More events can be added to this tree, such as the detection and alarm system that alerts staff or the event that the fire department will respond to help control major fires. The event tree can grow significantly as more events are taken into consideration. For very large trees, there are techniques for reducing the necessary number of branches. In many applications a truncated or reduced event tree is sufficient. Figure 3.8.6 is an example of a more detailed event tree.

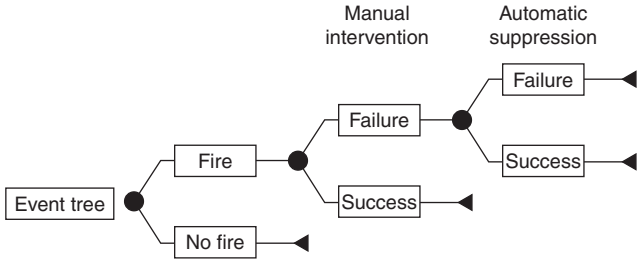

FIGURE 3.8.5 Simplified Event Tree

Event trees show all possible event options and chance events with a branching structure. They proceed chronologically, left to right, showing events as they occur in time. All outcomes along with the values and probabilities associated with them can be shown directly on the tree. There is very little ambiguity as to the possible outcomes and events the tree represents; any node gives all possible outcomes resulting from the node and the events that follow.

The advantages of event tree analysis (ETA) include, but are not limited to, the following:

- Event trees are easy to draw once the sequence of events is established.
- Event trees are easy to understand.
- It is easy to compute probabilities from an event tree.

The disadvantages of ETA include, but are not limited to, the following:

- It may be difficult to identify all consequences.
- The event tree can become very large.

ETA is a comprehensive tool for modeling all possible outcomes of a sequence of events. Event trees are used to model the selected fire scenarios. They provide a framework for the

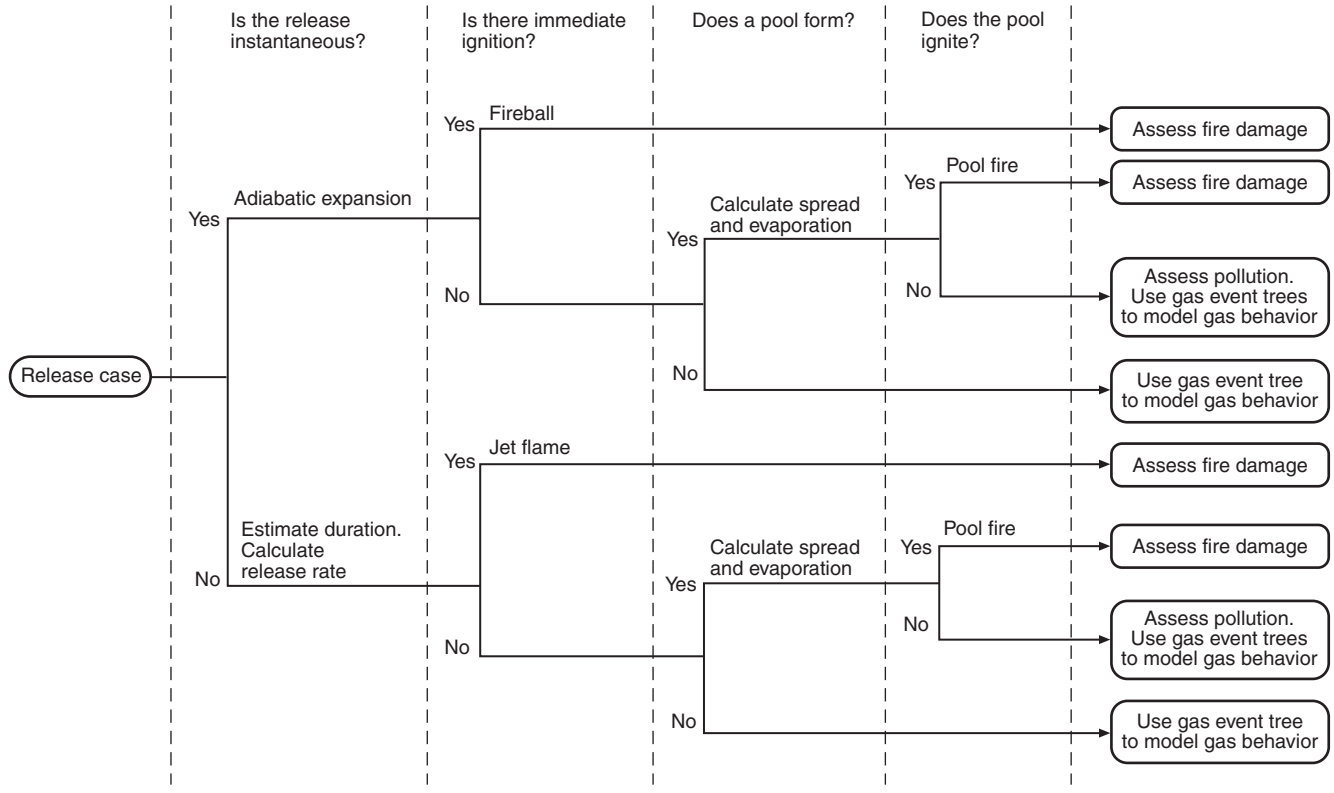

FIGURE 3.8.6 Flammable Liquid Event Tree (Source: Center for Chemical Process Safety[6])

utilization of probability data associated with the events that make up the fire scenario.

An event tree is a risk-analysis format appropriate to the Consequence Analysis oval in Figure 3.8.3. Alternatively, one can use deterministic fire protection engineering models—possibly in combination with probabilistic models for reliability or human behavior—to produce estimates of consequence for a defined scenario.

Probability Weights

Once the event tree is constructed, the frequency or probability of each outcome, or consequence, can be determined. In the example above, the calculations are done to determine the likelihood or frequency of the system incurring major destruction from failure of both strategies (consequence 1), partial damage with successful activation of the suppression system (consequence 2), and minimal damage with successful manual intervention (consequence 3). The probability of occurrence of each path is the product of the given event probabilities since they all must occur for the given outcome to occur. The total for each outcome is then the summation of all the probabilities leading to that outcome.

SUMMARY

Fire risk analysis (assessment) is a comprehensive evaluation approach that permits examination of all the types of fires that can challenge a design or other decision, including the likelihood and consequences associated with each fire type (or scenario). Recently published standards provide more detailed guidance on different aspects of fire risk analysis. This chapter has provided a brief overview of what is entailed in fire risk analysis and the methods available for performing such analysis.

Chapter Contents

Enclosure Fires
Energy Release Rate Estimates
Quantification of Fire Hazards
Enclosure Fire Effects
Comprehensive Example Application

Key Terms

axisymmetric fire, closed form equation, enclosure fire, energy release rate, fire growth rate, fire plume, flashover, heat flux, heat release rate (HRR), ignition temperature, liquid fuel fire, pool fire, preflashover, smoke exhaust rate, smoke filling rate, steady-state fire

As part of a fire protection analysis, it is often desirable to estimate the burning characteristics of selected fuels and their effects in enclosures. Also important for many analyses is the estimation of when fire protection devices such as heat detectors or automatic fire sprinklers will activate for specific fire conditions. Closed form equations are available, based principally on experimental correlations, which permit the user to estimate these effects for simple configurations and arrangements.

In this chapter, a brief introduction to enclosure fires is presented, along with equations that can be evaluated using hand calculators to provide estimates of particular effects. The equations presented are well documented and are widely used for such estimates. However, the user is cautioned that most of the equations were developed based on data from experiments that were conducted for very specific, and sometimes idealized, conditions. Therefore, caution is necessary when applying these equations to situations that may exceed the test parameters on which they are based.

The methods presented in this chapter are intended to be used in evaluating fire conditions in enclosures during the preflashover fire growth phase of a compartment fire. (See Section 2, Chapter 4, "Dynamics of Compartment Fire Growth.") The methods do not apply to fully developed room fires and postflashover conditions but some methods are provided that may be used to predict whether or not such conditions would occur. In addition, these calculations apply only to the room of fire origin and to a single burning fuel package, such as a single item or a contiguous grouping of combustibles like an upholstered chair and ottoman or a bookcase full of books. More advanced approaches are available for fully developed fire conditions, multiple rooms, and multiple fuel package fires, but they are beyond the scope of this chapter; see Section 3, Chapter 5, "Introduction to Fire Modeling" for additional information.

The topics covered in this chapter are grouped into the following four categories:

- Enclosure fires
- Energy release rate estimates
- Quantification of potential hazards from a fire
- Enclosure fire effects

Material properties, such as the heat of combustion and the heat release rate, are listed in Section 6, Chapter 17, "Tables and Charts." For additional information on material properties or the topics introduced in this chapter, refer to relevant chapters in Section 3 of the *SFPE Handbook of Fire Protection Engineering.*[1]

All calculations in this chapter are presented in SI units. For U.S. customary units, see Table 3.9.1.

If T_K is the temperature in degrees Kelvin, then the same temperature in degrees Celsius or centigrade ($T_{°C}$) is given by $T_{°C} = T_K + 273.15$. The same temperature in degrees Fahrenheit ($T_{°F}$) is given by $T_{°F} = 1.8T_{°C} + 32$.

ENCLOSURE FIRES

Enclosure Fire Defined

Enclosure fires represent a general class of unwanted fires that are characterized by boundaries that confine or restrict the flow of combustion products from the fire. Examples include room fires, attic fires, crawl-space fires, atrium fires, and so on. Enclosure fire effects are often characterized by a time-temperature profile or a transient energy release rate; countless scenarios are possible ranging from a smoldering cigarette that self-extinguishes to a postflashover fully developed fire environment that breaches the boundaries and results in fire spread and/or structural collapse. Figure 3.9.1 depicts the development of an idealized enclosure fire in terms of both the compartment temperature and the energy release rate.[2,3]

Phases of an Enclosure Fire

Four distinct phases are shown; however, one or more phases may be absent in any given enclosure fire. The incipient phase may include smoldering combustion, electrical arcing, or radiant heating of a combustible material. This phase may be very short or prolonged and typically does not result in the development of hazardous conditions per se. An incipient fire may progress into a growing flaming fire. During this phase, the energy release rate and the compartment temperature are both increasing with time; the fire typically remains confined to a single fuel package or a group of fuel packages initially involved by direct interaction with the fire and is defined as a fuel-controlled fire. When the enclosure temperature is sufficiently high, the radiant energy from the flame or combustion products may be sufficient to cause fuel surfaces other than those already burning to undergo chemical reactions yielding flammable vapors (i.e., pyrolize); an accumulation and rapid ignition of these combustible vapors often results in an instability that is typically described as flashover.[2] When flashover occurs, the energy release rate in the compartment usually increases to a level supported by the room ventilation, provided sufficient fuel is available, representing the beginning of the steady-state or fully developed postflashover compartment fire. If sufficient fuel is available such that the ventilation controls the fire size, then this stage of the fire is defined as a ventilation-controlled, fully developed enclosure fire. In the absence of structural collapse, fire spread to adjacent areas, or manual or automatic intervention, the fully developed compartment fire will eventually transition into a decay phase once sufficient fuel has been consumed and less becomes available for combustion.

The methodologies presented in this chapter are focused on predicting potential hazards and possible fire effects arising during the fire growth phase for simple fuel arrangements and

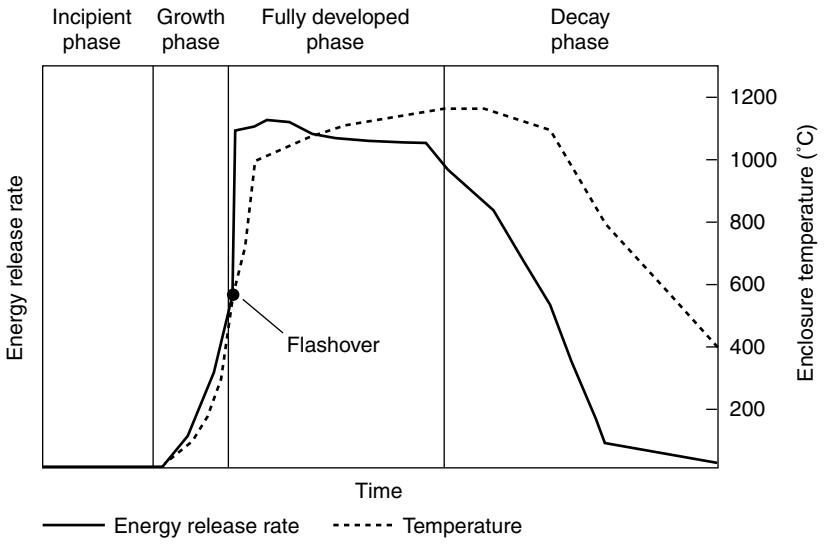

FIGURE 3.9.1 Enclosure Fire Development

enclosure geometries. The *SFPE Engineering Guide for Fire Exposures to Structural Elements*[4] as well as various chapters in Section 3 of the *SFPE Handbook of Fire Protection Engineering*[1] provide information for calculating fire hazards associated with more complex fully developed enclosure fires and interactions between the space and the development of the fire.

ENERGY RELEASE RATE ESTIMATES

Energy Release Rate Defined

Calculation procedures for fire effects in enclosures require knowledge of the *energy release rate* of the burning fuel. The term *energy release rate* is frequently used interchangeably with *heat release rate,* and it is usually expressed in units of kilowatts (kW) and symbolized by $\dot{Q}$. The energy release rate is also thermodynamically equivalent to power. The heat released by the fire oxidation process is transferred to the surroundings by convection through the heated combustion products and by thermal radiation from the heated combustion products capable of emitting thermal radiation. The convective component of the heat release rate is symbolized by $\dot{Q}_c$ and the radiant component by $\dot{Q}_r$. The sum of the convective and radiant components is equal to the total heat release rate, $\dot{Q}_T$ or just $\dot{Q}$. The radiant fraction is given by $\chi_r = \frac{\dot{Q}_r}{\dot{Q}_T}$ and is typically between 0.2 and 0.4.[1]

Currently, no broadly accepted methods exist for prediction of energy release rates based solely on basic measurements of material properties. Recent efforts in this area show promise.[5] However, it is expected that generalized methods will not be available for some time. In addition, in any enclosure fire, the actual rate of heat release is dependent not just on the burning fuel but also on the fire environment (i.e., enclosure geometry and ventilation, the manner in which the fuel is volatilized, the efficiency of the vapor combustion, and other physical and chemical effects). Therefore, for the immediate future one must rely on available laboratory test data for the specific or similar fuels. Such laboratory data may include small-scale burning properties as would be obtained in the cone calorimeter, full-scale open burning characteristics as would be obtained in a furniture calorimeter, or room burns as would be obtained from an ISO 9705 test. It is important for the data to correspond with the application considered or correlation used. Section 3 of the *SFPE Handbook of Fire Protection Engineering*[1] provides additional information on such considerations.

Knowledge of the complete energy release rate history may be required for many situations. This is particularly desirable when the fuel package exhibits unsteady or transient burning in which the mass loss rate varies with time as shown in Figure 3.9.2. The mass loss rate for unsteady fires may increase, decrease, or fluctuate with time depending on the fuel and the exposure boundary conditions. For those cases where only limiting conditions or worst-case analysis is required, it may be reasonable to assume that the fuel is burning at a constant rate representing the peak rate, which simplifies the calculation considerably.

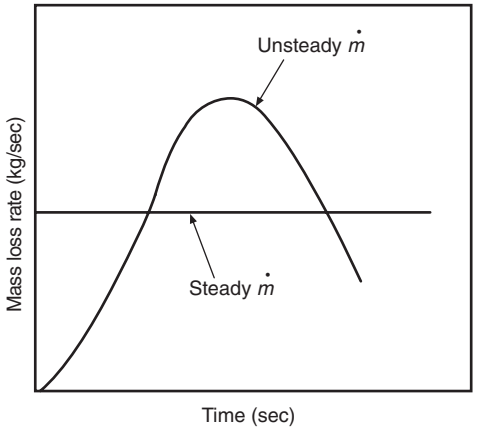

FIGURE 3.9.2 Steady and Unsteady Burning Rates

Procedures for Estimating Energy Release Rate

Several simple procedures are presented here for estimating the energy release rate from certain fuel packages burning in enclosures. A more rigorous treatment of energy release rates is available for selected material types such as wood cribs, wood and plastic slabs, and liquid pool fires where experimental correlations have been established. Section 3, Chapter 1, in the *SFPE Handbook of Fire Protection Engineering*[6] provides a detailed discussion of the prediction of burning rates from various materials. Detailed discussions and data for energy release rates for specific fuels are also available elsewhere.[7–10]

It should be recognized that most enclosure fires of interest do not exhibit constant energy release rates. Rather, as illustrated in Figure 3.9.2 for selected items of furniture, the mass loss rate and, therefore, the energy release rate vary over time. Depending on the detail required, one might select a constant mass loss rate, such as a peak value or an average value, as the basis for analysis.

In the absence of specific test data for a fuel package, a reasonable estimate of the potential energy release rate from the burning fuel package may be made based on test data for similar items. Figure 3.9.3 depicts the order of magnitude for the energy release rate for common fuel packages and burning objects.[11,12] Some fuel packages such as wastebaskets, chairs, and beds exhibit a large range of potential energy release rates. Very low energy release rates were noted in some tests due to the configuration or materials, thus resulting in a large span. Given the simplicity of the calculations, it may be prudent in many cases to select an upper bound value for the type of fuel package under consideration where postulating a larger fire is conservative.

Maximum Enclosure Fire Size

Calculating the maximum enclosure fire size is useful for establishing an upper bound for the energy release rate from a single fuel package within a space. This information can be used in combination with other data to determine whether or not a fire

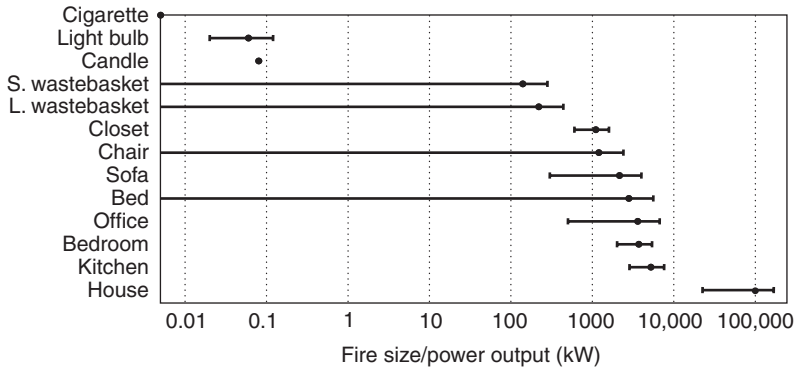

FIGURE 3.9.3 Maximum Fire Sizes for Common Combustible Objects (Sources: NUREG 1805, "Fire Dynamics Tools (FDTs)"[11]; ASTM STP 614, *Fire Standards and Safety*[12])

could become large enough to actuate detection or automatic fire suppression devices and for assessing whether or not flashover conditions could develop. This information also provides a means of establishing the reasonableness for an assumed fuel package fire size.

The maximum fire size within enclosures having a single vertical opening such as an open door or window and combustible contents dominated by wood-based materials may be estimated using the following equation:[13]

$$\dot{Q}_m = 1500 A_o \sqrt{H_o} \qquad (1)$$

where

$\dot{Q}_m$ = Maximum total energy release rate (kJ/sec or kW)

A_o = Total opening area (m^2)

H_o = Opening height (m)

The opening height is the distance between the top of the opening and the bottom of the opening. When there are two or more openings, the total opening area is the sum of each individual area and the opening height is usually assumed equal to a weighted average. Because the height appears in both the area and height terms, the most severe ventilation combination is not necessarily the largest. A sensitivity analysis may be performed in which different openings are assumed closed in order to identify the most adverse opening combination.

