly specific packaging, stowage, ventilation, and segregation requirements for the loading of hazardous materials.

Breakbulk cargo holds are large open warehouse type spaces surrounded by steel bulkheads and decks. For efficiency in loading, and to maximize the quantity of goods that may be loaded, the decks and surrounding bulkheads are made as smooth and regularly shaped as possible. Lighting and ventilation systems are the main support equipment normally found in cargo holds. Some ships may have battery chargers for the forklifts as well as electrical systems that allow the stowage of refrigerated containers. Fires in cargo holds are mainly attributable to electrical sources, although there have been some cases reported of spontaneous combustion occurring in the cargo.[6] The tight stowage of the cargo in the holds limits the air available for combustion; if a fire does occur, it is generally a deep-seated, slowly developing event.

The standard protection for cargo holds consists of smoke detection and total flooding carbon dioxide systems. Because the cargo handling operations in the holds could damage or impair the function of electrical fire detection devices, an air-sampling detection system (called a sample extraction system in SOLAS regulations) is used. There are no smoke detectors in the holds; they are located in the system control cabinet. Cargo hold detection systems are combined with the carbon dioxide system discharge piping. The system control cabinet is located outside the cargo area and arranged to take suction through the carbon dioxide system discharge piping in each hold. The air samples are aspirated from each hold individually and then routed in sequence through an optical smoke detection chamber. If the system goes into alarm, valves are provided to isolate the discharge piping from the detection system prior to the release of the extinguishing gas. The carbon dioxide system is designed to provide a quantity of extinguishing agent intended for fire control until the ship can make it to a port of refuge. Because of the tight stowage arrangements and the likelihood of deep-seated fires, it is not considered realistic to expect the system to extinguish the fire.

Container Holds. Cargo holds designed for the carriage of shipping containers are similar to those on breakbulk ships; thus the same fire protection measures are provided. Unlike general cargo ships, however, container ship cargo holds are designed with very large hatch covers and do not have 'tween decks. This arrangement permits the entire hold to be loaded by the overhead gantry cranes, without movement of the cargo below decks. The containers are lifted into the holds and aligned and restrained by vertical cell guides. The clearances between the rows of containers is only several inches, making access to

the loaded hold impossible. The fire hazards and protection for container holds is the same as for general cargoes. The steel, aluminum, or fiberglass shipping containers further segregate the combustible material and may restrict the spread of fire. However, they can also act as a shield to limit the application of extinguishing agents. The fire risks presented by containerized cargo are considered equivalent to those involved with the breakbulk shipment of commodities.

Bulk Cargo Holds. Bulk cargoes are loose commodities such as grain, ores, minerals, and coal, which are usually loaded and unloaded using conveyor belts, blowers, or grab buckets. The likely fire hazards involving these cargoes are very limited and may involve dust explosions and self-heating of some agricultural commodities. Detection and suppression systems would provide limited benefit and are therefore not required.

Some bulk cargo ships are self-unloaders, with a conveyor belt running beneath the cargo holds. These systems are common on both U.S. and Canadian vessels on the Great Lakes. The holds are hopper-shaped and have doors at the bottom to discharge the cargo onto the belt. At the end of the belt, another set of belts lifts the cargo above the deck and onto a conveyor boom, which can be turned to either side of the vessel to discharge the cargo. These conveyor systems with their numerous rollers, motors, and gearboxes can be the source of fires and should be protected with detection and suppression systems.

Vehicle Holds. Cargo ships designed for the carriage of vehicles can have a variety of different hold arrangements. These ships commonly transport automobiles, trucks, trains, military vehicles, or trailers. There are two basic loading arrangements for these ships. The vehicles may either be lifted on and off the ship by cranes, or they may be driven onto and off of the ship. Lift on/lift off (lo-lo) cargo holds designed for vehicles are similar in configuration to general cargo holds. Cargo holds designed for driving, or roll-on/roll-off (ro-ro) service, have multiple 'tween decks generally with only enough overhead clearance for one level of vehicles, to maximize the load-out of the ship.

If the vehicles are lifted on and off of the ship or if the vehicles are tractor-trailer trucks (briefly driven onto the ship just to deposit the trailer), there is no fuel in the vehicles, in which case the vehicles pose no greater fire hazard than general cargoes. If the vehicles are driven on and off of the ship and contain gasoline and charged batteries, additional fire protection is required. A higher concentration of carbon dioxide is specified by the regulations because the expected fires in the vehicle holds are not slow-developing, deep-seated fires, but flammable liquid fires. Additionally, protected electrical fixtures and mechanical ventilation systems are provided to protect against the ignition of explosive gasoline vapors.

Cargo Tanks. Tank vessels are designed for the carriage of bulk liquids, including crude oil, refined petroleum products, vegetable oils, alcohols, and chemicals. The most common types of tank vessels are designed for the carriage of petroleum products such as crude oil, heating oil, or gasoline. The greatest fire risk on tankships is the chance of flammable cargo vapors coming into contact with an ignition source. To protect against this, the ships are provided with restricted ventilation systems and are often arranged with a cargo pump room located between the engine room and the first row of tanks (in the aft portion of the vessel), to isolate the cargo from the ignition hazards in the engine room. Additionally, all deckhouses and machinery must be located aft of the cargo tank area to minimize contact of flammable vapors with possible ignition sources. Furthermore, the forward-facing portions of the deckhouse that face the cargo area are constructed of fire-rated bulkheads, with closeable steel covers over the windows.

Crude oil carriers are perhaps the most common type of oceangoing tankships. Crude oil carriers are generally designed with a series of large tanks of similar volume. The fire hazards of crude oil vary due to its elemental makeup and the geographic region where it was obtained. Crude oil contains all of the products that are separated during the refining process; thus crude oil includes volatile elements (such as gasoline) that have very low flashpoints. The fire risk of petroleum products is based on the flashpoint and volatility of the liquid. The volatile gases rising from the surface of the petroleum are the fire hazard, and burning gases produce the visible flames. The rate at which the gases are given off is expressed by the product's Reid vapor pressure. In order for the petroleum to burn, it must be mixed with air in the correct ratio. The flammable range for typical petroleum products carried on tankships is between 1 and 10 percent by volume in air. Air spaces in the cargo tanks and piping systems are inerted to further guard against the possibility of a cargo fire. Tankships have inert gas generators or use treated flue gas to provide the oxygen-deficient atmosphere that is needed for this purpose.

The cargo tanks may be connected with the ship's hull, in which case a grounding or collision is likely to result in an explosion and fire involving the cargo, or they may be independent from the hull. The public reaction over the *Exxon Valdez* oil spill in March 1989, where the cargo tanks were connected, resulted in the Oil Pollution Act of 1990. This law requires new tankers built after June 1995 to have independent cargo tanks separated from the hull by a void space. Existing single hull tankers must be retrofitted with double hulls over a 20 year period that began in 1995 and terminates in 2015. The required date of compliance is based on the original build date or date of major conversion of the tankship. The void space between the outer hull and the cargo tank provides added protection against damage in a grounding.

Fire protection of the cargo tank deck area is provided by manually operated deck foam systems that discharge through fixed monitors. The foam system controls, pumps, and concentrate storage tanks are located in a protected room aft in the deckhouse. In the event of a fire, the system can be started from the protected location and aligned to supply foam solution into the mains. The monitors are arranged to allow the crew to fight the fire from aft to forward.

Chemical tankers differ from oil tankers because they carry a variety of different chemical cargoes in varying lot sizes. These ships have numerous smaller tanks, generally of unequal capacity. The deck foam system must be specifically designed to protect against the different chemical and fire hazard properties of the chemicals. In some cases, the chemicals may be water sol-

uble, requiring specialized "polar solvent" foam concentrates. Protection of chemical tankers can be further complicated by the use of cargo heating systems and the use of specialized piping materials. Compatibility of cargo represents an additional factor that complicates chemical tanker protection. Criteria have been established that restrict certain products from being stored in adjacent tanks.[7]

Liquefied natural gas (LNG) carriers are another type of specialized tank vessel seeing expanded service in the United States. Current vessel designs have a capacity sufficient to hold approximately 4.4 million ft^3 (125,000 m^3) of LNG, but tankers with larger capacities are in the design stages. The liquefied natural gas is contained in specially insulated cargo tanks at a temperature of approximately –256°F (–161°C) at atmospheric pressure. By cooling the gas to cryogenic temperatures, the volume of the cargo can be reduced by a factor of 600 for more cost-effective transport. LNG carriers do not have onboard refrigeration capability to keep the liquid cargo cold. Instead, the cargo tanks are heavily insulated; however, a small amount of the liquid will boil off during the voyage. This gas must either be reliquefied or used as fuel in the ship's boilers.

The composition of natural gas depends on the geographic location where it is produced, but consists primarily of methane with small amounts of other hydrocarbons such as ethane, pentane, and butane. When the natural gas is cooled and liquefied, any of the constituent elements that solidify must be removed to prevent damage to the gas compressors and cargo pumps. As a result, the liquefied cargo being carried on the ship is primarily methane. There are two customary LNG cargo tank designs: freestanding spherical tanks and prismatic membrane tanks.

Freestanding spherical tanks are constructed of either aluminum or nickel steel and are mounted inside the steel hull of the ship with the top half of the tank exposed above the main deck. A double hull arrangement is provided with several feet of separation between the tank and the ship's outer hull to protect the tanks from damage in the event of a collision or grounding. The tanks are surrounded by highly efficient insulation, and a metal weather cover is installed over the exposed parts of the sphere.

Membrane tanks conform to the shape of the hull and consist of an inner membrane constructed of a special nickel-iron alloy that has a very low coefficient of thermal expansion at cryogenic temperatures. A second metal or composite outer membrane is provided that is separated from the inner barrier by several layers of insulation. The space between the two barriers is inerted with nitrogen and monitored for leakage. Similar to the spherical tank design, a double hull is provided to protect the tanks in the event of a collision. Membrane tanks are fitted, for the most part, within the hull, allowing such vessels a lower overhead clearance than spherical tank designs.

For both types of LNG tank designs, fixed dry chemical monitors or hand hose lines are required for the protection of the cargo area. The dry chemical system is intended for the protection of the above-deck cargo area, tank domes, exposed cargo piping, and the cargo handling manifolds. In addition, a fixed water spray system is required for cooling the exposed cargo tank domes, the cargo manifolds, and the boundaries of any superstructures facing the cargo area.

Cargo Pumprooms. Tank vessels have cargo pumprooms that are used to convey the cargo onto and off the ship. On some vessels, deep-well pumps are installed in the cargo tanks, eliminating the need for a dedicated pumproom. The electrical equipment located in the pumproom must be electrically safe for hazardous atmospheres. The cargo pumps are usually arranged with electric motors in the engine room and the pump shafts passing through packing glands in the aft pumproom bulkhead. This arrangement eliminates the need for qualified electric motors in the pumproom. The standard protection for cargo pumprooms is a total flooding gaseous agent system. Some tankers may also have a water spray system or a foam system.

Cargo Ship Accommodation Areas. Accommodation areas are the part of the ship where the officers and crew are housed, and may include sleeping, galley, dining, laundry, and recreation areas. The typical crew staffing level on a modern cargo or tankship is about 20 to 30 persons. The officers and higher-ranking crew members have private rooms, whereas the remainder of the crew is assigned to rooms suitable for two to four occupants. U.S. Coast Guard regulations specify that the materials of construction in these areas must be noncombustible. The expected fire risks are limited to furnishings and personal articles placed in the berthing areas. Casualty statistics[6] show that the predominant fire risk in these areas is attributable to electrical sources, followed by failure to observe proper fire prevention practices.

U.S. flag cargo and tank vessels in domestic service are not required to have automatic sprinkler systems or fire detection systems for the protection of the crew accommodation areas. The primary fire protection measure is the use of noncombustible materials of construction. SOLAS allows three options for the design of cargo ship accommodation areas. They may be constructed of noncombustible materials (Method IC); or they may be constructed of limited combustible materials in conjunction with an automatic sprinkler system and a smoke detection system for the protection of all corridors, stairways, and escape routes (Method IIC); or they may be constructed of limited combustible materials in conjunction with an areawide detection system (Method IIIC). Only Method IC is accepted for U.S. flag vessels.

Passenger Ship Accommodation Areas. The fire risks anticipated in the accommodation areas on passenger vessels are the same as those on cargo ships; however, passenger ships have many more passengers who are not familiar with the vessel and there are public spaces such as casinos, restaurants, spas, movie theaters, and lounges in addition to the berthing areas. These larger public spaces present a higher level of risk because of the greater number of occupants that would have to be evacuated in an emergency. The furnishings in many of the public spaces also have the potential for a higher rate of heat release than those found in a berthing area—for example, a theater that has upholstered seating or a sales shop with combustible merchandise. SOLAS requires areawide automatic sprinkler protection and smoke detector coverage of all of the accommodation areas. The U.S. domestic vessel regulations vary depending on the size of the ship and the number of passengers carried. The individual vessel regulations should be consulted for these requirements.

Small domestic passenger vessels (Subchapter T and K vessels) are sometimes used for dinner cruises. The public spaces on these vessels may have a buffet line set up with portable, solid alcohol food warming equipment. Some vessels may also have casino gaming machines that are constructed with combustible materials and are electrically powered. The higher level of potential fire risk on these vessels is addressed by two additional provisions in the regulations. A limit on the allowable combustible load in the public spaces is applied to restrict the fuel load. For general public spaces, the maximum combustible load is limited to 7.5 lb/ft^2 (37.5 kg/m^2), considering the total volume of all construction and outfitting materials, furniture, furnishings, carpets, draperies, interior finish materials, electrical cable insulation, plastic light diffusers, mattresses, and similar materials. In addition, all accommodation, service, and control spaces must be equipped with a smoke detection system.

Passenger vessels may be designed with architectural features such as balconies and atriums (Figure 21.10.8). The domestic passenger vessel regulations permit atriums if they are of sufficient size for the occupants to be able to observe the outbreak of a fire at any location in the atrium. This concept is based on the minimum opening dimensions taken from the NFPA *101*®, *Life Safety Code*®, requirements for buildings. In addition, areawide automatic sprinklers, smoke detection, and a smoke control system are specified. The smoke control system must be designed to clear all of the smoke from the atrium within 10 minutes.

FIRE PREVENTION ON SHIPS

The basic fire protection philosophy applied to ships is to limit the use of combustible materials of construction, thereby restricting the available fire growth rates. This concept is applied to the materials of construction used for the decks, bulkheads, ceilings, interior finish materials, and any items incidental to the construction of the ship. There is still the possibility, however, that the vessel's furnishings, galley supplies, trash, and similar items can add up to a significant fire risk if safe operational practices are not followed. Although the regulations are not specific regarding housekeeping and fire prevention issues, good marine practice dictates that the handling and use of combustible materials, flammable liquids, and ignition sources be controlled. It is essential that the storage of consumable goods and their packaging be controlled to isolate combustible materials from sources of ignition.

FIGURE 21.10.8 Typical Atrium on a Passenger Ship

Important changes to the international regulations were adopted in 1997 that make fire prevention training mandatory for licensed seafarers serving onboard SOLAS vessels. This is intended to make the crew aware of the need to follow safe practices in the day-to-day operation of the ship. The International Convention on Standards of Training, Certification, and Watchkeeping for Seafarers (STCW), 1978, sets qualifications for masters, officers, and watchkeeping personnel on seagoing merchant ships. These requirements became effective on February 1, 1997, and require candidates for licenses and other certificates to establish competence through both subject-area examinations and demonstration of skills in basic safety training.

Controlling Flammable and Combustible Liquids Storage

The control of flammable and combustible liquids used for daily maintenance and repair activities is an important marine fire prevention practice. Steel lockers should be provided for the storage of paint and other flammable liquids. Hazardous liquids should be stored in the approved lockers at the end of each work shift. It is particularly important to store these materials in protected lockers on fiberglass and wooden hull vessels. The preferred location for these lockers is on the open deck, although the engineer's stores (such as lubricants and solvents) are ordinarily kept inside an approved flammable liquids cabinet in the engine room. Stowage of ordinary combustibles in paint and flammable liquid lockers should not be permitted. In the engine room, lube oil and fuel spills should be routinely cleaned up to keep the bilges from accumulating waste oils. Oily wiping rags should be stowed in sealed metal containers to guard against their spontaneous combustion.

Controlling Fuel Oil Transfers

Fuel oil transfers introduce the possibility of flammable or combustible vapors being released at the dock and in the vicinity of the fuel manifolds on board the ship. Precautions also need to be taken prior to and during fueling operations to lessen the chance of a fuel spill, caused by a fuel hose leak or the overfilling of a tank on the ship. All smoking, open lights, and other ignition sources should be prohibited in the vicinity of the fuel manifold, and only authorized personnel should be allowed to remain in the area. All open doors and windows near the manifold should be closed. The mooring lines should be confirmed tight before fueling is begun. An effective means of communication should be available at all times to permit the rapid shutdown of the fuel pumps in case of an emergency. A calibrated means of determining tank levels should be continuously available to prevent overfilling the ship's fuel tanks. If there are language difficulties between the crew and the fuel

terminal, prior agreement should be made on the verbal expressions to be used for the transfer operations. Appropriate lighting should be readily available in the vicinity of the manifold in the event of a fuel spill.

Controlling Flammable and Combustible Cargo Vapors

On tank vessels, there is a significant fire risk from the release of flammable or combustible cargo vapors. To minimize vapor production, tankships have an inert gas system that maintains an inert atmosphere in the cargo tank and piping system vapor spaces, except when the tanks are required to be gas-free. Inert gas systems are designed to inert empty cargo tanks by displacing the atmospheric air in the tanks with inert gas. When the tanks have been inerted, the cargo can be loaded without the fear of an explosion. During the voyage, the inert gas system supplies makeup volume to maintain the oxygen content in the cargo tank air spaces below 8 percent oxygen by volume, at a positive pressure. When the cargo is offloaded, additional inert gas is supplied to the tank to keep the atmosphere out of the flammable range.

If any work is to be done inside of the cargo tanks, they must first be cleaned and gas-freed. This operation poses a particular risk because the inert gas blanket is pumped out of the tank and air is introduced. In the process, the tank atmosphere changes from a fuel-rich condition to a condition that will not support combustion. The danger of this is the intermediate condition when the tank atmosphere is between the upper and lower flammable limits. An ignition source or static discharge while the tank is in the explosive range could have serious results. Ships in port or a shipyard must engage a marine chemist to certify tanks as being safe for workers or safe for hot work as the job requirements dictate.

NFPA 306, *Standard for the Control of Gas Hazards on Vessels,* provides further technical details on the role of marine chemists. Marine chemists are certificated to perform this service through an industry-sponsored certification program that is administered by NFPA. Basically, the marine chemist must verify that the concentration of oxygen is sufficient to support life and that the concentration of flammable or combustible vapors is below their flammable limits. The marine chemist also verifies that toxic vapors or substances that are harmful to humans are not present in significant concentrations. If any tank or void space entry is to be done while the vessel is at sea, the ships' crew must first verify that the tanks are safe for entry following similar confined space safe practices to those of the marine chemist. In all cases, portable gas analyzers are used to verify that oxygen levels are adequate and cargo vapors are below their flammable range.

STRUCTURAL FIRE PROTECTION

Domestic Service Vessels

The origins of shipboard structural fire protection measures can be traced to the 1930s, when the U.S. Department of Commerce first established regulations for vessel construction in the wake of the *Morro Castle* disaster and the U.S. Senate investigation that followed. The regulations mandated the use of noncombustible insulation and bulkhead panels to protect the steel structure of passenger ships. The laboratory fire test method originally used to approve these materials was ASTM E119, which, with minor modifications, is still used today. In the years that have followed, additional laboratory test methods have been developed for noncombustibility of materials, flame spread on interior finishes, and the fire resistance of deck coverings.

Shipboard structural fire protection is based on the use of fire barriers that are rated for either 60 minutes of structural integrity (designated A-class divisions) or 30 minutes of structural integrity (designated B-class divisions). Marine fire barriers are further classified in terms of their ability to limit temperature rise on the unexposed side of the barrier. Alphanumeric fire ratings are assigned to barriers to indicate their tested temperature rise limitation. For example, an A-0 division provides structural integrity for 60 minutes but provides no temperature rise limitation on the unexposed side of the barrier. Such barriers are typically used for exterior bulkheads that separate interior spaces from the weather decks. An A-30 division provides 60 minutes of structural integrity and will also prevent the average temperature rise on the unexposed side of the barrier from exceeding 284°F (140°C) above ambient for at least 30 minutes. The highest fire rating used is A-60. These barriers can be used to form main vertical zones, separate stair towers from adjacent accommodation areas, or to separate engine rooms from accommodation areas.

The present Coast Guard regulations for fire protection materials are contained in 46 CFR 164. These regulations detail the necessary fire tests that must be conducted for a material to be Coast Guard type-approved for use on U.S. flag vessels. The Coast Guard does not perform the actual fire testing of the materials. The manufacturer is required to have their materials tested to the Coast Guard criteria at an independent testing laboratory that has been accepted by the Coast Guard. Materials that successfully pass the required tests are issued a type approval certificate and the product is added to the list of approved materials posted on the Coast Guard's website.

The current list of approved structural fire protection materials is broken down into the following five categories:

- Deck coverings 46 CFR 164.006
- Structural insulation 46 CFR 164.007
- Bulkhead panels 46 CFR 164.008
- Noncombustible materials 46 CFR 164.009
- Interior finishes 46 CFR 164.012

The Coast Guard publishes Navigation and Vessel Inspection Circular (NVIC) 9-97, which explains the use of these materials for ship construction in detail.

The IMO International Code for Application of Fire Test Procedures (FTP Code) became mandatory for all international service vessels constructed after December 2003. Thus, materials type approved under the categories in the previous list are no longer acceptable for use on board U.S. flag vessels in international service. They may only be used on board domestic service vessels.

Deck Coverings. Deck coverings provide A-60 fire resistance for steel decks. As the name implies, these materials are installed on the top of the steel structure. The test method for deck coverings contains three specific test criteria: limited organic (carbon) content, limited smoke generation, and fire resistance and integrity. Although these requirements are not identical to the noncombustibility test, the resulting performance is very close. Therefore, it is assumed that the materials approved under 164.006 are noncombustible when used in their intended purpose as deck coverings. A limited amount of combustible content is permitted for deck coverings to allow the use of materials better suited as flooring surfaces. Deck coverings are typically cementitious materials, such as oxychloride cements, that are troweled in place.

Structural Insulations. Structural insulations form the primary fire boundaries that separate galleys and machinery spaces from accommodation areas. They are also used to form main vertical zone (MVZ) boundaries on passenger ships. Because the major subdivisions on board ships consist of steel bulkheads (walls) and decks (floors), a system has been devised that uses the steel structure as a component of the required fire separations—hence the term *structural insulation.* The fire test method described in 46 CFR 164.007 requires a 40 in. by 60 in. (100 cm by 150 cm) test sample to be attached to a 0.19 in. (5 mm) thick steel plate, which is considered representative of typical shipboard construction practice. The test specimen is then mounted in a vertical furnace with the insulation on the exposed surface of the test specimen. The assembly is then subjected to the standard time-temperature curve described in ASTM E119 for a 60 minute period. During the test, the average temperature rise on the unexposed side of the plate must not exceed 250°F (140°C) at the end of 60 minutes and the temperature at any one point cannot rise more than 325°F (180°C) above ambient.

A steel plate 0.19 in. (5 mm) thick will pass the standard fire test for a 60 minute period, however, without any limit on the unexposed surface temperature. A bare steel bulkhead is designated an A-0 class barrier. If approved structural insulation is applied, the thickness of insulation tested will limit the temperature rise of the steel boundary for 60 minutes. An insulated fire barrier with this amount of protection is designated an A-60 barrier. It has been found that 75 percent of this thickness will provide at least 30 minutes of fire endurance (A-30 barrier), and 50 percent of this thickness provides at least 15 minutes of protection (A-15 barrier). Structural insulations can be field applied to either side of a bulkhead or to the underside of a deck to form A-class boundaries, based on their testing under 46 CFR 164.007. Structural insulations are typically fibrous batts, or blankets, which may be faced with foil or other noncombustible materials. Calcium silicate panels and spray-on mixtures are also typical.

Bulkhead Panels. The secondary fire separations on ships are formed by non-load-bearing bulkhead panels used to enclose individual rooms and corridors. This construction technique is similar to the use of gypsum board panels in buildings, except that the panels are joined together by a system of metal tracks and connector hardware instead of wooden studs, because only noncombustible materials may be used. The connection system is traditionally called a joinerwork system. B-class bulkheads are typically either 0.75 in. (19 mm) thick homogeneous mineral board panels or 2 in. (50 mm) thick steel-faced, mineral wool sandwich panels. B-class bulkheads are intended to be installed in a single thickness, except where they are used as a component of A-60 class barriers. In such a case, there could be multiple layers of the B-class panels combined with structural insulations.

A variety of laminates and decorative covers can be used to conceal the joiner system and cover the panel surfaces. The tape and spackling system used for buildings is not practical on board ships because of vibration-induced cracking. The bulkhead panels used in this system are approved using the fire test method described in 46 CFR 164.008, which is intended to test the panel and its joinerwork as a complete system. This test is conducted in a vertical furnace, similar to that used for structural insulations; however, the sample size is 50 ft^2 (4.65 m^2) with a height of at least 8 ft (2.44 m).

Bulkhead panels are usually installed on ships with penetrations for lights, receptacles, switches, and controls. Because of this, the laboratory tests generally include a specimen with representative electrical fittings. Bulkhead panels that pass the required fire tests for a 30 minute period are designated B-0 bulkheads. Panels that pass the fire integrity tests for 30 minutes and also provide at least 15 minutes of limited temperature rise on the unexposed surface of the barrier are designated B-15 bulkheads. B-15 bulkheads are qualified to be used as a component of steel A-class construction to offer 60 minutes of fire endurance when combined with other insulating materials.

Noncombustible Materials. The materials used in shipboard construction must be qualified as noncombustible materials before they are subjected to the furnace testing used to establish their fire resistance. Materials that are approved as noncombustible materials must either pass the fire test method in 46 CFR 164.009 or be inherently noncombustible. The test requires a 4.88 $in.^3$ (80 cm^3) sample to be lowered into the test apparatus, which has been preheated to 1382°F (750°C). The pass/fail criteria include maximum temperature rise, flaming conditions, and a percent mass loss as follows:

- No more than 122°F (50°C) furnace temperature rise
- No more than 122°F (50°C) specimen surface temperature rise
- No more than 10 seconds total duration of flaming
- No more than 50 percent weight loss

This test is very stringent and thus, low flame spread and fire-resistant materials will not pass the test and do not qualify as noncombustible materials.

The Coast Guard considers the following materials as inherently noncombustible and no fire tests are required:

- Glass, clay, ceramics, or uncoated glass fiber
- All metals except magnesium or magnesium alloys
- Portland cement, gypsum, concrete with aggregates of only sand, gravel, vermiculite, silica, perlite, or pumice
- Woven or knitted glass fabric containing not more than 2.5 percent lubricant by mass

Interior Finishes. Interior finishes are coatings, overlays, or veneers that are used for decorative purposes. Interior finishes are normally applied to the exposed surfaces of bulkheads, ceilings, and decks, including exposed surfaces in concealed spaces. The two types of interior finishes used on domestic service vessels are approved finishes and combustible finishes. An approved interior finish is required to have a limited flame spread and smoke developed rating; a combustible interior finish may be a material with an unlimited flame spread or smoke developed rating.

Approved interior finishes are required in corridors and stairway enclosures as well as in concealed spaces within accommodation, service, and safety areas. They are also required in low-fire-risk accommodation spaces, which are sometimes required on board passenger ships. Combustible finishes may be installed in all other areas subject to thickness and volume restrictions. On all ships, the maximum allowed thickness of a combustible veneer is 0.075 in. (2 mm). On passenger ships, an additional volume limitation is imposed to restrict the volume of the installed veneer plus any moldings, trim, or decorations to a maximum of 0.1 in. (2.5 mm) times the aggregate surface area of the walls and ceilings in the space. This allows the use of decorative trim pieces of irregular shape. If thicker veneers or trim are installed, they must pass the noncombustibility test of 46 CFR 164.009.

Approved interior finishes must comply with 46 CFR 164.012, which requires the materials to be subjected to either ASTM E84 or NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials.* The acceptance criteria for either test method is a flame spread of 20 or less and a smoke developed rating of 10 or less. The interior finish materials must be tested using the same mounting method or adhesives that are intended for use in the shipyard.

In addition to the type-approved material categories for deck coverings, structural insulations, bulkhead panels, noncombustible materials, and interior finishes, the Coast Guard has developed accepted construction specifications for the design of fire doors, fire dampers, and electrical and piping penetrations. These construction specifications are based on standard shipyard practices, and, as a result, the materials are not required to be fire tested. The details of these construction requirements are listed in the various subchapters applicable to each vessel category. Type approvals are not issued for these materials.

International Service Vessels

CFRs historically contained the requirements for Coast Guard approval of structural fire protection materials and assemblies aboard U.S. flag vessels on both domestic and international routes. Coast Guard approved materials were accepted for vessels on international voyages, because SOLAS did not include fire testing procedures. The IMO Subcommittee on Fire Protection recently decided that uniformly applied fire test procedures should be developed and made mandatory to assure that structural fire protection materials do not deviate significantly among the member states. Effective July 1, 1998, the fire test methods in the International Code for the Application of Fire Test Procedures (FTP Code) were made a mandatory part of SOLAS. All U.S. flag ships that require a SOLAS safety certificate must now use structural fire protection materials that have been tested in accordance with the FTP Code instead of the CFR. The fire test procedures in the FTP Code cover more types of materials than the CFR does, and require the completion of complex fire test protocols using test apparatus that is newer than that used for domestic service materials.

The FTP Code is divided into parts, each dealing with a specific set of performance criteria as follows:

- Part 1: Noncombustibility test
- Part 2: Smoke and toxicity test
- Part 3: Test for Class A and Class B divisions
- Part 4: Test for fire door control systems
- Part 5: Test for surface flammability
- Part 6: Test for primary deck coverings
- Part 7: Test for vertically supported textiles and films
- Part 8: Test for upholstered furniture
- Part 9: Test for bedding components

To implement the new FTP Code requirements, the Coast Guard established the following type approval categories:

• Deck assemblies	164.105
• Primary deck coverings	164.106
• Structural insulations	164.107
• Bulkhead panels	164.108
• Noncombustible materials	164.109
• Structural ceilings	164.110
• Draperies, curtains, and suspended textiles	164.111
• Interior finishes	164.112
• Floor coverings	164.117
• Fire doors	164.136
• Windows	164.137
• Penetration seals (firestops)	164.138
• Fire dampers	164.139
• Bedding components	164.142
• Upholstered furniture	164.144
• Fire-restricting materials for high-speed craft	164.201
• Fire-resisting divisions for high-speed craft	164.207

U.S. flag ships that engage only in domestic voyages have the option of using structural fire protection materials that comply with either the CFRs or the FTP Code, because the FTP Code approval tests requirements are deemed to be more stringent. U.S. flag vessels that engage in international service must meet the FTP Code.

There are many differences between the FTP Code tests and the existing Coast Guard regulations. One major variation is between the Coast Guard's deck covering test and the FTP Code's primary deck covering test. The FTP Code defines primary deck covering as the first layer of a floor construction that is applied directly on top of the deck plating and is inclusive of any primary coat, anticorrosive compound, or adhesive that is necessary to provide protection or adhesion to the deck plating. Primary deck coverings may be installed beneath a floor covering such as tile or carpet, in which case they are tested for ignitability. If the primary deck covering will be used as an exposed surface, it must be tested for surface flammability and smoke and toxic gas production. Primary deck coverings are not tested for their fire-resisting ability. This category has no counterpart in the CFR.

The FTP Code requires structural insulations to be tested in the orientation in which the material will be installed, that is, materials to be installed on both bulkheads and decks must be tested in vertical and horizontal orientations. The bulkhead insulation being tested must be installed on the side of the steel bulkhead not facing the fire (i.e., on the cold side), and deck insulation must be installed on the hot side (i.e., below the steel deck). Insulation tested on only one side is issued a restricted approval, limiting the installation to locations where there is no fire hazard from the uninsulated side.

The FTP Code requires a steel core to be part of a B-class bulkhead panel test assembly for panels that are to be used as a component of A-class construction. To receive an unrestricted approval, two separate tests must be conducted: one test with the B-class bulkhead facing the fire and one test with the steel core facing the fire.

Interior finish materials tested to the FTP Code must pass a flame spread test using a radiant panel test apparatus that differs from the apparatus used to test interior finishes for U.S. domestic approval. In addition, they must pass smoke and toxicity testing in accordance with ISO 5659:1994.

The Coast Guard has not previously issued type approval certificates for fire doors, windows, or fire dampers. However, since the FTP Code requires these materials to meet the referenced fire resistance tests, the Coast Guard has established approval categories for these items.

Coast Guard type approval of structural fire protection materials requires the establishment of a follow-up inspection program monitored by an independent testing laboratory or other accepted organization to ensure that the materials shipped from the factory are representative of the test specimens. If production changes occur because of refinements in the base materials or the dimensions of the approved materials, additional fire testing must be conducted to confirm that the fire performance of the material has not been reduced.

High-Speed Craft

In the latter part of the twentieth century, the maritime industry began developing high-speed vessels for applications such as for use as rapid commuter ferries. Unfortunately, the prescriptive fire protection regulations in SOLAS did not allow the freedom to design and build fast ships that were cost effective. The traditional fire protection materials required by SOLAS add too much weight to a high-speed vessel's design. In response, IMO has developed the High Speed Craft Code (HSC Code) as a valid alternative to SOLAS for designers, builders, and operators to use for ships that meet the definition of a high-speed craft (HSC). HSCs are typically vessels 131 to 328 ft (40 to 100 m) in length, used to transport people, automobiles, and cargo at speeds generally in excess of 20 knots and, in some cases, up to 50 knots. Among other differences from SOLAS, the HSC Code allows the use of lighter-weight materials for the ship's structure, compartment divisions, bulkhead and ceiling linings, and furniture components. Materials of construction must be either noncombustible as defined by SOLAS or fire restricting. Fire-restricting materials are defined by the HSC Code as having low flame-spread characteristics, limited rate of heat release, and low smoke and toxic gas production. Fire-restricting materials are qualified using the ISO 9705 room corner test for ship's structures and compartment linings and the ISO 5660 cone calorimeter test for furniture components (not including upholstery).

Coast Guard Type Approval Program

All structural fire protection materials installed on U.S. flag vessels must be Coast Guard type approved. There are two methods for obtaining type approval; the type approval can be issued by the U.S. Coast Guard, or a European Community representative can issue the approval on behalf of the Coast Guard.

For a Coast Guard–issued type approval, the manufacturer is required to submit the product to a Coast Guard accepted independent laboratory for testing. When the laboratory testing is completed, the test report, pertinent component drawings, installation instructions, and the follow-up services agreement are submitted to the Coast Guard for review. If the appropriate acceptance criteria are satisfied, a type approval certificate is issued and the product is added to the list of approved materials on the Coast Guard website.

Coast Guard–issued type approvals are required to be under a production control or follow-up program conducted by the testing laboratory. The laboratory is required to visit the factory to witness the fabrication of the test specimen prior to conducting the approval tests. After the type approval certificate is issued, the laboratory is required to make periodic factory visits to ensure that the raw materials and production methods for the approved materials have not changed and that the materials being produced remain representative of the specimen that was tested.

The other means for obtaining type approval is to have the material tested at a European Community recognized laboratory. On February 27, 2004, the United States entered into a Mutual Recognition Agreement (MRA) with the European Community (EC) that recognizes type approvals issued by either party. Under the terms of the agreement, manufacturers can obtain a Coast Guard type approval directly from a European Community Notified Body.

MRA type approvals are issued by the EC Notified Body without any review or approval by the Coast Guard. The materials are tested at laboratories specified by the Notified Bodies, using test methods that follow the FTP Code. The Coast Guard does not maintain a listing of MRA approved materials.

FIRE PROTECTION SYSTEMS

The Coast Guard's philosophy on shipboard fire protection emphasizes the use of noncombustible materials and limited fire loads to control the magnitude and severity of expected fires. The use of flammable and combustible liquid fuels and cargoes could result in fires that require supplemental fire-extinguishing systems. The CFR, therefore, specifies protection of engine rooms, larger generator rooms, cargo holds and tanks, certain galley areas, and cargo pumprooms with fixed fire-extinguishing systems. Most of these systems are designed for manual activation to prevent an inadvertent discharge from adversely impacting operation of the ship.

Fire Main System

A fire pump and fire main system are required for the general protection of all shipboard areas. The fire main is intended as the primary means of fire protection in the accommodation and service areas. It is considered a supplemental system for the protection of the machinery spaces and the cargo areas, which are provided with other specialized fire-extinguishing systems. The fire pumps can be sized to supply the fire main and other water-based extinguishing systems such as foam systems, sprinkler systems, or water spray systems. The fire main is required to be arranged so that effective hose station coverage is available in all areas of a vessel. In the fire hose station on board a cruise ship shown in Figure 21.10.9, note the preconnected hose and nozzle, gate valve, and spanner wrench.

Each part of 46 CFR lists specific requirements for the number and capacity of fire pumps. The water supply capacity is based on the expected fire-fighting needs for vessels of the size and service regulated by that part of the rules. Typically, the main fire pump is an independently driven electric motor pump located in the main machinery space, although diesel engine and steam-driven pumps may be encountered. If multiple pumps are required, the pumps must be located in separate fire areas to prevent damage from a fire or accident from impacting all of the pumps.

In addition to separation of the pumps, the regulations also specify that the arrangement of sea connections and sources of power shall be such as to ensure that a fire in any one space will not put all of the fire pumps out of operation. Fire pumps take their suction from an opening in the hull of the ship, called a sea connection. It is common for ships to have several sea connections to supply water pumps for cooling of the machinery, as well as the fire pump.

Because of the many different hose coupling dimensions and thread patterns found worldwide, it is likely that the fire hoses on a ship may not easily connect to those in the various ports visited by the ship. To provide a backup means of supplying fire-fighting water to vessels in port, a universal adapter flange, called an international shore connection, was developed. International shore connections are required on all SOLAS vessels; they consist of a flat-bolted flange that can be attached to the ship's fire main.The flange has a flat face on one side and a permanently attached coupling that fits the ship's hydrants and hose connections on the other side. The international shore connection is bolted to a mating flange from the port using a gasket suitable for 150 psi (1034 kPa) service, together with four ⅝ in. (16 mm) bolts, 2 in. (50 mm) long through a predrilled bolt pattern (Figure 21.10.10).

Automatic Sprinkler Systems

Until recently, automatic sprinkler systems were required on large passenger vessels for the protection of only cargo spaces considered accessible during the voyage. In 1993, the domestic commercial vessel industry expressed an interest in constructing casino gambling vessels and dinner cruise vessels, using alternative designs that featured large, open public areas. Some proposed designs also incorporated atriums that connected multiple decks. The structural fire protection regulations require main vertical zone bulkheads every 131 ft (40 m), which effectively prevent the use of this "open space" concept. For design flexibility, the Coast Guard developed a method to permit the use of this new concept without main vertical zones if areawide automatic sprinklers are installed. In 1996, NFPA 13, *Standard for the Installation of Sprinkler Systems,* was modified to include a Coast Guard–sponsored chapter on marine sprinkler systems, which is used for the design of sprinkler systems on board domestic service vessels. NFPA 13 may also be used to design sprinkler systems for SOLAS vessels, provided the SOLAS requirements for automatic sprinklers, which may exceed those in NFPA 13, are also satisfied.

Marine sprinkler systems are arranged differently from those in buildings because of the quality of the water supply. In buildings, potable fresh water from tanks or the public water supply mains is generally available, whereas the water supply on ships is usually taken from salt water, or water which may contain sediment or other foreign materials. Because of this, clogging and corrosion of the sprinkler system piping and components can occur if they are not designed to accommodate

FIGURE 21.10.9 Typical Fire Hose Station on Board a Cruise Ship

FIGURE 21.10.10 Typical International Shore Connection Manifold Arrangement

raw water supplies. Additional components are thus required to maintain wet pipe marine sprinkler systems filled with potable fresh water. A limited capacity tank is also provided to supply the system for a short period, until the seawater pumps can pressurize the system. In the event the system operates, the sprinkler piping is flushed with fresh water before it is put back into service to prevent degradation. The limited exposure to salt water does not adversely affect the system piping.

Manual Sprinkler Systems

Manual sprinkler systems are intended for the protection of partially enclosed vehicle decks where the use of total flooding carbon dioxide is not practical. The systems use open head 3/8 or 0.375 in. (9.5 mm) sprinkler heads, arranged to discharge on the manual activation of a deluge or control valve. The systems are arranged to protect zones of approximately equal size on each deck area. The zones are overlapped so the end sprinklers on adjacent zones protect the same deck area.

Water Mist Systems

Marine water mist extinguishing systems were originally developed as a replacement for total flooding Halon 1301 systems in engine rooms. However, it was learned that they could be used as an alternative to automatic sprinklers for the protection of light-hazard accommodation and service occupancies. Because of their much lower flow rates, water mist system pipe sizes can be reduced, yielding measurable savings in cost and weight. The lesser amounts of water expelled by mist systems also benefit the overall stability of a vessel. Water mist systems require specialized strainers, components, and piping due to the very small orifices in the discharge nozzles.

Design and approval information regarding water mist systems intended for the protection of accommodation and service areas is contained in IMO Resolution A.800 (19), adopted in November 1995. This guide includes component testing information for water mist nozzles that is based on UL standard 199. It also contains four different fire test protocols using stateroom, corridor, public space, and shopping and storage area fuel packages. The tests are conducted in mock-up full-scale rooms that are considered representative of shipboard hazards. The acceptance criteria are based on maximum ceiling temperatures or a combination of maximum temperatures and damage to simulated furniture placed in the test rooms. Additional information about water mist system design is contained in NFPA 750, *Standard on Water Mist Fire Protection Systems.*

Design and approval information for total flooding water mist systems for the protection of machinery spaces and pumprooms is based on IMO MSC/Circ. 1165, *Revised Guidelines for the Approval of Equivalent Water-Based Fire-Extinguishing Systems for Machinery Spaces and Cargo Pump-Rooms.* This test procedure contains three separate elements: component test standards that evaluate the suitability of the water mist nozzles for use in the marine environment, fire-extinguishing tests that confirm the nozzle's ability to extinguish a variety of fuel oil and heptane pan and spray fires, and thermal management tests that determine the nozzle's ability to cool the test enclosure to less than 212°F (100°C) no later than 5 minutes after the activation of the system. Test experience with total flooding water mist systems has shown that it is not currently possible to positively extrapolate design parameters from a tested volume to a larger protected space; however, advances with computer modeling may allow this in the future. As a result, Coast Guard type approvals for total flooding systems are limited to installation in protected shipboard spaces with a volume no larger than that tested.

The 2000 SOLAS amendments require ships with engine rooms larger than 17,650 ft^3 (500 m^3) to have a fixed local application fire-fighting system in addition to a total flooding system. Casualty data has shown that fuel oil leaks and pressurized sprays striking heated surfaces are the leading causes of engine room fires. The requirement for a local application system is intended to provide a system capable of immediate release to cool the machinery space and limit fire damage until the engineering staff can be evacuated and the total flooding system is activated. Design and approval information for fixed local application water mist systems for the protection of high-hazard areas in machinery spaces is based on IMO MSC/Circ. 913, *Guidelines for the Approval of Fixed Water-Based Local Application Fire-Fighting Systems for Use in Category A Machinery Spaces.* Although the local application system is not intended to have the capability of extinguishing typical flammable liquid fires, its early activation can many times lead to extinguishment before the total flooding system is discharged. On ships with a total flooding water mist system, a branch of the total flooding system can be arranged with appropriate section valves to act as the local application system, provided the nozzles have successfully passed the required MSC/Circ. 913 fire testing.

Foam Systems

Foam fire-fighting systems are approved for tank vessel deck protection, machinery space boiler flat protection, and helicopter deck protection on mobile offshore drilling rigs and offshore supply vessels. Foam systems intended for marine use are required to be Coast Guard type approved as a system, because standard industrial foam system products installed on board ships may not provide effective protection. The primary concern is the tankship structure and piping systems that can be heated to temperatures significantly above the breakdown temperature of the foam blanket. The mass of steel components on ships is much greater than that typically involved with shoreside foam system applications. Thus, marine foam concentrates are tested to ensure that they provide superior breakdown resistance when in contact with hot metal surfaces, and that they continue to provide a seal adjacent to heated metal surfaces for an extended cooling period.

Another significant concern with tankship fires is the large quantities of flammable liquids available for combustion. The laboratory testing of marine foam liquid concentrates, therefore, evaluates their capability to extinguish significant, in-depth flammable liquid fires.

A third concern is the use of seawater to supply the foam system. Standard fire-fighting foams used by municipal fire de-

partments are only tested for their fire-extinguishing capability using fresh water. When they are mixed with salt water, these foam concentrates do not have equal fire-extinguishing effectiveness. The Coast Guard approval tests thus require the use of synthetic seawater.

The final concern is a foam concentrate's ability to contain reignited areas of the fuel after sections of the foam blanket have been disturbed. Coast Guard–approved foam liquids are approved by using a small-scale laboratory test derived from Federal Specification O-F-555C, which is no longer in print. The test standard currently appears in Annex F of NFPA 11, *Standard for Low-, Medium-, and High-Expansion Foam.* Breakdown of the foam on contact with heated surfaces is judged by the use of a square 10 ft by 10 ft (3 m by 3 m) steel test pan, 3 ft (0.9 m) in height. The fuel in the test pan is ignited and allowed to burn for 60 seconds before foam application is started. The fire-fighting effectiveness of the foam is evaluated by the use of 75 gal (284 L) of gasoline as the test fuel. The sealability of the foam is determined by the use of a square test pan instead of a round one, in conjunction with a torch test. The foam being tested is required to cover the entire fuel surface, including corners, in 2 minutes. It must also extinguish the test fire within 5 minutes. A burning torch is then passed over the foam blanket beginning 10 minutes after the start of foam application. The torch is eventually touched into the blanket to ensure that an effective seal remains present. The burnback resistance is determined at the end of the test by removing a 6 in. by 6 in. (152 mm by 152 mm) square section of the foam blanket and igniting the exposed fuel. The area of the burning fuel cannot increase beyond an opening measuring 20 in. by 20 in. (508 mm by 508 mm) after 5 minutes of burning.

During the laboratory fire testing, the quality of the foam is measured through a determination of its expansion ratio and its ability to retain water. The foam expansion ratio is measured by comparing the weight of a fixed volume of aerated foam to the weight of the same volume of nonaerated foam solution. Most of the foam concentrates approved for shipboard use have an expansion ratio between 6 to 1 and 12 to 1. The foam's ability to retain water is measured by determining the amount of time it takes for one-quarter of the water to drain out of an aerated foam sample. This measurement is called the foam's 25 percent drainage time.

The quality of the foam used to successfully pass the laboratory fire tests is characterized by its expansion ratio and 25 percent drainage time. The system discharge nozzles and monitors are flow tested to ensure that they produce foam that is comparable to that measured in the laboratory fire tests, thereby ensuring that the foam produced on the ship will be of the same quality. The construction of all devices used in an approved foam system must ensure that they will operate under the extreme environmental conditions likely in the marine environment. Foam system components are installed at exposed locations on deck, where they are routinely exposed to salt spray. Because of this, only corrosion-resistant materials, including stainless steel, brass, or bronze, are acceptable.

In addition to the usual petroleum products, some ships may carry chemical cargoes such as polar solvents, ethers, alcohols, and ketones. Protection of the cargo areas on these ships requires a different design approach because these types of cargoes are partially or completely miscible with water. Such cargoes require an alcohol-resistant foam concentrate capable of forming a barrier between the foam and the cargo. Significantly increased foam application rates may be necessary, depending on the fire hazard of the product. As a result, it is essential that the chemical properties and stowage locations of the cargo are known, to allow the design limitations of the system to be established. Systems may be designed either to protect against the "worst-case" product stored in any tank on the vessel or to protect specific chemicals located only in designated tanks. Because of the large amounts of foam required for "worst-case" products, designing for specific products or a group of products with similar fire-extinguishing requirements is a more typical situation. For further technical information regarding marine foam systems, see NFPA 11.

Carbon Dioxide Systems

The regulations in 46 CFR require the installation of total flooding carbon dioxide systems for the protection of machinery spaces and similar enclosed spaces where there is a possibility of a fire involving flammable or combustible liquids. Carbon dioxide extinguishing systems are also required for the protection of cargo holds whenever combustible Class A materials are carried.

For the successful use of shipboard total flooding carbon dioxide systems, it is necessary to discharge the system and then allow a "soak" time for the heated structures surrounding the space to cool below the reignition temperature of the fuel. Shipboard carbon dioxide systems are designed for a single application. After the system is discharged, there is no backup quantity of agent available. It is critical that the protected space be kept sealed until the danger of reignition is past. For machinery space systems, the discharge of carbon dioxide will likely extinguish the combustible liquid fire in a matter of minutes. However, the potential for reignition exists until all of the heated metal surfaces and other materials have cooled below the autoignition temperature of the fuel. This usually requires a waiting period of several hours after complete extinguishment before a machinery space can be reentered.

In contrast, cargo-hold extinguishing systems are designed to contain the fire until the vessel can make it to port. This is a result of the different combustion properties of solid materials versus liquids. With burning solids, the physical properties of the material and configuration of the surface can vary greatly, allowing combustion to penetrate into the core portions of the material and become a "deep-seated fire." The physical structure of the material then shields the active combustion zone from the surrounding air and causes a lower rate of heat loss. Complete extinguishment of burning Class A materials is very difficult using carbon dioxide and requires very high concentrations of agent.

Cargo-hold systems are not intended to completely extinguish a fire but to provide a reasonable degree of control. They are designed for an initial application of agent followed by periodic release of cylinders to maintain the extinguishing concentration. The system should keep the fire under control

until port is reached and extinguishment is completed by the local fire authorities. If the cargo hold is entered after the carbon dioxide is discharged, there is a serious concern that the fire could rekindle from the introduction of fresh air. There is also a significant risk to personnel attempting to enter the space. The hatches should be left secured until the vessel makes port. In cases where it appears that the fire has been extinguished by the system, the hatches should be kept sealed and regular checks of the temperature of the surrounding bulkheads made for at least 24 hours after extinguishment before reentry is attempted. Even in such cases, it is recommended that the hold not be entered until the vessel reaches port.

Marine carbon dioxide systems are designed to be self-contained. No power source on the ship is needed to discharge the system. The pressure to discharge the gas and operate the warning sirens and the interlocked ventilation and fuel shutoff equipment is provided by the internal pressure in the cylinders.

Shipboard fire-extinguishing systems are designed for a minimum concentration of 34 percent carbon dioxide by volume. A carbon dioxide concentration of 6 to 7 percent is considered the maximum level that humans can be exposed to without harmful effects. Because the quantity of carbon dioxide required for fire-extinguishing systems is well above that which can cause serious injury or death to humans, spaces that are protected by such systems must be evacuated before the extinguishing agent is released. Careful attention must also be paid to areas where carbon dioxide could be inadvertently discharged. Specific safety precautions must be followed whenever carbon dioxide systems are being inspected or serviced. The 2005 edition of NFPA 12, *Standard on Carbon Dioxide Extinguishing Systems,* requires that manually operated total flooding systems installed for the protection of normally occupied engine rooms must have a system lockout valve, a pneumatic time delay with pneumatic predischarge warning sirens, and two independent manual release controls.

The Coast Guard approves both high- and low-pressure total flooding carbon dioxide systems. Low-pressure systems are usually specified where a large quantity of extinguishing agent is needed. The decision to install a high-pressure system or a low-pressure system is generally made on an economic basis.

Two types of system releasing arrangements are approved. A manually released configuration is used on the majority of systems and heat detectors are used to automatically release small systems. Coast Guard regulations permit automatically released carbon dioxide systems only for the protection of unoccupied spaces that are less than 6000 ft^3 (170 m^3) and have a suitable means of horizontal escape.

All manually released systems must be located in a protected storage room outside of the protected space. This requirement ensures that the equipment is not damaged by the fire and that if the remote releasing controls are inoperable, crewmembers can still access the carbon dioxide storage room and discharge the system by using the local manual controls. Automatically released systems that protect unoccupied spaces that are less than 6000 ft^3 (170 m^3) may be located inside the protected space. Additional information on the design of carbon dioxide systems can be found in NFPA 12.