Equation 1 assumes that only air flowing into an opening supports the combustion process. This assumption may not be valid in large spaces where the initial enclosure air volume could support a larger fire prior to the development of ventilation-limited conditions. The amount of combustion that the initial air volume could support may be estimated using the following equation derived from a constant energy release rate of 3000 kJ/kg air:[13]

$$\dot{Q}_{air,i} = \frac{3600 \cdot V}{t_b} \qquad (2)$$

where

$\dot{Q}_{air,i}$ = Total fire size (i.e., energy release rate) supported by the initial air volume in an enclosure (kJ/sec or kW)

V = Compartment volume (m^3)

t_b = Time period (sec)

Equation 2 assumes that all oxygen in the enclosure is available for consumption. The maximum fire size that could be supported in a space prior to the development of ventilation-limited conditions over a time period specified by t_b is, thus, the sum of Equations 1 and 2, assuming that all oxygen within the space supports combustion and that the airflows into the compartment can be approximated by Equation 1. The approach is an upper bound; if greater accuracy or resolution is required for a particular application, then a computer fire model analysis would be necessary. The time period should be equal to the time period over which the effects are considered.

EXAMPLE 1. Estimate the maximum sustainable fire size that could be supported in a compartment that is 10.0 m × 5.0 m × 3.0 m tall with a single door opening measuring 0.9 m wide × 2.1 m tall. What could the maximum fire size be within the first minute? What could the maximum fire size be if there is an open window measuring 0.5 m wide × 0.5 m tall that has a sill 1.0 m above the floor?

SOLUTION 1. The maximum fire size may be computed directly from Equation 1 substituting the area of the opening and the height of the opening A_o and H_o. The opening area is 2.1 m × 0.9 m or 1.89 m^2; thus, the maximum sustainable fire size in this space is $1500(1.89)\sqrt{(2.1)}$ or approximately 4110 kW. If a 0.5 m × 0.5 m window is included, the total opening area A_o increases to 2.14 m^2. The opening height is determined from the weighted average height of the door and window. The door area is 2.1 m × 0.9 m or 1.89 m^2 and the window area is 0.5 m × 0.5 m or 0.25 m^2. Since the door height is 2.1 m and the window height is 0.5 m, the weighted average is equal to 0.5 m × .25 m^2/2.14 m^2 + 2.1 m × 1.89 m^2/2.14 m^2 or 1.91 $m^{1/2}$. The maximum sustainable fire size, as computed using Equation 1, is then 4440 kW.

The maximum sustainable fire size that could develop in this compartment within the first minute, before ventilation-limited conditions have developed, may be estimated using Equations 1 and 2. Enclosure fires where ventilation-limited conditions have

been reached are ventilation-controlled fires, as previously described in the subsection titled Enclosure Fires. The maximum fire size based only on airflows through the opening is 4110 kW; the maximum fire size that the initial oxygen volume in a compartment could support over a 1-minute time scale may be computed from Equation 2 as follows:

$$\dot{Q}_{air,i} = \frac{3600 \cdot V}{t_b} = \frac{3600 \cdot (10)(5)(3)}{60} = 9000 \text{ kW}$$

The maximum fire size over the first minute could thus be about 4110 kW + 9000 kW or about 13,110 kW, assuming complete combustion using all available oxygen. Large initial fire sizes that are supported by the initial oxygen mass within an enclosure would typically only be a factor for fires involving fuels that could support a very rapid fire growth rate such as flammable liquids. Typical Class A combustible materials (solids) have a slower growth rate such that the time scale would be large and the fire size supported by the initial compartment volume would be small in comparison to the fire size supported by the airflow through the openings.

Liquid Fuel Pool or Spill Fires

The energy release rate from liquid fuel fires is a function of the energy release rate per unit area for the specific liquid and the exposed surface area of the pool or spill and can be expressed by

$$\dot{Q}_m = \dot{q}'' \cdot A \tag{3}$$

where

$\dot{Q}_m$ = Maximum total energy release rate from the liquid fuel fire (kJ/sec or kW)

$\dot{q}''$ = Energy release rate per unit area for the specific fuel (kJ/sec·m^2 or kW/m^2)

A = Exposed liquid fuel surface area (m^2)

The energy release rate per unit area is a function of the liquid fuel type, the spill area, and the spill depth.[8,14] The maximum energy release rate per unit area for a given fuel occurs when the emissive power of the flames is maximized (i.e., the radiant transmissivity through the flames approaches zero such that all radiation from the direction of the flames originates from the fire process). Confined fuel fires would represent liquid fuel fires in containers or curbed areas. A liquid fuel fire having a diameter greater than about 0.2–1.0 m is typically treated as optically thick.[2,14] Unconfined fuel spills where the liquid is free to spread and the liquid depth is a function only of the liquid and surface tension properties have been shown to burn at a reduced energy release rate relative to an equivalent diameter confined liquid pool.[14] The reduction in the energy release rate is generally on the order of ⅘ (80%) and is attributed to thermal losses from the liquid and flames into the surface under the fuel. Unconfined liquid spill depths vary with spill volume and surface type; for concrete surfaces the unconfined liquid spill depth is about 2.8 mm or less. It is reasonable to assume that pools that are deeper than 2.8 mm are confined.

Table 3.9.2 summarizes the energy release rate per unit area for common liquid fuels in either confined or unconfined configurations. It is often conservative to assume a maximum energy release rate; thus, values for optically thick confined liquid fuel fires would be appropriate. It should be cautioned that there may be instances where it is not conservative to maximize the energy release rate, for example, when considering the actuation of fire detectors or automatic fire suppression devices. Detailed discussions on estimating the energy release rate in liquid fuel fires is available in the *SFPE Handbook of Fire Protection Engineering* (Section 2, Chapter 15,[6] and Section 3, Chapter 1[14]) as well as other sources.[2,7,8,15,16]

TABLE 3.9.2 Energy Release Rates per Unit Area for Optically Thick Liquid Fuel Fires[6,8,14]

	Energy Release Rate per Unit Area (kW/m^2)	
Fuel	*Confined Liquid Fire*	*Unconfined Liquid Fire*
Gasoline	2400	480
Kerosene	1680	340
Diesel	1950	390
Transformer oil	1790	360
Fuel oil, heavy	1390	280

The duration of a pool fire may be computed using the total mass of fuel available for combustion, the fire size, and the fuel heat of combustion as follows:

$$t_{FD} = \frac{M\Delta H_c}{\dot{Q}_m} \tag{4}$$

where

t_{FD} = Fire duration (seconds)

M = Mass of fuel (kg)

ΔH_c = Fuel heat of combustion (kJ/kg), a fuel-specific material property

$\dot{Q}_m$ = Maximum total energy release rate from the liquid fuel fire (kJ/sec or kW)

The duration of a liquid fuel fire is sometimes computed using a regression rate, or a liquid depth recession velocity, and the total liquid depth rather than the mass of fuel available; that is, $dt_{FD} = \delta/\dot{y}$, where δ is the spill depth (m) and $\dot{y}$ is the regression rate (m/sec). Caution is necessary to ensure that the regression rate data correspond to the heat release rate data to ensure mass is conserved.

By noting that the mass is equal to the product of the density and the volume and that the burning duration is independent of the source fire area, it can be shown that the regression rate approach to computing the fire duration and Equation 4 are the same.

EXAMPLE 2. A transformer leaks transformer oil into a curbed confined region having a surface area of 5 m^2, forming a deep pool. The total mass of oil is 50 kg and the heat of combustion is 40,000 kJ/kg. Estimate the maximum energy release rate and fire duration from the transformer oil if it were to ignite. What would the energy release rate and fire duration be if the

transformer oil formed a 5 m^2 pool on a flat, unconfined concrete surface through a continuous leak ignoring any liquid spreading time over the concrete surface?

SOLUTION 2. The transformer oil liquid pool fire size may be computed using Equation 3 and data in Table 3.9.2. In the case of a deep or curbed liquid pool, the plan area is 5 m^2 and the total energy release rate per unit area is 1790 kW/m^2. The total energy release rate is, thus, $\dot{Q}_m = \dot{q}'' \cdot A = (1790)(5) = 8950$ MW. The fire duration is computed from Equation 4 where the mass is 50 kg, the heat of combustion is 40,000 kJ/kg, and the total fire size is 8950 kW or (50)(40,000)/(8950) = 223 seconds. If the liquid pool is formed on an unconfined concrete surface, the energy release rate would be less due in part to thermal losses to the substrate: $\dot{Q}_m = \dot{q}'' \cdot A = (360)(5) = 1800$ MW. The fire duration is also computed from Equation 4 where the total fire size is now 1800 kW or (50)(40,000)/(1800) = 1110 seconds. Note that an unconfined liquid fuel will tend to form a larger pool surface area than a confined fuel spill for a given volume of liquid but the burning rate is reduced substantially. For a continuous leak scenario involving a fixed volume of liquid, the duration increases by a factor of five.

Growing Fires

Most methods presented in this chapter assume a steady or approximately steady heat release rate for the fire. There may be circumstances where it is of interest to estimate the time to reach a hazardous condition or to reach a minimum fire size necessary for fire detector or automatic fire suppression device actuation. In this case, knowledge of the fire growth rate history is necessary. The energy release rate for growing fires in solid fuels is often characterized by a relationship where the fire grows as a function of the square of time (t^2), expressed as[15]

$$\dot{Q}(t) = \alpha t^2 \tag{5}$$

where

$\dot{Q}(t)$ = Total energy release rate (kJ/sec or kW)

t = Time (sec)

α = Fire growth rate constant (kJ/sec^3 or kW/sec^2)

The fire growth rate constant (α) relates to the speed at which the fire grows and has been characterized as "slow," "medium," "fast," and "ultrafast." (See Section 2, Chapter 4, "Dynamics of Compartment Fire Growth.") Common fire growth rate constant values are shown in Table 3.9.3. The fire growth rate constant for specific fuel packages and fuel package arrangements is normally obtained from test data. Section 3, Chapter 1, in the *SFPE Handbook of Fire Protection Engineering*[15] and Appendix B of *NFPA 72®*, *National Fire Alarm Code®*, provide growth constants for a variety of fuel packages and fuel package configurations. Other fire growth rate constant data sources are available.[2,10]

EXAMPLE 3. Estimate the energy release rate in a fuel package array consisting of paper products densely packed in cartons and stacked 6.1 m high 1, 2, and 3 minutes after ignition.

TABLE 3.9.3 Fire Growth Rate Constants

Growth Rate	*Growth Rate Constant (kJ/sec^3 or kW/sec^2)*
Slow	0.0029
Medium	0.0117
Fast	0.0469
Ultrafast	0.1876

SOLUTION 3. A growing fire is expected in such a fuel package array. Appendix B in *NFPA 72* indicates that the growth rate would correspond to a slow t-squared profile up to about 8 minutes. As such, Equation 5 may be used to estimate the energy release rate at specific times before 8 minutes. The growth constant for a slow-growing t-squared fire is 0.0029 kW/sec^2; the energy release rate is then computed using Equation 5 as follows:

$$\dot{Q}(t) = \alpha t^2 = (0.0029)t^2$$

where the time t is in seconds. Thus, 1 minute after ignition the fire size is 10 kW; 2 minutes after ignition it is 42 kW; and 3 minutes after ignition it is 94 kW.

QUANTIFICATION OF FIRE HAZARDS

Fire hazards are defined for the purposes of this chapter as conditions within an enclosure that arise as a direct result of the fire. These conditions are characterized by a temperature increase and/or an exposure heat flux that could cause harm to occupants, impede occupant egress, damage contents or the structure, cause flashover conditions to develop, or actuate detection/suppression devices.

Flashover

A critical point in room fire growth is an event often referred to as *flashover,* the event generally associated with rapid transition in fire behavior from localized burning of fuel to involvement of all the combustibles in the enclosure.

Experimental work indicates that this transition can occur when upper room gas temperatures are between 400 and 600°C, which roughly coincides with an incident heat flux of about 20 kW/m^2 to unignited combustible material located in the enclosure.[3,12,17] Using a value of 932°F (500°C) for the transition to flashover, the heat release rate necessary to cause flashover may be estimated for a naturally ventilated enclosure with a single opening using the following equation:[3]

$$\dot{Q}_{fo} = 610[(k/\delta)A_s A_o \sqrt{H_o}]^{1/2} \tag{6}$$

where

$\dot{Q}_{fo}$ = Total heat release rate at flashover (kJ/sec or kW)

k = Thermal conductivity of enclosure material (kW/m·°C)

δ = Enclosure material thickness (m)

A_s = Total enclosure surface area excluding the opening area (m^2)

A_o = Opening area (m^2)

H_o = Opening height (m)

Equation 6 assumes that an enclosure has been heated thoroughly before flashover such that heat losses to the enclosure boundaries are roughly constant. It is also assumed that the openings are fixed (i.e., the opening does not increase in size) and are not smaller than a typical window or door. Other calculation methods, including computer fire models, are available for estimating flashover potential where boundary heat losses are not steady or where the ventilation conditions are not characteristic of a typical window or door.[3,18–20]

EXAMPLE 4. Would a 500 kW fire lead to the development of flashover conditions inside a space that is 4 m wide, 3 m long, and 3 m tall and has a single opening that is 0.9 m wide and 2.1 m tall? Assume the compartment boundaries are 1.6-cm-thick gypsum having a thermal conductivity of 0.00018 kW/m·°C.

SOLUTION 4. Equation 6 may be used to compute the minimum fire size necessary to cause flashover conditions in the space. All parameters are specified except the internal surface area A_s, which is computed directly from the compartment and opening dimensions as follows: $A_s = 2 \times (L \times W + L \times H + W \times H) - A_o$ where L is the compartment length (m), W is the compartment width (m), H is the compartment height (m), and A_o is the opening area (m^2). The internal surface area is $A_s = 2 \times (4 \times 3 + 4 \times 3 + 3 \times 3) - (2.1 \times 0.9) = 64.1$ m^2. The minimum fire size that could cause flashover is then

$$\dot{Q}_{fo} = 610[(k/\delta)A_s A_o \sqrt{H_o}\,]^{1/2}$$
$$= 610[(0.00018/0.016) \times (64.1) \times (1.9)\sqrt{2.1}\,]^{1/2}$$
$$= 860 \text{ kW}$$

Since 860 kW is greater than 500 kW, it may be inferred that a 500 kW fire would not cause flashover in the space.

Preflashover Compartment Temperature

Knowledge of the preflashover compartment temperature may be useful for predicting when a space becomes hazardous to occupants, estimating when contents may be damaged, or assessing the potential for automatic suppression or heat detection devices to actuate. In most cases, the preflashover compartment temperature is best determined using computer fire models due to the growing fire terms, boundary heat losses, and changes in ventilation that normally occur during a fire.

Although it is recognized that the enclosure gas temperature varies within the compartment, Equation 7 is based on the assumption that an average upper-layer temperature and an average lower-layer, or ambient, temperature reasonably approximate temperature conditions in the enclosure. Several researchers have developed correlations for predicting temperature rise in developing enclosure fires where the energy release rate is constant and there is a single opening. McCaffrey et al. suggest the following expression for naturally ventilated fires in a compartment with a single opening and relatively homogeneous boundary materials, based on a correlation of enclosure fire experiments:[21]

$$\Delta T = 6.85\left(\frac{\dot{Q}^2}{h_k A_s A_o \sqrt{H_o}}\right)^{1/3} \tag{7}$$

where

ΔT = Temperature rise of gas layer in the compartment above ambient (°C)

$\dot{Q}$ = Total energy release rate (kJ/sec or kW)

h_k = Effective enclosure conductance (kW/m·°C) , a measure of the capacity of the boundary to conduct heat out of the enclosure (see Equations 8 and 9)

A_s = Opening area (m^2)

A_o = Opening height (m)

H_o = Total surface area of enclosure interior excluding the opening area (m^2)

Equation 7 applies to enclosures that are naturally ventilated (doors or windows only). For the case of completely forced ventilation conditions, a correlation for enclosure temperature rise has been developed by Foote et al.[16] The temperature rise in enclosures having multiple materials may be estimated by performing a summation of $h_k A_s$ for each material surface in the enclosure, where A_s represents the exposed surface area of a single material within the enclosure. The effective enclosure conductance is determined from the following assuming that the material properties do not vary with temperature (i.e., constant material properties):

$$h_k = \left(\frac{k\rho c_p}{t}\right)^{1/2} \qquad t \le t_p \tag{8}$$

and

$$h_k = \left(\frac{k}{\delta}\right) \qquad t > t_p \tag{9}$$

where

h_k = Effective enclosure conductance (kW/m^2·°C)

k = Thermal conductivity of enclosure surface material (kW/m·°C)

ρ = Density of enclosure materials (kg/m^3)

c_p = Specific heat of enclosure material (kJ/kg·°C)

t = Time (sec)

t_p = Thermal penetration time (sec), which is the time required for the unexposed surface temperature to begin increasing as a result of the thermal boundary conditions on the exposed surface

δ = Enclosure material thickness (m)

The material properties for most materials vary with temperature, especially the heat capacity and the thermal conductivity. However, given the uncertainty associated with other

parameters such as the fire size, the flashover temperature, and the ventilation conditions, assuming constant material properties provides a reasonable result.

The thermal penetration time can be computed from the material properties and thickness of the boundary material, assuming constant material properties, using the following equation:

$$t_p = \frac{\rho c_p}{k}\left(\frac{\delta}{2}\right)^2 \tag{10}$$

where

t_p = Thermal penetration time (sec)

ρ = Density of enclosure materials (kg/m^3)

c_p = Specific heat of enclosure material (kJ/kg·°C)

δ = Enclosure material thickness (m)

k = Thermal conductivity of enclosure surface material (kW/m·°C)

Appendix B of the *SFPE Handbook of Fire Protection Engineering*[1] provides thermophysical property data that may be used to estimate the thermal penetration time and the enclosure conductance. Table 3.9.4 summarizes density, specific heat, and thermal conductivity data for several common building materials. The values in Table 3.9.4 are reasonable for the classes of materials cited but material properties can vary widely, even among specific types of materials, and they should, therefore, be researched carefully for the application at hand.

EXAMPLE 5. Estimate the temperature after 5 minutes in a space that is 4 m wide, 3 m long, and 3 m tall and has a single opening that is 0.9 m wide and 2.1 m tall. Assume a constant fire size of 500 kW, compartment boundaries that are 1.6-cm-thick gypsum having a thermal conductivity of 0.00018 kW/(m·°C), a specific heat of 1.1 kJ/(kg·°C), and a density of 960 kg/m^3. Note that this is the same space containing the same fire as that used for Example 4.

SOLUTION 5. The solution requires three steps: first, compute the thermal penetration time using Equation 10; next compute the effective enclosure conductance using either Equation 8 or Equation 9, depending on the thermal penetration time; and, finally, estimate the enclosure gas temperature using Equation 7.