Clean Agent Systems

The Coast Guard regulations specify that machinery spaces and pumprooms must be protected by gaseous-type fire-extinguishing systems. Traditionally, total flooding carbon dioxide systems have been used for this purpose. In the 1970s, the use of Halon 1301 systems became common because of concerns with the accidental discharge of carbon dioxide in occupied areas. Later, unease over the global warming potential of fluorocarbons led to the Montreal Protocol of 1987, which placed functional limits on the use of Halon 1301 as a fire-extinguishing agent. Because of the deterioration of the earth's ozone layer, the use of Halon 1301 in total flooding systems was effectively banned. It is specifically prohibited in SOLAS. As a result, new types of environmentally friendly halogenated and inert gas fire-extinguishing agents were developed. Although these agents are considered safe for use in occupied areas, their chemical properties require that they be used within defined safety parameters.

The U.S. Environmental Protection Agency is responsible for regulating the use of substances that are harmful to the environment. In 1994, new regulations were issued to establish the Significant New Alternatives Policy (SNAP) program. This program is intended to identify acceptable alternatives to known ozone-depleting substances that do not have adverse affects on human health or the environment. FM-200, FE-241, NOVEC 1230, and Inergen are SNAP-approved alternatives to Halon 1301 that are used in Coast Guard–approved systems. NFPA 2001, *Standard on Clean Agent Fire Extinguishing Systems,* provides detailed information on the design of these systems.

FIRE DETECTION SYSTEMS

Marine fire detection systems are Coast Guard approved to the criteria listed in 46 CFR 161.002. Basically, shipboard detection systems are identical to those used in buildings, except that the circuit boards, wiring, and connectors are designed to handle the corrosion and vibration common to shipboard installations. Fire alarm control panels are tested to typical industry standards such as UL 864, and the panels must undergo supplemental testing for exposure to increased levels of humidity and vibration. The control panels must also be shown to function properly when inclined. Coast Guard approved detection systems have specific circuit testing and power transfer features that differ from those found on standard panels. Coast Guard approval is granted for complete detection systems; the mixing of components between different approved systems is not permitted.

Initiating devices used for detection systems include heat, smoke and flame detectors, and manual pull stations. Notification appliances can be either audible or visual. The Coast Guard has no particular approval tests for these devices and relies instead on independent laboratory approval and listing. The vessel regulations specify which type of device is to be installed for the protection of specific hazards.

Fire detection systems on large passenger vessels are complex due to the large number of detection devices required throughout the ship. Typical systems monitor several thousand

devices. The fire alarm control panels are usually located on the navigating bridge or in a continuously attended fire control station. It is typical for these systems to be designed with a presignal feature that allows the crew to investigate the fire before an evacuation signal is given. This arrangement is preferred because the evacuation procedures on passenger ships require careful coordination of the crew members to channel passengers to the correct embarkation stations and survival craft. The time delay between notification of the crew and sounding of the general evacuation alarm enables the crew to assemble and make necessary preparations. However, a series of casualties in the 1990s revealed that immediately evacuating passengers from the fire-affected area while the crew investigates may be advantageous.[8] Many of the major cruise lines have since voluntarily decided to supplement the required SOLAS fire alarm system with spot-type smoke detectors that give immediate occupant notification in the local area.

LIFE SAFETY CONSIDERATIONS

The following discussion focuses on the means of egress requirements for large passenger ships. The means of egress requirements for smaller passenger ships (Subchapter T and K), cargo ships, and tankers are much less complex. The individual vessel regulations should be consulted for more information on these type ships.

Means of Egress

The means of egress from occupied shipboard spaces is based on many of the fundamental principles inherent in NFPA *101,* with a number of characteristic differences relating to the design and operation of ships. All ships are required to be designed with two means of egress from occupied areas. However, the arrangement of the means of egress, the components of the means of egress, and the evacuation procedures used in an emergency can vary significantly. Cruise ships usually carry passengers with a broader diversity of physical abilities, cognitive skills, and languages than are found in most buildings, which may cause confusion and delays during an evacuation. However, trained crew members are always present to respond to emergencies and assist the occupants. The trained crew has the potential to rapidly suppress the fire, limiting its effect on the passengers. The crew can also assist in speeding the evacuation by taking control of the situation and directing the passengers to the correct exits. The use of a directed evacuation eliminates many of the human behavioral delays associated with the public response to an unanticipated fire emergency.

The exit system on ships is not designed to move passengers to the public way, since the water surrounding the ship is not considered a safe refuge area. The occupants are, instead, directed to refuge areas called *assembly stations.* (These areas are also referred to as muster stations on some ships.) The assembly stations are adjacent to or near the location where the survival craft are boarded. If a fire occurs that requires a general evacuation, the passengers are first moved to the protected assembly stations while the crew fights the fire. The ship is evacuated only if it is likely to sink.

General Life Safety Requirements. The goals and objectives for occupant life safety on ships are similar to those in buildings, namely, the construction features must be arranged to provide two safe escape routes for the passengers and crew, the escape routes must be maintained in a safe condition clear of obstacles, and additional aids must be provided to clearly identify and illuminate the escape paths. Two means of egress must be available from all areas, and they must be separated to the extent necessary that a single fire will not block both paths. On passenger ships, however, there are additional considerations not relevant to building construction. For example, the bulkheads and decks below the waterline must be watertight to limit the possible extent of flooding during an accident. Any openings in these watertight bulkheads are fitted with heavy steel watertight doors, which are either power operated or manually secured by multiple latching dogs. In Figure 21.10.11, which shows a typical watertight sliding door installation, the door is on the left of the doorway and the hydraulic mechanism and its operating lever for closing and opening the door are located on the right side of the doorway. Watertight doors cannot always be opened in a reasonable time period. The regulations thus specify that one of the means of egress must be independent of watertight doors to prevent unnecessary delays in evacuation times.

Means of Egress Components. Shipboard means of egress components are similar to those in buildings. Doors, ramps, and stairs commonly provided are similar to their land-based counterparts. However, because of space limitations on ships, the effective width of the components is usually less than that permitted by NFPA *101*. Another design consideration is the prospect that the ship could list or roll to one side, which would seriously impair the occupants' ability to rapidly traverse corridors and stairways. SOLAS thus requires stairways intended for use by more than 90 occupants to be situated in a fore and aft direction. In this configuration, the stair treads are parallel to the width of the ship. If the ship lists to one side, the angle of inclination of the stair remains fixed. Fire doors are also designed to close against a 3.5 degree opposing angle for the same reason.

Arrangement of Means of Egress. The stairways on ships are not required to be remotely located based on a diagonal dimension criterion, similar to NFPA *101*. This sort of requirement is

FIGURE 21.10.11 Typical Watertight Sliding Door Installation

not practical to implement on ships due to their horizontal arrangement and varying deck areas. Because the decks on a ship are usually not the same length, the stairways may not serve all areas on each deck. It is common to have a vessel design where some of the stairways end before they reach the level of the assembly stations. In such cases, horizontal means of egress are provided to allow the occupants to access an adjacent stairway to continue toward the assembly stations.

Measurement of Travel Distance. SOLAS requires large passenger ships to be divided into fire areas by the installation of 1-hour-rated main vertical zone bulkheads every 131 ft (40 m). Each main vertical zone is required to have two means of egress, which essentially limits the maximum travel distance to an exit. The requirement for main vertical zones is applicable to all areas on the ship, notwithstanding the type of occupancy. The vessel regulations, therefore, do not contain provisions for maximum travel distances.

Discharge from Exits. The exit discharge provisions on passenger ships are significantly different from those required for buildings. Emergency response procedures do not call for an immediate evacuation. Ships operate at sea, where the ship and its survival craft are the only buoyant platforms available for the safe refuge of the occupants. The ship is designed to safely and comfortably transport the passengers and crew in almost any weather or sea state. The survival craft are a last recourse for the occupants, if the sinking of the ship is imminent. Consequently, if a fire occurs, the occupants are initially marshaled to areas of safe refuge on the ship. The assembly stations may be near the survival craft or in large public restaurants or theaters. The direction of travel from the assembly stations to the survival craft could ultimately be different from the direction of travel the passengers originally followed to reach the assembly areas. The structural fire protection features and installed fire detection and suppression systems are designed to allow the crew to control the fire, making evacuation unnecessary except in extreme situations.

Emergency Lighting

Passenger ships are fitted with emergency lighting systems to illuminate the egress paths along the normal corridors and stairways to the assembly stations and survival craft areas. In addition, emergency lighting is provided to illuminate the survival craft boarding areas and the sides of the ship, including the water below. This is different from emergency lighting in typical buildings. Most building codes do not require illumination of the public way, only the egress paths leading to the public way. Additional emergency lighting is needed on ships to coordinate the launching of the survival craft and, if necessary, the rescue of persons who may have fallen or jumped into the water. The regulations also call for a specialized emergency lighting and exit marking system throughout the accommodation areas. Low-location lighting, using either electrical or photoluminescent strips installed no more than 1 ft (0.3 m) above the deck, is provided to help direct the occupants to the assembly stations. This additional level of emergency lighting is intended to supplement the overhead lighting during a power failure and also allows the occupants to more readily recognize the location of the exits if the corridors become smoke-filled.

IMO has recognized a new development in evacuation guidance systems that uses sound signals to identify evacuation routes. Although the low-location lighting is required to be mounted close to the deck, there is the possibility that smoke obscuration could reduce its effectiveness. The directional sound guidance system consists of strategically placed speakers that produce a broadband sound pattern optimized to allow the occupants to distinguish the direction of exit travel despite visibility. Performance standards for such systems have been developed and are listed in IMO MSC/Circ. 1168, *Interim Guidelines for the Testing, Approval and Maintenance of Evacuation Guidance Systems Used as an Alternative to Low-Location Lighting Systems.* Systems that successfully pass the testing criteria may be substituted for the required low-location lighting system.

Evacuation of Large Passenger Ferries

Passenger ferries have particular stability concerns attributable to the design of their vehicle carrying decks. The vehicle decks on ferries are usually large open spaces, without the benefit of main vertical zones or other means of subdivision. Past casualty experience has shown that an accident that causes flooding of the vehicle decks may cause the ship to capsize or sink much more rapidly than is the case in a standard passenger ship.[9] To offset this, SOLAS requires that the evacuation routes of all roll-on/roll-off passenger vessels built on or after July 1, 1999, be evaluated by an evacuation analysis during the design process. Typical ferry-loading operations have the passengers drive their vehicles on board and park in the designated lanes. The passengers then leave their vehicles and proceed to the accommodation or waiting areas of the ship for the duration of the voyage.

Depending on the duration of the trip, the passengers may wait in large public waiting areas, or, if the voyage is overnight, the passengers may be assigned to individual cabins. The evacuation analysis is intended to identify possible areas where congestion could slow the escape process. The analysis is also used to evaluate the flexibility of the egress design by simulating the blockage of one of the two required escape paths. Similar evacuation analysis requirements will be applied to all passenger ships in the future.

PERFORMANCE-BASED DESIGN

CFR and SOLAS fire protection regulations contain prescriptive requirements based on many years of practical operating knowledge, combined with lessons learned from marine casualty investigations. The regulations address typical ship designs and the expected fire risks on standard cargo, passenger, and tankships. The shipbuilding industry is continually developing novel and unique ship designs to carry different cargoes, to carry cargoes more economically, or to provide passengers with more luxury and entertainment options. Unconventional ship designs must be fit into these few basic regulatory categories. Unfortunately, the regulations offer no mechanism to determine

if the prescriptive level of fire protection required is adequate or overly excessive for the particular arrangement.

A positive step in the advancement of alternative ship design and arrangements was taken by IMO in the 2000 revision of SOLAS. A new regulation was included that allows the use of fire safety engineering to show that alternative design and arrangements offer an equivalent level of safety as the prescriptive regulations. This new regulation allows ship designers to use industry-accepted fire safety engineering principles such as the *SFPE Engineering Guide to Performance-Based Fire Protection Analysis and Design of Buildings* and comparable guides for this purpose.

There is one major point in the application of this concept that differs significantly from land-based projects. If a building is approved using a performance-based design approach, it does not need to be reevaluated by the AHJ unless it changes occupancy. The SOLAS Convention permits ships open access to ports around the world, because all signatory countries are obligated to accept a SOLAS safety certificate as evidence of a ship's compliance with the convention. If the port state was not a participant in the review of the alternative design concept for a particular ship, compliance to the prescriptive regulations may be expected and the ship could be denied entry. To remedy this, IMO has issued guidelines that describe the necessary steps that should be followed to approve an alternative design. The guidelines also include suggested levels of documentation to carry on board the ship at all times for the use of port state inspectors.

EMERGENCY RESPONSE TO SHIP FIRES

Fires on board ships present a number of unique circumstances that must be carefully considered before a fire department reacts to a marine emergency. Fire departments in port cities must respond to ship fires, yet they may have limited experience in the differences between building fires and ship fires. Careful preincident planning of the roads and water supplies to the port, the vessels using the port, and the expected cargoes being handled is essential to ensuring an effective response.

Comprehensive training, operational information, and guidance for shoreside responders to shipboard fires are contained in NFPA 1405, *Guide for Land-Based Fire Fighters Who Respond to Marine Vessel Fires.* Despite the information the standard provides, many shoreside fire fighters are ill prepared for the complexity of fighting a shipboard fire, as found in the accident investigation of the tankship *Seal Island,* which occurred in the U.S. Virgin Islands on October 8, 1994.[10] Ships' decks and main bulkheads are steel, retain the heat of combustion for a long period of time, and can make locating the fire more difficult; spaces and access are more restricted than is the case in buildings, thus making fire fighting and retreating confusing; and the accumulation of water on decks can worsen the situation.

Most importantly, the command structure for fighting a shipboard fire is not always understood. At sea, only the crew is available to respond to fire emergencies; in port, shoreside fire fighters are likely to be called by the Coast Guard.

One readily available piece of information critical for fire fighting is located aboard the ship. All U.S. vessels of 1000 gross tons and over and all vessels subject to SOLAS must permanently display a fire-fighting plan or fire control plan of the ship. Although the plan's primary purpose is to guide shipboard personnel, it should contain the following information to assist port fire-fighting groups:

- Fire control stations for each deck
- Sections enclosed by fire-resistive divisions
- Fire alarms, detection systems, and sprinkler systems
- Fire-extinguishing appliances
- Access to different compartments, decks, and so on
- Ventilating systems, including master fan controls, positions of dampers, location of remote controls, and identification numbers of ventilating fans serving each section

Instead of being posted on a plan, the information listed can be described in a fire-fighting booklet. The booklet is required to be aboard ship at all times. Whether posted as a fire-fighting plan or presented in booklet form, information should be available on all watertight compartments, openings therein, and means of closure, controls, and arrangements for correcting any list due to flooding.

SOLAS '74 requires that a duplicate set of fire control plans be permanently stowed in a prominently marked, weathertight enclosure outside the deckhouse to assist shoreside fire-fighting personnel. Figure 21.10.12 illustrates a fire-fighting plan for the aft end of a super tanker.

The international community has also agreed on standard symbols for fire control plans (Figure 21.10.13). Most symbols are to be shown in red on the general arrangement plan to highlight their location for shipboard and shoreside fire fighters.

NFPA MARINE STANDARDS

In 1994, the U.S. Coast Guard and the marine community embarked on an ambitious project to shift development and maintenance of fire protection regulations applicable to U.S. flagged commercial ships to consensus standards-making organizations. The cornerstone of this effort is NFPA 301, *Code for Safety to Life from Fire on Merchant Vessels,* a "life safety code" for ships. Additionally, chapters on marine application have been added to NFPA 11, NFPA 12, NFPA 13, NFPA 750, and NFPA 2001.

Other NFPA standards relating to marine vessels are contained in NFPA 306; see also NFPA 312, *Standard for Fire Protection of Vessels During Construction, Conversion, Repair, and Lay-Up.* NFPA 306 describes the conditions necessary for safety before repairing any vessel carrying or having carried fuel as cargo, combustible or flammable liquids, flammable compressed gases, and bulk chemicals. NFPA 306 is also the basis for confined space safety in the maritime industry and must be followed by the NFPA-certificated marine chemist. It also contains a section on flammable cryogenic liquid carriers. NFPA 312 covers measures for preventing and controlling fires on vessels in the building or repair yard or on vessels that are laid up. Provisions for each circumstance appear separately in the standard.

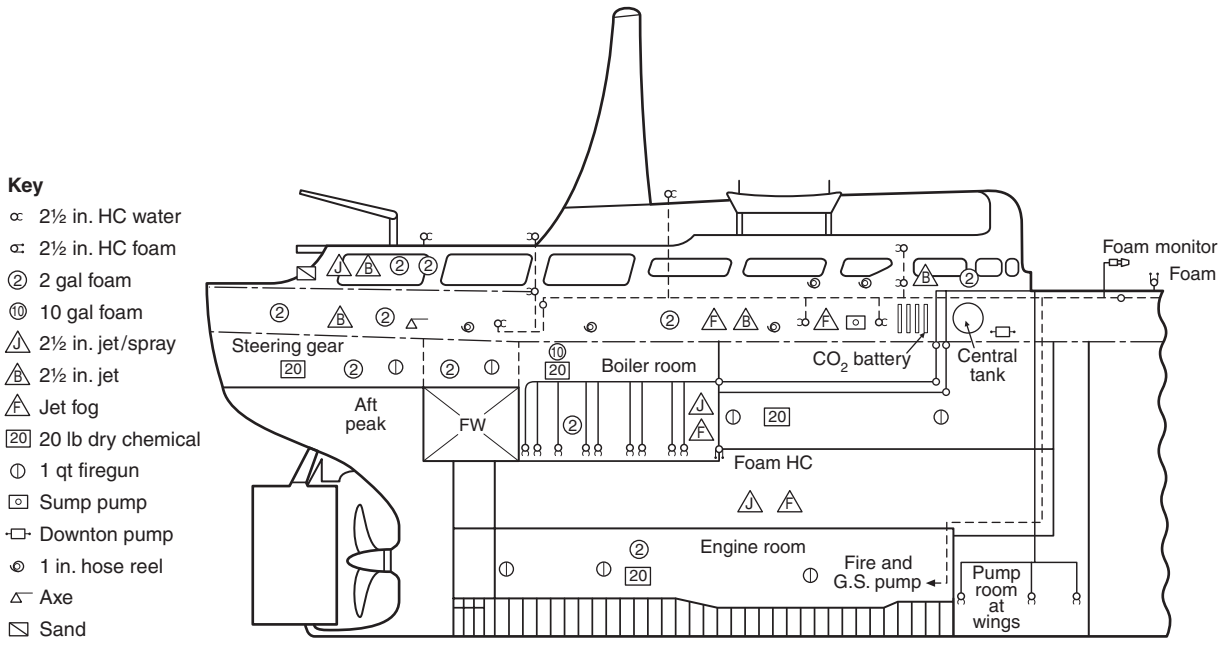

FIGURE 21.10.12 Fire-Fighting Plans for the Aft End of a Super Tanker

OTHER ORGANIZATIONS CONTRIBUTING TO MARINE FIRE SAFETY

American Bureau of Shipping

The American Bureau of Shipping (ABS) is the American classification society whose technical committees develop rules for the dimensions and use of materials in the construction and conversion of marine vessels. After a vessel is completed according to the rules and under the constant supervision of an ABS field inspector, the bureau classes and lists it as having met all design and structural safety requirements.

American Petroleum Institute

In the area of marine fire fighting and fire protection, the American Petroleum Institute (API) is active in developing domestic and international standards, codes, and regulations. Under the policy direction of the API Central Committee on Transportation by Water, most actions are directed by the API Committee on Tank Vessels. Ad hoc groups are sometimes formed for special studies of a nonrepetitive nature.

Marine Chemist Association, Inc.

Established in May 1938 as the Marine Chemists' Subsection of the NFPA Marine Section, the Marine Chemists organized its present association in 1948 after the Marine Section disbanded. This professional organization of chemists is certificated for marine work by NFPA in accordance with provisions of NFPA 306.

National Cargo Bureau, Inc.

The National Cargo Bureau is a nationwide, nonprofit membership organization established in 1952 as a private, nongovernmental agency that formulates recommendations to various governments for regulating the safe stowage of dangerous goods and other cargoes and for regulating related cargo-handling gear.

National Transportation Safety Board

The National Transportation Safety Board (NTSB) is an independent federal agency dedicated to promoting aviation, marine, railroad, highway, pipeline, and hazardous materials safety. Established in 1967, the agency is mandated by Congress through the Independent Safety Board Act of 1974 to investigate transportation accidents, including those involving fire, explosion, and pollution; determine the probable cause of accidents; issue safety recommendations; study transportation safety issues; and evaluate the safety effectiveness of government agencies involved in transportation. The Safety Board makes public its actions and decisions through accident reports, safety studies, special investigation reports, safety recommendations, and statistical reviews.

USCG Advisory Committee on Hazardous Materials

This committee of the National Academy of Sciences, National Research Council, is charged with advising the U.S. Coast Guard on scientific and technical matters relating to safe maritime transportation of hazardous materials.

FIGURE 21.10.13 Continued

SUMMARY

Fires and explosions are frequent contributors to marine vessel injuries and fatalities. In pleasure and small commercial boats, gasoline is commonly used for both propulsion engines and onboard generators, and liquefied petroleum gas (LP-gas) is commonly used for cooking. Boats are constructed in such a way that they are closed on the bottom and on all sides, resulting in less effective ventilation than found in other types of vehicles such as trains and aircraft. Means of fire protection include leak-free fuel systems, ventilating systems, unobstructed areas and escape hatches, fire-retardant coatings for flammable materials, lightning protection, proper installation of electrical systems, and fire extinguishers. Safety procedures include thorough maintenance, inspection, and testing, careful fueling operations, and proper storage of the boat when not in use.

Fire protection regulations for commercial ships and offshore marine vessels are covered by the *Code of Federal Regulations* (CFR) and, for international voyages, the International Convention for the Safety of Life at Sea (SOLAS). The regulations are specific to different types of vessels, such as passenger ships, cargo vessels, and supply vessels. Marine fire protection considerations include construction materials and design, fire-extinguishing and fire detection systems, and evacuation. Fire hazards should be analyzed and controlled in the three major occupancies common to all ships: the engine room, the cargo holds or tanks, and the accommodation and service areas. Fire prevention measures include limiting the use of combustible construction materials and the safe handling and use of combustible materials, flammable liquids, and ignition sources.

This chapter addresses the unique fire protection and life safety considerations and challenges posed by road tunnels and road bridges. A road tunnel is defined as any enclosed facility through which road vehicles (cars, vans, buses, and trucks) travel. These vehicles are typically powered by internal combustion engines using traditional fuels such as gasoline and diesel. However, in recent years vehicles powered by alternative fuels such as CNG, LP-gas, LNG, or one of the blends of gasoline and feedstock fuel such as ethanol are becoming prevalent in the vehicle fleet.[1]

Road tunnels are usually constructed to overcome an obstacle, such as a mountain or a body of water. However, several new road tunnels result from the developmental benefits of the real estate created by putting roadways below the surface and developing the air rights above. Road tunnels are therefore typically catagorized, based on the obstacle encountered, as follows: mountain tunnel, subaqueous (underwater) tunnel, urban tunnel, or air-rights tunnel.

Fire protection for road tunnels requires a unique application of common fire protection, fire fighting, and fire suppression systems and techniques. The fire load in a tunnel is continuously changing and is basically unpredictable. The potential always exists, however, for fires to occur that are of significant scale in comparison to most commercial structures. Also, unlike commercial or industrial buildings and facilities, road tunnels do not offer any compartmentalization, making evacuation and rescue far more difficult. The entire population to be rescued will most likely be in the same "compartment" as the fire, and because a tunnel is essentially a linear structure, the fire must be fought from a position in the same compartment. This chapter addresses the unique aspects of road tunnel fire protection and explores the application of standard fire protection, fire suppression, and fire-fighting system practices and techniques to road tunnels.

Similar to road tunnels, bridges designed to carry vehicle traffic offer very limited access to emergency responders and can therefore pose unique challenges in the ability to ensure motorist life safety protection in the case of a fire. This chapter addresses the fire protection considerations for bridges built to transport road vehicles over another road, a railroad, a waterway, or a valley.

For related topics, see Section 12, Chapter 15, "Public Emergency Services Alarm, Dispatch, and Communications Systems"; and Section 16, Chapter 8, "Water Mist Fire Suppression Systems."

ROAD TUNNELS

History of Road Tunnel Fires

There are more than 150 road tunnels in the United States and several thousand more throughout the world. Table 21.11.1 lists some of the major operating U.S. road tunnels and their categories, length, and ventilation systems.

There have been over 30 reported serious road tunnel fires since the first one occurred over 60 years ago in New York's Holland Tunnel in 1949.[2] Serious road tunnel fires are those in which there

Arthur G. Bendelius, P.E., is president and principal consultant at A&G Consultants, Inc. He has served as a senior vice-president and technical director at Parsons Brinckerhoff. His technical expertise is in tunnel services, primarily in tunnel ventilation and fire protection systems. He has served as chair of the Technical Committee for NFPA 502, *Standard for Road Tunnels, Bridges, and Other Limited Access Highways,* and currently serves as animateur of World Road Association (PIARC) Working Group's "Ventilation Fire and Smoke Control in Road Tunnels."

*A combined road/rail tunnel.

has been loss of life or significant property damage to either vehicles or tunnel structure. Table 21.11.2 lists selected road tunnel fires involving either loss of life, damage to vehicles, or damage to a significant portion of the tunnel, beginning with the 1949 Holland Tunnel fire.[2] In 1999 and 2001 several extremely serious road tunnel fires occurred. Three of these occurred in long single-bore, bidirectional trafficked, Alpine tunnels. (As illustrated in Figure 21.11.1, a bore is defined as a longitudinal compartment of a tunnel, either in a separate structure or in a single structure divided by a solid wall or rock.) The first of these Alpine tunnel fires occurred in the Mont Blanc Tunnel between France and Italy on March 24, 1999,[3,4] the second occurred in the Austrian Tauern Tunnel on May 29, 1999,[4] and the third occurred in the Swiss St. Gotthard Tunnel in October 2001.[4] Details of these three serious road tunnel fires are shown in Table 21.11.3.

Unknown Fire Loads

One of the major factors to be considered in the fire protection of a road tunnel is the unknown nature of the potential fire load. In other transportation tunnels, such as transit tunnels, the potential fire load can be estimated with reasonable accuracy, since both the vehicles and the passenger load are controlled by the operating agency. Such is not the case for the typical road tunnel, where an innocent-looking truck may be carrying a load that is capable of supporting a fast-growing, potentially lethal fire, but that is not necessarily "classified" as hazardous cargo.