Step 1. The thermal penetration time is computed directly from Equation 10 using the material properties and dimension provided:

$$t_p = \frac{\rho c_p}{k}\left(\frac{\delta}{2}\right)^2 = \frac{(1.1)\cdot(960)}{0.00018}\left(\frac{0.016}{2}\right)^2$$

$$= 375 \text{ seconds} = 6.3 \text{ minutes}$$

Step 2. Since the thermal penetration time is greater than 5 minutes, Equation 8 must be used to determine the effective enclosure conductance:

$$h_k = \left(\frac{k\rho c_p}{t}\right)^{1/2} = \left[\frac{(0.00018)\cdot(960)\cdot(1.1)}{300}\right]^{1/2} = 0.025 \text{ kW/m·°C}$$

Step 3. The enclosure gas temperature rise is computed using Equation 7:

$$\Delta T = 6.85\left(\frac{\dot{Q}^2}{h_k A_s A_o \sqrt{H_o}}\right)^{1/3}$$

$$= 6.85\left[\frac{500^2}{(0.025)\cdot(64.1)\cdot(1.9)\sqrt{2.1}}\right]^{1/3} = 263°\text{C}$$

If the ambient temperature is 20°C, then the gas temperature after 5 minutes would be 263°C + 20°C or 283°C. Note that this is well below the temperature threshold of 400 to 600°C for flashover as described in the preceding section.

Other calculation methods, including computer fire models, are available for estimating the preflashover compartment temperature when the fire size is variable, the ventilation conditions are not characteristic of a typical window or door, or they are mechanically forced and possibly vary with time.[3,18–20] For detailed discussions of methods that address multiple vents as well as forced ventilation, the reader is referred to DiNenno,[1] Foote et al.,[22] and Deal and Beyler.[23]

Flame Height

The flame height is a means of directly assessing the potential for a fire to spread to other fuel packages or cause structural damage. Figure 3.9.4 depicts an idealized fuel package and the relevant features when quantifying the potential hazards. The experimentally determined "mean" flame heights have been correlated by several researchers.

TABLE 3.9.4 Constant Temperature Thermophysical Properties for Some Common Building Materials[1]

Material	*Temperature for Properties (°C)*	*Thermal Conductivity (kW/m·°C)*	*Heat Capacity (kJ/kg·°C)*	*Density (kg/m³)*
Steel	20	0.043	0.43	7800
Gypsum	20	0.00018	1.10	960
Cement	23	0.00137	0.88	1900–2300
Wood (oak)	30	0.000166	2.40	540
Glass	20	0.00078	0.84	2700
Insulation (glass wool)	23	0.000038	0.70	24

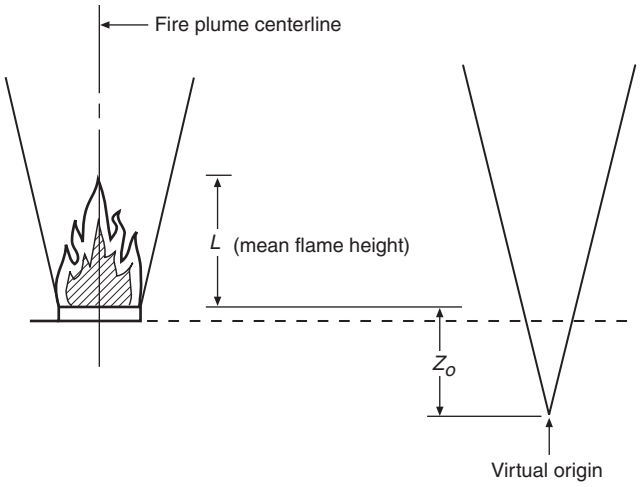

FIGURE 3.9.4 Flame and Fire Plume Characteristics

Axisymmetric Fires

Axisymmetric source fires are fires with circular plan areas. Rectangular source fires with small aspect ratios (~1) are also treated as axisymmetric source fires whereas rectangular source fires with large aspect ratios are treated as line or one-dimensional source fires. The distinction arises because of the manner in which the thermal plume develops and is related to the shape of the plume that develops as well as the plume ambient air entrainment characteristics. Correlations are available (Yokoi,[24] for example) for source fires that are neither axisymmetric nor one-dimensional, but these are beyond the scope of this section and are not addressed further.

A simple form of the developed correlation for flame heights for pool or horizontal burning fuels is based on only the diameter and heat release rate of the fire. Figure 3.9.5 provides a graphical version of the relationship.

The equation on which Figure 3.9.5 is based is as follows:

$$L = -1.02D + 0.23\dot{Q}^{2/5} \tag{11}$$

where

L = Average flame height (m)

D = Diameter of fire source (m)

$\dot{Q}$ = Total energy release rate of the fire (kJ/sec or kW)

This flame height equation is valid for Standard Temperature and Pressure (STP) conditions (101,325 Pa and 15°C). The buoyancy forces within the plume above a given fire source may vary with different ambient temperature and pressure; a more general version of Equation 11 was developed by Heskestad[25] and is found in Section 2, Chapter 1, of the *SFPE Handbook of Fire Protection Engineering.*[26]

For noncircular fuel packages, an effective fire diameter can be estimated by

$$D = 2\left(\frac{A_f}{\pi}\right)^{1/2} \tag{12}$$

which can also be expressed as

$$D = 2\sqrt{\frac{A_f}{\pi}}$$

where

D = Effective fire diameter (m)

A_f = Area of the fire (m^2)

Since flames are unsteady, the average flame height L is generally taken to be the height above the fire source where the flame tip is observed to be at or above this point 50 percent of the time. Equation 11 is considered suitable for pool fires or

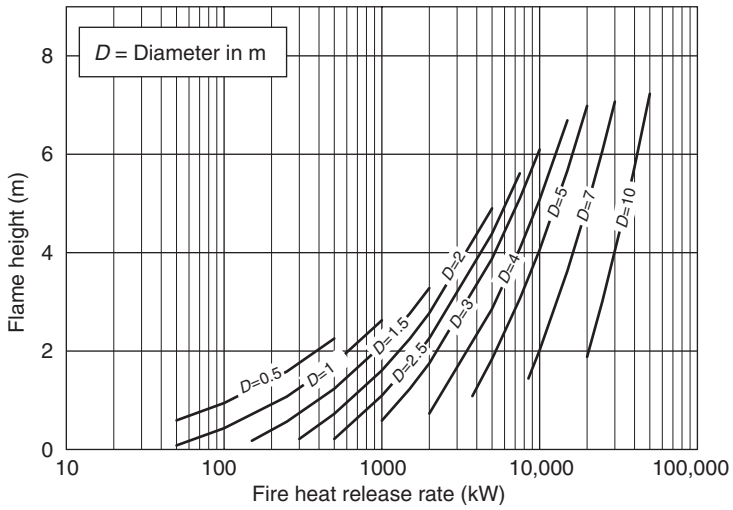

FIGURE 3.9.5 Flame Heights for Steady Fires with Various Diameters Plotted Using Equation 11

for horizontal surface burning. It should be noted that this correlation will produce negative values for L at small heat release rates. The available experimental data indicate that the most reliable region of application is where $\dot{Q}^{2/5}/D$ is greater than 16.5. For more detail on flame height calculations, the reader is referred to Beyler[27] and Section 2, Chapter 1, of the *SFPE Handbook of Fire Protection Engineering*.[26]

EXAMPLE 6. Consider a short stack of wooden pallets (1.2 m × 1.2 m) burning at a heat release rate of 900 kW. What is the height of the resulting flame?

SOLUTION 6. In order to determine the flame height, the heat release rate (given) and diameter are needed. In this case, an effective diameter is calculated using Equation 12:

$$D = 2\sqrt{\frac{(1.2 \times 1.2)}{\pi}} = 1.35 \text{ m}$$

Using the given heat release rate and effective diameter in Equation 11 provides an estimate of the mean flame height:

$$L = -1.02(1.35) + 0.23(900)^{2/5} = 2.1 \text{ m}$$

Alternatively, Figure 3.9.5 could be used to directly determine the flame height after calculation of the effective diameter. To do this, locate on the horizontal axis (i.e., the x-axis) the value 900 kW; next move vertically up from this location to the line with the diameter nearest 1.35 m, which is 1.5 m. A minor interpolation is necessary to account for the difference in actual and plotted diameters; since the next lowest diameter plotted is 1.0 m, a point somewhat between the 1.0 m and 1.5 m lines, somewhat closer to the 1.5 m line, is desired. Once found, the flame height is read by moving horizontally to the vertical or y-axis. A flame height just above 2.0 m is then read.

Wall and Line Fires

Equations have also been developed for elongated fires that are either (1) against a wall so that air is entrained (i.e., drawn in) from one side only (i.e., wall fires) or (2) sufficiently in the open so that air is entrained along both of the longitudinal sides (i.e., line fires).[28] In these equations, the flame height is based on the rate of heat release per meter of length of the fire source. The flame height for wall fires is[29]

$$L = 0.034(\dot{Q}')^{2/3} \tag{13}$$

and the flame height for a line fire is[29]

$$L = 0.017(\dot{Q}')^{2/3} \tag{14}$$

where

L = Flame height (m)

$\dot{Q}'$ = Length of total heat release per meter length of the fire source (kW/m)

EXAMPLE 7. Compare the flame height from a 100 kW/m wall fire and a 100 kW/m line fire.

SOLUTION 7. Equation 13 may be used directly to compute the line fire flame height: $L = 0.034(\dot{Q}')^{2/3} = 0.034(100)^{2/3} = 0.73$ m. Likewise, Equation 14 may be used directly to compute the wall fire flame height: $L = 0.017(\dot{Q}')^{2/3} = 0.017(100)^{2/3} = 0.37$ m. Thus, for a given heat input per unit length, the wall fire flame height is one-half the line fire flame height.

Thermal Plumes

The plume centerline temperature and velocity are parameters that are useful for determining the exposure to objects that are located within the fire plume, above the tops of flames, and below the ceiling. For detector response at the ceiling level, Alpert's plume and ceiling jet correlations are more commonly applied (see section on thermal detector response).

The plume centerline excess temperature and velocity at elevations above the mean flame height can be estimated from the following simplified equations[30] (see Figure 3.9.4):

$$T_{plume,cl} = \frac{18.8\dot{Q}^{2/3}}{(h - Z_o)^{5/3}} + T_\infty \tag{15}$$

$$U_{plume,cl} = \frac{0.77\dot{Q}^{1/3}}{(h - Z_o)^{1/3}} \tag{16}$$

where

$T_{plume,cl}$ = Centerline plume gas temperature above the fire (°C)

$U_{plume,cl}$ = Centerline plume gas velocity above the fire (m/sec)

$\dot{Q}$ = Total fire energy release rate (kJ/sec or kW)

h = Distance above fuel surface (m)

Z_o = Position of the virtual origin (m), Equation 15

T_∞ = Ambient temperature (°C)

Equations 15 and 16 assume that the convective fraction of the total heat release rate is 0.65 and the fire is in a location with standard atmospheric conditions (i.e., the pressure is 101,325 Pa and the temperature is 15°C). A convective fraction of 0.65 to 0.7 is fairly typical for common combustible materials,[27,31] but it is fuel specific and can vary from about 0.5 to almost 1.0.[31] A conservative computation would assume a convective fraction of 1.0. Data for specific fuels may be measured from small-scale tests such as the Cone Calorimeter or may be tabulated as in Sections 3–4 of the *SFPE Handbook of Fire Protection Engineering*.[31] Equations 15 and 16 are derived from more general equations presented in Heskestad.[13] If the convective fraction of the heat release rate is known to be other than 0.65, the value of $\dot{Q}$ in Equations 16 and 17 should be substituted with $[(x/0.65)\dot{Q}]$. In this substitution, x is the alternate convective fraction. Equations 16 and 17 are also only valid at heights above the mean flame height L.

Although methods exist to calculate excess temperature and velocities at locations other than along the plume centerline, the highest confidence is placed on centerline estimates. The reader is referred to Heskestad,[26] Beyler,[27] and Heskestad[30] for detailed discussions of noncenterline temperature and velocity estimates.

Calculation of the Virtual Origin

In order to estimate the plume centerline mean temperature and velocity (see next section), it is necessary to determine the virtual origin of the source fire. The virtual origin is the hypothetical location or elevation associated with substitution of a point source fire for the actual fire in question (see Figure 3.9.4). The consideration of a virtual origin is most important for evaluating centerline conditions near the fire. As the distance above the fire increases, the impact of the discrepancy that results from neglecting the virtual origin decreases. It is common practice to ignore virtual source considerations for calculations where the distance above the fire is many times the diameter of the fire. For centerline elevations near the fire, however, a more accurate estimate of the position of the virtual source is necessary. The following expression, limited to pool fires and horizontal burning, provides an estimate of the location of the virtual origin:[25]

$$Z_o = -1.02D + 0.083\dot{Q}^{2/5} \qquad (17)$$

where

Z_o = Location of virtual fire origin (m)

D = Diameter of fire source (m)

$\dot{Q}$ = Total energy release rate of the fire (kJ/sec or kW)

The intent of the virtual source computation is to find the location where a point source would produce an equivalent thermal plume to be consistent with the strong plume equation derivation. Because of variations in the source fire strength and the fire diameter, this equivalent point source location may be at, above, or below the base of the burning fuel. Typically, the point source is located below fires with a low energy release rate per unit area because the plume width is wide, thereby requiring a long entrainment distance from a point heat source having the same power to be equivalent. Conversely, fires with a high unit energy release rate may have the virtual origin located above the fire base because the plume width is narrow; thus, a short entrainment distance is required for a point source having the same power to be equivalent. Figure 3.9.6 can be used to directly determine the height of the virtual origin when the diameter and heat release rate are known in the same manner as Figure 3.9.5 can be used to estimate the flame height. Refer to Example 7 for additional details on the use of these figures.

EXAMPLE 8. A 500 kW fire is burning on the floor of a large, open industrial facility with a ceiling height of 10 m. The fire is underneath a power cable tray, which is 7 m above the floor. Assume that the fire diameter is approximately 1 m, the interior ambient temperature is 20°C, and the failure temperature of the power cables is 200°C. Will the cables potentially sustain damage from the fire?

SOLUTION 8. The first step in solving this problem is to determine the location of the virtual origin of the fire. Using Equation 17,

$$Z_o = -1.02(1) + 0.083(500)^{2/5} = -0.02 \text{ m}$$

With the location of the virtual origin known, the plume centerline temperature at a height of 7 m can be determined from Equation 15:

$$T_{plume,cl} = \frac{18.8(500)^{2/3}}{[7 - (-0.02)]^{5/3}} + 20 = 66°\text{C}$$

In this case, the plume above the fire would not be hot enough to damage the power cables in the tray above the fire.

Radiant Heat Flux

For many fires, it is of interest to estimate the radiation transmitted from a burning fuel package array to a target located at a distance from the fire. Knowledge of the incident radiant heat flux at a specific location is useful for assessing the likelihood

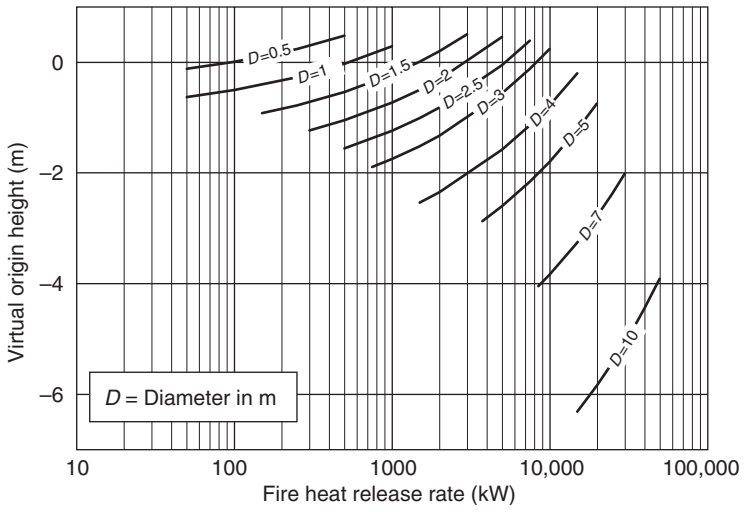

FIGURE 3.9.6 Virtual Origins for Steady Fires with Various Diameters

of fire propagation, presenting a hazard to occupants, impeding egress, or causing damage to enclosure contents. Fairly sophisticated methods and models for such estimates exist in the literature.[32,33] These methods are derived primarily from correlations of experimental flammable liquid pool fire data. The simplified methods provided here are to be used primarily as screening methods.

Lawson and Quintiere Method. Lawson and Quintiere[34] developed a simple hemispheric point source type model based on correlations of available experimental data (see Figure 3.9.4). Experimental evidence suggests that such methods are reasonably accurate provided the predicted heat flux is less than about 5 kW/m^2.[32] The following expression was developed, based on these correlations, to estimate the radiant heat flux from a fire to a target positioned normal to the radial distance:

$$\dot{q}''_r = \frac{\chi_r \dot{Q}}{4\pi R_o^2} \tag{18}$$

where

$\dot{q}''_r$ = Incident radiation on the target (kW/m^2)

χ_r = Radiative fraction

$\dot{Q}$ = Total energy release rate (kJ/sec or kW)

R_o = Distance from center of fire base to the target (m)

The radiative fraction varies from 0.2 to 0.4, depending on the fuel type and pool diameter.[31] The radiative fraction for most common materials is between 0.3 and 0.35, but, like the convective component of the heat release rate, it may vary from about 0 to 0.5 or more.[31] The radiative fraction for may be measured from small-scale fire tests such as the cone calorimeter; other sources for this parameter include tabulated data such as that provided by Tewarson.[31]

The experimental measurements relied on indicate that Equation 18 has good accuracy for

$$\frac{R}{R_o} > 4 \tag{19}$$

where

R = Radius of the base of the fire (m)

R_o = Distance from center of fire to the target (m)

At values of R/R_o less than 4, the methods tend to underpredict the incident heat flux.

Recent investigations have found that a safety factor of two should be applied to a point source model similar to the Lawson and Quintiere method.[32] Because the two approaches reflect the same type of thermal radiation model, a safety factor of two should be applied to the Lawson and Quintiere method as well.

Point source type methods assume that the pool fire is circular or nearly circular. The point source configuration factor assumption is more appropriate at larger distances from the fire, that is, where the ratio of the distance from the pool center to the pool diameter (L/D as defined in Equation 20 below) is greater than 2.5. This is in addition to meeting the constraint imposed by Equation 19. At closer locations, these methods tend to underpredict the incident heat flux. Because this method is limited to prediction of incident heat fluxes at or below 5 kW/m^2 (due to limited data), it is not suitable for use in estimating the potential for ignition of combustibles. However, reasonable estimates of lower heat fluxes associated with damage to electronics or other thermally sensitive equipment as well as the onset of burns can be expected.

Shokri and Beyler Correlation. An alternative approach to the Lawson and Quintiere method is the Shokri and Beyler correlation,[32] which was developed from large-scale pool fire data. This simple correlation can be used to estimate the heat flux to a vertically oriented surface (i.e., target) at ground level. The incident heat flux is given by

$$\dot{q}''_r = 15.4\left(\frac{L}{D}\right)^{-1.59} \tag{20}$$

where

$\dot{q}''_r$ = Incident radiation on the target or surface of interest (kW/m^2)

D = Diameter of the pool fire (m)

L = Distance from the center of the pool fire to the target (m)

Noncircular pool fires with length to width ratios of approximately 1 (e.g., square surfaces) can be evaluated based on the use of an equivalent diameter D_e rather than an actual diameter D. D_e is given by

$$D_e = \sqrt{\frac{4A}{\pi}} \tag{21}$$

where A is the surface area of the noncircular pool (m^2).

This correlation is based largely on liquid fuels that have pool diameters ranging from 1 m to 50 m and that produce luminous flames. Further, the data used were limited to values of L/D that were greater than the range of 0.7 to 15.0. Use of this correlation for L/D values less than 0.7 could underpredict the estimates of radiant heat flux.

This correlation provides realistic predictions of incident heat flux levels. When using the method of Shokri and Beyler, it is recommended that a safety factor of two be applied for general design applications.[32,35]

EXAMPLE 9. Compute the maximum radiant flux incident on a target surface 5 m from the edge of a 2000 kW pool fire confined to a 1 m^2 curbed area. Use both the Lawson and Quintiere method and the method of Shokri and Beyler.

SOLUTION 9. Per Equation 19, the maximum heat flux at the target surface may be computed using the Lawson and Quintiere method provided R/R_o is greater than 4, where R is the fire radius and R_o is the distance between the center of the fire and the target (target separation distance). The fire radius is 0.5 m and the target separation distance is 5.5 m (5.0 m from the fire edge plus 0.5 m from the fire edge to the fire center, i.e., the radius). R/R_o is thus 11, meeting the constraint imposed by Equation 19. Thus, the maximum incident heat flux computed using the

Lawson and Quintiere method is determined using Equation 18 as follows:

$$\dot{q}''_r = \frac{\chi_r \dot{Q}}{4\pi R_o^2} = \frac{(0.4)(2000)}{4\pi(5.5)^2} = 2.1 \text{ kW/m}^2$$

where the radiative fraction χ_r is conservatively assumed to be 0.4 since the maximum incident heat flux is the desired result. A safety factor of two is recommended for this method; thus, the maximum incident heat flux at the target location is predicted to be 4.2 kW/m^2.

The maximum heat flux at the target surface may be computed using the method of Shokri and Beyler provided *L/D* is between 0.7 and 15.0 where *L* is the target separation and *D* is the fire diameter. The target separation is 5.5 m and the fire diameter is 1.0 m; thus, *L/D* is equal to 5.5 m and the method of Shokri and Beyler is applicable. The radiant heat flux is readily computed using Equation 21 as follows:

$$\dot{q}''_r = 15.4\left(\frac{L}{D}\right)^{-1.59} = 15.4\left(\frac{5.5}{1}\right)^{-1.59} = 1.02 \text{ kW/m}^2$$

A safety factor of two is recommended for this method; thus, the maximum incident heat flux at the target location is predicted to be 2.0 kW/m^2, or about one-half that predicted by the Lawson and Quintiere method.

Enclosure Smoke Filling

The smoke accumulation and descent of a smoke layer within an enclosure represents a means by which to establish occupant immersion. When occupants are immersed in a smoke layer, the ability to egress is impeded and it becomes more difficult to enter an area to perform rescue and suppression activities. Smoke from a fire begins to fill an enclosure as it accumulates below the ceiling. The rate of smoke filling depends on the rate of smoke production and the size and location of vents as well as any forced ventilation or extraction rate in an area. The minimum smoke layer elevation may be computed if the smoke production rate and the vent mass flow are known. This information may also be used to establish a minimum mechanical exhaust rate necessary to maintain a smoke layer at a desired elevation, typically above occupants.

Detailed discussions on smoke filling and smoke venting calculations may be found in NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria, and Large Spaces,* and in the *SFPE Handbook of Fire Protection Engineering.*[36–39]

Smoke Production Rate

The rate of smoke-filled gas produced by a fire is nearly equal to the rate of air entrained into the rising fire plume; therefore, the mass production rate of smoke-filled gas can be estimated as equal to the mass flow rate of gas in the fire plume. This mass flow rate into a plume above the visible flame height may be estimated using the following expression developed by Zukoski:[40]

$$\dot{m}_s = 0.065 \dot{Q}^{1/3} Y^{5/3} \tag{22}$$

where

$\dot{m}_s$ = Rate of smoke-filled gas production (kg/sec)

$\dot{Q}$ = Total energy release rate (kJ/sec or kW)

Y = Distance from the virtual point source for the fire to the bottom of the smoke layer (m)

The elevation of the virtual point source may be calculated using Equation 15. Figure 3.9.7 provides graphical results of Equation 22 as a function of the fire size for different smoke layer elevations. Clearly, Figure 3.9.7 demonstrates that the production rate is a strong function of the smoke layer elevation above the virtual origin elevation.

Equation 22 is valid only when the smoke layer height is above the flame height. McCaffrey[41] has investigated gas

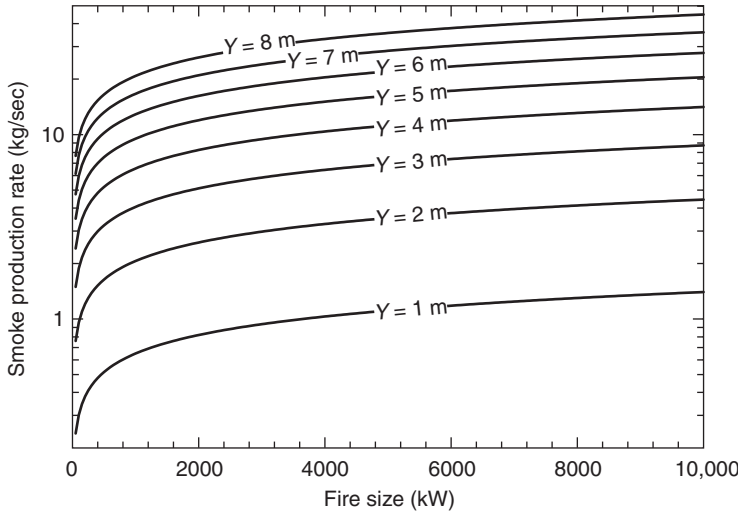

FIGURE 3.9.7 Smoke Production Rates for Steady Fires with Various Distances from the Virtual Origin

temperatures and velocity distributions in the flame region. Alternative methods are also presented by Butcher and Parnell.[42]

EXAMPLE 10. Compute the smoke production rate from a 1 m^2 Class A combustible material fire having a heat release rate per unit area of 400 kW/m^2 and a diameter of 1.1 m if the smoke layer is to be maintained at 1.8 m above the floor. What is the smoke production rate if the smoke layer is to be maintained 3.1 m above the floor?

SOLUTION 10. Equation 22 may be used to assess the smoke production rate for the source fire. The fire size is equal to the fire area multiplied by the heat release rate per unit area or 400 $kW/m^2 \times 1\ m^2 = 400$ kW. The virtual origin must first be computed using Equation 17: $Z_o = -1.02D + 0.083\dot{Q}^{0.4}$, which is equal to –0.21 m for a 400 kW source fire having a diameter of 1 m. Equation 22 may now be used directly to compute the smoke production rate for a smoke layer: $\dot{m}_s = 0.065\dot{Q}^{1/3}Y^{5/3}$. For a smoke layer maintained 1.8 m above the floor, Y is equal to 1.8 m plus 0.21 m or 2.01 m, since the virtual source is located *below* the fire base (i.e., Z_o is negative). In this case, the smoke production rate is $0.065 \times (400^{1/3}) \times (2.01^{5/3})$ or 1.53 kg/sec. Similarly, for a smoke layer maintained 3.1 m above the floor, Y is equal to 3.31 m and the smoke production rate is equal to $0.065 \times (400^{1/3}) \times (3.31^{5/3})$ or 3.52 kg/sec. Note that the smoke production rate more than doubles when the height at which the smoke layer is maintained is increased by 70 percent, or in this case about 1.3 m.

Volumetric Smoke Exhaust Rate

The minimum exhaust rate necessary to maintain the smoke layer elevation at a fixed height above the virtual origin may be estimated using Equation 22 and the estimated preflashover compartment temperature as follows:

$$\dot{V}_m = 0.065\left(\frac{T+273}{352}\right)\dot{Q}^{1/3}Y^{5/3} \qquad (23)$$

where

$\dot{V}_m$ = Minimum volumetric flow rate (m^3/sec) necessary to maintain smoke layer at an elevation Y (m) above the virtual origin

$\dot{Q}$ = Total energy release rate (kJ/sec or kW)

T = Compartment gas temperature (°C)

Equation 23 only applies to situations where the exhaust is taken only from the smoke layer and the smoke layer elevation is greater than the flame height. The reader can consult NFPA 92B or the *SFPE Handbook of Fire Protection Engineering*[38,39] for more complicated arrangements and applications.

EXAMPLE 11. Compute the volumetric flow rates necessary to maintain a smoke layer above 1.8 m inside a compartment having a 3000 kW source fire. Assume gas layer temperatures of 100°C, 200°C, and 300°C and an ambient temperature of 20°C.

SOLUTION 11. Equation 23 may be used to assess the layer height under this condition:

$$\dot{V}_m = 0.065\left(\frac{T+273}{352}\right)\dot{Q}^{1/3}Y^{5/3}$$

$$= 0.065\left(\frac{T+273}{352}\right)(3000)^{1/3}(1.8)^{5/3}$$

$$= 0.0071(T+273)\ m^3/sec$$

Thus, for a 100°C compartment temperature, the minimum exhaust flow rate would be 2.6 m^3/sec; for a 200°C compartment temperature, the minimum exhaust flow rate would be 3.4 m^3/sec; and for a 300°C compartment temperature, the minimum exhaust flow rate would be 4.1 m^3/sec. This calculation is useful to provide a quick estimate of the adequacy of the ventilation to maintain habitable conditions within a space. More detailed computation methods should be used if a greater resolution is required or when designing smoke exhaust systems.

ENCLOSURE FIRE EFFECTS

Enclosure Fire Effects Defined

Enclosure fire effects are defined in the context of this chapter as those changes or consequences that may occur as a direct result of a fire in the enclosure. These consequences are typically brought about by exposure to one or more specific fire hazards such as temperature increase, incident heat flux, or flashover. Fire effects considered in this section include ignition of adjacent solid fuel packages and actuation of detection and suppression devices. Typically, to assess such effects a knowledge of the fire size or growth profile and the hazard variable(s) that cause the effect is required. These elements have been presented in previous sections of this chapter.

Ignition of Solid Fuel Packages

The potential for a fire to ignite nearby solid fuel packages provides insight into the likelihood for fire spread within an enclosure. Conversely, separation distances between fuel packages could be established based on the requirement that one burning fuel package not cause a second fuel package to ignite.

Ignition is a complex phenomenon, dependent on physical and chemical properties of the materials, the environment in which the material exists, and the source(s) of heat exposing the material. A quantitative description of the physical and chemical processes associated with ignition of heated solids can be found in Kanury[5] and Babrauskas.[43] Solutions for ignition of solids are developed by Kanury[5] for specific applications.

Nelson and Forssell[44] developed an approach for prediction of ignition of solids that relies on material properties and data from a cone calorimeter or similar heat release rate test. The ignition time (t_{ign}) for a material exposed to a constant heat flux, as in the cone calorimeter, is estimated using empirical correlations and available test data.

For "thermally thick" materials, that is, materials that have sufficient thickness such that the time to ignition is less than the thermal penetration time through the solid, a "trial and error" fit is used to estimate the ignition time. Such an approach is outside the scope of this chapter; therefore, the reader is referred

to Kanury,[5] Babrausksas,[43] and Nelson and Forssell[44] for a detailed discussion of this approach.

A somewhat less complicated problem involves estimates of ignition time for "thermally thin" materials. These are solids that are so thin or so highly conductive that temperature gradients are essentially nonexistent within the material slab, and the temperature of the material is dependent only on the exposure time to the source of heating such as a fabric curtain or a sheet of paper. Under such conditions the heating can be treated as a bulk heating process, using the following expression where convective losses are assumed to be zero:[5]

$$t_{ign} = \frac{\rho_s c_s V_S (T_{ign} - T_S)}{\dot{q}''_{net} A_S} \qquad (24)$$

where

t_{ign} = Time to ignition (sec)

ρ_s = Density of the solid (kg/m^3)

c_s = Heat capacity of the solid (kJ/kg·°C)

V_S = Solid volume (m^3)

T_{ign} = Solid ignition temperature (°C)

T_S = Initial solid temperature (°C)

$\dot{q}''_{net}$ = Net absorbed heat flux at the solid surface (kW/m^2)

A_S = Exposed surface area of solid (m^2)

The ignition temperature for several common materials is listed in Table 3.9.5. Additional information is provided by Babrauskas,[43] Quintiere,[15] and Quintiere.[45] For the purposes of a screening analysis, the incident heat flux may be assumed for the net absorbed heat flux. If more accuracy is desired, a thermal balance at the solid surface is necessary as described by Lattimer,[46] Drysdale,[13] Tien et al.,[47] and Atrea.[48]

Caution is recommended in using the formulas provided here for estimating ignition times. As stated earlier, ignition is a complex phenomenon and the limitations associated with the use of these expressions are important. The reader is encouraged to review the more detailed discussions in Kanury,[5] Babrauskas,[43] and Nelson and Forssell.[44]

In cases where a separation distance is established, it is often appropriate to use a critical ignition heat flux as a basis for the separation distance. The critical ignition heat flux is the minimum heat flux at which a solid could ignite given the presence of a pilot such as a burning ember or a spark. These values are experimentally determined and material specific. Table 3.9.5 summarizes the critical ignition heat flux for common solid combustible materials. Additional information is provided by Babrauskas,[43] Quintiere,[15] Quintiere,[45] Babrauskas et al.,[7] and Drysdale.[13]

TABLE 3.9.5 Ignition Temperature and Critical Ignition Heat Fluxes for Common Materials[15]

Material	*Ignition Temperature (°C)*	*Critical Ignition Heat Flux (kW/m²)*
Plywood	390	16
Plywood (FR)	620	44
PMMA	278–378	9–15
Polycarbonate	528	30
Polystyrene	630	46
Hardboard	298–400	10–17
Carpet	300–465	10–23

EXAMPLE 12. Estimate the ignition time for a 1-mm-thick PVC laminate initially at 20°C that is exposed to an incident heat flux of 50 kW/m^2. Assume the flux is uniformly distributed over the surface, that the heat capacity is 0.84 kJ/kg·°C, that the density is 1450 kg/m^3, and that the ignition temperature is 220°C, typical properties for PVC as found in the *SFPE Handbook of Fire Protection Engineering*[1] and other sources.[49]

SOLUTION 12. Because the material is a thin laminate, Equation 24 is applicable. Also, since the exposure is uniform over the surface, V_s/A_s is equal to the material thickness, where V_s is the material volume (m^3) and A_s is the exposed surface area (m^2). It is also conservatively assumed that the net heat absorbed at the surface is equal to the incident heat flux, or 50 kW/m^2. In this case, the ignition time may be estimated as:

$$t_{ign} = \frac{\rho_s c_s V_S (T_{ign} - T_S)}{\dot{q}''_{net} A_S} = (0.001)\frac{(1450)(0.84)(220 - 20)}{(50.0)} = 5 \text{ sec}$$

Note that in Equation 24, V_s/A_s is replaced with the material thickness, which is 0.001 m for this example.

Thermal Detector and Automatic Fire Sprinkler Response

Plume and ceiling jet temperatures and velocities are parameters that are necessary for the evaluation of the potential for ceiling detectors to activate or to estimate their activation time. The methods in this section are appropriate for automatic fire sprinklers or fixed-temperature heat detectors. For exposure to objects within the fire plume, mean centerline plume parameters are more appropriate (see section on the plume centerline temperature and velocity).

A simplified plume temperature correlation for a steady-state fire is as follows:

$$T_{m(plume)} = 16.9\frac{\dot{Q}^{2/3}}{h_{ceil}^{5/3}} + T_\infty \qquad \text{for } r/h_{ceil} \le 0.18 \qquad (25)$$

where

$T_{m(plume)}$ = Centerline plume gas temperature above the fire (°C)

$\dot{Q}$ = Total heat release rate (kW)

h_{ceil} = Distance from the fuel surface to the ceiling (m)

T_∞ = Ambient temperature (°C)

r = Radial distance from the axis of the fire (m)

Based on cases where the hot gases have begun to spread under a ceiling located above the fire, Equation 25 also applies for a small radial distance, *r,* from the impingement point on the ceiling (Figure 3.9.8).

Over this distance, up to $r/h = 0.18$, where the gas is turning to flow outward under the ceiling, the highest temperature in the flow remains equal to the value at the impingement point directly over the fire. At greater distances from the axis of the fire, a ceiling jet temperature correlation is more appropriate. This correlation takes into account the actual distance from the impingement point:

$$T_{m(jet)} = 5.38\frac{(\dot{Q}/r)^{2/3}}{h_{ceil}} + T_\infty \qquad \text{for } r/h_{ceil} > 0.18 \qquad (26)$$

where

$T_{m(jet)}$ = Maximum ceiling jet temperature at position r (°C)

$\dot{Q}$ = Total heat release rate (kW)

r = Distance from the fire (m)

h_{ceil} = Distance from the fuel surface to the ceiling (m)

T_∞ = Ambient temperature (°C)

Correlations are also available for maximum velocities in the ceiling jet flow under a ceiling. As with the temperature correlations, there are two regions: (1) one close to the impingement point where velocities are nearly constant and (2) the other farther away where velocities vary with radial position. The two correlations are expressed as follows:

$$U_{m(plume)} = 0.096\left(\frac{\dot{Q}}{h_{ceil}}\right)^{1/3} \qquad \text{for } r/h < 0.15 \qquad (27)$$

$$U_{m(jet)} = 0.195\left(\frac{\dot{Q}^{1/3}h_{ceil}^{1/2}}{r^{5/6}}\right) \qquad \text{for } r/h_{ceil} \geq 0.15 \qquad (28)$$

where

$U_{m(plume)}$ = Maximum ceiling jet gas velocity near the plume impingement point (m/sec)

$U_{m(jet)}$ = Maximum ceiling jet gas velocity (m/sec)

$\dot{Q}$ = Total heat release rate (kW)

h_{ceil} = Distance from the fuel surface to the ceiling (m)

r = Radial distance from the fire (m)

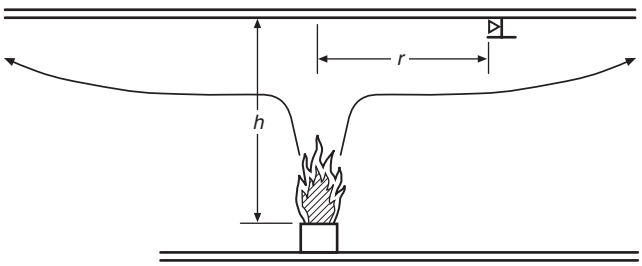

FIGURE 3.9.8 Parameters *h* and *r* Both Related to Calculation of Sprinkler or Heat Detector Actuation Time

Equations 25 and 26 can be used to determine whether the temperature of the fire-driven gas flow past a detection device is high enough to operate the device. However, more information is needed to calculate the amount of time needed to heat the detector or automatic fire sprinkler-sensing element to the operating temperature. Often, these elements are made of metal, such as the ordinary solder-type fusible link used in the link and lever automatic fire sprinklers, or they are liquid-filled glass vials, such as those used in bulb-type automatic fire sprinklers. Both of these sensing elements require some time to absorb the heat transferred from the hot gas flowing around the device.