Frejus	2005	Glue

A good example is the primary cargo—margarine and flour—in the incident truck involved in the Mont Blanc fire in 1999. Table 21.11.4 contains a list of the materials carried by the incident vehicle for many of the tunnel fires shown in Table 21.11.2.

Global Guidelines and Standards

Guidelines and standards for road tunnel fire protection have been published worldwide by both international organizations and individual countries. Both the National Fire Protection Association (NFPA) and the World Road Association (PIARC) publish standards and guidelines on road tunnel fire protection. Table 21.11.5 provides a sample list of some of the more pertinent global guidelines and standards.

Three NFPA standards address the fire protection requirements for the underground environment: NFPA 130, *Standard for Fixed Guideway Transit and Passenger Rail Systems;* NFPA 502, *Standard for Road Tunnels, Bridges, and Other Limited Access Highways;* and NFPA 520, *Standard on Subterranean Spaces.* The definitive standard for road tunnels is NFPA 502. Although the other two standards contain material that may be applicable to road tunnels, the NFPA Technical Committee on Road Tunnels and Highway Fire Protection has reviewed all of the material contained in these two documents and has applied what was determined to be truly pertinent and included references where appropriate. Elements of several other NFPA codes and standards may be applied to fire protection systems within road tunnels; these codes and standards are appropriately referenced in NFPA 502 and also appear at the end of this chapter. The fire protection requirements prescribed by NFPA Standard 502 are graphically displayed in Table 21.11.6. These prescribed fire protection requirements vary based on tunnel length. PIARC has published a number of documents particularly in the technical area of ventilation and fire and smoke control. The most important document is *Fire and Smoke Control* published in 1999.[5]

KEY ELEMENTS OF ROAD TUNNEL FIRE PROTECTION

The following are the primary objectives of road tunnel fire protection:

- Permit and encourage escape and evacuation of all motorists (i.e., motor vehicle occupants including the driver and passengers) from the tunnel
- Facilitate the entrance of fire-fighting personnel into the tunnel to combat the fire
- Protect the tunnel structure and facilities

Tunnel Categories. For the purpose of the 2008 edition of NFPA 502, tunnel length shall dictate the minimum fire protection requirements, as follows:

X—Where tunnel length is less than 300 ft (90 m), the provisions of this standard shall not apply.

A—Where tunnel length is 300 ft (90 m) or greater, standpipe systems and traffic control systems shall be installed in accordance with the requirements of Chapter 9 and Section 7.6, respectively, in NFPA 502.

B—Where tunnel length equals or exceeds 800 ft (240 m) and where the maximum distance from any point within the tunnel to a point of safety exceeds 400 ft (120 m), all provisions of this standard shall apply.

C—Where the tunnel length equals or exceeds 1000 ft (300 m), all provisions of this standard shall apply unless noted otherwise in this document.

D—Where the tunnel length equals or exceeds 3280 ft (1000 m), all provisions of this standard shall apply.

Source: Adapted from NFPA 502, *Standard for Road Tunnels, Bridges, and Other Limited Access Highways,* 2008 edition, Table 7.2, p. 502-10.

An effective road tunnel fire protection system program must contain the following elements:

- Fire identification, verification, and detection
- Emergency communications
- Smoke management
- Fire suppression
- Emergency response planning
- Evacuation and rescue

Traffic control, which is another element in an effective road tunnel fire protection system program, is not addressed in this chapter.

A road tunnel's fire protection system must be able to readily identify, verify, and locate a fire anywhere within the tunnel. Determining the location of the fire is critical to safe evacuation, since the success of many companion fire and life safety systems such as smoke control (ventilation) depend on knowing where the fire is within the tunnel to permit the appropriate operational response.

The mission during the initial phase of a tunnel fire-based emergency is to establish safe evacuation and rescue options for those persons within the tunnel. Safe evacuation and rescue requires the establishment of a tenable environment for the entire evacuation path. If the fire incident occurs relatively near one of the tunnel portals, the path to the portal may be the shortest route to a safe area. When the fire incident occurs deeper into the tunnel, the evacuation path will be through an emergency stairway to the surface or a cross passage to a parallel bore (Figure 21.11.2). The entrance to a typical cross passage to a parallel tunnel bore is shown in Figure 21.11.3. The tenable environment in the evacuation path is typically created by the operation of a smoke control or ventilation system. When all of the motorists in the tunnel have been either evacuated or rescued, the responding fire department must proceed with the necessary efforts to extinguish the fire.

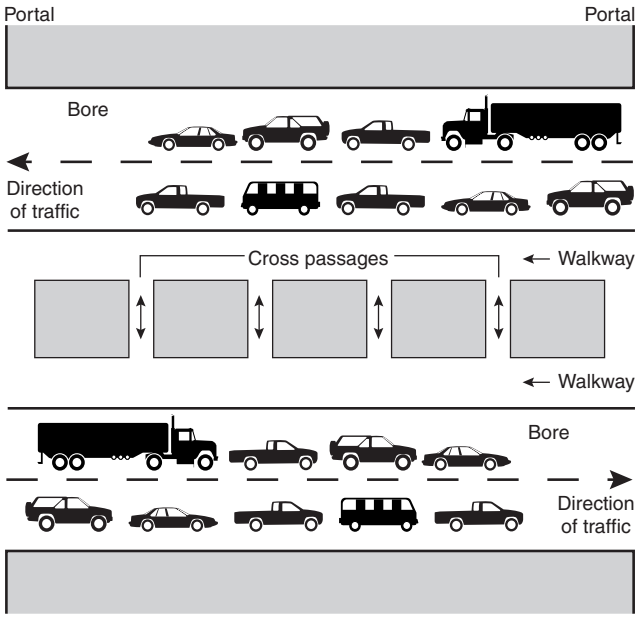

FIGURE 21.11.2 Cross Passages Leading to a Parallel Tunnel Bore

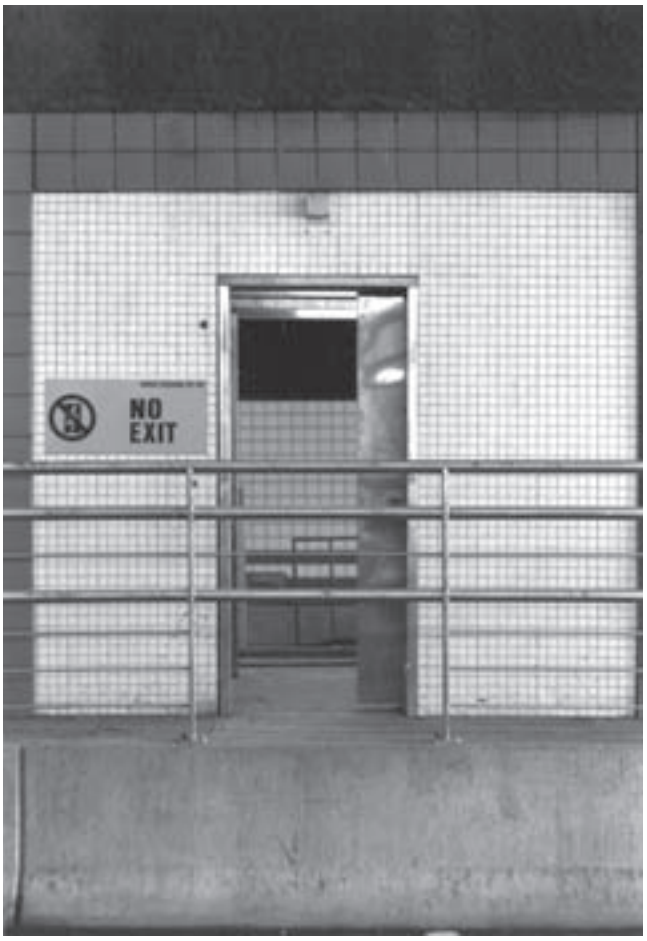

FIGURE 21.11.3 Typical Cross Passage Entrance

IDENTIFICATION, VERIFICATION, AND LOCATION OF FIRES

As previously stated, quick response is critical to the effective management of a fire emergency in a road tunnel. Once a fire has been detected and its location verified, it may take several minutes to fully initiate all necessary emergency response systems and procedures. Therefore, a reliable means to identify, verify, and locate a fire incident is required by NFPA 502 in all road tunnels over 1000 ft (300 m). There are several practical methods considered acceptable within NFPA 502 as a reliable means to identify, verify, and locate a fire within a road tunnel.

Visual Identification

Closed circuit television (CCTV), although not a listed fire detection device, has proven to be one of the most effective means for identifying and verifying a fire within a road tunnel. NFPA

502 considers CCTV monitoring an acceptable means of fire detection if the tunnel is fully monitored by dedicated staff on a 24 hour basis.

Manual Detection

Pull Box. The manual pull-box alarm is a common device used in most building fire protection systems. In a road tunnel, the installation of a pull box provides an opportunity for motorists within the tunnel to send a manual alarm in the event of an emergency, without relying on voice communication. NFPA 502 requires manual pull-box alarms (Figure 21.11.4) to be spaced at 300 ft (90 m) intervals within a road tunnel.

Emergency Telephone. Emergency telephones, generally located adjacent to where the main pull-box alarms are installed (they are at 300 ft [90 m] spacing), provide another means for sending an alarm manually, although the noise level within the tunnel roadway may prohibit clear voice communications. A number of European road tunnel owners have installed telephone booths to combat the problem of high ambient noise. However, the concept is not universally accepted because many believe that motorists might view the enclosure as a point of safety, which is not the case, unless the booths are designed specifically as a refuge with an appropriate fire-rated enclosure and environmental control system.

FIGURE 21.11.4 Fire Alarm Pull Box

Mobile Telephone. It is becoming more and more common for road tunnels to provide capability for signal reception for the use of mobile telephones. As such, the universal popularity of mobile phones provides another manual means for motorists to report an emergency within the tunnel.

Automatic Detection

Heat detectors, flame detectors, and digital imaging systems (using CCTV) are the most applicable forms of automatic fire detection systems for road tunnels. The most prevalent type of detector used in road tunnels worldwide is the heat detector—more specifically the linear heat detector. Flame detectors are found predominantly in Japanese road tunnels. CCTVs using digital imaging are a relatively new technology compared to linear heat detectors.

Linear Heat Detectors. Linear heat detectors are designed to sense an increase in temperature anywhere along the detector's length, to send a signal to a control center, and with this signal to identify the specific location of the alarm site within the tunnel. They are usually installed in zones (generally correlated with the ventilation zones) along the entire length of the road tunnel. The types of linear heat detectors that have been utilized in a road tunnel include the following:

- Electrical cable
- Fiber optic cable
- Thermocouple cable
- Gas-filled cable

Linear heat detectors have not yet received universal approval for application in road tunnels primarily due to their ensuing maintenance needs and their tendency to provide false and late alarms. To be effective, linear heat detectors must be installed directly above the travel lanes. Maintenance of any device mounted over the traveled roadway is always a more costly process, due to the need to close one or two lanes of traffic and use a unique maintenance vehicle with an elevating overhead platform.

Spot Heat Detectors. Spot heat detectors have been installed in a number of tunnels worldwide. However, one of the major drawbacks of spot heat detectors is the number of individual detectors necessary to locate the fire site as quickly and as precisely as possible. This required precision creates the need for a system with a number of spot detectors that may become unmanageable.

Other Detection Systems

Flame Detectors. Flame detectors were installed in over 60 tunnels in Japan beginning in the early 1960s. The early installed versions of the flame detector suffered from false alarm problems. As the products evolved in the ensuing years, flame

detectors were developed to a point where the false alarms were limited. Some of the design modifications were believed to result in more sensitive detectors and the need for fewer detectors per length of tunnel. The most recent designs allow addressing individual detectors in order to identify the fire location within 75 ft (25 m).

Digital Imaging. A recent development is the ability of CCTV systems to automatically detect a fire through digital image analysis. CCTV surveillance systems are typically installed in road tunnels; therefore, the ability of this system to automatically detect and locate a fire in a road tunnel is extremely attractive. This capability, coupled with the existing capability of the CCTV systems to automatically monitor traffic, would enhance the ability of the tunnel operator to respond to a fire in a timely fashion. However, this technology has not yet been proven in the road tunnel environment, although it continues to be tested in trial tunnel installations.

Gas Detectors. Gas detectors, primarily for detection of carbon monoxide (CO), are used in almost all road tunnels to monitor vehicle emission levels during normal tunnel operations. They have not been used for fire detection in road tunnels primarily due to the difficulty in differentiating between concentrated vehicle exhaust and the hot gases from a fire.

Smoke Alarms. Smoke alarms are designed to sense the presence of particles of combustion, either by photoelectric or by ionization sensors. These systems are not designed for outdoor application and would not perform well in a tunnel environment due to a tendency for false alarms caused by heavy diesel engine exhaust.

Visibility Detectors. Visibility measurements are conducted in some road tunnels to monitor for safe operating conditions and in a limited number of tunnels to control the ventilation system during normal operation. These units can also be utilized for detection of a fire. An alarm is triggered once the preset limit value is attained. These detectors are based on either diffused light or illumination.

Research

A study to investigate the performance of fire detection systems in road tunnels was initiated by the Fire Protection Research Foundation (FPRF) in 1999. For Phase II the FPRF has teamed with the National Research Council of Canada (NRCC) and with the Port Authority of New York and New Jersey (PANYNJ). A Technical Advisory Group consisting of fire and transportation officials, engineering firms, researchers, and system manufacturers was formed to oversee the project.

The following are the goals of this research:

- Investigate the performance attributes of current fire detection technologies for road tunnel protection
- Develop performance criteria for fire and smoke detection systems in road tunnel applications
- Optimize technical specifications and installation requirements for this application

The first phase of this project, literature review of past and current research and application of fire detection systems for road tunnels, has been completed.[6] The second phase of the research program will include the following tasks performed at the following locations:

- Laboratory tests—NRCC Fire Research Facilities
- Laboratory tunnel tests—Carleton University–NRCC Test Facility
- Computation modeling—NRCC
- Field fire tests—operating tunnel in Montreal (Viger Tunnel)
- Environmental monitoring – PANYNJ operating tunnel (Lincoln Tunnel)
- Simulated fire tests—PANYNJ operating tunnel (Lincoln Tunnel)

The benefits of this research will be a better understanding of the reliability of various types of fire detection systems and how the operational and environmental factors within a road tunnel influence their performance.

EMERGENCY COMMUNICATIONS

Emergency communications permit the operator to communicate with the motorists within the tunnels and permit emergency responders to communicate with each other during an emergency in the tunnel. Emergency communication devices should have the following features:

- Conspicuous by means of indicating lights or other suitable markers
- Identified by a readily visible number plate or other appropriate device
- Posted with suitable instructions for use by motorists

Loudspeakers

Loudspeakers are prevalent in many European road tunnels. These systems are used to alert the motorists of an emergency situation and to provide directions and guidance. The use of loudspeakers in road tunnels is not a universally accepted safety concept. There are several problems with their application to the tunnel environment, including the following:

- Hard surfaces within the tunnel roadway that make it extremely difficult to understand most announcements
- Motorists' vehicles moving
- Vehicle windows closed (due to air conditioning)
- Potential language barriers

Therefore, the use of loudspeakers within a road tunnel is not a recommended means of reliable communication for emergencies.

Radio

Radio communication systems, such as highway advisory radio (HAR) and AM/FM commercial station overrides can be an effective means to communicate an emergency to motorists and to provide them with direction.

Regardless of type, all communications and messaging systems used within road tunnels should be capable of real-time composition and selection by the emergency response authority, and should not be of the recorded type. All areas planned for use of emergency refuge or assembly should be equipped with reliable two-way voice communication with the emergency response authority.

SMOKE MANAGEMENT

In a road tunnel, smoke management requires either direct extraction at the fire site or the generation of a longitudinal velocity in the tunnel capable of transporting the smoke and heated gases in the desired direction to a point of extraction or discharge from the tunnel. Without a smoke management system, the direction and rate of movement of the smoke and heated gases will be determined by fire size, tunnel grade, prefire tunnel conditions, and external meteorological conditions.

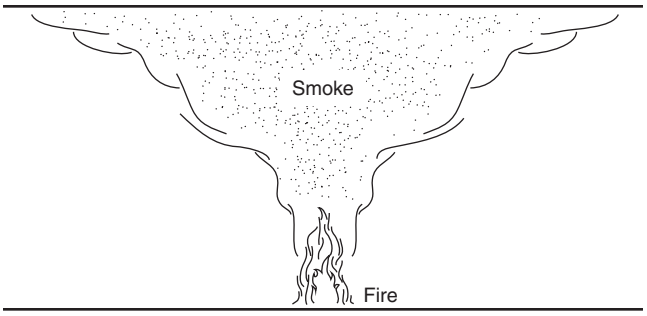
The primary purpose for controlling smoke in a tunnel is to protect life and to permit safe evacuation of the tunnel. This involves creating a safe path of egress for both motorists and any operating personnel located within the tunnel when the fire starts. The secondary purpose of smoke control ventilation is to assist fire fighters in accessing the fire site, by again providing a clear path to the fire site if possible.

The tunnel ventilation system is not specifically designed to protect property, although the effect of ventilation in diluting smoke and heated gases, thus removing some of the heat, results in reduced damage to the facilities and vehicles. The primary method of smoke management is the tunnel ventilation system, which provides the means for controlling smoke movement in the event of a fire incident. The approach used for smoke management varies depending on the type of ventilation system being used and whether the tunnel is serving unidirectional or bidirectional traffic.

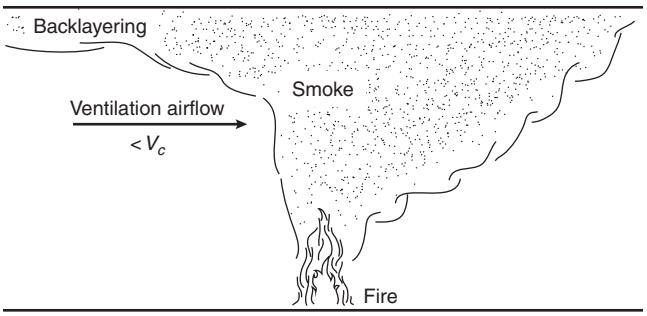
Road Tunnel Ventilation System Types

The primary purpose of tunnel ventilation systems in a tunnel fire emergency is to control and/or remove the heated gases and smoke from the egress path. In essentially all emergency cases, protection of motorists and employees is enhanced by prompt activation of emergency ventilation procedures as planned in advance. The effectiveness of an emergency ventilation system in providing a sufficient quantity of uncontaminated air and in minimizing the hazard of smoke backlayering (i.e., the movement of smoke and hot gases contrary to the direction of the ventilation airflow) in an evacuation pathway is a function of the fire load (Figure 21.11.5).

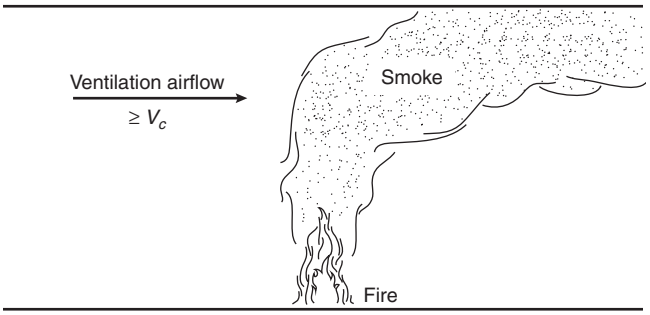
Ventilation is required in many road tunnels to limit the concentrations of vehicle-emitted contaminants to acceptable levels during normal traffic operations. The ventilation systems can also be used to control smoke and heated gases generated during a fire emergency in the tunnel. There are many short tunnels that are ventilated naturally (without fans); such tunnels, however, may still require mechanical ventilation to assist in a fire emergency.



(a) Tunnel fire. No ventilation and 0% grade



(b) Tunnel fire. Underventilated tunnel with backlayering



(c) Tunnel fire. Sufficiently ventilated tunnel to prevent backlayering

FIGURE 21.11.5 Backlayering of Smoke and Hot Gases

Natural Ventilation

Tunnels with natural ventilation only (no fans) rely chiefly on both the ambient meteorological conditions and on the piston effect generated by the moving traffic to maintain a satisfactory environment within the tunnel during normal operations (Figure 21.11.6). However, to handle a fire-based emergency within the naturally ventilated tunnel, an emergency ventilation system may be needed. NFPA 502 requires the consideration of emergency ventilation for all road tunnels over 1000 ft (300 m) in length. Given the lack of a mechanical ventilation system, the smoke and heated gases will, in the case of a tunnel without a grade (level) and without external wind, flow out of both portals. If the tunnel has a grade, the smoke will most likely flow toward the higher portal unless

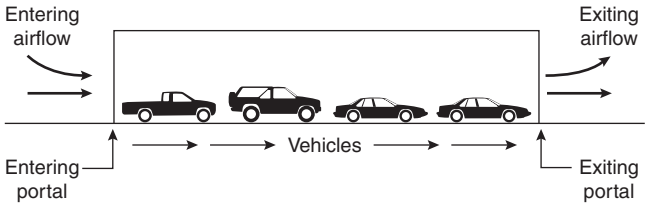


FIGURE 21.11.6 Natural Ventilation

there are abnormal meteorological conditions at the time of the incident.

Mechanical Ventilation

The systems used for mechanical, or fan-driven, ventilation can be classified as longitudinal or transverse. The longitudinal ventilation system achieves its objectives through the longitudinal flow of air within the roadway; the transverse system achieves its objectives by the uniform distribution and/or collection of air continuously throughout the length of the tunnel. The transverse ventilation system also experiences some longitudinal airflow, with the quantity dependent on the type of system.

Longitudinal Ventilation. Longitudinal ventilation is a system in which the air is introduced into or removed from the tunnel roadway at a limited number of points (such as at a portal or a shaft), thus creating a longitudinal flow of air within the roadway discharging at the exiting portal. Longitudinal ventilation systems can be further classified into those using central fans and those using local, or jet, fans.

Central fan longitudinal ventilation systems employ centrally located fans to inject air into the roadway usually through a high-velocity, or Saccardo, nozzle (Figure 21.11.7). The injection of air can take place at the entering portal or in midtunnel. Both concepts can provide the required longitudinal ventilation within the tunnel. An exhaust shaft may be combined with the injection nozzle to increase the quantity of air introduced into the tunnel. Jet fan–based longitudinal ventilation employs a series of axial fans mounted at the ceiling level of the tunnel roadway. These fans, through the effects of the high-velocity discharge thrust, induce a total longitudinal airflow through the length of the tunnel (Figure 21.11.8).

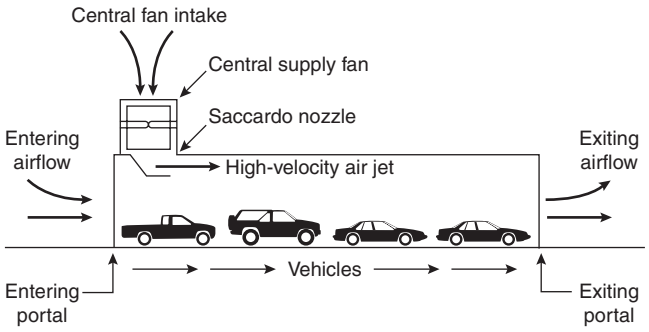

FIGURE 21.11.7 Longitudinal Ventilation with Saccardo Nozzle

Longitudinal ventilation can only be used in a unidirectional tunnel. In all longitudinal systems the smoke and heated gases (or pollutants during normal operations) will discharge from the exit portal. To achieve the required longitudinal movement of smoke, the longitudinal velocity must be sufficient to prevent backlayering of smoke over the stopped vehicles. The critical velocity must be achieved with the tunnel cross section (discussed later in the section "Engineering Analysis"). Longitudinal ventilation systems do not require a longitudinal duct with the tunnel, and systems employing jet fans do not require a ventilation building.

Transverse Ventilation. Transverse ventilation systems, which can be used in either bidirectional or unidirectional trafficked tunnels, are those that feature the uniform collection and/or distribution of air throughout the length of the tunnel. There are full transverse and semitransverse systems. In addition, there are both supply and exhaust versions of semitransverse systems.

Full transverse ventilation systems have both supply and exhaust systems throughout the length of the tunnel (Figure 21.11.9). When a full transverse system is employed, the majority of the smoke and heated gases (or pollutants during normal operations) will be discharged through a stack with a portion

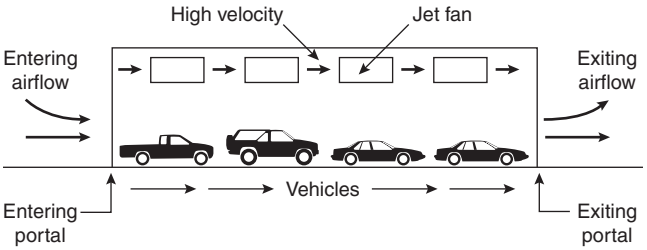

FIGURE 21.11.8 Longitudinal Ventilation with Jet Fans

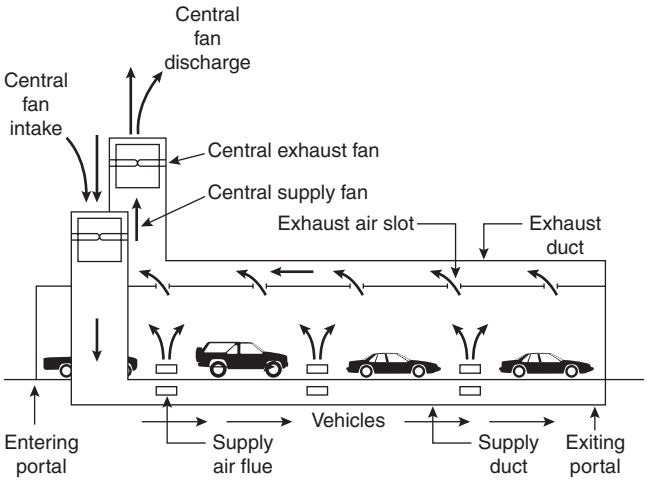

FIGURE 21.11.9 Full Transverse Ventilation

of the smoke exiting through the portals. A full transverse ventilation system can be either balanced (exhaust equals supply) or unbalanced (exhaust is greater than supply). Semitransverse systems are those that have only supply (Figure 21.11.10) or exhaust elements (Figure 21.11.11). The effluent exhaust from the tunnel is discharged at either the portals (supply system) or through ventilation stacks (exhaust system).