For steady fires, the time required to heat the sensing element of a thermal detection or suppression device from room temperature to operation temperature is given by

$$t_{\text{operation}} = \frac{\text{RTI}}{\sqrt{U_m}}\log_e\left(\frac{T_m - T_\infty}{T_m - T_{\text{operation}}}\right) \qquad (29)$$

where

$t_{\text{operation}}$ = Activation time of the detector (sec)

RTI = Response time index of the detector ($m^{1/2}\cdot sec^{1/2}$)

$T_{\text{operation}}$ = Activation temperature of the thermal element/detector (°C)

T_m = Exposure temperature (°C)

T_∞ = Initial ambient temperature (°C)

The RTI is a measure of the ease of heating thermal elements in heat detectors and automatic fire sprinklers. The larger the RTI value, the greater the lag in heating the sensing element for a given fire exposure. RTI values for automatic fire sprinklers have been measured[50] in the range of 15 $m^{1/2}\cdot sec^{1/2}$ to 400 $m^{1/2}\cdot sec^{1/2}$. NFPA 13, *Standard for the Installation of Sprinkler Systems,* defines standard response sprinklers as those having an RTI greater than or equal to 80 $m^{1/2}\cdot sec^{1/2}$, and fast response sprinklers as those having an RTI less than or equal to 50 $m^{1/2}\cdot sec^{1/2}$.

For the case of fixed-temperature detectors, the minimum total heat release rate, $\dot{Q}$, needed to operate a fixed-temperature detection or suppression device at the ceiling can be estimated by rearranging Equations 25 and 26, solving for $\dot{Q}$ with T_m set equal to the activation temperature of the thermal device. In this form, Equations 25 and 26 become

$$\dot{Q} = 0.014(T_{\text{operation}} - T_\infty)^{3/2}(h_{ceil})^{5/2} \qquad \text{for } r/h_{ceil} \leq 0.18 \qquad (30)$$

$$\dot{Q} = 0.08(T_{\text{operation}} - T_\infty)^{3/2}(h_{ceil})^{3/2}(r) \qquad \text{for } r/h_{ceil} > 0.18 \qquad (31)$$

where

$\dot{Q}$ = Total heat release rate (kW)

$T_{\text{operation}}$ = Activation temperature of the thermal element/detector (°C)

T_∞ = Initial ambient temperature (°C)

r = Radial distance from the fire (m)

h_{ceil} = Distance from the fuel surface to the ceiling (m)

A common practice when estimating thermal detector response is to assume that the fire is centrally located between evenly spaced heat detectors or automatic fire sprinklers on the ceiling. This assumption normally maximizes the estimated response time of a detector in a space completely covered by detectors. The following equation can be used to calculate r, based on the spacing of detectors:

$$r = \sqrt{\left(\frac{a}{2}\right)^2 + \left(\frac{b}{2}\right)^2} \tag{32}$$

where

r = Radial distance from fire (m)

a = Spacing in one direction (m)

b = Spacing in the direction perpendicular to a (m)

See Figure 3.9.9.

EXAMPLE 13. An 1800 kW wood pallet fire is burning in a space with a ceiling height of 4.0 m. The fire is centrally located between four automatic fire sprinklers spaced at 4.5 m. The automatic fire sprinklers are standard response with an activation temperature of 74°C and an RTI of 80 $m^{1/2}\cdot sec^{1/2}$. The ambient temperature in the space is 20°C. How long will it take for the fire to activate an automatic fire sprinkler? What is the minimum heat release rate needed to activate an automatic fire sprinkler in this configuration? Assume that the sprinkler is exposed to the maximum ceiling jet temperature and velocity at a given location.

SOLUTION 13. The first step in solving this problem is to determine the radial distance r between the automatic fire sprinkler and the fire. Using Equation 32:

$$r = \sqrt{\left(\frac{4.5}{2}\right)^2 + \left(\frac{4.5}{2}\right)^2} = 3.18 \text{ m}$$

Because the ratio r/h_{ceil} is 0.8, Equations 26 and 28 are appropriate to use for determining the temperature and velocity of the ceiling jet.

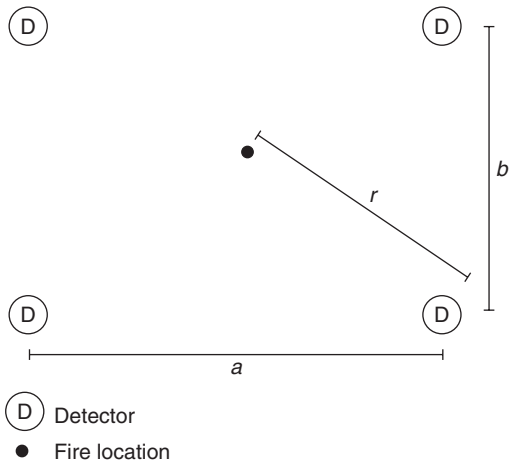

FIGURE 3.9.9 Parameters a, b, and r as They Relate to the Spacing of Detectors Described in Equation 32

$$T_{m(jet)} = 5.38\frac{(1800/3.18)^{2/3}}{4} + 20 = 112°\text{C}$$

$$U_{m(jet)} = 0.195\left[\frac{(1800)^{1/3}(4)^{1/2}}{(3.18)^{5/6}}\right] = 1.8 \text{ m/sec}$$

Equation 29 can be used to estimate the time of detection:

$$t_{\text{operation}} = \frac{80}{\sqrt{1.8}}\log_e\left(\frac{112-20}{112-74}\right) = 53 \text{ sec}$$

The minimum heat release rate needed to activate the automatic fire sprinklers in this configuration is determined from Equation 31:

$$\dot{Q} = 0.08(74-20)^{3/2}(4)^{3/2}(3.18) = 810 \text{ kW}$$

As seen in the example, the fire involving the small stack of pallets is large enough to activate the automatic fire sprinklers in this case.

The measurement of thermal lag for an automatic fire sprinkler is a topic of current research investigations and validation.[51,52] Recent progress has included means to account for the effects of heat loss due to conduction.[53] It has been found that, for cases when the gas temperature does not substantially exceed the activation temperature for the automatic fire sprinkler, significant error can occur in the prediction for activation time. In these cases, it is possible for small changes in predicted gas temperatures to result in large changes in predicted operation time.[51] In the case of constant or slowly varying gas temperatures this effect may be important where

$$\frac{T_m - T_{\text{operation}}}{T_m - T_\infty} < \frac{1}{4} \tag{33}$$

where

T_m = Exposure temperature (°C)

T_∞ = Initial ambient temperature (°C)

$T_{\text{operation}}$ = Activation temperature of the thermal element/detector (°C)

Another factor that contributes to the inaccuracy of predicted results, using Equation 29 under low gas temperatures and gas velocities and also for low RTI values, is that no means is included to account for loss of heat from sensing element, either link or glass bulb, to the automatic fire sprinkler frame and piping by conduction. Heskestad and Bill[53] and Ingason[54] have studied means to account for the effects of conduction loss and measured values for it for automatic fire sprinkler hardware. Following Heskestad and Bill,[53] Equation 29 can be modified to account for the conduction losses to the frame and piping, which are assumed to be at constant temperature equal to the initial ambient temperature (T_∞) as

$$t_{\text{operation}} = \frac{\text{RTI}}{\sqrt{U_m}\left(1 + \dfrac{C}{\sqrt{U_m}}\right)}\log_e \left[\frac{T_m - T_\infty}{T_m - T_{\text{operation}} - \dfrac{C}{\sqrt{U_m}}(T_{\text{operation}} - T_\infty)}\right] \tag{34}$$

where

$t_{operation}$ = Activation time of the detector (sec)

RTI = Response time index of the detector ($m^{1/2} \cdot sec^{1/2}$)

U_m = Ceiling jet or plume impingement gas velocity (m/sec)

C = A conduction loss parameter obtained from measurement $(m/sec)^{1/2}$

T_m = Exposure temperature (°C)

$T_{operation}$ = Activation temperature of the thermal element/detector (°C)

T_∞ = Initial ambient temperature (°C)

A realistic range of values for the conduction loss parameter is 0.5 to 1.6 $(m/sec)^{1/2}$. Using a C value of 0.9, the expected operation time for the automatic fire sprinkler in the Example 12 would increase to 139 seconds as predicted using Equation 34, which is nearly three times as slow as the prediction of 53 seconds (using Equation 29 or Equation 34 with $C = 0$). At a value of C greater than 0.94 $(m/sec)^{1/2}$, the heat loss would be great enough to prevent automatic fire sprinkler operation even though the gas temperature was sustained above the indicated operating temperature of the automatic fire sprinkler.

All calculations in use today for determining times to operation only consider the convective heating of sensing elements by the hot fire gases. The foregoing equations do not account for the additional heating of thermal elements due to conduction from the presence of a hot gas layer, nor do they account explicitly for any direct heating by radiation from the flames. Research is continuing to evaluate and improve calculations of operation for heat-activated devices, such as automatic fire sprinklers.

Automatic Fire Sprinkler Suppression

Fire suppression with water is an extremely complex physical, thermal, and chemical problem. Recently, work has been performed to aid in the design and analysis of sprinkler fire suppression experiments using fire modeling to predict the heat release rate of a fire after sprinkler operation.[55] Often, all that is needed is to gain some insight into the probable conservative bounds for time needed for suppression of fires. In that regard, a limited series of experiments has been conducted to measure the heat release rate during suppression for a series of light hazard occupancy fires involving furnishings. Data from these experiments have been correlated and bounded by a simple expression that permits hand calculations of the rate of heat release from fires during suppression by sprinklers.

Figure 3.9.10 shows the results of the measured heat release rate for furnishing and wood cribs normalized to the rate of heat release at the time of sprinkler operation. As expected, there is a wide range of behaviors. Some furnishing fires are more easily suppressed than others. The heat release rate from the sofa fire decreases rapidly—less than 10 percent of its initial value in about 20 seconds. The more complex Office I Fuel Package takes about 500 seconds to decrease by the same percentage. The regular array of wood sticks that makes up a wood crib

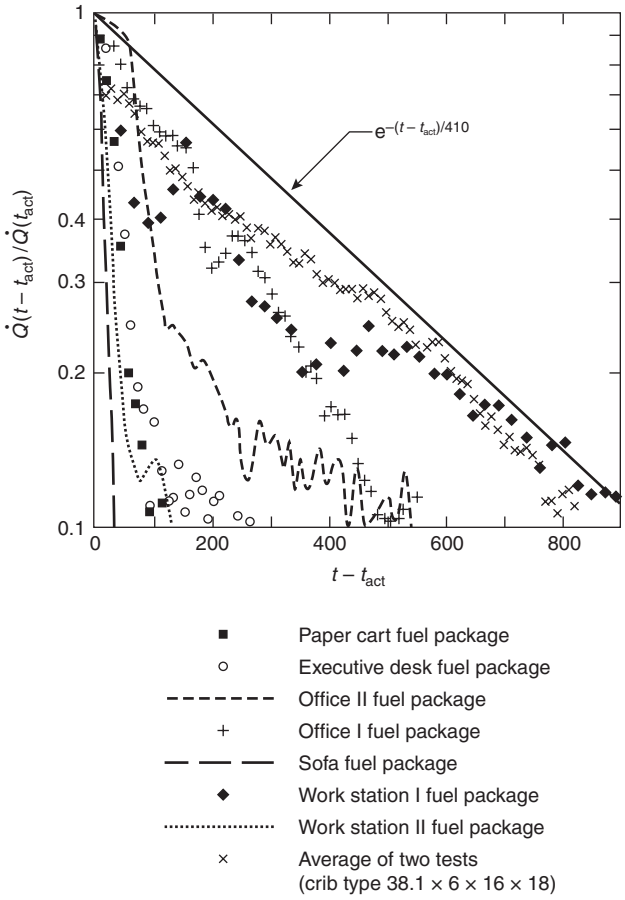

FIGURE 3.9.10 Heat Release Reduction During Suppression of Furnishing Fires with Ordinary Sprinklers. Data for spray density of 0.07 mm/sec (0.1 gal/min/ft^2). (Source: *A Sprinkler Fire Suppression Algorithm for the GSA Engineering Fire Assessment System,* NISTIR 4833)

presents both exposed and hidden burning surfaces that are difficult to extinguish. Over 800 seconds of sprinkler water spray is needed to reduce the heat release rate by 90 percent for the wood cribs tested. All of this test data were collected using a water spray density of 0.07 mm/sec.[54] This spray density is consistent with that suggested by NFPA 13 for the upper range of Light Hazard or the lower range of Ordinary Hazard I.

An upper bound for the data can be constructed by drawing a straight line of the semilog plot. This line results in an expression for the conservative bound (meaning least expected reduction in heat release rate) for suppression of a furnishing fire. This line represents the heat release rate during suppression as a decaying exponential function of time as follows:

$$\frac{\dot{Q}(t-t_{act})}{\dot{Q}(t_{act})} = \exp\left(-\frac{t-t_{act}}{t_e}\right) \qquad (35)$$

where

$\dot{Q}$ = Total heat release rate (kW or kJ/sec)

t = Time (sec)

t_{act} = Time spray suppression begins (sec)

t_e = Time constant for exponential decay (sec)

A limited experimental study of wood crib fire suppression was conducted by Walton[56] and analyzed by Evans.[57] Using the results of an earlier study[58] that showed the time to extinction of wood crib fires was proportional to the water application rate per unit of exposed surface area of the crib, the data from experiments using two different height cribs were collapsed into a single correlation. The wood crib fire suppression was analyzed in the same way as furniture fires have been analyzed previously. Although the data were scattered, as is common with suppression experiments, results[57] showed that for water spray densities varying from 0.03 mm/sec to 0.13 mm/sec, the time constant for the exponential decay in heat release rate varied as

$$t_e = 3 \cdot (m_w)^{-1.85} \tag{36}$$

where

t_e = Time constant for exponential decay (sec)

m_w = Water spray density (mm/sec)

At flow rates below the minimum, no substantial effect on heat release rate was measured.

Using Equation 36, the conservative estimate for exponential decay in heat release rate for furnishing fires suppressed with a water spray density of 0.07 mm/sec is

$$t_e = 3 \cdot (0.07)^{-1.85} = 410 \text{ sec} \tag{37}$$

where

t_e = Time constant for exponential decay (sec)

Using this time constant, the predicted values of the normalized energy release rate during suppression appear along the straight line in Figure 3.9.9. This line provides a conservative upper bound for almost all of the data as shown in Figure 3.9.9.

EXAMPLE 14. Estimate the time required for an automatic fire sprinkler having a water spray application density of 6 mm/sec to reduce an office fire fuel package having a peak energy release rate of 750 kW by 90 percent. Assume the time at which the automatic fire sprinkler actuates is 0 seconds.

SOLUTION 14: The water application flow rate is between 0.03 mm/sec and 0.13 mm/sec; thus, Equations 35 and 36 may be used to estimate the energy release rate reduction. The solution requires two steps: Equation 36 is first used to determine the exponential decay constant; Equation 35 is next used to estimate the time at which the fire size is reduced by 90 percent.

The decay constant is computed using Equation 36 directly:

$$t_e = 3 \cdot (m_w)^{-1.85} = 3 \cdot (0.06)^{-1.85} = 546 \text{ sec}$$

The time at which the fire size is reduced by 90 percent, or is equal to 10 percent of the peak value, is computed using Equation 35:

$$\frac{\dot{Q}(t - t_{act})}{\dot{Q}(t_{act})} = \exp\left(-\frac{t - t_{act}}{t_e}\right) \text{ or } 0.1 = \exp\left(-\frac{t}{546}\right)$$

rearranging:

$$t = -546 \cdot \ln(0.1) = 1260 \text{ sec} = 21 \text{ min}$$

where the inverse function of exp is the natural log.

COMPREHENSIVE EXAMPLE APPLICATION

This section provides a comprehensive example problem, drawing on several of the calculation methods described in this chapter.

EXAMPLE 15. A light manufacturing facility contains a utility room, which houses a backup diesel generator and 400 liter fuel tank that the facility uses to maintain operations during periods of city power loss. The full fuel tank has a curbed area underneath to contain any spills from the tank. The space is fully sprinklered. At some point in the past, a general-purpose workshop was placed in this space for facility support. The workshop contains typical items, including workbenches, tools, power equipment, and large trash containers. One workbench is located approximately 1.3 m from the edge of the curbed spill area, oriented such that the end of the workbench faces the curbed spill area. The ends of this workbench are made of 1.2-cm-thick plywood. An overview of this arrangement is shown in Figure 3.9.11.

A typical goal of automatic sprinkler systems is to control the fire before it spreads to a secondary fuel package. Given rupture of a pipe or of the fuel tank and a subsequent 0.2 m deep pool fire in the curbed area, is the fire likely to spread to the closest workbench prior to the activation of the automatic sprinkler system? Assume the following parameters:

- Curbed spill area dimensions: 1.4 m × 1.4 m × 0.21 m deep (ignore area occupied by tank)
- Area of plywood on workbench end: 1.0 m^2 (facing curbed area)
- Plywood density: 640 kg/m^3
- Plywood heat capacity: 2.8 kJ/(kg·°C)
- Plywood ignition temperature: 390°C
- Ceiling height: 5 m
- Sprinkler spacing 4.5 m × 4.5 m
- Sprinkler height: within maximum ceiling jet temperature and velocity
- Sprinkler operation temperature: 74°C
- Sprinkler RTI: 120 $m^{1/2}sec^{1/2}$
- Sprinkler conduction loss parameter: 0.5 $(m/sec)^{1/2}$
- The size and ventilation of the workshop are such that the heat release rate of the fire will not be limited in this case.

SOLUTION 15. This problem can be solved in three parts. The first part is determining the heat release rate of the fire. The second part is determining the potential ignition time of the workbench. The last part is determining the activation time of the automatic sprinklers.

Step 1. In order to estimate both the potential workbench ignition and the sprinkler activation time, the heat release rate of the fire must be determined. This can be accomplished using

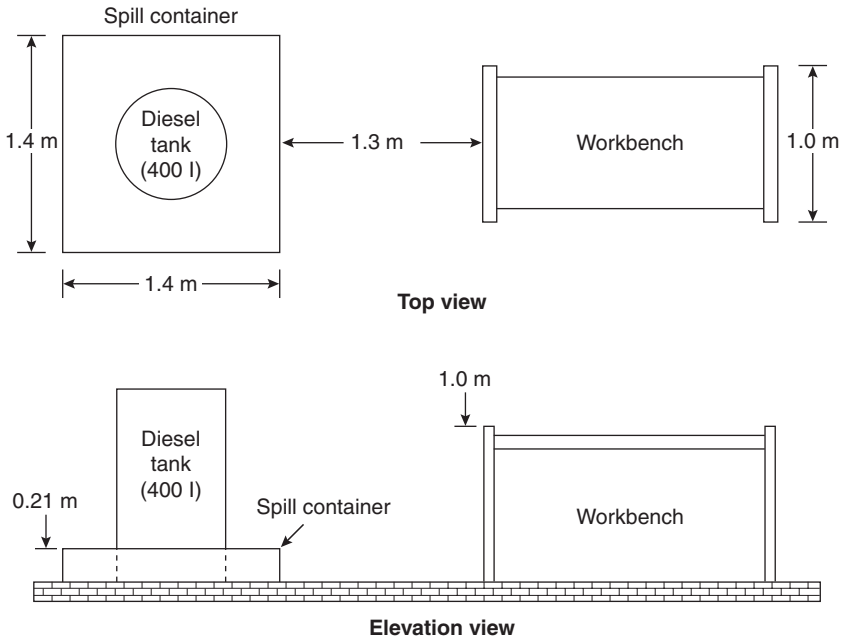

FIGURE 3.9.11 Comprehensive Example Setup

Equation 3. The value for energy release per unit area can be taken from Table 3.9.2 for a confined diesel pool: 1950 kW/m^2. The area is simply calculated from the given dimensions (1.4 m × 1.4 m = 2.0 m^2):

$$\dot{Q}_m = (1950)(2.0) = 3900 \text{ kW}$$

The effective diameter of this fire can be estimated using Equation 21:

$$D_e = \sqrt{\frac{4(2)}{\pi}} = 2.54 \text{ m}$$

Step 2. The next step is to determine the ignition time of the plywood workbench, which can be done using Equation 24. All parameters of this equation are given by the problem statement or are easily deduced, except for the net absorbed heat flux at the solid surface, $\dot{q}''_{\text{net}}$. In this case, the absorbed heat flux is conservatively estimated to be the incident flux from the fire. The incident heat flux can be calculated using Equation 20 because *L*/*D* is 0.8(2.0/2.54), which is within the valid *L*/*D* range of 0.7 to 15.0. Equation 18 is not valid because the ratio R/R_o is equal to 0.64(1.27/2.0), significantly below the minimum limit of 4.0. The resulting incident heat flux, as calculated using Equation 20, is as follows:

$$\dot{q}''_r = 15.4\left(\frac{2.0}{2.54}\right)^{-1.59} = 22.6 \text{ kW/m}^2$$

Note that the value for *L* in this equation is measured from the center of the fire to the plywood (1.3 m + ½(1.4 m) = 2.0 m). In order to be conservative, a safety factor of two is applied, resulting in an incident flux of 45.2 kW/m^2. Comparing the original and conservative incident flux values to the critical heat flux for plywood (16 kW/m^2 as shown in Table 3.9.5) indicates that the incident flux is high enough to ignite the plywood.