Smoke and heated gases from a tunnel fire can be mitigated in a tunnel outfitted with transverse ventilation in one of the following methods:

- Dilution
- Longitudinal airflow
- Extraction

Dilution was shown to be effective only up to a 20 MW fire and not effective beyond that.[7] Longitudinal airflow is an extremely effective method of controlling smoke and heated gases during a tunnel fire. Longitudinal airflow can be achieved in a multizone full transverse system by varying the operation mode between supply and exhaust for different zones.

Extraction is also an excellent method to control the smoke and heated gases within a tunnel. This concept will work with a transverse system with an overhead exhaust duct by outfitting the exhaust duct with a limited number of operable dampered openings. When a fire is identified and located, the control system can open the damper or dampers nearest the fire and extract the smoke and heated gases as close to the fire site as possible, thus removing most of the smoke. The capacity of the emergency ventilation system must be based on the design fire size selected for each specific tunnel.

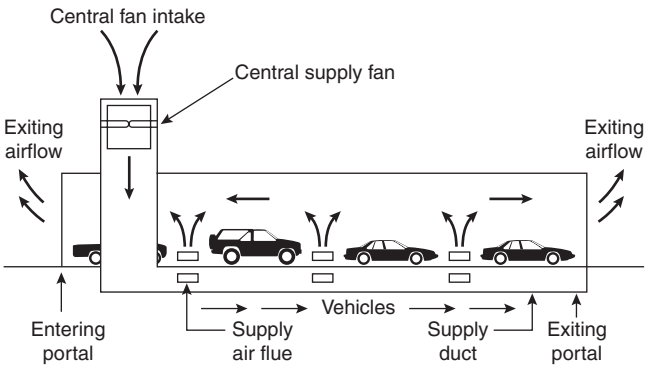

FIGURE 21.11.10 Semitransverse Supply Ventilation

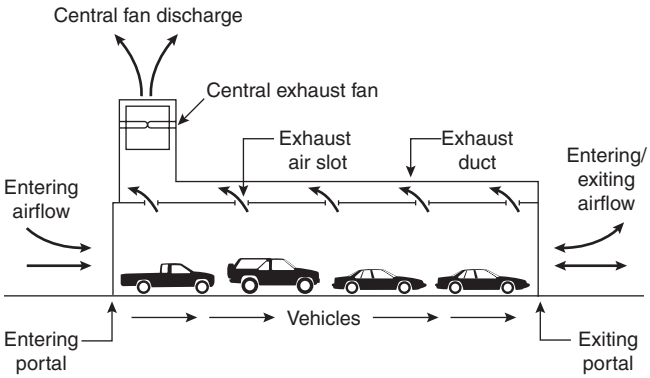

FIGURE 21.11.11 Semitransverse Exhaust Ventilation

FIRE SUPPRESSION

Portable Fire Extinguishers

NFPA 502 requires portable fire extinguishers to be located in the tunnel roadway in wall cabinets at 300 ft (90 m) spacing (Figure 21.11.12). The size and type of portable extinguishers are defined as 2-A:20-B:C and 20 lb (9 kg) as defined in NFPA 10, *Standard for Portable Fire Extinguishers.* It is prudent to install a device to provide the operator with an alarm indication that a fire extinguisher has been removed from its station. This signal could be an indication either of a fire within the tunnel or of the theft of an extinguisher (a common occurrence in some locations).

Standpipe

According to NFPA 502, a Class 1 standpipe system is required in all road tunnels over 300 ft (90 m) in length. The system should be of the wet type. However, if a wet-type system is not possible due to climatic conditions, a dry system is acceptable, provided that the system fill time is less than 10 minutes.

As specified in NFPA 502, the road tunnel standpipe system must be designed to provide support to a minimum of two fire hose streams delivering 250 gpm (16 L/sec) each. The standpipe system must be installed in accordance with NFPA 14, *Standard for the Installation of Standpipe and Hose Systems.*

Water Supply

The water supply system, whether municipal or private, should have adequate waterflow and pressure along with the required system integrity. The water supply system considered should have a minimum supply capacity of 1 hour of fire fighting as

FIGURE 21.11.12 Portable Fire Extinguisher in Cabinet

prescribed by NFPA 502 and should be configured in accordance with NFPA 14. If a storage tank is required to meet the water supply capacity, it should be installed in accordance with NFPA 22, *Standard for Water Tanks for Private Fire Protection.*

Hose Connections

According to NFPA 502, standpipe hose connections or hose valves should be installed in the road tunnel, so that no point on the protected tunnel roadway is more than 150 ft (45 m) from an active hose valve. The spacing of the standpipe hose valves should not be greater than 275 ft (85 m), and the hose connection should be equipped with 2½ in. (65 mm) external threads (see NFPA 1963, *Standard for Fire Hose Connections*). Figure 21.11.13 illustrates a diagram of a typical hose valve installation in a cabinet with a portable fire extinguisher. Figure 21.11.14 shows an actual installation of hose valves in a road tunnel. A fire cabinet with hose valves is shown in Figure 21.11.15.

Fire Hose

Some tunnels outside the United States provide a fire hose within the tunnel at each hose valve location. In many circumstances, this is a small diameter first aid hose. However, in the United States, fire departments are reluctant to use hose that they have not maintained. Consequently, in the United States, fire hose is not placed or stored in the tunnel but carried on the responding fire apparatus.

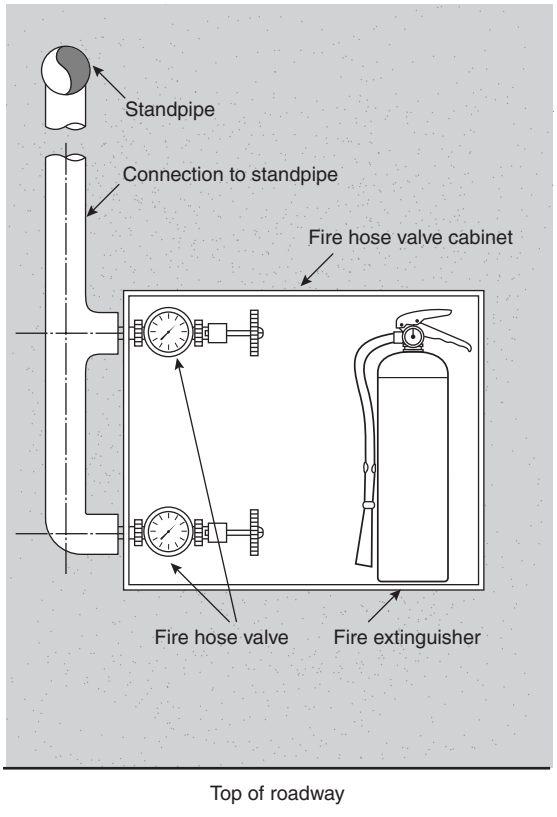

FIGURE 21.11.13 Typical Hose Valve Cabinet

Fire Pumps

When fire pumps are required to provide the necessary flow capacity and pressure in the road tunnel standpipe system, they should be installed in accordance with NFPA 20, *Standard for*

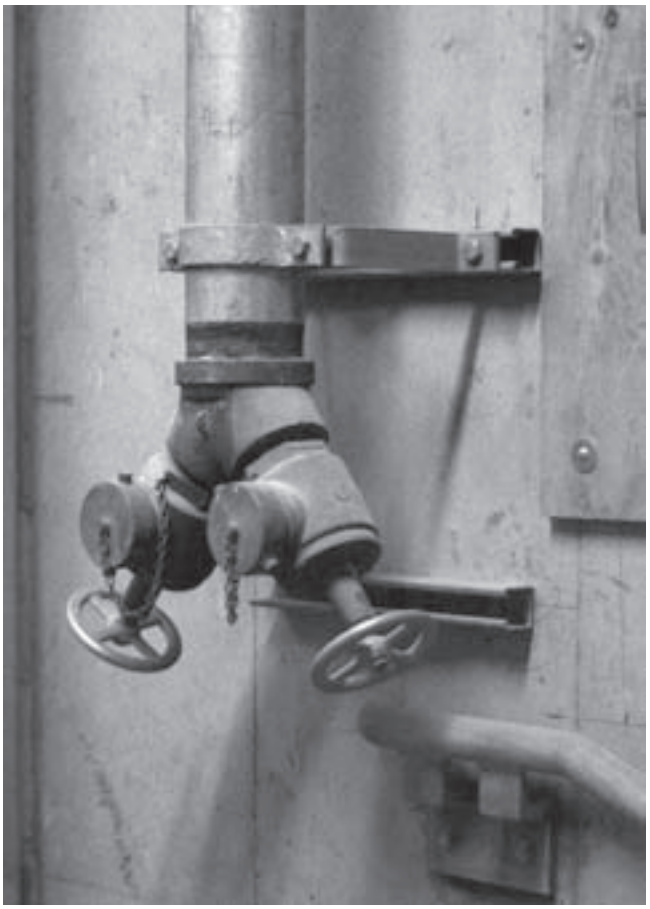

FIGURE 21.11.14 Hose Valves

FIGURE 21.11.15 Hose Valves in Fire Cabinet

the Installation of Stationary Pumps for Fire Protection. Figures 21.11.16 and 21.11.17 show typical installations of fire pumps and controls in a road tunnel application.

Fire Department Connection

Fire department connections are required to allow the fire department to charge the standpipe line. Two connections should be provided for every standpipe system and installed in accordance with NFPA 14. Each fire department connection should be installed within 100 ft (30.5 m) of an active hydrant that is tied into an approved water supply. A typical road tunnel fire department connection (FDC) and its active hydrant are shown in Figure 21.11.18.

Fixed Fire-Fighting Systems (FFFSs)

In road tunnels, fixed fire-fighting systems are defined as consisting of fire-fighting equipment, permanently attached to the tunnel, consisting of a piping system with a fixed supply of water or extinguishing agent which, when operated, has the intended effect of reducing the heat release and fire growth rates by discharging the water or extinguishing agent directly on the fire. Examples of fixed fire-fighting systems include sprinkler and deluge systems.

FIGURE 21.11.16 Fire Pump

FIGURE 21.11.17 Fire Pump Control Cabinet

FIGURE 21.11.18 Fire Department Connection (FDC) with Hydrant

Sprinkler Systems. These are fixed fire-fighting systems consisting of an integrated system of piping designed in accordance with fire protection engineering standards. The system is designed for each sprinkler head to be activated individually by heat from a fire itself so as to dispense water in the areas where it is needed to ensure rapid suppression of the fire.

Deluge Systems. These are fixed fire-fighting systems employing open nozzles that are attached to a zoned piping system that is connected to a water supply through a valve that is opened either manually or automatically. When this valve opens, water flows into the piping system and discharges from all nozzles in the designated zone.

Water Mist Systems. Water mist systems are pressurized fixed fire-fighting systems that operate by propelling very small droplets of water with high momentum which absorbs the fire's energy, cools the surrounding hot air and gases, and prevents oxygen from entering the combustion area.

Additives. Additives such as AFFF (aqueous film-forming foam) are being considered for in-tunnel fixed fire-fighting systems in lieu of water-only systems. The use of water only poses several concerns when applied to roadway tunnels. The high water demand rate needs to be available from the local supply, and this demand requires that in-tunnel drainage piping, storage, and pumping systems all become much larger.

History

The use and effectiveness of fixed fire-fighting systems in road tunnels has not been universally accepted; however, the recent severe fires in road tunnels in Europe have focused attention on the issue of fixed fire-fighting systems in road tunnels. NFPA

502 states that "the use of sprinklers (FFFS) in road tunnels generally is not recommended" (2004), and the World Road Association (PIARC) states that "sprinklers (FFFS) are generally not considered as cost effective and are not recommended in usual road tunnels"[4] (1999). Australia and Japan routinely install FFFS in their road tunnels. In addition, Austria, the Netherlands, Spain, and the United States have installed such systems in tunnels or are planning to do so in the near future. There are currently five U.S. road tunnels that have been equipped with fixed fire-fighting systems as shown in Table 21.11.7. Full-scale tests of fixed fire-fighting systems are or have been conducted by France, the Netherlands, Norway, and Spain.

Design and Control

System Design. When a fixed fire-fighting system is designed and installed in a road tunnel, the system should be designed as a manually activated deluge system to help ensure against accidental discharge of a sprinkler system. The system piping should be arranged using interval zoning so that the discharge can be focused in the zone or zones of incident without necessitating discharge for the entire length of the tunnel. Each zone should be equipped with its own proportioning valve set to control the appropriate water/foam mixture percentage if a water additive is being employed. Discharge heads should provide an open deluge and be spaced so that coverage extends to roadway shoulders and, if applicable, maintenance/patrol walkways. The system should be designed with enough water (and/or foam) capacity to allow operation of at least two zones adjacent to the incident zone. Zone length should be based on activation time as determined by the authority having jurisdiction (AHJ). Piping should be designed to allow drainage of the fixed fire-fighting systems after flow is stopped.

System Control. A full-time attended control room should be available for any road tunnel facility in which safe passage necessitates fixed fire-fighting system protection. Therefore, consideration should be given to human interaction in the system control and activation design to minimize false alarms and accidental discharges. Any automatic mode of operation should include a discharge delay to allow incident verification and assessment of in-tunnel conditions by trained operators. An integrated graphic display of the sprinkler system zones, fire detection system zones, tunnel ventilation system limits, and emergency access and egress locations should be provided at the control room to allow tunnel operators and responding emergency personnel to make appropriate initial response decisions.

Standards and Guidelines

NFPA 502 currently addresses road tunnel–based fixed fire-fighting systems as follows:

> Where sprinklers (fixed fire-fighting systems) are installed in road tunnels, the sprinkler systems (fixed fire-fighting systems) shall be installed, inspected and maintained in accordance with NFPA 13.

The catastrophic tunnel fires experienced in Europe during the last several years have prompted industry experts to revisit the potential benefit of fixed fire-fighting system applications in road tunnels. Research and test initiatives have been, and continue to be, performed by various organizations in both Europe and Japan that have provided new insight on the effectiveness of various FFFS technologies and their advantages and disadvantages under varying in-tunnel fire scenarios.

The technical committee for NFPA 502 has continued to monitor these programs and has acknowledged that when properly designed and maintained, FFFS can offer a potential life safety benefit in some road tunnel applications. As such the 2008 edition of NFPA 502 will reflect the latest technical considerations on the benefits of FFFS in road tunnels and will permit the installation of an FFFS where it can be shown by engineering analysis that the current level of safety can be equaled or exceeded by the use of fixed fire-fighting systems. As part of an integrated approach to the management of safety, such systems will be permitted in accordance with an engineering installation, inspection, and maintenance schedule using the design parameters for a particular tunnel which demonstrate that the level of performance provided by the fire-fighting systems will be maintained.

Source: Adapted from NFPA 502, *Standard for Road Tunnels, Bridges, and Other Limited Access Highways,* 2008 edition, Table E.3, p. 502-28.

In addition where fixed fire-fighting systems are installed in road tunnels, the fixed fire-fighting system should be installed, inspected, and maintained in accordance with other NFPA standards such as the following:

- NFPA 11, *Standard for Low-, Medium-, and High-Expansion Foam*
- NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection*
- NFPA 16, *Standard for the Installation of Foam-Water Sprinkler and Foam-Water Spray Systems*
- NFPA 18, *Standard on Wetting Agents*
- NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems*
- NFPA 750, *Standard on Water Mist Fire Protection Systems*

The reader is referred to Annex D of NFPA 502 for an extensive discussion on the use of fixed fire-fighting systems (sprinklers) in road tunnels. In addition, the subject of fixed fire-fighting systems is addressed by the World Road Association (PIARC) in their technical reports titled *Fire and Smoke Control in Road Tunnels,*[5] *Systems and Equipment for Fire and Smoke Control in Road Tunnels,*[8] and *Road Tunnels: An Assessment of Fixed Fire Fighting Systems.*[9]

Tunnel Drainage

A tunnel drainage system of sufficient capacity must be provided in any road tunnel to collect and discharge the water from seepage, rain, and fire-fighting activities, including the deployment of fixed fire-fighting systems. This system can be either gravity or pumped and should be designed, installed, and maintained in accordance with NFPA 502.

EMERGENCY RESPONSE PLANNING

The operation of any road tunnel includes many operation elements, but one of the most important from a safety viewpoint is the operation of the tunnel facility during a fire emergency. Key components necessary to be prepared for an emergency incident are the development of an integrated emergency response plan, the training of all participants, and the conducting of regularly scheduled exercises.

Emergency Response Plan Participants

An effective emergency response plan includes the interaction of not only the operators of the tunnel but of all outside agencies that might become active in an emergency response to a tunnel incident. Some or all of the following external agencies could be included:

- Police department
- Fire department (brigade)
- Civil defense
- Emergency medical services
- U.S. Department of Transportation (USDOT)
- Local private firms (equipment)
- Department of Public Works
- Water company
- U.S. Coast Guard
- U.S. Federal Emergency Management Agency (FEMA)
- Power company
- Telephone company

NFPA 502 contains a sample outline of a typical emergency response plan in Annex F.

Training and Exercises

A regular training program, which must be included as a part of an emergency response plan, should be scheduled for and should involve all operating personnel and all anticipated responders from external agencies. Because staff assignments within the responding agencies can change frequently, training should be continuous. Retraining of personnel should also be considered because the opportunity to participate in an actual response in a specific road tunnel may be infrequent.

Full-scale exercises should be conducted at least once a year and preferably twice a year. All potential responding external agencies should participate in these exercises so that all external agency representatives become familiar with the unique aspects of a road tunnel emergency response. Tabletop exercises, although extremely beneficial, do not replace the need for full-scale exercises.

Mutual-Aid Response

Arrangements for the response of nearby fire companies and emergency squads should be made a part of the emergency response planning process. Means of access that allows the entrance of outside aid companies to the facility should be provided, and procedures for utilizing such access need to be included in the emergency response plan. Appropriate precautions should be taken at the points of entry to alert and control traffic to allow safe entrance by emergency equipment.

Fire Apparatus

Fire apparatus suitable for fighting fires within road tunnels should be available within the general facility area, thus permitting a rapid response to a fire emergency. This apparatus should be equipped to deal effectively with flammable liquid and hazardous material fires. The responding fire apparatus should be appropriately equipped to fight fire within the road tunnel for a minimum of 30 minutes. If water supply is not available, suitable arrangements are needed to transport water so that the required apparatus delivery rate at the fire can be maintained for an additional 45 minutes. These fire-fighting units should carry multipurpose dry chemical extinguishers and an extinguishing agent for Class D metal fires.

Where the road tunnel is a high-capacity facility in a congested urban area, it may be appropriate to house such apparatus at the tunnel portal or portals. It may also be appropriate at these urban tunnels to combine the fire apparatus with the apparatus provided to effect retrieval and removal of disabled vehicles from the tunnel. Provisions should be taken to permit operation of vehicles and fire fighters in a potentially hazardous smoke and high-temperature gas-laden environment that may also have insufficient oxygen.

EVACUATION AND RESCUE

Point of Safety

A *point of safety* is defined by NFPA 502 as a location outside the incident structure that affords adequate protection for the motorist. Thus in the case of a road tunnel, the potential points of safety are the outside, the parallel nonincident bore (if it is a multibore facility), and a safety refuge (if one is provided). The potential egress paths would include the roadway, the cross passages, the emergency exits, and the safety refuge as shown in Figure 21.11.19. The egress path must be provided with a tenable environment for a sufficient period of time to permit motorist evacuation from the incident bore.

Tenable Environment Criteria

To a large extent, the quantitative aspect of the criteria for emergency situations is arbitrary because there are no universally accepted tolerance limits pertaining to air temperature and velocity. In fact, tolerance limits vary with age, health, weight, sex, and acclimatization.

Air Temperature Criteria. Motorists should not be exposed to maximum air temperatures exceeding 140°F (60°C) during emergencies. It is anticipated that the 140°F (60°C) air temperature will place a physiological burden on a few motorists, but the exposure also is anticipated to be brief and to produce no lasting harmful effects.

Air Velocity Criteria. When ventilation air is needed in evacuation routes to control smoke and heated gases, it might be necessary to expose motorists to high air velocities. The only upper limit to the ventilation rate occurs when the air velocity becomes great enough to create a hazard to persons walking in that airstream. According to the descriptions of the effects of various air velocities given in the Beaufort scale, motorists

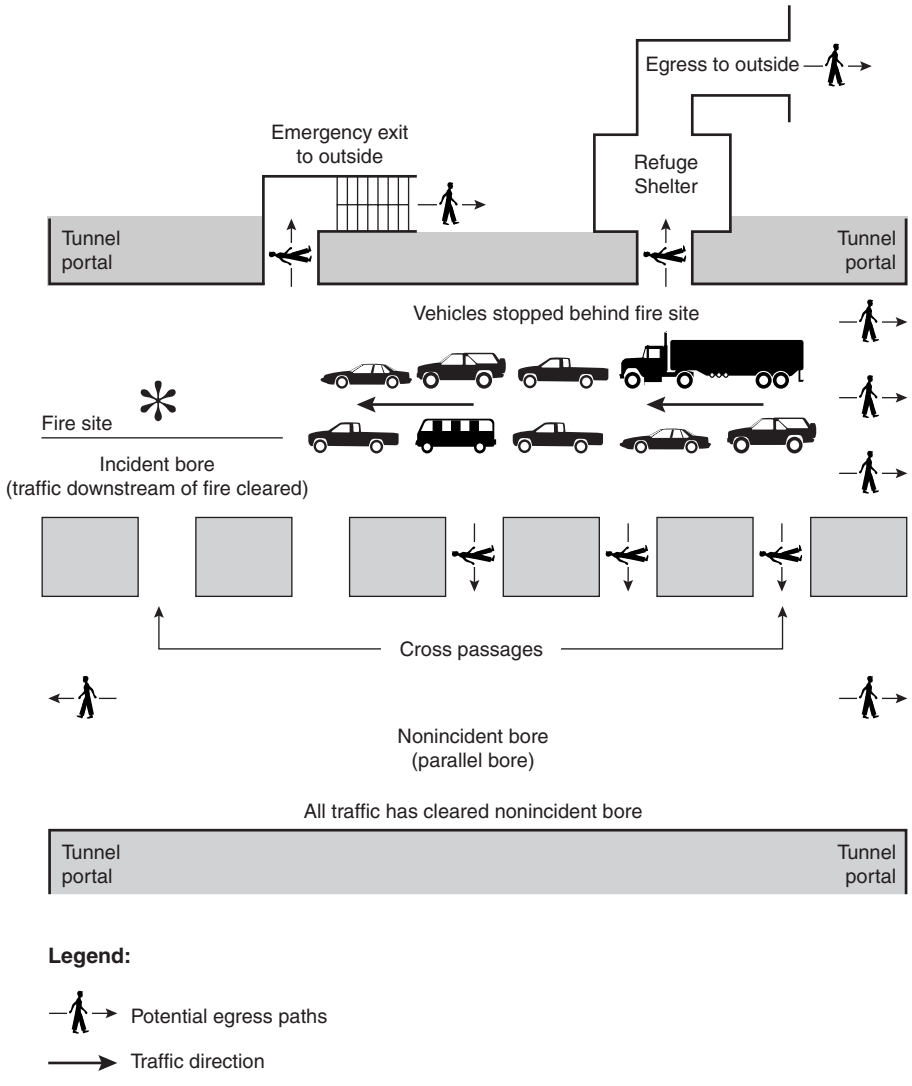

FIGURE 21.11.19 Typical Tunnel Means of Egress

under emergency conditions can tolerate as much as 2200 ft/min (11 m/sec).

ENGINEERING ANALYSIS

Engineering analysis is one of the key elements of the evaluation, development, and approval of any tunnel fire protection system. Many of the design concepts developed must be evaluated and their applicability and capacity demonstrated to the AHJ prior to approval. These analyses may be performed manually or by use of a computer program.

Calculations

Fire Heat Release Rate—Design Fire. The first design issue to be resolved is the selection of the design fire or fires—that is, the value of heat released that will provide the basis for the design of the emergency ventilation system. In a road tunnel, the vehicle fire load is either unknown or inconsistent. As a result, the review of data, such as those contained in Table 21.11.8, is extremely useful in the establishment of the design fire or fires.

Critical Velocity. The minimum air velocity within the tunnel section experiencing the fire emergency should be sufficient to mitigate backlayering of the smoke. The simultaneous solution of Equation 1 and Equation 2, by iteration, determines the critical velocity. The grade in these equations is taken in the direction of the airflow as shown in Figure 21.11.20.

The critical velocity (Figure 21.11.21) is the minimum steady-state velocity of the ventilation air moving toward the fire that is necessary to prevent backlayering:

TABLE 21.11.8 Typical Design Fire Size Data

Cause of Fire	*Peak Fire Heat Release Rate (MW)*
Passenger car	5–10
Multiple passenger cars (2–4 vehicles)	10–20
Bus	20–30
Heavy goods truck	70–200
Tanker*	200–300

Notes:
1. The designer should consider the rate of fire development (peak heat release rates may be reached within 10 minutes), the number of vehicles that could be involved in the fire, and the potential for the fire to spread from one vehicle to another.
2. Temperatures directly above the fire can be expected to be as high as 1832 to 2552°F (1000 to 1400°C).

*Flammable and combustible liquids for the tanker fire design should include adequate drainage to limit the area of the pool fire and its duration. The heat release rate may be greater than in the table if more than one vehicle is involved.