The ignition time is estimated by using Equation 24:

$$t_{ign} = 0.012\frac{(640)(2.8)(390-20)}{(45.2)} = 186 \text{ sec}$$

Note that the V_s/A_s term in Equation 24 is replaced with the material thickness, or 0.0127 m. Since the ambient temperature of the space or plywood is not given in this problem, it is assumed to be 20°C, which is a reasonable estimate for an interior environment.

Step 3. Prior to estimating the activation time of the automatic sprinklers, the flame height should be compared with the ceiling height. If the flames impinge on the ceiling, then the methods presented in this chapter for sprinkler activation are likely to underpredict the activation time. Using Figure 3.9.5, the flame height is estimated to be approximately 3.7 m or 3.8 m. The sprinkler activation methods in this chapter will be valid, since the flame height is less than the ceiling height of 5.0 m.

The last part of the problem is to estimate the activation time of the automatic sprinklers. The temperature and velocity of the fire gases at the detector must be determined in order to estimate the activation time. The location of the fire is conservatively chosen as equidistant from four sprinklers. Equation 32 is used to determine the radial distance between the center of the fire and the automatic sprinkler:

$$r = \sqrt{\left(\frac{4.5}{2}\right)^2 + \left(\frac{4.5}{2}\right)^2} = 3.18 \text{ m}$$

The ratio r/h_{ceil} is used to determine which temperature and velocity equations are appropriate for use. In this case, the ceiling jet correlations (Equations 26 and 28) are appropriate, since $r/h_{ceil} = 0.64$.

$$T_{m(jet)} = 5.38\frac{(3900/3.18)^{2/3}}{5.0} + 20 = 143°C$$

$$U_{m(jet)} = 0.195\left[\frac{(3900)^{1/3}(5.0)^{1/2}}{(3.18)^{5/6}}\right] = 2.62 \text{ m/sec}$$

With the temperature, velocity, and other given information, the activation time of the automatic sprinkler system can be estimated using Equation 34 since the conduction parameter is defined:

$$t_{operation} = \frac{120}{\sqrt{2.62}\left(1+\frac{0.5}{\sqrt{2.62}}\right)}\log_e \left[\frac{143-20}{143-74-\frac{0.5}{\sqrt{2.62}}(74-20)}\right] = 48 \text{ seconds}$$

Because automatic sprinklers activate (48 seconds) prior to the ignition of the plywood (186 seconds), fire spread beyond the initial pool fire is unlikely in this case.

SUMMARY

This chapter provides equations that can be evaluated using hand calculators to estimate fire conditions in enclosures. The chapter deals with fire during the preflashover fire growth period in which fire detection and automatic fire sprinklers may be activated by the fire. Means to estimate the fire size in an enclosure, flame heights, plume temperatures, radiant heat flux to targets, enclosure temperatures, smoke-filled gas production rate, ignitability of solids, and thermal fire detector and automatic fire sprinkler response are given. The methods presented were developed from systematic studies of data from experiments that were conducted for very specific, and sometimes idealized, conditions. Therefore, judgment must be used in applying the methods to particular complex fire conditions.

Chapter 10

Performance-Based Codes and Standards for Fire Safety

Milosh T. Puchovsky ❏ Morgan J. Hurley

Over the past century, the basic question concerning fire safety design for the built environment has been this: does the building comply with the detailed requirements of the code? Implied in this question is that meeting the code provides an acceptable level of safety. However, the level of safety implicit in the code was not explicitly defined. For example, how much safety, for whom, and under what conditions? How much property damage or business downtime is tolerable in the event of a fire? For what types of fires was this level of safety to be achieved?

Although code compliance remains at the center of ensuring fire and life safety in buildings, the means of achieving such compliance has taken on different forms. The traditional cookbook mentality of simply verifying prescribed code requirements is being supplemented in numerous cases by performance-based design methods. The emergence of computer fire models, design guides, and other tools, as well as a maturing fire-engineering profession, is changing the landscape.[1] The availability of these new resources prompts a host of new questions about fire safety.

Whereas traditional questions concerning fire safety design center on code compliance, new ones focus on measurement and calculation. The principal argument is that fire safety can be accomplished more effectively, and in some cases for less money, by quantifying the level of safety required and verifying that the entire fire safety package delivers that level of safety. The conventional approach of providing fire safety through the direct application of prescribed solutions embodied in traditional codes and standards might not present the best approach for all projects.

The newer approach in fire safety is commonly referred to as *performance-based design,* and its success hinges on the ability of the fire protection engineer to accomplish three overlapping tasks. The first is to effectively articulate the hazards or threats to be guarded against. Ideally this would be accomplished through some type of risk-informed analysis. The second is to quantify the point or measure at which adequate safety is provided. The third is the effective utilization of calculation or verification methods, many of which are packaged as computer models. It is these methods that embody the scientific principles that allow for the calculation of fire-related phenomena such as the spread of fire effects, the response of fire protection systems, and the reaction of building occupants, and for verifying that the hazards identified in the first task do not result in a failure to meet the specific threshold criteria established in the second task under the design solution proposed. These methods serve as the tools for engineers and other qualified professionals for evaluating fire safety solutions not prescribed by codes or standards.

Depending on the project, performance-based approaches can offer a number of advantages over traditional prescriptive-based methods. The overall intent aims at providing more effective and efficient fire safety solutions and building construction practices. By allowing greater freedom in the design process, proponents argue that the overall outcome results in an optimal level of fire safety at reduced construction costs.

Milosh T. Puchovsky, P.E., is an assistant vice-president with NFPA and secretary to the Standards Council. He leads NFPA's performance-based codes development initiatives and is also adjunct faculty at the Department of Fire Protection Engineering at the Worcester Polytechnic Institute.

Morgan J. Hurley, P.E., is the technical director of the Society of Fire Protection Engineers, where he is responsible for advancing the science and practice of fire protection engineering internationally. He is also adjunct faculty in the University of Maryland's Department of Fire Protection Engineering.

International Use of Performance-Based Regulations

Key Terms

authority having jurisdiction (AHJ), design fire, design fire scenario, functional statement, performance-based approach, performance-based design, performance objective, uncertainty

In an effort to realize these benefits, a number of nations have enacted efforts to better support performance-based design and remove barriers to its broader application.[2] The lack of quantifiable fire safety goals and hazards, as well as a tangible interface between regulations and the relevant tools and data needed to conduct performance-based design, present such barriers. A key activity across the globe, which is still ongoing, focuses on the development and implementation of performance-based building and fire codes. With few exceptions, most codes and standards were developed in a manner that did not accommodate or support the use of calculation methods and other resources. Furthermore, many current computer models were developed and distributed without an established link to the codes and standards that have dictated fire safety design over the past century. A more direct path for the application of these tools in conjunction with fire safety regulations would result in more effective use of these tools.

PERFORMANCE-BASED VERSUS PRESCRIPTIVE-BASED REGULATIONS

Ideally, a performance-based code or standard explicitly states its fire safety goals and clearly defines the desired level of safety.[3] Any solution that meets or exceeds the fire safety goals would be permitted. Fire safety would be designed for a specific use or application, rather than for a generic occupancy. Means to achieve compliance with the code begin with a scientific understanding of fire safety, followed by the application of proven engineering methods.

Most fire safety codes and standards used today are considered to be prescriptive. Prescriptive-based documents provide fire safety in a generic fashion by prescribing a combination of specific requirements, such as construction materials, limiting dimensions, or protection systems, but without referring to how these measures achieve a desired level of safety or outcome. Even those documents that require measurement of performance through a fire test or calculation procedure do not explicitly state their goals or objectives in terms of the performance measures considered by the tests. In many cases, neither do they indicate how to connect the goals and objectives to the performance measured by a test. In fact, a measurable level of safety is usually neither stated nor defined as a goal or objective. Usually there is only one way of providing the specified fire safety—the prescribed way.[4]

Concerns about the reliability of systems and features, as well as other uncertainties of performance, are addressed through redundancies, often in the form of requirements for two or more independent safety provisions, each designed to be sufficient by itself to provide safety. This crude, unquantified approach to redundancy can mean excessive and costly overdesign if each of the systems and features has high reliability.

Prescriptive codes find their roots in the nineteenth century when major conflagrations created the need for specific building provisions.[4–6] Revisions to the codes resulted primarily from other significant fires that revealed deficiencies. To prevent recurrence of such disasters, changes were incorporated into the codes. However, these changes were often instituted without effectively evaluating their adequacy, excessiveness, redundancy, or conflicts with other requirements. The overall outcome has been regulations based on empiricism and experience, rather than on a scientific understanding of fire, building performance, and occupant behavior.

Many of the advances in the understanding of fire and fire safety have not been effectively incorporated into everyday fire safety practice partly because of the prescriptive nature of current codes and standards. Some argue that this lack of technology transfer has allowed fire safety to fall behind other engineering disciplines, such as structural design.

PERFORMANCE-BASED DESIGN GOALS

Fire safety is designed into buildings to achieve one or more of the fundamental fire safety goals: life safety, property protection, mission continuity, and environmental protection.[7] Presently, most fire safety design resources are expended on commercial properties, and commercial properties have performed very well in fire. For example, in 2001, there were 6196 civilian fire deaths in the United States. Excluding the 2451 of these deaths that were directly caused by the terrorist actions on September 11, there were 3745 civilian fire deaths; 3110, or 83 percent, of these deaths occurred in a home.[8]

Therefore, there is limited potential for performance-based design to improve fire safety in commercial buildings. Regardless of whether buildings are designed according to a prescriptive or a performance basis, it is not possible to achieve a risk-free environment. Application of additional resources will eventually run up against the law of diminishing returns.

However, the regulation of buildings is a balancing act of the safety requirements and the burden on society to provide those requirements. The more stringent the safety requirements, the more it costs to meet those safety requirements. Regulations are intended to identify the proper balance between the level of safety that society requires and the attendant costs of providing that level of safety.

Although the buildings to which engineering has traditionally been applied have an excellent history of fire performance, they also have an unknown safety margin. If this safety margin is too large, the extra costs associated with providing this margin have a negative impact on the economy, as the added construction costs could show up as higher costs for products and services or dissuade the construction of new or renovated buildings. Performance-based design allows the fire protection (or any other safety provision) that is provided in a building to be tailored to the characteristics of the building, the items stored within the building, and the people who would use the building.

Another advantage of performance-based design is that it allows application of the most current scientific knowledge available. Application of prescriptive-based regulations typically is accomplished with minimal reference to up-to-date engineering and scientific literature. Additionally, it takes at least three years for a code revision cycle to be completed. Therefore, one cannot be sure that the most effective job possible is being done with only the application of prescriptive-based solutions.

THE PERFORMANCE-BASED DESIGN PROCESS

General Concepts

Although many groups in many countries have independently developed their approaches to performance-based design, the underlying framework for conducting performance-based design remains relatively consistent.[7,9] Performance-based design is an iterative process that requires the completion of a series of tasks, each of which must be properly documented. The process is graphically depicted in Figures 3.10.1 and 3.10.2. Although the entire process is quite involved, the following three general concepts are employed in most performance-based design frameworks:

1. *Establish fire safety goals.* Goals indicate the overall outcome to be achieved with regard to fire. Because the desired outcomes must be quantified in some manner, goals are usually expressed as a series of requirements that begin with general statements about fire safety and conclude with measurable performance criteria (e.g., temperatures, energy levels, concentration of fire products).

2. *Specify design parameters.* Design parameters define the conditions under which the proposed fire safety goals are to be achieved. They include details and assumptions about the fire challenges (hazards) to be considered, the people and property to be protected, the characteristics of the building in question, and ultimately the proposed fire safety solution.

3. *Verify proposed solutions.* Calculation methods, computer models, and physical tests are employed to verify that the fire safety goals have been achieved for the design parameters specified. This procedure entails an iterative process in which those aspects of the design parameters pertaining to or affecting the proposed fire safety features are revised and refined until the fire safety goals are satisfied.