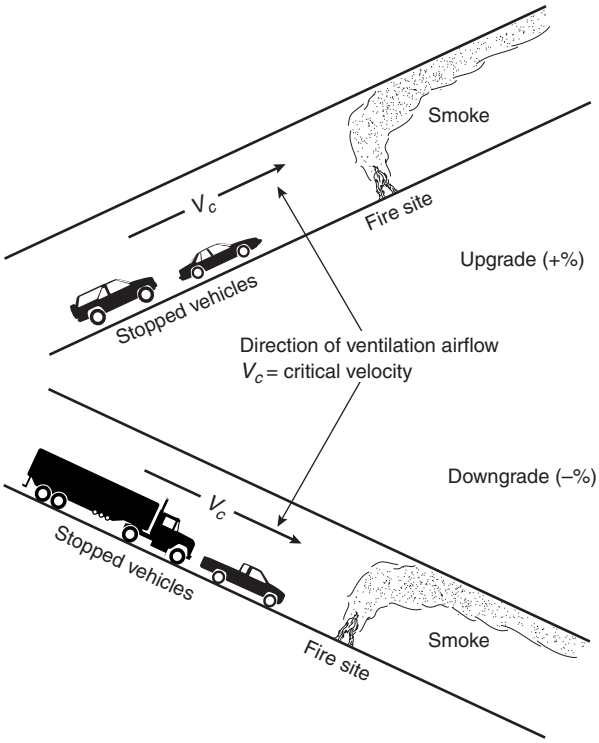

FIGURE 21.11.20 Grade Determination

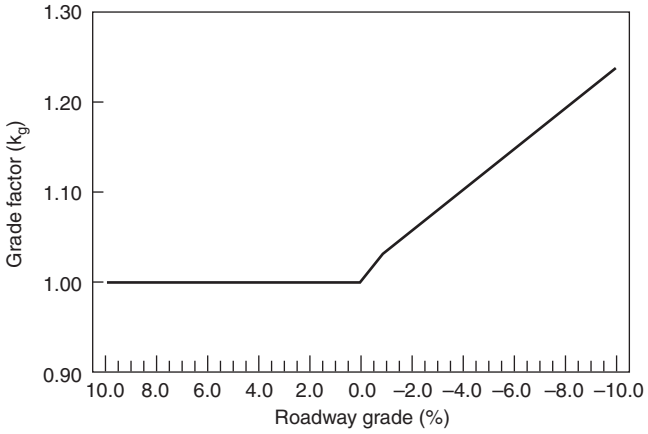

FIGURE 21.11.21 Critical Velocity Grade Factor

$$V_c = K_1 K_g \left(\frac{gHQ}{\rho C_p A T_f} \right)^{1/3} \quad (1)$$

$$T_f = \left(\frac{Q}{\rho C_p A V_c} \right) + T \quad (2)$$

where

A = Area perpendicular to the flow (ft^2 [m^2])
C_p = Specific heat of air (Btu/lb R [kJ/kg K])

g = Acceleration caused by gravity (ft/sec^2 [m/sec^2])
H = Height of the tunnel at the fire site (ft [m])
K_1 = 0.606
K_g = Grade factor (Figure 21.11.21)
Q = Heat the fire is adding directly to the air at the fire site (Btu/sec [MW])
T = Temperature of the approach air (degrees R [K])
T_f = Average temperature of the fire site gases (degrees R [K])
V_c = Critical velocity (ft/min [m/sec])
ρ = Average density of the approach (upstream) air (lb/ft^3 [kg/m^3])

Fire Models as Analytical Tools

The three following types of fire models can be applied to the road tunnel environment:

- One-dimensional models
- Zone models
- Field models

One-dimensional models are extremely useful and effective if the bulk results (i.e., the average values for results like airflow and temperature) are satisfactory. The zone models developed for use in buildings, which utilize room configurations, do not lend themselves to a linear configuration such as a road tunnel. Field models or computational fluid dynamics (CFD) will provide detailed results, including temperature and smoke profiles, and are therefore ideally suited to perform analyses for road tunnels. However, CFD simulation can be expensive to conduct.

A number of computer-based analytical tools have been developed that are applicable to road tunnels. Models are available to evaluate smoke control and ventilation requirements as well as emergency egress. Ventilation analyses have moved from the one-dimensional models developed 20 to 30 years ago to the three-dimensional aspects of computational fluid dynamics. CFD has been in use in other industries for many years, but only in the last 10 years has it begun to be used in tunnel fire protection applications.

SES. An excellent example of a one-dimensional model used in the analysis of road tunnel emergency ventilation requirements is the Subway Environment Simulation (SES) program. The SES is a one-dimensional network model that is extremely effective in the evaluation of tunnel/shaft configurations.

The SES program, which is essentially a one-dimensional, incompressible, turbulent, slug-flow model, comprises a series of interdependent computation subprograms to address vehicle performance, aerodynamics, temperature/humidity, heat sink, environmental control, and fire. The SES computer model provides a dynamic simulation of bidirectional traffic in a road tunnel and permits continuous reading of the average air velocity, temperature, and humidity throughout any arrangement of tunnels, ventilation buildings, and shafts.

The SES fire model, which has the ability to model the aerodynamic and thermodynamic effects of a tunnel fire, was designed to simulate the overall effects of a tunnel fire on the ventilation system. This level of detail is considered sufficient for evaluating the adequacy of an emergency ventilation system. The input/information required by the program and the outputs produced are tailored for use by design engineers concerned with practical environmental problems. The SES model[10] is available from the Volpe Transportation Center in Cambridge, Massachusetts.

TUNVEN. The TUNVEN computer program[11] solves the coupled one-dimensional steady-state road tunnel aerodynamics and advection equations to obtain the longitudinal air velocities and pollutant concentrations for a given road tunnel design, traffic load, and ventilation rate. The effect of ambient conditions external to the tunnel, such as portal winds and local pollutant levels, can also be included. This program can be used to determine ventilation requirements for natural, longitudinal, semi-transverse, and full transverse ventilation systems.

A road tunnel is modeled in the TUNVEN computer program as a one-dimensional longitudinal air duct with inflow and outflow at each end and along its length. Airflow through the tunnel is caused by a pressure differential between the ends, by the piston action of the vehicles, and by addition or removal of air through the ventilation system. The forces generated by these effects are balanced in the steady-state case by opposing friction forces along the tunnel walls and flow entrance and exit losses.

Vehicles traveling through the tunnel also emit pollutants, which are diluted by the tunnel air to a concentration that depends on the pollutant sources in the upstream sections of the tunnel and on the local airflow velocity. The dependence on pollutant sources couples the aerodynamic and advection (or concentration) equations, making it necessary to compute the flow field before the concentrations can be determined. The TUNVEN model is available from National Technical Information Services (NTIS).

SOLVENT. SOLVENT[12] is a computational fluid dynamics model developed as a part of the Memorial Tunnel Fire Ventilation Test Program, for the simulation of fluid flow, heat transfer, and smoke transport in road tunnels. SOLVENT can be applied to all of the ventilation systems deployed in road tunnels, including longitudinal ventilation using jet fans, transverse ventilation, and natural ventilation.

The primary objective for the model is the ability to simulate the interactive effects of a tunnel fire and the ventilation system to determine the unsafe regions of the tunnel, where the hazardous effects of the fire (smoke and high temperature) are confined, and how these regions are affected by the ventilation system configuration, capacity, and operation.

For transverse ventilation systems, a flow network model is used to predict the flow rates, temperatures, and pressures in the ducts. The ventilation ducts and the tunnel (which uses the CFD model) are coupled via boundary conditions. SOLVENT is being applied to develop the emergency ventilation operating mode matrix for the many operating road tunnels. The matrix identifies how each ventilation zone is to be operated as a function of fire incident location and traffic direction. Figure 21.11.22 is a copy of the animation of the SOLVENT output

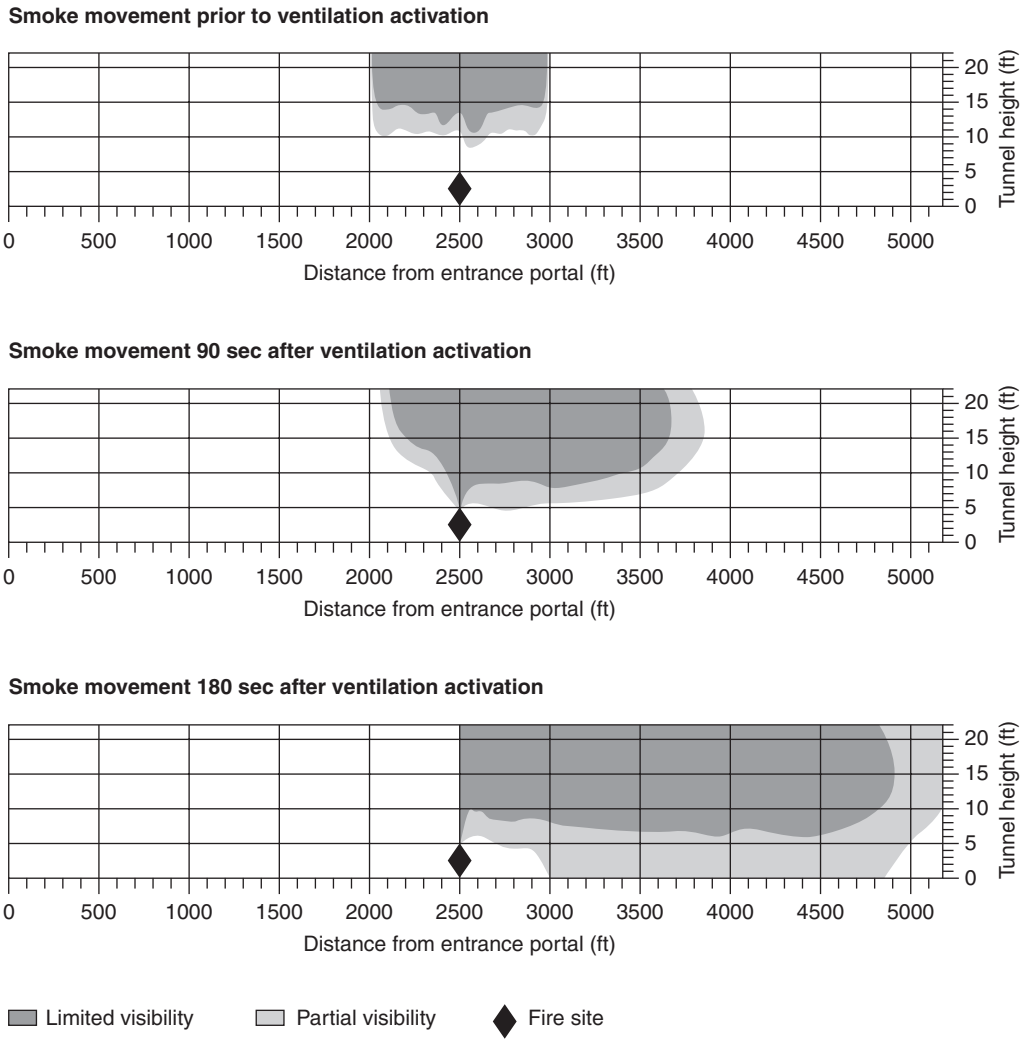

FIGURE 21.11.22 Smoke Movement Simulation

from simulations for a road tunnel with a longitudinal ventilation system. These graphics show the movement of the smoke before and after ventilation activation. They clearly show the progressive movement of the smoke and the ultimate elimination of any backlayering.

The SOLVENT model has been validated against the data compiled from the Memorial Tunnel Fire Ventilation Test Program.[12] The SOLVENT model is available, under license, from Parsons Brinckerhoff Quade & Douglas, Inc., in New York and Innovative Research, Inc., in Minneapolis.

Emergency Egress Models

Evacuation modeling software, such as SIMULEX, can be employed to simulate the escape movement of people to a point of safety during incidents within road tunnels. The algorithms for the movement of individuals are based on real-life data. The program shows the evacuation process graphically on the screen, with the plan view of passengers moving toward emergency exits or cross passages, and predicts where the exiting choke points occur within the tunnel. The egress times computed by this program can be used to evaluate alternative distances between emergency exits and can allow comparisons among alternative sizes of cross-passageways, exit stairways, and walkways. The program has been upgraded to simulate walkways in road tunnels and people walking at the 200 fpm (1 m/sec) exiting speed (the design speed for exiting passengers) specified in NFPA 130.

Current applicable standards for road tunnels require emergency exits and cross-passageways be provided throughout the tunnels and spaced so that the distance between exits is not greater than the limit specified in the standard. There is an ongoing interest to determine the most appropriate distance between emergency exits, minimum size of exit stairways, and widths of walkways in road and rail tunnels, which will ultimately lead to the development of more performance-based codes. The output in Figure 21.11.23 is a printout of an emergency egress simulation for a road tunnel employing SIMULEX. This figure shows the motorists in the process of leaving their vehicles and subsequently entering an emergency exit enclosure leading to an emergency exit stairway. The SIMULEX model is available, under license, from Integrated Environmental Solutions

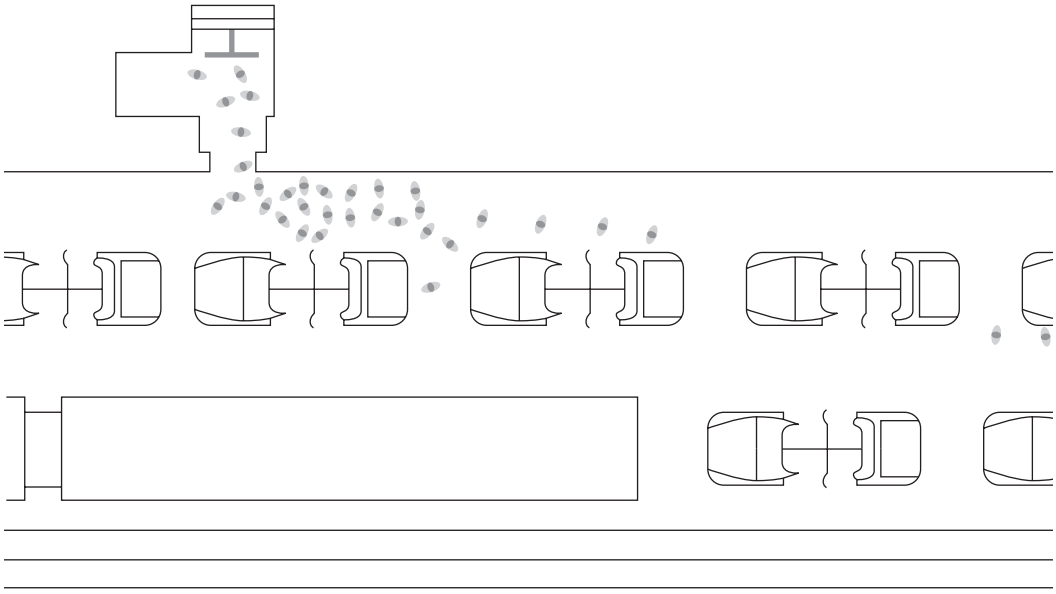

FIGURE 21.11.23 Emergency Egress Model Output

(IES) of Glasgow, Scotland.[13] There are other egress models currently being applied to tunnel egress such as STEPS, Exodus, and Legion.

TUNNEL FIRE TESTS

Over the past 40 years, a series of full-scale tunnel fire tests have been conducted to permit fire protection and ventilation engineers to better understand the phenomenon of fire and smoke within a tunnel. These tests were conducted in Switzerland, Austria, Japan, Norway, and the United States, as shown in Table 21.11.9. The most recent of these were the Eureka Project 499 FIRETUN, conducted in an abandoned mining tunnel in northern Norway by nine European countries;[14] the Memorial Tunnel Fire Ventilation Test Program (MTFVTP),[7] conducted in the United States; and the Runehamer tests,[15] conducted in Norway in 2003.

The most significant to the tunnel industry in the United States were the tests conducted at the Memorial Tunnel, an

abandoned road tunnel in West Virginia. This comprehensive test program, which began with the initial fire tests in September 1993 and concluded with the final tests in March 1995, produced data that were acquired in a full-size facility, under controlled conditions, and over a wide range of system parameters.

Hot-Smoke Testing in Tunnels

Hot-smoke tests were initially conducted as a means of verifying smoke modeling predictions. More recently it has become common practice to use a hot-smoke test to actually test the smoke management systems of a completed tunnel. These tests have become valuable as a commissioning tool, allowing testing of the integrational functioning of all systems related to the fire life safety of the tunnel, including the detection, ventilation, smoke exhaust, dampers, fire-fighting systems, and fire control panels.[16]

Memorial Tunnel Fire Ventilation Test Program

The Memorial Tunnel Fire Ventilation Test Program[7] represented a unique opportunity to evaluate and develop design methods and operational strategies leading to safe road tunnels. The purpose of this test program was to develop a database that provides tunnel design engineers and operators with an experimentally proven means to determine the ventilation rates and ventilation system configurations that provide effective smoke control management during a tunnel fire emergency. It was even more important to establish specific operational strategies to permit effective reconfiguration of ventilation operational parameters for existing tunnel facilities.

The Memorial Tunnel, a two-lane, 2800 ft (854 m) road tunnel located near Charleston, West Virginia, was built in 1953 as part of the West Virginia Turnpike and abandoned in 1987 when it was bypassed by an open-cut section of a new six-lane interstate highway. The tunnel has a 3.2 percent uphill grade from the south to the north tunnel portal. The existing ventilation equipment was replaced with new variable speed, reversible, axial flow central ventilation fans. Fires were produced in roadway-level steel pans, with average fire heat release rates as shown in Table 21.11.10.

The ventilation systems, tested under varying flow rates and varying heat release rates with one or two zones of ventilation, included the following:

- Natural ventilation
- Longitudinal ventilation with jet fans
- Longitudinal ventilation with central fans and Saccardo nozzles
- Transverse ventilation
- Transverse ventilation with point extraction and oversized exhaust ports

Suppression System. A fire suppression system employing a 3 percent aqueous film-forming foam (AFFF) solution was installed in the Memorial Tunnel primarily to suppress the test fire in an emergency; however, it was also used during several tests to evaluate the impact of horizontal roadway ventilation airflow on the operation of a foam suppression system.

The effectiveness of the foam suppression system tested was not diminished by operation in high-velocity longitudinal airflow (825 fpm [4.2 m/sec]). The time for the suppression system to extinguish the open pan fire with the nozzles located at the ceiling, 14 ft (4.3 m) above the roadway, ranged from 5 to 25 seconds for a 50 MW fire. This was the configuration for the transverse tests.

When the longitudinal ventilation tests with jet fans were conducted, the nozzles were located on the west wall, 7 ft (2.1 m) above the roadway. In this configuration the time to extinguishment was 102 seconds (50 MW) and 11 seconds (100 MW). The results of these suppression tests are shown in Table 21.11.11.

Video Recording System. The CCTV system included seven video cameras, two located within the tunnel with water-cooled enclosures, one roadway-level camera north of the fire to secure added video footage of smoke movement, two located at the tunnel portals, and two located on the north and south meteorological towers. This system provided essential video footage of smoke behavior during the fires.

Findings and Conclusions of the Memorial Tunnel Fire Ventilation Test Program. *Natural ventilation* resulted in extensive spread of smoke and heated gases upgrade of the fire but relatively clear conditions downgrade of the fire. Other conclusions related to natural ventilation included the following:

TABLE 21.11.11 Foam Suppression Tests

Ventilation System	*Fire Size (MW)*	Air Velocity Across Fire *(fpm)*	Air Velocity Across Fire *(m/sec)*	*Time to Extinguish (sec)*
Full transverse	50	115	0.6	5
Semitransverse—exhaust	50	210	1.1	8
Exhaust—single port	50	825	4.2	25
Longitudinal—jet fans	50	500	2.5	102
Longitudinal—jet fans	100	400	2.0	111

Source: "Memorial Tunnel Fire Ventilation Test Report."[7]

- The spread of smoke and heated gases during a 50 MW fire was considerably greater than during a 20 MW fire. The depth of the smoke layer increased with fire size.
- The time for the smoke layer to descend to a point where it posed an immediate life safety threat was dependent on the fire size and tunnel geometry, specifically the tunnel height.
- In the Memorial Tunnel, smoke traveled between 950 and 1200 ft (290 and 365 m) along the arched tunnel roof before cooling and descending into the roadway.
- The restriction to visibility caused by the movement of smoke occurred more quickly than did a temperature high enough to be debilitating.
- Exposure to high levels of carbon monoxide was never more critical than smoke or temperature for any test.

Longitudinal Ventilation System. A longitudinal ventilation system employing jet fans was highly effective in managing the direction of the spread of smoke for fires sizes tested up to 100 MW in a 3.2 percent grade tunnel. Jet fans located downgrade from the fire site were subjected to the temperatures shown in Table 21.11.12.

Transverse Ventilation. It was demonstrated in the MTFVTP that dilution as a sole means for temperature and smoke control was not very effective. Some means of extraction should be incorporated. Extraction and longitudinal airflow when combined can significantly increase the effectiveness of a road tunnel ventilation system to manage and control the movement of smoke.

Single-zone balanced full transverse ventilation systems operated at 100 cubic feet per minute per lane foot (cfm/lf) (0.155 cubic meters per second per lane meter [m^3/sec/lm]) were ineffective in the management of smoke and heated gases for fire sizes 20 MW and larger. Single-zone unbalanced full transverse ventilation systems generate some longitudinal airflow in the roadway. The result of this longitudinal airflow was to offset some of the effects of buoyancy for a 20 MW fire. The effectiveness of unbalanced full transverse ventilation systems is sensitive to the fire location, since there is no control over the airflow direction.

The tested two-zone transverse ventilation system provided control over the direction and magnitude of the longitudinal airflow. Airflow rates of 100 cfm/lf (0.155 m^3/sec/lm) contained high temperatures from a 20 MW fire within 100 ft (31 m) of the fire in the lower elevations of the roadway and smoke within 200 ft (61 m). The maximum temperatures experienced at the inlet to the central fans closest to the fire are shown in Table 21.11.13.

Smoke and Heated Gas Movement. The time for the smoke layer to descend to a point where it poses an immediate life safety threat is dependent on the fire size and tunnel geometry, specifically the tunnel height. As noted under the section on natural ventilation, smoke traveled between 950 and 1200 ft (290 and 365 m) along the arched tunnel roof before cooling and descending into the roadway. Selected smoke movement data for a naturally ventilated tunnel with a 3.2 percent grade is shown in Table 21.11.14.

Fan Operation Delays. The spread of hot gases and smoke was significantly greater with a longer fan response time. Hot smoke

TABLE 21.11.12 Temperatures at Jet Fans

layers were observed to spread very quickly—1600 to 1900 ft (490 to 580 m) in the initial 2 minutes of a fire.

Ventilation System Enhancements. The ability to extract smoke quickly and as close as possible to the fire location can significantly reduce smoke and heat migration in undesired directions and facilitate two-way traffic operations. This localized extraction is possible with the application of single-point extraction openings (SPE) to a transverse ventilation system. SPE systems are applicable to two-way traffic flow with a dependency on the location, size, and spacing of the SPE openings. Smoke and heat drawn from the fire to the SPE could pass over or possibly around stalled traffic and vehicle occupants. An SPE located upgrade of the fire is very effective in temperature and smoke management. With the SPE located downgrade of the fire, only minimal improvement in temperature and smoke conditions over a single-zone partial transverse exhaust system was achieved. A single-point opening of 300 ft^2 (27.9 m^2) was most effective in temperature and smoke management of the SPE sizes tested. Significantly greater smoke and heat spread was observed with a 100 ft^2 (9.3 m^2) opening compared to the 300 ft^2 (27.9 m^2) opening.

For 20 MW fires, partial transverse ventilation exhaust ventilation operated with 100 cfm/lf (0.155 m^3/sec/lm) and supplemented with a large (300 ft^2 [27.9 m^2]) single-point opening limited smoke and heated gases migration to 200 ft (61 m) from the fire. A partial transverse exhaust system supplemented with oversized exhaust ports and operated with 85 cfm/lf (0.132 m^3/sec/lm) limited high temperatures to an area extending 100 ft (31 m) from the fire and sustained the stratified smoke layer above the occupied zone. For 50 MW fires, partial transverse ventilation exhaust ventilation operated with 110 cfm/lf (0.170 m^3/sec/lm) and supplemented with a large (300 ft^2 [27.9 m^2]) single-point opening limited smoke and heated gases migration to 280 ft (85 m) from the fire.

ROAD BRIDGES

The 2004 version of NFPA 502 provides the fire protection requirements for road bridges spanning more than 400 ft (122 m). A fire occurring on a bridge is a much less serious situation than that posed by the same fire size in a tunnel for the very basic reason that the resulting heat and smoke is not contained within the same confined space as the motorists. However, depending on the severity and location (on or under the bridge) of the fire, the risk to structure may threaten the life safety of motorists traveling both on and below the bridge. Similar to a tunnel, most bridges afford only limited access for emergency responders; therefore, emergency response planning for longer span bridges is recommended. Further, the fact that cargo restrictions are far less stringent on bridges (and likely nonexistent beneath bridges) than in tunnels suggests that the potential for a large-scale fire is far greater on such structures. This issue of structure fire resistance and methods for fire protection on bridges is likely to become an increasingly important consideration as more lightweight and double-decked bridges are built.

Recent Road Bridge Fires

Fires on or under road bridges can be devastating to the integrity of the bridge support structure. Examples of several such fires that have occurred on Interstate 95 (I-95) are briefly described as follows:

- A fire broke out under the elevated section of I-95 in Pennsylvania, near Philadelphia, in 1996, between Westmoreland Street and Tioga Street and caused three spans of the 26-span, 1707 ft (520 m) Westmoreland Viaduct to buckle. The cause of the fire was a stack of discarded tires in an illegal dump underneath the viaduct.
- A tanker truck loaded with 8700 gal (33,000 L) of gasoline was traveling on I-95 in Pennsylvania in 1998. While swerving to avoid a passing car, the tanker truck jumped the Jersey barrier and exploded after striking a pickup truck in the southbound lanes. Both drivers died at the scene. Nine steel support girders, each 6 ft (2 m) long and 8 in. (20 cm) tall, and between 65 and 80 ft (20 and 24 m) of the bridge crossing the Chester Creek, were damaged.[17]
- In 2004 a tanker truck carrying 12,000 gal (45,500 L) of fuel oil collided with another vehicle and caught fire on Interstate 95 near Bridgeport, Connecticut. The resulting blaze was hot enough to melt steel support beams on the southbound side of the bridge over Howard Avenue. I-95 was closed in both directions.

Recommendations for Road Bridge Fire Protection

Currently, NFPA 502 provides that the following fire protection system elements be considered for application on long span road bridges:

- Emergency communications
- Signage
- Traffic control
- Fire suppression
- Drainage
- Control of hazardous materials
- Emergency response planning

Emergency Communications. Emergency communications, where required by the AHJ, will be provided by the installation of outdoor-type telephone boxes, coded alarm telegraph stations, radio transmitters, or other approved devices. These devices should have all of the following features:

- Made conspicuous by means of indicating lights or other approved markers
- Identified by a readily visible number plate or other approved device
- Posted with instructions for use by motorists
- Located in approved locations so that motorists can park vehicles clear of the travel lanes

Signage. Signs, mile markers, or other approved location reference markers will be installed along the highway to allow mo-

torists to provide authorities with accurate locations for accident or emergency areas.

Traffic Control. A traffic control procedure will be established so that vehicles either stop or proceed with caution. Traffic will not be permitted to block or otherwise interfere with the response of emergency and fire apparatus.

Fire Suppression System. Where the distance from an acceptable water supply source to any point on the bridge exceeds 400 ft (120 m), the bridge will be provided with a Class I standpipe system in accordance with NFPA 14. The maximum flow of the standpipe system will be 500 gpm (1920 L/min) for one hour. Standard hose connections will be provided so that no location on the roadway is more than 150 ft (45 m) from the hose connection; however, the spacing will not exceed 275 ft (85 m). Two standard fire department connections (FDC) will be provided for each independent standpipe system.

Drainage. Drainage systems on bridges will be designed to channel and collect spilled hazardous or flammable liquids to drain areas that cannot cause additional hazards. Expansion joints will be designed to prevent spillage to the area below the bridge.

Control of Hazardous Materials. Control of hazardous materials will be in accordance with the requirements of Chapter 13 of NFPA 502.

Emergency Response Plan. The designated agency (operating) will carry out a complete and coordinated program of fire protection that will include written preplanned emergency response procedures and standard operating procedures. Emergency response procedures and the development of an emergency response plan will comply with the requirements of Chapter 12 of NFPA 502.

SUMMARY

Road tunnels, which include mountain tunnels, underwater tunnels, urban tunnels, and air-rights tunnels, represent a unique challenge in fire protection. The linear shape, limited accessibility, and lack of compartmentalization of road tunnels make fire fighting and evacuation difficult. For most road tunnels, the potential fire load is unknown because of the variety of vehicles and cargoes that pass through. The primary objectives of a road tunnel fire protection system are to permit evacuation, facilitate the entrance of fire fighters, and protect the tunnel structure and facilities. The key elements of road tunnel fire protection are fire identification, verification, and location; emergency communications; smoke management; fire suppression; emergency response planning; and evacuation and rescue.

Means of fire identification, verification, and detection include closed circuit television, pull boxes, emergency telephones, and detection systems such as heat, flame, and smoke detectors. Emergency communications can be transmitted by radio, whereas the use of loudspeakers is not recommended. Smoke management can be achieved by a variety of ventilation systems. Fire suppression systems include portable fire extinguishers, standpipes, hoses, fire pumps, and sprinklers. The emergency response plan should include the interaction of all potential responders such as nearby fire companies and emergency squads. For evacuation and rescue, potential egress paths are the roadway, the cross passages, the emergency exits, and the safety refuge. When developing an effective fire protection system for a road tunnel, an engineering analysis, performed manually or by use of a computer program, is essential.

Road bridges, providing long span crossings of waterways, railroads, and other roadways, would appear to pose minimum life safety risk since they are not enclosed as is a tunnel. However, there are significant motorist life safety risks created by the potential for much larger-scale fires due to the less restrictive regulation of cargo and the failure of the bridge supporting structure from a fire located either on or under the bridge. Double-decked bridges create the additional risk of a fire developing on the lower level and ultimately impacting the integrity of the support structure of the upper level. In addition to proper methods for fire resistance protection of the bridge structure and the provision of minimal fire protection systems as required by NFPA 502, bridge operators and emergency responders must also develop an emergency response plan similar to that recommended for road tunnels.

ASTM E603, *Standard Guide for Room Fire Experiments,* 2-41, 6-50, 6-227, 18-39
ASTM E605, *Standard Test Methods for Thickness and Density of Sprayed Fire-Resistive Material Applied to Structural Members,* 19-52
ASTM E648, *Standard Test Method for Critical Radiant Flux of Floor-Covering Systems Using a Radiant Heat Energy Source,* 2-43, 18-33, 18-35
ASTM E659, *Autoignition Temperature of Liquid Chemicals,* 8-171
ASTM E662, *Standard Test Method for Specific Optical Density Smoke Generated by Solid Materials,* 2-44, 6-45–6-46, 18-32, 18-35
ASTM E680, *Standard Test Method for Drop Weight Impact Sensitivity of Solid-Phase Hazardous Materials,* 17-151
ASTM E799, *Standard Practice for Determining Data Criteria and Processing for Liquid Drop Size Analysis,* 16-149
ASTM E800, *Standard Guide for Measurement of Gases Present or Generated During Fires,* 2-45
ASTM E814, *Standard Test Method for Fire Tests of Through-Penetration Fire Stops,* 6-39, 18-19, 18-74
ASTM E906, *Standard Method of Test for Heat and Visible Smoke Release Rates for Materials and Products Using a Thermopile Method,* 2-38, 6-7, 6-41, 6-46, 6-71, 6-227
ASTM E970, *Standard Test Method for Critical Radiant Flux of Exposed Attic Floor Insulation Using a Radiant Heat Energy Source,* 2-43
ASTM E1226, *Standard Test Method for Pressure and Rate of Pressure Rise for Combustible Dusts,* 2-100, 17-146
ASTM E1317, *Test Method for Flammability of Marine Surface Finishes,* 2-43, 6-45
ASTM E1321, *Test Method for Determining Material Ignition and Flame Spread Properties,* 2-42, 6-41, 6-45
ASTM E1352, *Standard Test Method for Cigarette Ignition Resistance of Components of Upholstered Furniture Assemblies,* 6-111
ASTM E1352, *Standard Test Method for Cigarette Ignition Resistance of Mock-Up Upholstered Furniture,* 6-111
ASTM E1354, *Standard Test Method for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter,* 2-39, 6-7, 6-41, 6-47, 6-119, 6-134, 6-228, 6-283, 9-128
ASTM E1385, *Standard Practice for Separation and Concentration of Ignitable Liquid Residues from Fire Debris Samples by Steam Distillation,* 3-36
ASTM E1386, *Standard Practice for Separation and Concentration of Ignitable Liquid Residues from Fire Debris Samples by Solvent Extraction,* 3-36
ASTM E1387, *Standard Test Method for Ignitable Liquid Residues in Extracts from Fire Debris Samples by Gas Chromatography,* 3-36
ASTM E1388, *Standard Practice for Sampling of Headspace Vapors from Fire Debris Samples,* 3-36
ASTM E1412, *Standard Practice for Separation of Ignitable Liquid Residues from Fire Debris Samples by Passive Headspace Concentration with Activated Charcoal,* 3-36
ASTM E1413, *Standard Practice for Separation and Concentration of Ignitable Liquid Residues from Fire Debris Samples by Dynamic Headspace Concentration,* 3-36
ASTM E1472, *Standard Guide for Documenting Computer Software for Fire Models,* 3-132
ASTM E1474, *Standard Test Method for Determining the Heat Release Rate of Upholstered Furniture and Mattress Components or Composites Using a Bench Scale Oxygen Consumption Calorimeter,* 6-47, 6-120
ASTM E1529, *Test Methods for Determining Effects of Large Hydrocarbon Pool Fires on Structural Members and Assemblies,* 2-67, 6-39
ASTM E1537, *Standard Test Method for Fire Testing of Upholstered Furniture,* 6-49, 6-50, 6-116
ASTM E1546, *Standard Guide for Development of Fire-Hazard-Assessment Standards,* 21-11–21-12
ASTM E1550, *Standard Test Method for Determination of Fire-Test-Response Characteristics of Components or Composites of Mattresses or Furniture for Use in Correctional Facilities after Exposure to Vandalism, by Employing a Bench Scale Oxygen Consumption Calorimeter,* 6-47
ASTM E1590, *Standard Method for Fire Testing Mattresses,* 4-77, 6-49, 6-50, 6-228
ASTM E1618, *Standard Test Method for Ignitable Liquid Residues in Extracts from Fire Debris Samples by Gas Chromatography-Mass Spectrometry,* 3-36
ASTM E1623, *Test Method for Determination of Fire and Thermal Parameters of Materials, Products, and Systems Using an Intermediate Scale Calorimeter,* 2-41, 6-48, 6-134
ASTM E1678, *Standard Test Method for Measuring Smoke Toxicity for Use in Fire Hazard Analysis,* 2-45, 6-19, 6-20, 6-22
ASTM E1725, *Standard Test Methods for Fire Tests of Fire-Resistive Barrier Systems for Electrical System Components,* 2-66
ASTM E1740, *Standard Test Method for Determining the Heat Release Rate and Other Fire-Test-Response Characteristics of Wallcovering Composites Using a Cone Calorimeter,* 6-47
ASTM E1776, *Standard Guide for Development of Fire-Risk-Assessment Standards,* 3-136
ASTM E1822, *Standard Test Method for Fire Testing of Stacked Chairs,* 6-49, 6-50, 6-116
ASTM E1966, *Test Method for Fire-Resistive Joint Systems,* 6-39
ASTM E1995, *Standard Test Method for Measurement of Smoke Obscuration Using a Conical Radiant Source in a Single Closed Chamber, with the Test Specimen Oriented Horizontally,* 6-46, 18-33
ASTM E2010, *Standard Test Method for Positive Pressure Fire Tests of Window Assemblies,* 2-64
ASTM E2058, *Test Methods for Measurement of Synthetic Polymer Material Flammability Using a Fire Propagation Apparatus,* 2-32, 2-38, 6-41, 6-46, 6-228, 9-128, Fig. 2.3.7
ASTM E2061, *Standard Guide for Fire Hazard Assessment of Rail Transportation Vehicles,* 6-50, 6-51
ASTM E2067, *Standard Practice for Full-Scale Oxygen Consumption Calorimetry Fire Tests,* 6-227, 18-39
ASTM E2074, *Standard Test Method for Fire Tests of Door Assemblies, Including Positive Pressure Testing of Side-Hinged and Pivoted Swinging Door Assemblies,* 2-64
ASTM E2101, *Standard Test Method for Measurement of Mass Loss and Ignitability for Screening Purposes Using a Conical Radiant Heater,* 6-47
ASTM E2154, *Standard Practice for Separation and Concentration of Ignitable Liquid Residues from Fire Debris Samples by Passive Headspace Concentration with Solid Phase Microextraction (SPME),* 3-36
ASTM E2187, *Standard Test Method for Measuring the Ignition Strength of Cigarettes,* 6-112
ASTM E2226, *Standard Practice for Application of Hose Stream,* 2-67
ASTM E2231, *Standard Practice for Specimen Preparation and Mounting of Pipe and Duct Insulation Materials to Assess Surface Burning Characteristics,* 6-44, 6-53
ASTM E2257, *Standard Test Method for Room Fire Test of Wall and Ceiling Materials and Assemblies,* 2-41, 6-49, 18-32
ASTM E2280, *Standard Guide for the Fire Hazard Assessment of the Effect of Upholstered Seating Furniture Within Patient Rooms of Health Care Facilities,* 6-51
ASTM E2307, *Standard Test Method for Determining Fire Resistance of Perimeter Fire Barriers Using Intermediate-Scale, Multi-Story Test Apparatus,* 2-69
ASTM E2404, *Standard Practice for Specimen Preparation and Mounting of Paper or Vinyl Wall or Ceiling Coverings to Assess Surface Burning Characteristics,* 6-44
ASTM E2573, *Standard Practice for Specimen Preparation and Mounting of Site-Fabricated Stretch Systems to Assess Surface Burning Characteristics,* 6-44
ASTM F567, *Standard Practice for the Installation of Chain-Link Fence,* 14-122
ASTM F955, *Standard Test Method for Evaluating Heat Transfer through Materials for Protective Clothing upon Contact with Molten Substances,* 6-94
ASTM F1001, *Standard Guide for Selection of Chemicals to Evaluate Protective Clothing Materials,* 12-157
ASTM F1060, *Standard Test Method for Thermal Protective Performance of Materials for Protective Clothing for Hot Surface Contact,* 6-93
ASTM F1358, *Standard Test Method for Effects of Flame Impingement on Materials Used in Protective Clothing Not Designated Primarily for Flame Resistance,* 6-92

  state adoptions, 1-65, Fig. 1.3.4
NFPA 10, *Standard for Portable Fire Extinguishers,* 4-74, 8-35, 8-61, 9-18, 9-125, 9-154, 9-160, 17-40, 17-71, 17-82–17-83, 17-88, 17-124, 21-22, 21-198
NFPA 11, *Standard for Low-, Medium-, and High-Expansion Foam,* 17-62, 17-63, 17-67, 17-68, 21-181
NFPA 12, *Standard on Carbon Dioxide Extinguishing Systems,* 8-62, 9-186, 17-8, 17-12, 17-127, 21-178, 21-181
NFPA 12A, *Standard on Halon 1301 Fire Extinguishing Systems,* 8-63, 17-94, 17-127
NFPA 12B, *Standard on Halon 1211 Fire Extinguishing Systems* (discontinued), 21-94, 21-109
NFPA 13, *Standard for the Installation of Sprinkler Systems,* 3-162, 3-177, 3-189, 4-74–4-75, 4-97, 6-226, 6-238, 6-259, 7-11, 8-12, 8-62, 8-69, 8-111, 9-160, 11-42, 15-15, 16-6, 16-8, 16-33, 16-42, 16-51, 16-68, 16-80, 16-91, 16-102, 16-162, 17-35, 17-124, 18-29, 20-20, 20-43, 20-53, 20-102, 20-151, 20-160, 20-214, 21-106
  commercial vessels, 21-175, 21-181
  and passenger elevator systems, 10-62, 10-63
  solid waste storage rooms, 11-4, 11-5
  storage occupancies, 10-157, 20-158
  and water supplies for sprinkler systems, 15-24, 15-30, 15-65, 15-67, 15-68, 15-69, 15-70, 15-81
  woodworking processes/facilities, 9-18, 9-25
NFPA 13D, *Standard for the Installation of Sprinkler Systems in One- and Two-Family Dwellings and Manufactured Homes,* 15-24, 16-23, 16-42, 16-91, 16-94–16-95, 18-29, 20-20, 20-53, 20-55
NFPA 13E, *Recommended Practice for Fire Department Operations in Properties Protected by Sprinkler and Standpipe Systems,* 16-51, 16-204
NFPA 13R, *Standard for the Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height,* 4-97, 15-24, 16-23, 16-42, 16-91, 16-103, 18-29, 20-20, 20-25, 20-29, 20-53
NFPA 14, *Standard for the Installation of Standpipe and Hose Systems,* 9-160, 11-43, 12-195, 14-45, 16-162, 16-194, 16-196, 16-197, 20-165, 21-198, 21-199, 21-211
NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection,* 7-11, 8-22, 9-187, 16-56, 16-109, 16-110, 16-150, 16-162, 17-40
NFPA 17, *Standard for Dry Chemical Extinguishing Systems,* 10-81, 17-29
NFPA 17A, *Standard for Wet Chemical Extinguishing Systems,* 10-81, 17-26, 17-29
NFPA 18, *Standard on Wetting Agents,* 17-36, 17-48
NFPA 18A, *Standard on Water Additives for Fire Control and Vapor Mitigation,* 17-37
NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection,* 8-139, 14-45, 15-30, 15-64, 15-86, 15-92, 15-93, 15-94, 15-95, 15-99, 15-100, 15-102, 16-172, 20-151, 21-199–21-200
  and controller power supplies, 15-11, 15-106–15-107, 15-109, 15-110
  and pump controllers, 15-105–15-107, 15-116, 15-117, 15-118, 15-119, 15-122, 15-123–15-124, 15-125, 15-127, 15-130, 15-133, 15-141, 15-142, 15-143
NFPA 22, *Standard for Water Tanks for Private Fire Protection,* 14-45, 15-6, 15-8, 15-14, 15-64, 15-65, 15-67, 21-199
NFPA 24, *Standard for the Installation of Private Fire Service Mains and Their Appurtenances,* 9-18, 11-43, 12-195, 14-45, 16-33, 16-68, 20-165
NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems,* 9-160, 12-186, 15-80, 15-105, 15-139, 16-51, 16-189, 20-29, 20-192, 20-214
NFPA 30, *Flammable and Combustible Liquids Code,* 3-17, 3-126, 6-238, 6-257, 7-60, 8-110, 8-172, 9-15, 9-40, 9-62, 9-126, 9-137, 9-184, 11-24, 11-54, 11-61, 11-78, 12-184, 12-187, 13-94, 14-100, 16-34, 17-38, 17-64, 17-149, 20-208, 20-215, 21-30
  fuel oil storage, 10-15, 10-16
  and laboratories using chemicals, 9-163, 9-164
  storage of flammable and combustible liquids, 7-16, 7-18, 7-24, 7-25, 7-28
NFPA 30A, *Code for Motor Fuel Dispensing Facilities and Repair Garages,* 8-162, 8-172, 20-169, 21-30, 21-68, 21-88
NFPA 30B, *Code for the Manufacture and Storage of Aerosol Products,* 6-257, 6-258, 6-259, 6-261–6-262, 20-160
NFPA 31, *Standard for the Installation of Oil-Burning Equipment,* 7-25, 8-69, 9-184, 10-15, 10-16, 10-35, 11-24, 15-99, 20-69
NFPA 33, *Standard for Spray Application Using Flammable or Combustible Materials,* 8-172, 9-18, 9-29, 9-62
NFPA 34, *Standard for Dipping and Coating Processes Using Flammable or Combustible Liquids,* 8-172, 9-42
NFPA 35, *Standard for the Manufacture of Organic Coatings,* 9-62
NFPA 36, *Standard for Solvent Extraction Plants,* 9-134, 9-136, 9-137–9-138
NFPA 37, *Standard for the Installation and Use of Stationary Combustion Engines and Gas Turbines,* 8-106, 8-107, 12-255, 15-99, 21-63
NFPA 40, *Standard for the Storage and Handling of Cellulose Nitrate Film,* 6-224
NFPA 42, *Code for the Storage of Pyroxylin Plastic,* 6-224
NFPA 45, *Standard on Fire Protection for Laboratories Using Chemicals,* 8-154, 9-158, 9-163, 9-164, 9-165, 9-197
NFPA 49, *Hazardous Chemicals Data* (discontinued), 7-43, 7-44
NFPA 51, *Standard for the Design and Installation of Oxygen-Fuel Gas Systems for Welding, Cutting, and Allied Processes,* 9-78, 20-215
NFPA 51B, *Standard for Fire Prevention During Welding, Cutting, and Other Hot Work,* 9-73, 9-80, 11-51, 12-187, 20-161, 20-213, 20-215
NFPA 52, *Vehicular Fuel Systems Code,* 8-110, 21-19, 21-21, 21-60, 21-63, 21-74, 21-157
NFPA 54, *National Fuel Gas Code,* 1-67, 3-17, 6-168, 8-69, 8-107, 8-110, 9-184, 10-17, 10-25, 10-35, 10-39, 10-41–10-42, 10-44, 10-47, 10-48, 11-25, 20-69
NFPA 55, *Standard for the Storage, Use, and Handling of Compressed Gases and*

Cryogenic Fluids in Portable and Stationary Containers, Cylinders, and Tanks, 6-165, 6-168, 8-110, 9-165
NFPA 57, *Liquefied Natural Gas Vehicular Fuel Systems Code* (discontinued), 21-60, 21-65
NFPA 58, *Liquefied Petroleum Gas Code,* 3-17, 6-172–6-173, 7-36, 8-107, 8-110, 9-184, 10-26, 11-54, 12-184, 13-94, 20-91, 20-215, 21-19, 21-21, 21-60
NFPA 59, *Utility LP-Gas Plant Code,* 21-60
NFPA 59A, *Standard for the Production, Storage, and Handling of Liquefied Natural Gas (LNG),* 21-65
NFPA 61, *Standard for the Prevention of Fires and Dust Explosions in Agricultural and Food Processing Facilities,* 9-86–9-87, 9-91, 20-169
NFPA 68, *Standard on Explosion Protection by Deflagration Venting,* 2-99, 6-148, 6-175, 7-7, 8-14, 8-124, 9-22, 9-23, 9-25, 9-43, 9-61, 9-99, 9-217, 9-220, 12-184, 16-130, 17-141, 17-154, 17-155, 18-79, 18-83, 18-84, 18-85, 18-86, 18-87
NFPA 69, *Standard on Explosion Prevention Systems,* 2-100, 6-147, 8-14, 9-22, 9-23, 9-25, 9-61, 9-217, 9-220, 11-24, 16-110, 17-7, 17-141, 17-149, 17-151, 17-154, 17-158
NFPA 70, *National Electrical Code®,* 1-62, 1-67, 3-15, 6-178, 6-239, 7-10, 7-25, 7-41, 8-40, 8-61, 8-76, 8-107, 8-124, 9-15, 9-34, 9-45, 9-62, 9-79, 9-159, 9-182, 10-22, 11-10, 11-80, 12-187, 14-6, 14-26, 14-102, 16-111, 17-125, 17-151, 20-9, 20-69, 20-213, 20-221, 21-86, 21-148, 21-158
air-conditioning systems, 10-71, 10-75
electrical cables, 6-45
and electrical systems, 8-127, 8-137, 8-139, 8-140, 8-142–8-143, 8-145, 8-151, 8-152, 8-153, 8-154, 8-158, 8-159, 8-160, 8-161, 8-162, 8-163, 8-172, 10-63, 20-184
and emergency/standby power supplies, 10-3–10-4, 10-5, 10-6
fire pump components, 15-105, 15-106, 15-112, 15-114, 15-143
state adoptions, 1-65, Fig. 1.3.4
stationary fire pumps, 15-98, 15-100
storage/handling of grain mill products, 9-98, 9-101–9-102
NFPA 70E, *Standard for Electrical Safety in the Workplace,* 8-137
NFPA 72®, National Fire Alarm Code®, 3-127, 3-150, 4-97, 8-163, 9-22, 9-155, 9-160, 10-62, 10-75, 11-42, 12-262, 13-118, 14-45, 14-106, 14-114, 15-100, 16-111, 16-172, 20-28, 20-53, 20-151, 20-161, 20-163, 21-106
evacuation signals, 4-4–4-5, 4-8, 8-64
fire alarm systems, 14-4, 14-5, 14-6, 14-7, 14-9, 14-10, 14-12
fire detectors, 14-23, 14-27
fire loss investigations and, 3-37, 3-38
inspection/testing/maintenance of alarm systems, 14-57, 14-60
notification appliances, 14-30, 14-32, 14-34, 14-35
security communications, 1-104–1-105
smoke alarms/detectors, 8-63, 14-27, 14-68, 14-73, 14-80, 14-81, 14-82, 14-83, 14-86
NFPA 74, *Household Fire Warning Equipment* (discontinued), 14-80
NFPA 75, *Standard for the Protection of Information Technology Equipment,* 8-137, 9-107, 17-41, 17-125
NFPA 76, *Standard for the Fire Protection of Telecommunications Facilities,* 9-172, 9-174, 9-176, 9-177
NFPA 77, *Recommended Practice on Static Electricity,* 7-30, 8-14, 9-34, 9-62, 11-61, 12-187
NFPA 79, *Electrical Standard for Industrial Machinery,* 8-48, 8-137
NFPA 80, *Standard for Fire Doors and Other Opening Protectives,* 6-239, 8-37, 10-61, 10-73, 18-15, 18-16, 18-18, 19-33, 20-52
NFPA 80A, *Recommended Practice for Protection of Buildings from Exterior Fire Exposures,* 1-161, 2-71, 11-43, 18-14
NFPA 82, *Standard on Incinerators and Waste and Linen Handling Systems and Equipment,* 7-66, 11-4, 11-5, 11-8, 11-9, 11-10, 11-24, 20-152
NFPA 85, *Boiler and Combustion Systems Hazards Code,* 8-69, 9-184, 10-103
NFPA 86, *Standard for Ovens and Furnaces,* 8-6, 8-72–8-73, 8-77, 8-97, 9-19, 11-13, 11-24, 11-25, 17-34
NFPA 88A, *Standard for Parking Structures,* 8-172, 20-168, 20-169, 20-220
NFPA 90A, *Standard for the Installation of Air-Conditioning and Ventilating Systems,* 1-127, 8-3, 8-61, 10-26, 10-69, 10-71, 10-72–10-73, 10-74, 11-31, 11-41, 20-47, 20-50
NFPA 90B, *Standard for the Installation of Warm Air Heating and Air-Conditioning Systems,* 1-127, 8-153, 10-21, 10-22, 10-27, 11-41, 20-70
NFPA 91, *Standard for Exhaust Systems for Air Conveying of Vapors, Gases, Mists, and Noncombustible Particulate Solids,* 8-3, 9-62, 9-101, 17-149, 21-33
NFPA 92A, *Standard for Smoke-Control Systems Utilizing Barriers and Pressure Differences,* 8-3, 10-73, 18-43, 18-44, 18-51, 20-29, 20-81, 20-89, 20-102, 20-152, 20-164
NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria, and Large Spaces,* 3-96, 3-157, 3-192, 8-3, 10-73, 18-43, 18-44, 18-45, 18-52, 18-53, 20-29, 20-81, 20-89, 20-102, 20-220
NFPA 96, *Standard for Ventilation Control and Fire Protection of Commercial Cooking Operations,* 10-25, 10-81, 10-85, 11-32, 14-47, 20-90, 20-103, 20-120, 20-152
NFPA 99, *Standard for Health Care Facilities,* 1-139, 8-137, 8-154, 8-173, 10-4, 20-152
NFPA *101®, Life Safety Code®,* 1-32, 1-56, 1-57, 1-67, 1-101, 1-114, 1-121, 1-132, 1-139, 3-19, 3-22, 3-23–3-24, 3-176, 3-177, 3-178, 3-190, 4-3, 4-44, 4-101, 5-68, 6-35, 6-120, 8-163, 9-158, 9-181, 9-182, 10-4, 10-57, 10-65, 10-73, 13-7, 14-33, 14-47, 14-123, 15-25, 16-31, 16-106, 18-12, 18-50, 19-4, 19-62, 20-5, 21-31, 21-101, 21-147, 21-170
apartment buildings, 20-37, 20-41, 20-42, 20-43, 20-44, 20-45
assembly occupancies, 20-85, 20-87, 20-89, 20-90, 20-94
board and care facilities, 20-15–20-16, 20-17, 20-20
business occupancies, 20-110, 20-112
day-care occupancies, 20-123, 20-124, 20-125, 20-126, 20-127
design fire scenarios, 3-122–3-123, 3-124
detention/correctional occupancies, 20-129, 20-130, 20-135, 20-137
educational occupancies, 20-119, 20-120, 20-122
and egress design, 4-69, 4-71–4-81, 20-193–20-194
elevator use, 4-42
evacuations, 4-104, 4-106, 4-107, 4-108, 4-109
exit signs, 4-8
fundamental requirements, 20-11
health care occupancies, 20-139, 20-140, 20-147, 20-149, 20-150, 20-151, 20-152, 20-153, 20-154
high-rise buildings, 20-73, 20-81
hotels, 20-23, 20-25, 20-29
industrial occupancies, 20-204, 20-205, 20-208–20-209
and interior finish, 6-96, 18-24, 18-26, 18-27, 18-29, 18-35, 18-36, 18-37
library/museum collections, 20-190, 20-193, 20-194
life safety in buildings, 20-7, 20-13, Fig. 20.1.8
lodging/rooming houses, 20-49, 20-50, 20-51, 20-53
mercantile occupancies, 20-98, 20-99
motion picture/television soundstages, 20-214
occupancies in special structures, 20-217, 20-218, 20-219, 20-220, 20-222, 20-223, 20-225
occupancy load factors, 20-7, Table 20.1.3
one-/two-family dwellings, 20-55, 20-56
state adoptions, 1-65, Fig. 1.3.5
storage occupancies, 20-158, 20-162, 20-163, 20-168, 20-169, 20-170
university housing, 20-23, 20-35
vocal alarm systems, 4-43
NFPA 101A, *Guide on Alternative Approaches to Life Safety,* 20-7, 20-112, 20-153
NFPA 102, *Standard for Grandstands, Folding and Telescopic Seating, Tents, and Membrane Structures,* 3-22, 6-98, 20-171
NFPA 105, *Standard for the Installation of Smoke Door Assemblies and Other Opening Protectives,* 18-50
NFPA 110, *Standard for Emergency and Standby Power Systems,* 8-61, 8-163, 10-4, 10-7, 12-255, 14-6, 15-108, 15-115
NFPA 111, *Standard on Stored Electrical Energy Emergency and Standby Power Systems,* 8-12, 12-255
NFPA 120, *Standard for Fire Prevention and Control in Coal Mines,* 9-216, 9-218
NFPA 122, *Standard for Fire Prevention and Control in Metal/Nonmetal Mining and Metal Mineral Processing Facilities,* 9-216, 9-219, 11-57
NFPA 130, *Standard for Fixed Guideway Transit and Passenger Rail Systems,* 18-32, 21-103, 21-104, 21-115, 21-191, 21-206
NFPA 140, *Standard on Motion Picture and Television Production Studio Soundstages and Approved Production Facilities,* 20-213–20-214
NFPA 204, *Standard for Smoke and Heat Venting,* 8-3, 11-41, 18-57, 18-58
NFPA 211, *Standard for Chimneys, Fireplaces, Vents, and Solid Fuel-Burning Appliances,* 10-27, 10-35, 10-46, 10-47, 10-48, 10-53, 10-54, 11-9
NFPA 220, *Standard on Types of Building Construction,* 6-239, 9-152, 9-196, 12-130, 13-40, 19-3, 19-4, 19-13, 19-59, 20-205, 21-105
NFPA 221, *Standard for High Challenge Fire Walls, Fire Walls, and Fire Barrier Walls,* 18-14, 19-15, 19-34, 20-213
NFPA 225, *Model Manufactured Home Installation Standard,* 19-63, 20-67
NFPA 232, *Standard for the Protection of Records,* 9-109
NFPA 241, *Standard for Safeguarding Construction, Alteration, and Demolition Operations,* 11-48, 20-103