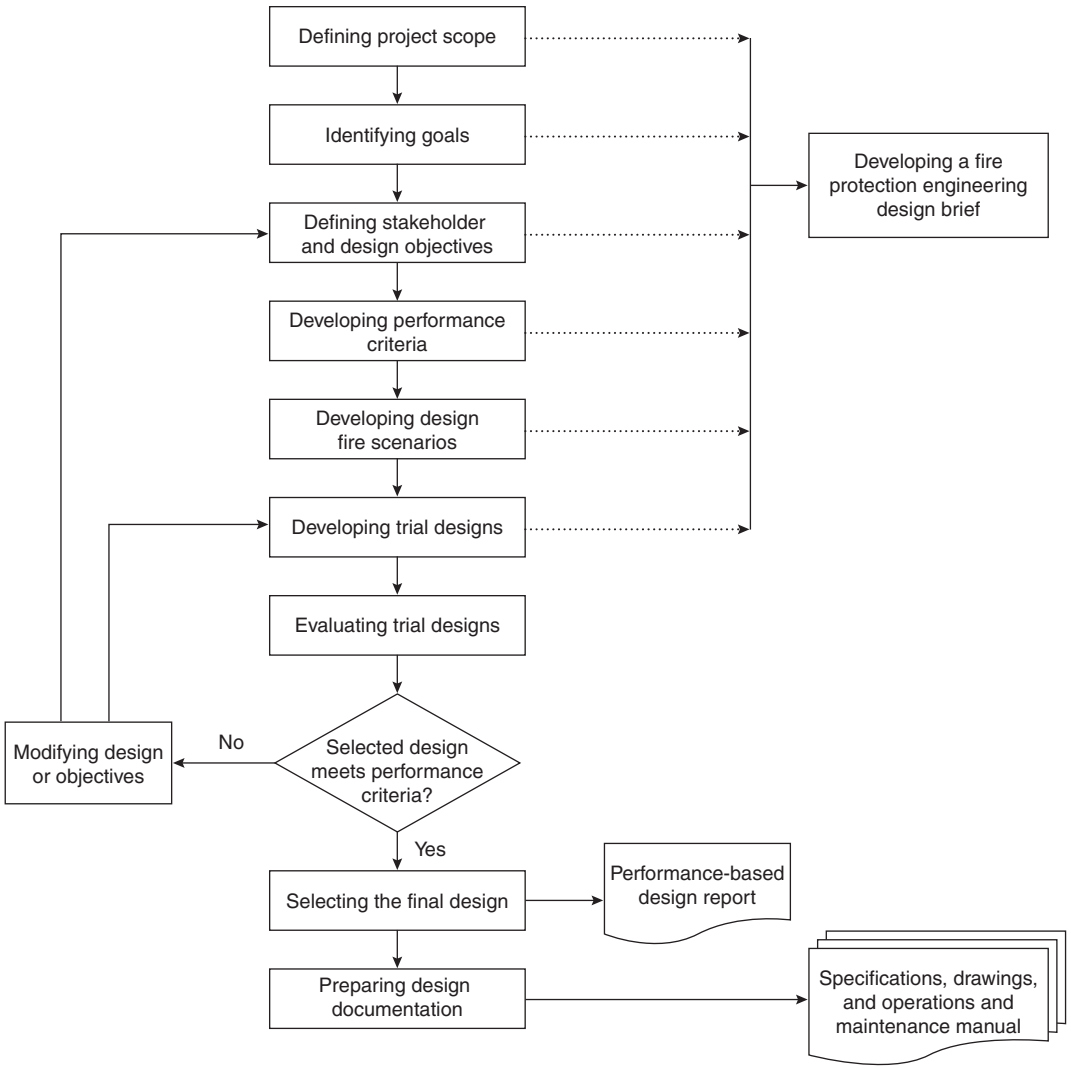

FIGURE 3.10.1 Steps in the Performance-Based Analysis and Design Procedure

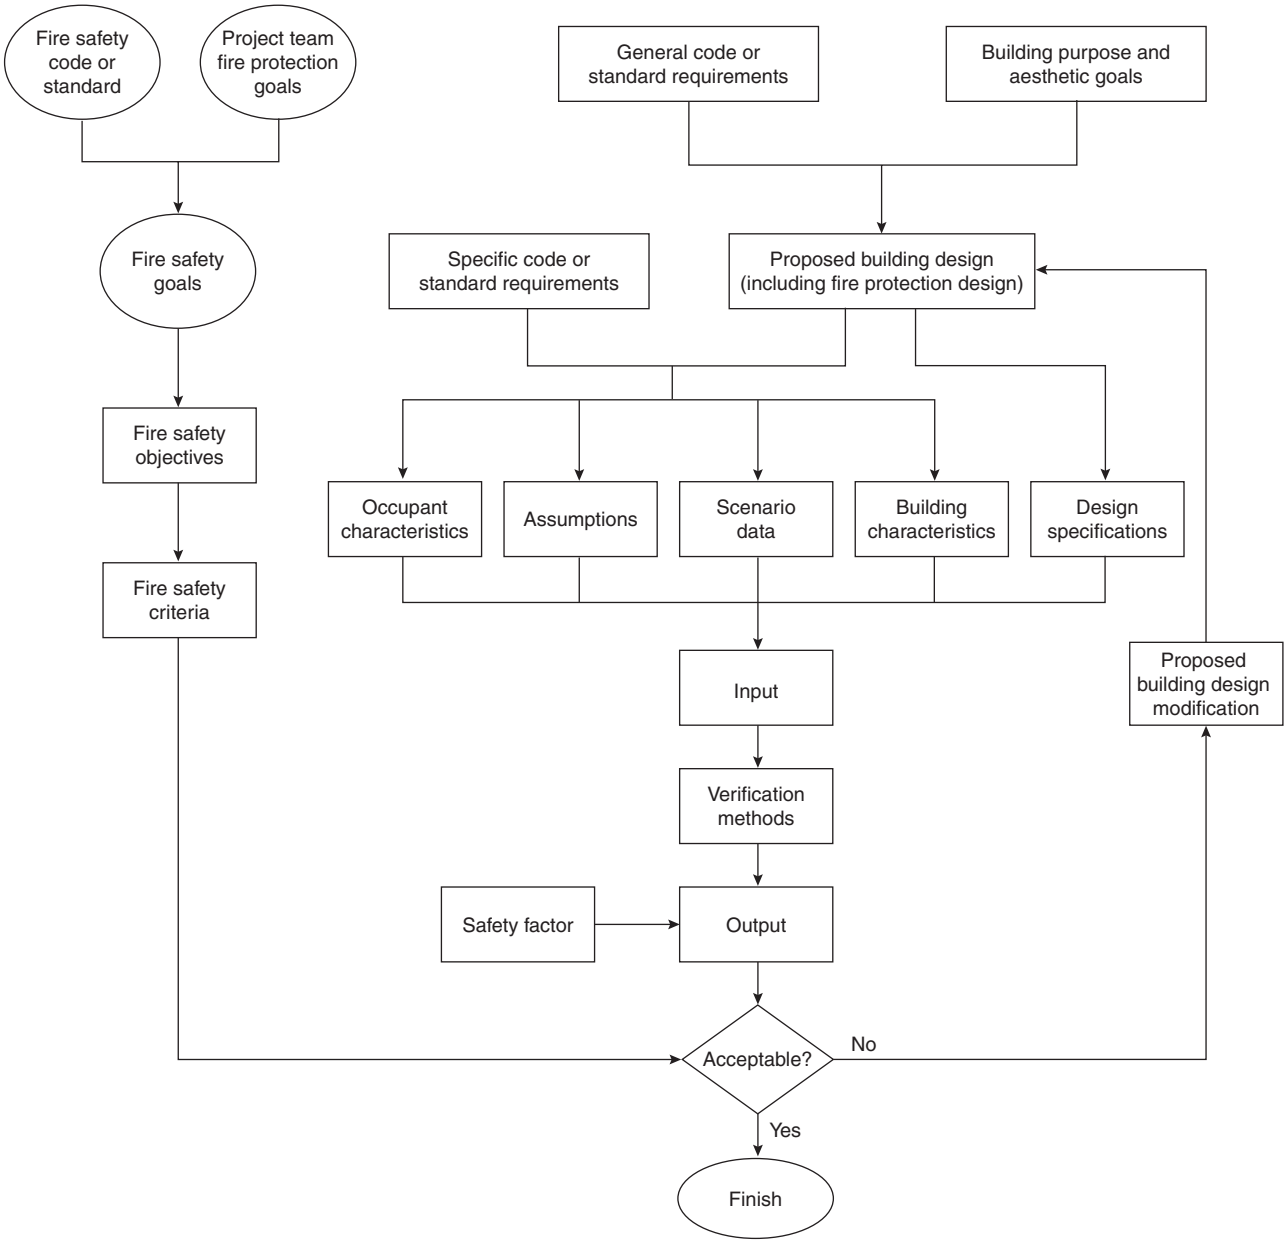

FIGURE 3.10.2 Performance-Based Design Process

Regardless of the verification method used—a computer model that calculates occupant movement, a calculation method that determines time to flashover, or a fire test that measures smoke movement—all require specific input data and knowledgeable users to produce effective results that represent reality. Input data consist of information contained within the design parameters. Those aspects of the design parameters not entered directly into the verification methods will be retained as assumptions in the design process. Depending on the method used, specific information about the fire, occupants, building, and fire protection features will be required. For example, the sprinkler/detector response model used in FPEtool would require the heat release rate of a specified fire, the horizontal and vertical distance between the sprinkler and the fire, the sprinkler's activation temperature and thermal sensitivity, and other data as input.[10]

Another example is Fire Dynamics Simulator (FDS), which can be used to predict sprinkler activation time as well as the effects of sprinkler activation on a fire compartment.[11] However, FDS requires more detailed input than does the sprinkler/detector response model in FPEtool. In order to make these predictions, FDS requires that the user input the full geometry of the space in which the sprinklers will be installed, including all obstructions and vents, as well as surface properties of all obstructions. A fire must be specified using such parameters as the heat release rate per unit area or the heat of vaporization of a fuel. Specific

sprinkler properties, including the response time index (RTI), activation temperature, operating pressure, and C-factor, as well as the sprinkler's location in the space, are input and allow FDS to predict when the sprinkler will activate. Additionally, a sprinkler's K-factor can be specified and waterflow from the sprinkler into the fire domain can be modeled.

The verification method's output will likely be produced in engineering terms such as *time, temperature,* and *heat release.* This output, in combination with the assumptions and decisions employed in the design process, will be evaluated against the performance criteria to determine whether the fire safety goals have been achieved for the design parameters specified. It is important to note that more than one verification method will likely be used to verify the various aspects of a fire safety solution.

Fire Safety Goals, Performance Objectives, and Performance Criteria

Fire Safety Goals. Fire safety goals are the overall outcomes to be achieved with regard to fire.[12,13] They should be nonspecific and expressed on a qualitative basis. Fire safety goals should be stated in terms of conditions that are intrinsically desirable and do not rely on any assumptions. Goals should be stated in language such that they can be understood by people who are not necessarily fire safety professionals. Thus, they would typically be expressed in terms of impact on people or property, business interruption, or environmental impact.

Examples of fire safety goals[7] include the following:

- Minimize fire-related injuries and prevent undue loss of life.
- Minimize fire-related damage to the building, its contents, and its historical features and attributes.
- Minimize undue loss of operations and business-related revenue due to fire-related damage.
- Limit the environmental impact of fire and fire protection measures.

Stating fire safety goals in language that can be widely understood facilitates achieving agreement and buy-in from all project stakeholders on the desired fire safety performance of a building or facility.

Performance Objectives (Functional Statements). Because they are stated in qualitative terms, goals do not provide the detail necessary to judge whether a trial design provides the desired level of fire safety. Performance objectives are intermediate measures that provide more quantitative detail than do fire safety goals. Performance objectives answer the question of "how much fire safety is desired?" Performance objectives can be described as the requirements of the fire, building, or occupants that need to be obtained in order to achieve a fire safety goal.[9] The term *functional statement* is sometimes used in place of the term *performance objective* and serves a similar purpose.

For example, a performance objective stated in terms of impact on people might be to maintain that the risk of death due to fire is not higher than the current level for similar properties or not higher than x per 100,000 people exposed. Another example of a performance objective in terms of impact on people might be to increase the likelihood that anyone capable of self-evacuation and not intimate with ignition can safely escape.

An example of a performance objective stated in terms of impact on property might be to limit fire damage to x square feet (m^2) of building space. For a particular system, such as a sprinkler system, one of the performance objectives might be to provide for a system that will aid in the detection and control of residential fires and reduce the likelihood of injury and loss of life due to fire. Objectives could also include statements that call for prevention of structural damage, no life loss in the room of fire origin, the separation of occupants from fire effects for a specified length of time, or the containment of the fire to the room of origin.

Because they are more quantitative than fire safety goals, performance objectives allow stakeholders to understand more specifically the level of fire safety that will be provided. However, objectives are still not sufficiently detailed for comparison with the output from fire models or other evaluation methods. Therefore, performance criteria are necessary.

Performance Criteria. Performance criteria can be described as performance objectives for individual products, systems, assemblies, or areas that are further quantified and stated in engineering terms.[13] Engineering terms can include *temperatures, radiant heat flux,* or *levels of exposure* to fire and products of combustion. Performance criteria provide threshold values that are treated as data for calculations used to develop a proposed solution.

For example, performance criteria for occupant survivability might be that at a distance of 5 ft (1.5 m) above the floor the following conditions are met:

1. Temperature does not exceed 150°F (65°C).
2. Instantaneous carbon monoxide concentration does not exceed 10,000 ppm.
3. Cumulative carbon monoxide concentration does not exceed 25 percent carbon monoxide hemoglobin level.
4. Oxygen concentration is maintained at 14 percent or greater.

Criteria with regard to the prevention of flashover might be:

1. Upper layer temperature does not exceed 1100°F (or the threshold might be stated as 600°C, which is roughly the same).
2. Radiant heat flux at the floor does not exceed 20 kW/m^2 (or the threshold might be stated as 1.8 $Btu/sec/ft^2$, which is roughly the same).

Characteristics of and Assumptions About Occupants, Contents, and Building Features

It is unlikely that any proposed solution, performance-based or prescriptive-based, will be able to achieve the fire safety goals for everyone and everything under all possible conditions. This situation is due primarily to limitations and uncertainty with available technology and science in combination with society's unwillingness to accept the restrictions and costs associated

with attempting to achieve zero risk. Therefore, details about who or what is intended to be protected and under what conditions need to be specified.[9]

An evaluation of the characteristics of the occupants, contents, and building features is needed. All assumptions about who or what is being protected and all other factors that could invalidate the proposed solution need to be identified as part of the design parameters. For example, a proposed solution may be valid only for occupants who are capable of self-rescue and who have an unobstructed means of egress available to them, or for occupants who are familiar with their egress routes. The effectiveness of the proposed solution for occupants who fall outside the range of these assumptions or characteristics would be much less certain.

The Fire Challenge—Fire Hazards and Scenarios

The potential for ignition and development of a fire that presents a threat to building occupants or contents exists in virtually all locations. The conditions under which these hazards exist and their likelihood of occurring in a given location need to be considered. An analysis, preferably one based on risk analysis, will identify the hazards that are intended to be protected against. The specific hazards to be guarded against need to be precisely defined through a set of fire scenarios and included in the design parameters. *Fire scenarios* specify the fire conditions under which a proposed solution is expected to meet the fire safety goals. A fire scenario can be considered as the fire load to which an occupant or building would likely be subjected. Fire scenarios pose the challenges that the fire safety solution must overcome. The fire scenario describes factors critical to the outcome of the fire, such as the ignition source, the initial fuel package, the location of initial fire development, aspects of the building arrangement, and the available fuel load. Fire scenarios describe the specifications needed for a fire test and can serve as direct input for a fire-modeling run.

As the number and type of hazards to be considered for a given project can be quite large, so can the number of potential fire scenarios. To help manage the range of possible fire scenarios, those scenarios with similar properties can be grouped into categories or clusters. Using a risk-based approach, a representative scenario from each cluster would be included as part of the design parameters.[9] For instance, the scenario that best characterizes the most severe hazard of each cluster could be used. Another possibility includes the consideration of a set of fire scenarios that includes those scenarios that are common (i.e., high probability) for the facility in question and those that are general-purpose high-challenge scenarios but less likely to occur (i.e., likely to result in rapid, early onset of severe fire conditions). An example of such a grouping of scenarios for a single-family residence is described in Table 3.10.1. (Obviously certain terms, such as *free-burning fire,* would need to be more explicitly defined.)

The design parameters for a single-family dwelling might specify, among other conditions, that the fire safety goals be met for all of the six identified fire scenarios in Table 3.10.1. Any proposed solution that demonstrates success would be permitted. For example, a residential sprinkler system designed and installed in accordance with a specific sprinkler system standard might be presented as the proposed solution. However, the sprinkler system alone might not be sufficient, as typical sprinkler systems are not intended to protect against fires in areas that are not sprinklered (high-challenge scenario no. 2) or fires that enter the dwelling from outdoors (common scenario no. 3); additional fire safety features, such as a smoke detection system and certain construction materials, might also be needed.

Design Specifications

Design specifications refer to the physical design arrangement intended to achieve the goals under the fire scenarios, assumptions, and other conditions specified. Design specifications include details about the protection systems to be employed,

TABLE 3.10.1 Possible Set of Fire Scenarios for a Single-Family Residence

Scenario	*Initial Fuel*	*Ignition Source*	*Room or Location of Fire Origin*	*Fire Type*
Common no. 1	Ordinary combustibles	Small open-flame source such as a match or cigarette lighter	Principally occupied rooms such as living room and bedroom	Free-burning fire
Common no. 2	Upholstered furniture	Cigarette	Principally occupied rooms such as living room and bedroom	Smoldering fire
Common no. 3	Ordinary combustibles	Small open-flame source such as a match or cigarette lighter	Structural area such as an attic	Free-burning combustibles
High-challenge no. 1	Ordinary combustibles	Small open-flame source such as a match or cigarette lighter	Entryway of a principally occupied room of the dwelling	Free-burning fire
High-challenge no. 2	Ordinary combustibles	Small open-flame source such as a match or cigarette lighter	Small unprotected room such as a bedroom closet	Free-burning area
High-challenge no. 3	Ordinary combustibles	Small open-flame source or cigarette	Principally occupied rooms such as living room and bedroom	Shielded room-corner fire with a substantial initial smoldering period

whether the systems are active or passive, manual or automatic. They comprise that portion of the design parameters that allow for the most design flexibility and serve as another input for a verification method, either directly or as a retained assumption. As with traditional prescriptive-based approaches, the design specifications would also identify the materials and products to be used in the design and how they are to be assembled and constructed.

Verification Methods—Calculation Methods, Computer Fire Models, Fire Tests

Calculation methods, computer fire models, and fire tests serve as tools that help verify whether the fire safety goals have been achieved for the design parameters.[14–16] Due to the complex nature of the principles involved and the numerous calculations required, models are often packaged as computer software. However, hand calculations that can model certain aspects of a fire event are available.[17,18] (See Section 3, Chapter 9, "Closed Form Enclosure Fire Calculations," and Section 3, Chapter 7, "Fire Hazard Analysis Techniques.") All associated relevant input data, assumptions, limitations, and safety factors needed to properly implement the verification method should be provided.

It is important to note that verification methods do not provide the final solution, but rather help in the evaluation of a performance-based design. This fundamental concept is often misunderstood. The verification methods attempt to account for the physics that describe the fire phenomenon, occupant response, fire safety system performance, and their interaction, and quickly perform the necessary calculations, making performance-based design much more likely. However, the ultimate fire safety decisions lie with the designer and the authority having jurisdiction (AHJ) interpreting the methods' results.

Some fire protection engineers appear eager to apply performance-based methods and fire modeling to their projects as a means of validating non–code prescribed solutions. Currently, the majority of these approaches are used in special applications, such as in the development of unique design arrangements not addressed by current codes and standards, and to demonstrate that an alternative means of protection meets or exceeds code requirements. Although performance-based design can result in more effective solutions, preserve design vision, and reduce overall design and construction costs, it also requires increased time and effort by fire protection engineers and creates the potential for increased design costs.[12]

Although fire models can generate results with a reasonable degree of accuracy when properly employed by knowledgeable individuals, skepticism remains with regard to their routine use for designing fire safety. Overall a good deal of uneasiness exists due to the potential for misuse. Some of the reasons for this include a lack of available input data such as the fire-related properties of building materials, a lack of understanding of the model's purpose and limitations, and the improper interpretation of the model's output. These concerns are valid and efforts to resolve them continue.[19]

The increased application of performance-based design approaches and computer fire modeling warrants a higher level of scrutiny than required for prescriptive-based design. Calculation methods have limitations that may not be identified or known by their developers or users. Misuse of these methods and misinterpretation of their results can have a detrimental effect on safety and overall fire protection. Guidance is needed for users and AHJs so that they either understand or are aware of a verification method's assumptions, limitations, and proper application.[20,21] Further issues exist, as many models have not been validated to show under what conditions their results are valid, and much of the input data needed to run the models are not readily available.

Ideally, a model should be independently evaluated to demonstrate its suitability for use in the design context. At present, only one model has been independently evaluated: DETACT-QS.[22] Unfortunately, conducting a thorough evaluation of a computer fire model is quite complex and time consuming. In the absence of an independent evaluation of a model, the model user should be able to demonstrate why the model is appropriate for the proposed use. This demonstration might involve reference to the model's user's manual or other published reports or providing comparisons of model predictions to test data.

Although the development of calculation methods and fire models continues, more and improved versions are needed if a more complete performance-based design option is to be truly realized. Additional scientific research and testing are necessary for the development of new models and their input data. Existing models and methods do not provide all that is needed. However, it can be argued that fire models can become more effective once codes and standards explicitly state their fire safety goals and provide a direct connection to their application.

Uncertainty

The *SFPE Engineering Guide to Performance-Based Fire Protection* defines *uncertainty* as "the amount by which an observed or calculated value might differ from the true value."[7] Uncertainty can arise from two possible sources: epistemic and aleatory.

Epistemic uncertainty is uncertainty due to lack of (complete) knowledge. For example, it may not be possible to calculate precisely what the temperature would be in a postflashover fire due to imprecision of models and input values. It is possible to develop estimates; however, these estimates will not be exact, even if the input variables are well known. Gaining additional information or knowledge can reduce epistemic uncertainty.

Aleatory uncertainty is uncertainty due to random variation. For example, sprinklers that are manufactured may have slight variation in activation temperature and RTI. It might be known that these factors will vary by no more than a certain percentage, but it is impossible to reduce this uncertainty without changing the way the sprinklers are manufactured. Whether a coin toss will result in heads or tails is a form of aleatory uncertainty. No amount of additional research or information would reduce this uncertainty.

Uncertainty can arise from a number or sources. Performance-based designs must incorporate means of ensuring that uncertainty could not jeopardize the achievement of fire safety goals. The following techniques could be used to evaluate and address uncertainty.[7]

Safety Factors. Safety factors are frequently used in performance-based designs to deal with uncertainty or provide a margin of safety between what would be considered acceptable and unacceptable outcomes. In most cases, these safety factors are developed on an ad hoc basis, because generally few fire protection engineering methodologies provide specific safety factors.

Suppose the safety objective is for everyone to egress the building in less time than is required for fire effects such as toxic smoke to reach them. Then there are two time measures—time required for egress and time required for fire effects to reach occupied areas—and each time measure requires calculations using uncertain data, assumptions, and simplified models. A safety factor to reflect all these uncertainties could be increasing the estimated time for egress by some factor or decreasing the estimated time for fire effects to reach occupied areas by some factor, or both. Ideally, safety factors should reflect the actual magnitude of uncertainties.

Classical Uncertainty Analysis. Classical uncertainty analysis is possible in situations in which there is a large amount of measurement or test data available for a parameter. For example, wind velocity is a critical parameter in many smoke control system designs. In many cases, several years' worth of wind speed data may be available, which would enable a classical uncertainty analysis. The establishment of confidence intervals is an example application of a classical uncertainty analysis. A 50-year wind speed is another example.

Analysis Margin. Analysis margin is the difference between the estimated value of a parameter and the value used in analysis. Larger margins correspond to larger confidence that the value would not be exceeded. However, larger margins also correspond to more expensive designs, so the analysis margin should be selected carefully.

For example, consider the mass of combustibles per unit area found in an office. Field surveys and literature searches would yield a range of values. One could calculate a mean and standard deviation for this range. The mean would be the "best estimate." The best estimate value is a value that would be expected to be exceeded for half of the cases, whereas in the other half of the cases the actual value would be less.

Importance Analysis. For calculations that require multiple input variables, each input variable might not contribute equally to the uncertainty in the calculation. For example, consider Alpert's correlation for temperature rise above a fire plume:[23]

$$\Delta T = 16.9\frac{\dot{Q}^{2/3}}{H^{5/3}}$$

where

ΔT = Temperature rise above ambient (°C)
$\dot{Q}$ = Heat release rate (kW)
H = Height above base of fire (m)

When performing a calculation using this correlation, both H and $\dot{Q}$ might be subject to uncertainty, with $\dot{Q}$ most likely subject to a greater uncertainly than H. However, since $\dot{Q}$ is raised to the 2/3 power, any uncertainty in the heat release rate is reduced in its effect on the result. However, since the height above base of fire is raised to the 5/3 power, its uncertainty on the result is magnified.

Importance analysis rank orders the effect of uncertainty in each variable on the overall result. In the case of Alpert's correlation for temperature rise above a fire plume, the rank ordering would be (1) height above base of fire and (2) heat release rate.