NFPA 251, *Standard Methods of Tests of Fire Resistance of Building Construction and Materials,* 2-67, 6-37, 6-39, 6-71, 6-129, 12-130, 12-131, 18-4, 19-5, 19-30, 19-34, 19-45, 19-51, 19-55, 19-72, 19-83, 19-97, 21-103
NFPA 252, *Standard Methods of Fire Tests of Door Assemblies,* 2-67, 6-39, 10-61, 18-16
NFPA 253, *Standard Method of Test for Critical Radiant Flux of Floor Covering Systems Using a Radiant Heat Energy Source,* 2-43, 4-75, 6-97, 10-63, 18-16, 18-33, 18-34, 18-35, Figs. 6.5.9–6.5.10
NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials,* 2-42, 2-44, 4-75, 6-7, 6-42, 6-43, 6-49, 6-51, 6-70, 6-96, 6-129, 6-132, 6-133, 6-225, 6-227, 6-229, 8-7, 10-27, 10-63, 18-23, 18-25, 18-27, 18-28, 18-31, 18-32, 18-35, 18-36, 18-37, 18-39, 19-5, 19-62, 19-93, 21-103, 21-173
NFPA 256, *Standard Methods of Fire Tests of Roof Coverings,* 2-70, 9-153, 19-22
NFPA 257, *Standard on Fire Test for Window and Glass Block Assemblies,* 2-67, 6-39, 18-17, 19-54
NFPA 259, *Standard Test Method for Potential Heat of Building Materials,* 6-283, 19-5
NFPA 260, *Standard Methods of Tests and Classification System for Cigarette Ignition Resistance of Components of Upholstered Furniture,* 4-77, 6-94, 6-228
NFPA 261, *Standard Method of Test for Determining Resistance of Mock-Up Upholstered Furniture Material Assemblies to Ignition by Smoldering Cigarettes,* 4-77, 6-94, 6-228
NFPA 262, *Standard Method of Test for Flame Travel and Smoke of Wires and Cables for Use in Air-Handling Spaces,* 2-44, 6-43, 6-45, 6-228, 10-75
NFPA 264A, *Standard Method of Test for Heat Release Rates for Upholstered Furniture Components or Composites and Mattresses Using an Oxygen Consumption Calorimeter* (withdrawn), 6-119
NFPA 265, *Standard Methods of Fire Tests for Evaluating Room Fire Growth Contribution of Textile Coverings on Full Height Panels and Walls,* 2-41, 6-49, 6-96, 18-28, 18-31, 18-36
NFPA 268, *Standard Test Method for Determining Ignitibility of Exterior Wall Assemblies Using a Radiant Heat Energy Source,* 2-70
NFPA 269, *Standard Test Method for Developing Toxic Potency Data for Use in Fire Hazard Modeling,* 2-45, 6-8, 6-13, 6-19, 6-20, 6-230
NFPA 270, *Standard Test Method for Measurement of Smoke Obscuration Using a Conical Radiant Source in a Single Closed Chamber,* 6-22, 6-46, 18-33
NFPA 271, *Standard Method of Test for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter,* 2-39, 6-41, 6-47, 6-228, 9-128, 18-18
NFPA 272, *Standard Method of Test for Heat and Visible Smoke Release Rates for Upholstered Furniture Components or Composites and Mattresses Using an Oxygen Consumption Calorimeter,* 6-47, 6-228
NFPA 285, *Standard Fire Test Method for Evaluation of Fire Propagation Characteristics of Exterior Non-Load-Bearing Wall Assemblies Containing Combustible Components,* 2-69, 18-32, 18-76
NFPA 286, *Standard Methods of Fire Tests for Evaluating Contribution of Wall and Ceiling Interior Finish to Room Fire Growth,* 2-41, 4-75, 6-49, 6-96, 6-227, 18-25, 18-31, 18-32
NFPA 287, *Standard Test Methods for Measurement of Flammability of Materials in Cleanrooms Using a Fire Propagation Apparatus (FPA),* 2-38, 6-46, 6-48, 6-228, 9-128, Fig. 2.3.8
NFPA 288, *Standard Methods of Fire Tests of Floor Fire Door Assemblies Installed Horizontally in Fire Resistance-Rated Floor Systems,* 6-39
NFPA 289 (in process), 6-50
NFPA 301, *Code for Safety to Life from Fire on Merchant Vessels,* 18-33, 21-181
NFPA 302, *Fire Protection Standard for Pleasure and Commercial Motor Craft,* 21-157
NFPA 306, *Standard for the Control of Gas Hazards on Vessels,* 21-171, 21-181
NFPA 307, *Standard for the Construction and Fire Protection of Marine Terminals, Piers, and Wharves,* 20-168, 20-221
NFPA 312, *Standard for Fire Protection of Vessels During Construction, Conversion, Repair, and Lay-Up,* 21-181
NFPA 318, *Standard for the Protection of Semiconductor Fabrication Facilities,* 9-124, 9-127, Fig. 9.9.5, Table 9.9.1
NFPA 325, *Fire Hazard Properties of Flammable Liquids, Gases, and Volatile Solids* (discontinued), 7-43, 7-44
NFPA 329, *Recommended Practice for Handling Releases of Flammable and Combustible Liquids and Gases,* 7-24
NFPA 385, *Standard for Tank Vehicles for Flammable and Combustible Liquids,* 7-31, 21-19
NFPA 402, *Guide for Aircraft Rescue and Fire Fighting Operations,* 21-140
NFPA 403, *Standard for Aircraft Rescue and Fire-Fighting Services at Airports,* 13-103, 13-107, 21-144
NFPA 407, *Standard for Aircraft Fuel Servicing,* 21-19, 21-137
NFPA 408, *Standard for Aircraft Hand Portable Fire Extinguishers,* 21-141
NFPA 409, *Standard on Aircraft Hangars,* 8-172, 17-62, 21-146
NFPA 410, *Standard on Aircraft Maintenance,* 21-148
NFPA 412, *Standard for Evaluating Aircraft Rescue and Fire-Fighting Foam Equipment,* 17-68
NFPA 414, *Standard for Aircraft Rescue and Fire-Fighting Vehicles,* 12-280, 13-23, 17-64, 21-19, 21-143
NFPA 415, *Standard on Airport Terminal Buildings, Fueling Ramp Drainage, and Loading Walkways,* 2-67, 21-140, 21-147
NFPA 418, *Standard for Heliports,* 20-152, 21-145
NFPA 424, *Guide for Airport/Community Emergency Planning,* 21-140
NFPA 430, *Code for the Storage of Liquid and Solid Oxidizers,* 7-45, 7-47, 11-24, 17-125
NFPA 432, *Code for the Storage of Organic Peroxide Formulations,* 7-50
NFPA 434, *Code for the Storage of Pesticides,* 6-238, 6-243, 16-88
NFPA 450, *Guide for Emergency Medical Services and Systems,* 13-153, 13-157
NFPA 471, *Recommended Practice for Responding to Hazardous Materials Incidents,* 1-145, 6-243, 12-197, 13-95
NFPA 472, *Standard for Professional Competence of Responders to Hazardous Materials Incidents,* 1-145, 6-243–6-244, 12-168, 12-197, 13-90, 13-95
NFPA 473, *Standard for Competencies for EMS Personnel Responding to Hazardous Materials Incidents,* 13-96
NFPA 484, *Standard for Combustible Metals,* 6-153, 7-66, 8-36, 11-24, 17-41, 17-149, Fig. 6.9.1
NFPA 491, *Guide to Hazardous Chemical Reactions* (discontinued), 7-43
NFPA 493, *Spontaneous Heating and Ignition of Coal and Other Mining Products* (discontinued), 3-27
NFPA 495, *Explosive Materials Code,* 2-94, 6-247, 6-251, 7-46, 8-19, 21-19
NFPA 496, *Standard for Purged and Pressurized Enclosures for Electrical Equipment,* 7-41, 8-109, 8-169, 8-171, 9-138, 17-150, 17-151
NFPA 497, *Recommended Practice for the Classification of Flammable Liquids, Gases, or Vapors and of Hazardous (Classified) Locations for Electrical Installations in Chemical Process Areas,* 3-126, 8-168, 17-151
NFPA 498, *Standard for Safe Havens and Interchange Lots for Vehicles Transporting Explosives,* 6-251, 21-19
NFPA 499, *Recommended Practice for the Classification of Combustible Dusts and of Hazardous (Classified) Locations for Electrical Installations in Chemical Process Areas,* 17-151
NFPA 501, *Standard on Manufactured Housing,* 18-32, 19-63, 20-67, 20-69–20-70
NFPA 501A, *Standard for Fire Safety Criteria for Manufactured Home Installations, Sites, and Communities,* 20-67, 20-70, 21-97
NFPA 502, *Standard for Road Tunnels, Bridges, and Other Limited Access Highways,* 16-140, 21-191, 21-193, 21-194, 21-196, 21-198, 21-199, 21-201, 21-202, 21-203, 21-210, 21-211, Table 21.11.6
NFPA 505, *Fire Safety Standard for Powered Industrial Trucks Including Type Designations, Areas of Use, Conversions, Maintenance, and Operations,* 8-31, 8-32, 20-162
NFPA 520, *Standard on Subterranean Spaces,* 20-220, 21-191
NFPA 550, *Guide to the Fire Safety Concepts Tree,* 1-159, 3-139, 20-9, 20-192
NFPA 551, *Guide for the Evaluation of Fire Risk Assessments,* 3-136, 3-139
NFPA 555, *Guide on Methods for Evaluating Potential for Room Flashover,* 6-50–6-51
NFPA 557, *Standard Fire Loads for Structural Fire Protection Design* (proposed), 6-40
NFPA 600, *Standard on Industrial Fire Brigades,* 1-139, 1-145, 7-6, 9-180, 9-199, 11-55, 12-192, 12-194, 12-195, 20-166, 20-209
NFPA 601, *Standard for Security Services in Fire Loss Prevention,* 11-48, 14-98
NFPA 650 (withdrawn), 8-3
NFPA 654, *Standard for the Prevention of Fire and Dust Explosions*

from the Manufacturing, Processing, and Handling of Combustible Particulate Solids, 2-100, 8-3, 9-61, 9-101, 11-24, 17-149, 17-150
NFPA 664, *Standard for the Prevention of Fires and Explosions in Wood Processing and Woodworking Facilities,* 7-10, 9-5, 9-8, 9-9, 9-10, 9-11, 9-15, 9-18, 9-21
NFPA 701, *Standard Methods of Fire Tests for Flame Propagation of Textiles and Films,* 6-89, 6-94, 6-98, 6-99, 11-49, 11-57, 18-37, 20-93, 20-120, 20-135, 20-153
NFPA 702, *Classification of the Flammability of Wearing Apparel* (withdrawn), 6-89
NFPA 704, *Standard System for the Identification of the Hazards of Materials for Emergency Response,* 6-6, 6-239, 6-242, 7-44, 8-22, 8-24, 9-33, 9-158, 13-122
NFPA 705, *Recommended Practice for a Field Flame Test for Textiles and Films,* 2-35
NFPA 720, *Standard for the Installation of Carbon Monoxide (CO) Warning Equipment in Dwelling Units,* 14-114, 14-115
NFPA 730, *Guide for Premises Security,* 1-4, 1-98, 1-99–1-100, 1-133, 1-142, 12-205
NFPA 731, *Standard for the Installation of Electronic Premises Security Systems,* 1-99, 14-126
NFPA 750, *Standard on Water Mist Fire Protection Systems,* 2-86, 16-104, 16-136, 16-149, 16-154, 16-174, 17-36, 21-176, 21-181
NFPA 780, *Standard for the Installation of Lightning Protection Systems,* 8-142, 9-154, 11-69, 11-70, 11-73, 11-75, 11-76, 11-77, 11-78, 11-79, 17-62
NFPA 801, *Standard for Fire Protection for Facilities Handling Radioactive Materials,* 7-67, 9-162, 9-193, 9-196, 11-24
NFPA 805, *Performance-Based Standard for Fire Protection for Light Water Reactor Electric Generating Plants,* 9-193, 9-194
NFPA 806, *Performance-Based Standard for Fire Protection for Advanced Nuclear Reactor Electric Generating Plants* (proposed), 9-194
NFPA 820, *Standard for Fire Protection in Wastewater Treatment and Collection Facilities,* 9-150
NFPA 850, *Recommended Practice for Fire Protection for Electric Generating Plants and High Voltage Direct Current Converter Stations,* 7-5, 9-180, 9-181, 9-182, 9-183, 9-184, 9-185, 9-187, 11-25
NFPA 851, *Recommended Practice for Fire Protection for Hydroelectric Generating Plants,* 9-180, 9-186, 16-34
NFPA 853, *Standard for the Installation of Stationary Fuel Cell Power Systems,* 8-109, 9-180, 9-184
NFPA 901, *Standard Classifications for Incident Reporting and Fire Protection Data,* 3-61, 12-93
NFPA 909, *Code for the Protection of Cultural Resource Properties—Museums, Libraries, and Places of Worship,* 3-178, 9-108, 20-179
NFPA 914, *Code for Fire Protection of Historic Structures,* 3-178, 20-179, 20-200
NFPA 921, *Guide for Fire and Explosion Investigations,* 1-83, 1-91, 2-34, 2-35, 3-31, 3-33, 3-34, 3-68, 11-61, 19-70–19-71
NFPA 1001, *Standard for Fire Fighter Professional Qualifications,* 12-69, 12-95, 12-115
NFPA 1002, *Standard for Fire Apparatus Driver/Operator Professional Qualifications,* 12-250, 12-271
NFPA 1003, *Standard for Airport Fire Fighter Professional Qualifications,* 21-144
NFPA 1006, *Standard for Rescue Technician Professional Qualifications,* 13-14, 13-15
NFPA 1021, *Standard for Fire Officer Professional Qualifications,* 12-70
NFPA 1031, *Standard for Professional Qualifications for Fire Inspector and Plan Examiner,* 1-83
NFPA 1033, *Standard for Professional Qualifications for Fire Investigator,* 1-83, 3-33, 3-39, 12-170
NFPA 1035, *Standard for Professional Qualifications for Public Fire and Life Safety Educator,* 1-83, 5-21, 5-93, 5-136
NFPA 1037, *Standard for Professional Qualifications for Fire Marshals,* 1-83
NFPA 1041, *Standard for Fire Service Instructor Professional Qualifications,* 12-164
NFPA 1061, *Standard for Professional Qualifications for Public Safety Telecommunicator,* 12-260
NFPA 1071, *Standard for Emergency Vehicle Technician Professional Qualifications,* 12-283
NFPA 1081, *Standard for Industrial Fire Brigade Member Professional Qualifications,* 12-193
NFPA 1123, *Code for Fireworks Display,* 20-214
NFPA 1126, *Standard for the Use of Pyrotechnics Before a Proximate Audience,* 20-213–20-214
NFPA 1141, *Standard for Fire Protection in Planned Building Groups,* 11-40, 11-41
NFPA 1142, *Standard on Water Supplies for Suburban and Rural Fire Fighting,* 13-38, 13-41, 13-45
NFPA 1144, *Standard for Protection of Life and Property from Wildfire,* 6-136, 11-40, 11-41
NFPA 1145, *Guide for the Use of Class A Foams in Manual Structural Fire Fighting,* 17-37
NFPA 1150, *Standard on Foam Chemicals for Fires in Class A Fuels,* 17-37
NFPA 1192, *Standard on Recreational Vehicles,* 18-32, 21-96, 21-98, 21-99
NFPA 1194, *Standard for Recreational Vehicle Parks and Campgrounds,* 21-98
NFPA 1221, *Standard for the Installation, Maintenance, and Use of Emergency Services Communications Systems,* 12-17, 12-66, 12-220, 12-257, 12-260, 13-157, 13-157, Figs. 12.13.7–12.13.8
NFPA 1401, *Recommended Practice for Fire Service Training Reports and Records,* 12-70, 12-173
NFPA 1402, *Guide to Building Fire Service Training Centers,* 12-168, 12-250
NFPA 1403, *Standard on Live Fire Training Evolutions,* 12-163, 12-172, 12-173, 12-194, 12-250
NFPA 1405, *Guide for Land-Based Fire Fighters Who Respond to Marine Vessel Fires,* 21-181
NFPA 1410, *Standard on Training for Initial Emergency Scene Operations,* 12-12
NFPA 1452, *Guide for Training Fire Service Personnel to Conduct Dwelling Fire Safety Surveys,* 1-86, Figs. 1.5.1–1.5.2
NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program,* 12-60, 12-72, 12-109, 12-110, 12-117, 12-125, 12-144, 12-149, 12-162, 12-173, 13-6
NFPA 1501, *Standard for Fire Department Safety Officer* (discontinued), 12-144
NFPA 1521, *Standard for Fire Department Safety Officer,* 12-109
NFPA 1561, *Standard on Emergency Services Incident Management System,* 1-139, 12-109, 12-110, 12-123–12-124, 12-193
NFPA 1581, *Standard on Fire Department Infection Control Program,* 12-109, 12-114–12-115, 12-156
NFPA 1583, *Standard on Health-Related Fitness Programs for Fire Fighters,* 12-109
NFPA 1584, *Recommended Practice on the Rehabilitation of Members Operating at Incident Scene Operations and Training Exercises,* 12-109
NFPA 1600, *Standard on Disaster/Emergency Management and Business Continuity Programs,* 1-133, 1-134, 1-138, 1-139, 4-108, 12-190, 12-200
NFPA 1620, *Recommended Practice for Pre-Incident Planning,* 1-139, 1-144, 12-190, 13-4, 20-166
NFPA 1670, *Standard on Operations and Training for Technical Search and Rescue Incidents,* 1-145, 13-14–13-15, 13-20, 19-66
NFPA 1710, *Standard for the Organization and Deployment of Fire Suppression Operations, Emergency Medical Operations, and Special Operations to the Public by Career Fire Departments,* 12-5–12-6, 12-220, 13-157
NFPA 1720, *Standard for the Organization and Deployment of Fire Suppression Operations, Emergency Medical Operations, and Special Operations to the Public by Volunteer Fire Departments,* 12-5–12-6, 12-74, 12-220
NFPA 1851, *Standard on Selection, Care, and Maintenance of Protective Ensembles for Structural and Proximity Fire Fighting,* 12-145, 12-149
NFPA 1852, *Standard on Selection, Care, and Maintenance of Open-Circuit Self-Contained Breathing Apparatus (SCBA),* 12-145, 12-154
NFPA 1901, *Standard for Automotive Fire Apparatus,* 12-71, 12-267, 12-269, 12-272, 12-284, 13-23, 13-47, 16-197, 17-64, 21-19
NFPA 1906, *Standard for Wildland Fire Apparatus,* 12-267, 12-269, 13-23
NFPA 1911, *Standard for Service Tests of Fire Pump Systems on Fire Apparatus,* 12-282, 12-283
NFPA 1912, *Standard for Fire Apparatus Refurbishing,* 12-284
NFPA 1925, *Standard on Marine Fire-Fighting Vessels,* 12-279
NFPA 1931, *Standard for Manufacturer's Design of Fire Department Ground Ladders,* 12-284
NFPA 1932, *Standard on Use, Maintenance, and Service Testing of In-Service Fire Department Ground Ladders,* 12-284
NFPA 1951, *Standard on Protective Ensembles for Technical Rescue Incidents,* 12-159
NFPA 1961, *Standard on Fire Hose,* 12-284
NFPA 1962, *Standard for the Inspection, Care, and Use of Fire Hose, Couplings, and Nozzles and the Service*

Testing of Fire Hose, 12-284, 16-198
NFPA 1963, *Standard for Fire Hose Connections,* 12-286, 21-199
NFPA 1964, *Standard for Spray Nozzles,* 16-196
NFPA 1971, *Standard on Protective Ensembles for Structural Fire Fighting and Proximity Fire Fighting,* 12-144, 12-148, 12-150, 12-195, Fig. 12.9.1
NFPA 1975, *Standard on Station/Work Uniforms for Fire and Emergency Services,* 12-195
NFPA 1976, *Standard on Protective Ensemble for Proximity Fire Fighting* (discontinued), 12-148, 12-150
NFPA 1977, *Standard on Protective Clothing and Equipment for Wildland Fire Fighting,* 12-150, 13-74
NFPA 1981, *Standard on Open-Circuit Self-Contained Breathing Apparatus (SCBA) for Emergency Services,* 12-149, 12-150, 12-152–12-154, 12-195
NFPA 1982, *Standard on Personal Alert Safety Systems (PASS),* 12-149, 12-150, 12-154–12-155, 12-195
NFPA 1983, *Standard on Life Safety Rope and Equipment for Emergency Services,* 12-159
NFPA 1989, *Standard on Breathing Air Quality for Fire and Emergency Services Respiratory Protection,* 12-153
NFPA 1991, *Standard on Vapor-Protective Ensembles for Hazardous Materials Emergencies,* 12-157
NFPA 1992, *Standard on Liquid Splash-Protective Ensembles and Clothing for Hazardous Materials Emergencies,* 12-157
NFPA 1994, *Standard on Protective Ensembles for First Responders to CBRN Terrorism Incidents,* 12-149, 12-157, 12-158
NFPA 1999, *Standard on Protective Clothing for Emergency Medical Operations,* 12-156
NFPA 2001, *Standard on Clean Agent Fire Extinguishing Systems,* 3-34, 8-62, 16-130, 17-8, 17-94, 17-97, 17-110, 17-112–17-113, 17-123, 17-127, 17-128, 17-129, 17-149, 21-178, 21-181
NFPA 5000®, Building Construction and Safety Code®, 1-47–1-48, 1-67, 1-79, 1-114, 1-121, 1-127, 1-132, 3-178, 4-69, 9-124, 10-57, 14-123, 16-62, 16-106, 18-74, 19-13, 19-15, 19-19, 19-34, 19-56, 19-62, 19-70, 19-93, 20-5
  apartment buildings, 20-37, 20-40, 20-42, 20-43, 20-44, 20-45
  assembly occupancies, 20-85, 20-87, 20-89, 20-90
  board and care facilities, 20-15–20-16, 20-20
  business occupancies, 20-110
  day-care occupancies, 20-123, 20-124, 20-125, 20-126, 20-127
  detention/correctional occupancies, 20-129, 20-130, 20-135, 20-137
  educational occupancies, 20-119, 20-120, 20-122
  health care occupancies, 20-139, 20-147, 20-149, 20-150, 20-152, 20-154
  high-rise buildings, 20-73, 20-81
  hotels, 20-25, 20-29

FIRE-GAS

مدرس ، طراح و مشاور سیستم های (آتش نشانی ، تهویه ، اگزاست و فشار مثبت)

دارای صلاحیت سازمان آتش نشانی

اخذ تاییده از سازمان آتش نشانی

اولین هند بوک سیستم اطفاء حریق و مدیریت دود در ایران

Handbook of Smoke Control Engineering

AUTHOR QUILL PEN

طراحی سیستم های اطفا آبی ، گازی و فوم Sprinkler ,FM200,CO2,Foam

طراحی ، انتخاب ، تست و راه اندازی پمپ های آتش نشانی مطابق NFPA20

طراحی سیستم های اگزاست و تهویه پارکینگ ، فشار مثبت راه پله - آسانسور وآتریوم ها

SOFTWARE

نرم افزار کانتم Contam