Sensitivity Analysis. Sensitivity analysis is a technique that can be used to determine how changes in input variables affect the calculated result. A sensitivity analysis is conducted by holding all but one input variable constant while varying a single parameter and determining the effect.

The sensitivity of input variables is typically reported as a decimal, which is calculated as follows:

$$\frac{\text{Percentage change in output}}{\text{Percentage change in input}}$$

When conducting a sensitivity analysis, a base case is selected (which is usually the case of interest) and each parameter is individually varied by a percentage (e.g., 10%, 50%, etc.). If the calculated sensitivity is greater than one, then the output is more sensitive to that parameter. If the calculated sensitivity is less than one, then the output is less sensitive to that parameter. Sensitivity analysis is useful because it provides insight into the parameters that have the potential to contribute the most to the uncertainty in the calculated result.

Switchover Analysis. In a switchover analysis, the values of one or more input parameters are varied to determine which values would cause the calculated result to change from a value that would be considered acceptable (i.e., meet performance criteria) to a value that would be considered unacceptable (i.e., does not meet performance criteria).

If all foreseeable combinations of input values would not cause switchover, then the analyst can be confident in his or her conclusions. However, if some combinations of values could cause switchover, then the analyst should satisfy himself or herself that it would not be possible for a combination of factors that could cause switchover to occur.

Verification—The Role of the AHJ and Regulators

Verification is confirmation by the AHJ that a proposed solution meets the established fire safety goals under the conditions specified.[12] Verification can be thought of as a process similar to that used for the approval of traditional code prescribed solutions. However, the "cookbook" mentality associated with prescriptive-based methods is not applicable. The proposed solution developed through performance-based design cannot be easily confirmed by visual inspection for compliance with code requirements near the completion of the design process. The AHJ needs to be brought into the process early on and remain involved throughout. A different type of relationship is necessary. A solid understanding of and/or confidence level with the fire protection engineer and the engineering design concepts employed is essential.

Verification involves several steps not presently required under current prescriptive-based methods, as follows:

1. Verification that the proposed solution shows the building will meet the fire safety goals under the conditions (design parameters) established
2. Verification during construction that the building as built fits the design and data used in the proposed solution
3. Verification that the development of the proposed solution was completed by an individual or group qualified to perform such a task
4. Verification that the proposed solution implemented appropriate models, test methods, and other calculation procedures and that they were used in an appropriate manner
5. Verification that the assessment used appropriate data and that they were used in an appropriate manner

Verification confirms that the building is constructed as intended to a design that will achieve the intended goals under the conditions specified, and that the building's ability to achieve the stated goals has been demonstrated by qualified people using appropriate methods applied to correct data. SFPE recently undertook an effort to establish a more formalized approach to evaluating performance-based designs. The effect of this effort should be a more consistent approach in the verification process. More information can be found in the *SFPE Code Official's Guide to Performance-Based Design Review.*[24]

THE ROLE OF CODES AND STANDARDS IN THE PERFORMANCE-BASED DESIGN PROCESS

Value Judgments and Fire Safety Goals

When verification indicates that a proposed solution is inadequate, what can be changed to achieve success? One response might be to alter the fire safety goals. If the bar is lowered, success becomes more achievable. However, the establishment of fire safety goals represents one means by which society expresses its desires about safety. In this case society encompasses the broader community of interested parties and stakeholders who do not have a direct vested interest in the completion of a particular building project, but who require that a certain degree of safety be provided.

Goals set by society represent value judgments and cannot be compromised, even by AHJs responsible for verifying their compliance. However, other stakeholders with a more vested interest in the outcome of the project—such as the building owner, his or her financers and insurance interests, and the design and construction team—might also establish goals in excess of those embodied in building regulations. Unlike the goals of society, a degree of latitude exists for those goals set by the building owner or his or her representatives provided that they do not conflict with those of society.

Goals, whether those set by society or by the building owner, must be written in such a way that those responsible for verifying that they have been achieved can do so (i.e., the complete fire safety goal from the general statements about safety to the quantifiable performance criteria needs to be clearly stated in fire safety regulations and the project brief). This clarity is especially important, as the enforcing authority will be asked to verify a proposed solution that is based largely on the output produced by verification methods, such as computer models and calculation methods. The verification process becomes more workable when the terms used to measure the performance of a proposed solution (i.e., model output) resemble those used to quantify the fire safety goals (i.e., performance criteria).

Value Judgments and Design Parameters

The design parameters identify all the conditions about the fire, people, property, building, and protection features under which the fire safety goals are to be achieved. The severity and types of fire challenges (fire scenarios) considered as well as the condition and location of the occupants and the layout of the building affect the ability of a proposed solution to achieve the fire safety goals. If the fire scenarios encompassed within the design parameters are relatively undemanding, then a lesser degree of fire protection is necessary to achieve the fire safety goals.

A given building could be considered unsafe if it is required to meet stringent fire safety goals for a set of scenarios that does not adequately represent the associated hazards. For example, it would be less challenging for a sprinkler system in a rack storage warehouse to prevent fire spread across storage aisles if the fire load represented paper products instead of plastic commodities, as the fire challenge associated with the combustion of plastics is relatively more severe than that of paper.

A similar situation might arise if the results of an egress model indicate that building occupants will not be able to evacuate to an area of safe refuge before untenable conditions arise. Would it be acceptable to change the condition of the occupants so that their speed of movement is increased so that success could be achieved? A comparable condition would also arise if the fire safety solutions for a hotel did not consider occupants who were asleep when a fire occurred.

As in the specification of fire safety goals, the determination of the design parameters, particularly in the description of the applicable fire scenarios and character of the occupants and property, also embodies value judgments about fire safety, and therefore certain details about them need to remain fixed regardless of the specific project. The details pertaining to value judgments need to be captured by codes and standards and cannot be subject to modification by the building owner. Without securing this level of detail in building regulations, those responsible for verification would be much less certain about which conditions (fire scenarios) and what occupant characteristics the building owner must evaluate to demonstrate that the level of safety demanded by society has been achieved and remains consistent from building to building.

Value Judgments and Retained Assumptions

Although portions of the design parameters contain details that must remain fixed to meet the needs of society, they also include those details that can be modified to fit the needs of the building owner. The question about what aspects of the design parameters

need to be fixed by fire safety regulations remains. Details about the building and the potential protection features fall to the bottom of the list. After all, the intent of performance-based design is to provide for greater freedom in building design. Greater flexibility in designing fire safety in terms of the building's layout, construction materials, and protection features is the essence of performance-based design. Specifying this information in codes and standards would result in a practice no different than what has been done for the past 100 years.

Codes and standards used in conjunction with performance-based design, therefore, would not specify details about the building, but rather identify those characteristics about the building and the occupants that need to be defined by the building owner. For example, the 2006 edition of the NFPA *101*®, *Life Safety Code*®, requires details pertaining to the building's dimensions, construction materials, furnishings, spatial geometry, number and size of openings, and other facts that serve as input for specific calculation methods or models.[25]

For the most part, regulations should provide as much flexibility as possible in the layout of the building and the design of the protection features. However, there comes a point where the scale used to weigh design flexibility against practical safety considerations becomes unbalanced. It is at this point that decisions pertaining to fire safety design can impact value judgments, and this is where it becomes appropriate for codes and standards to set limits. Therefore, codes would need to further require that certain assumptions be made about any proposed solutions (design parameters). Such assumptions might include the following:

- Compliance with the fire safety goals shall not depend solely on any single safeguard.
- For life safety purposes, a minimum of two means of egress shall be provided unless it can be demonstrated that fire or smoke cannot block the occupants' egress from a single exit.
- Safeguards that comprise the proposed solution must be continuously exercised and maintained in accordance with specified requirements so that the safeguards remain properly operational for the life of the building.

Regulations and Their Impact on the Fire Challenge

The fire conditions under which the fire safety goals are to be achieved need to be specified during the design process. This clarification includes a qualitative description of the types of fires to be considered as well as a conversion of this description into quantifiable terms that can be used as input for a computer model or other evaluation method. The selection of fires to be considered embodies value judgments, as more stringent fires require more substantial safety measures that in turn raise the overall level of safety.

By providing a qualitative description of applicable fires, regulations begin to frame and scope the conditions under which a proposed solution is intended to perform. This description caps the range of potential fires to be examined and makes the design process more workable for all involved. This description also provides a reference for the AHJ when verifying a proposed solution and limits the possibilities of engineers having to prove the impossible.

Examples of the type of scenario data to be specified by regulations include the following:

- A single fire source is assumed
- An ultrafast-developing flammable liquids fire, in the primary means of escape, with interior doors open at the start of the fire
- A fire originating in a concealed wall or ceiling space adjacent to a large occupied room
- A fire starting in a normally unoccupied room that can potentially endanger a large number of occupants in a large room or other area

Because fire conditions largely depend on the characteristics of a given building, codes and standards are limited in the type of information they can provide about them. For instance, the building's operations, contents, dimensions, and so on will dictate the ignition mechanism, growth, and spread of potential fires. Additionally, because the fire conditions must be presented in quantifiable form, the final details about them need to be established by the owner through the application of pertinent data sources. As with the fire safety goals, the building owner may require that fire conditions, in addition to those specified by the regulations, be considered, and other appropriate measures would need to be implemented in this regard.

Regulations and Their Impact on Occupant and Property Characteristics

Characteristics of the occupants or property to be protected need to be specified, as they are critical in determining whether the fire safety goals can be achieved. Certain details about the occupants or property would be used as input data for computer models or be retained as key assumptions throughout the design process.

Codes and standards need to require that specific information be provided about the occupants, such as their sensibility, reactivity, mobility, and susceptibility. The building owner would need to provide specific information in this regard. However, the code might also require that specific assumptions be made about the occupants, such as the following:

- In every normally occupied room or area, at least one person shall be located at the most remote point from the exits.
- In every normally occupied room or area, the average maximum density of occupancy shall be present.

Additional details or other assumptions about the people or property exposed might be project specific, and the details about these would be the responsibility of the building owner.

Combining Performance-Based and Prescriptive Solutions

Performance-based design should not include the blind application of calculation methods and computer models. Performance-based design embodies a newer way of thinking about and

conducting fire safety design for the built environment. It is an approach that needs to be implemented from the start of a project and continued to its completion, even if all the tools and data needed for measurement and quantification are unavailable. As in the past, certain assumptions based on knowledge, judgment, experience, and existing prescriptive requirements will be needed to fill the gaps, and this information will result in a combination of prescriptive- and performance-based solutions in many cases. For example, an egress plan developed largely through performance-based design and the application of computer models is likely to rely on existing provisions for stair geometry and egress path lighting.

Another example considers the installation of sprinklers under a ceiling with varying elevations. NFPA 13, *Standard for the Installation of Sprinkler Systems,* requires that sprinklers be positioned not more than a certain distance below the ceiling to ensure that the sprinklers will activate in a timely manner.[26] However, in a ceiling that contains many changes in elevation or deep pockets, the application of the positioning rules becomes awkward as a sprinkler would be required in each pocket, and this situation could result in the installation of more sprinklers than would be needed to protect against the hazard. Computer modeling could be conducted to determine the length of time it takes for the ceiling pockets to fill with hot gases and activate the sprinklers at the lower ceiling elevation. This information could be used to determine whether sprinklers are necessary in each pocket. Although the modeling in this example might provide positioning rules that differ from NFPA 13, the other prescriptive installation rules of NFPA 13 would need to be followed unless other similar analyses are conducted.

It is worth noting that although prescriptive methods are occasionally characterized as overly burdensome, the push to performance-based design is not a result of their failure. Prescriptive methods still provide good results even though they may not be the most efficient in all cases.

PRECEDENTS FOR PERFORMANCE-BASED CODES AND STANDARDS

Although considered to be a relatively new concept, various forms of performance-based design have been performed for quite some time. Many building and fire safety codes and standards provide an option for developing an alternative means of protection or equivalency, provided the level of safety prescribed by the document is not lowered.[27,28] Obvious examples include the development of fire safety solutions for unique architectural or functional features not anticipated by building regulations, or the development of alternative means of protection to maintain the building owner's design vision. Many of the principles of performance-based design are also employed in the preparation of fire reconstructions.

Unfortunately, the application of many performance-based design approaches requires a major undertaking by both the designer and the AHJ. Most codes and standards do not serve performance-based design well. Any performance-based design attempted today must demonstrate a level of safety equivalent to the existing prescriptive standards. However, many existing codes and standards typically do not explicitly state their fire safety goals, nor do they identify the assumptions and fire scenarios under which the prescribed fire safety solution is to be effective. The task of determining what the code is intending to achieve, for whom, and under what conditions can prove to be difficult as each concerned individual typically has a differing opinion of what is intended.

To further complicate matters, most codes and standards do not reference computer models and other evaluation methods that have been demonstrated to be effective for the design and assessment of a proposed solution. Further efforts to validate models are needed. In addition, the current level of technology cannot produce the calculation methods and models that will properly address all of the relevant concerns. This situation calls for more awareness and documentation of a computer model's proper application and limitations. The overall effect is a less than ideal confidence level in performance-based design on a global level.

Once performance-based codes and their supporting design methods, tools, and data undergo a rigorous and acceptable level of standardization and evaluation, as other fire safety technologies have, they will enjoy greater acceptance overall. With the exception of a few documents, such as NFPA *101,* what primarily exist are general provisions allowing something vague called "equivalency," and a collection of experts, models, databases, and other resources that may lead to better solutions if used properly. What are needed are better definitions and procedures that allow the concerned parties to agree more explicitly on the goals against which equivalence is defined and how to demonstrate equivalence. This need is the reason NFPA initiated its development of performance-based codes and standards in 1993. Performance-based design was occurring without the presence of performance-based codes, but it was feared that an acceptable level of consistency in the application of these methods was lacking.

In the United States, a more direct call for the development of performance-based codes has recently been issued. The National Institute for Standards and Technology (NIST), through its report on the collapse of the World Trade Center towers, specifically recommends the development of performance-based standards and code provisions as an alternative to current prescriptive design methods.[29] NIST intends that such performance-based design options enable the design and retrofit of structures to resist real building fire conditions, including the building's ability to achieve the performance objective of burnout without structural or local floor collapse. Furthermore, NIST recommends the development of tools, guidelines, and test methods necessary to evaluate the fire performance of building structures as a whole system.

NFPA CODES AND STANDARDS

Although the application of performance-based methods will continue to increase, it is unlikely that performance-based approaches will entirely replace prescriptive-based methods. Prescriptive-based methods work, although their solutions might not be as effective or efficient as desired in certain situations.

It can also be said that prescriptive-based methods present a more straightforward design approach that requires less of an initial effort to implement. Last and probably most important, prescriptive-based codes are more easily enforced.

Because of the inherent advantages, NFPA codes and standards have been and will continue to be revised to include both performance-based and prescriptive-based options as appropriate.[13] In essence a dual-track approach has been advocated such that either the performance-based or prescriptive-based option could be applied to achieve the safety goals and objectives specified by the code or standard. This arrangement provides an option for either method, as one method might be better suited over the other for a certain project. The dual-track approach also connects the two design methods and supports the philosophy that performance-based options are the next level of sophistication for codes and standards. NFPA's overall approach in this regard is documented in the NFPA *Performance-Based Codes and Standards Preparation Primer.*[30]

NFPA intends to continue to revise its codes and standards to provide the necessary level of detail and standardization for the more robust application of performance-based design. A more formalized approach in codes and standards better supports the overall performance-based design and verification process by explicitly identifying the fire safety goals and by providing guidance on the establishment and use of specific fire safety criteria, assumptions, fire scenarios, and calculation methods. The overall outcome should result in more effective application and acceptance of performance-based design methods by both the design team and the AHJs. It is also anticipated that future NFPA codes and standards will provide a better direction for research efforts, improve the transfer of technology, and encourage prescriptive-based requirements to be based more on science and technology.

Since 1993, NFPA has been formally pursuing the development of performance-based codes and standards. While a number of initiatives continue, a major milestone was reached in the fall of 1999 when the NFPA membership voted to approve the 2000 edition of NFPA *101*. At that time NFPA *101* became the first code in wide use across North America to allow for and specifically address performance-based design. Specific life safety goals and objectives are stated and guidance is provided with regard to the establishment of performance criteria, fire scenarios, design assumptions, and occupant characteristics. Since then, a number of other NFPA documents have been revised to include formal performance-based design options. Some of these documents include NFPA 1, *Uniform Fire Code*™; NFPA 909, *Code for the Protection of Cultural Resource Properties—Museums, Libraries, and Places of Worship;* NFPA 914, *Code for Fire Protection of Historic Structures;* and *NFPA 5000*®, *Building Construction and Safety Code*®.

INTERNATIONAL USE OF PERFORMANCE-BASED REGULATIONS

Since the 1980s, initiatives across the globe have been effective in developing performance-based building regulations and in increasing the greater use and acceptance of performance-based design methods.[31,32] Governments and other interested parties in a number of nations have been urging the reform of their building regulations and their entire building construction industries. This has prompted the development and implementation of performance-based building regulations in a number of nations including the United Kingdom, New Zealand, Australia, the United States, and Canada. Related activities have also occurred in Japan, Norway, and Spain, among others. In some of these nations regulations have also been put forth that introduce competition and third-party review into the plans' approval process.[33] (See www.ircc.gov.au for a list of nations that have representation in the Inter-Jurisdictional Regulatory Collaboration Committee, an international consortium of officials and other professionals promoting the broader development and use of performance-based building regulations.)

The primary incentives for pursuing performance-based building regulations in some nations, such as the United Kingdom and Australia, were within the context of more global regulatory reform rather than an attempt to address specific fire safety concerns.[34] A number of government officials believed that the level of protection prescribed by traditional prescriptive building codes could be achieved by more cost-effective solutions, with the net result being increased economic growth and international competitiveness. Overall, it was thought that market forces should rule as much as possible and that regulatory interference should be minimized. New regulations were written to increase technology transfer and to promote innovation, flexibility, and deregulation with regard to building design.

Performance-based regulations in the United Kingdom and New Zealand call for simplified building codes identifying only major fire and life safety goals for an adequate and reasonable level of safety for persons within and in the vicinity of the building, and referencing design practices for achieving these goals.[35,36] The intent is to give designers more freedom to choose the methods to demonstrate compliance.

To provide guidance in achieving these goals, engineering design practices and "approved documents" have been put forth in a number of nations.[37,38] Approved documents are essentially user-friendly versions of the traditional prescriptive codes and other standards. Compliance with approved documents usually results in swift design acceptance; the use of other practices or methods typically requires more effort for acceptance. The creation of new performance-based building regulations has encouraged and promoted the development of engineering-based documents and methods for the support of performance-based design. Most notably, the Society of Fire Protection Engineers (SFPE) has initiated technical projects aimed at developing engineering design guides and other resources in this regard.

In some nations, the revised regulations have prompted the design team and the AHJ to work more as a team to identify the goals of the project and develop acceptable solutions. In certain cases, AHJs such as building and fire officials are more willing to recognize calculation methods, alternative designs, and trade-offs, as the new rules in certain countries have removed many of the constraints placed on their professional judgment. Coupled with this increased willingness is the availability of guidance materials and training programs to aid in decision making.

Examples of the application of performance-based designs have been presented at a number of conferences around the globe, one of the more recent being the SFPE's 6th International Conference on Performance-Based Codes and Fire Safety Design Methods held in Tokyo, Japan.

The International Code Council Approach

The International Code Council (ICC) has embarked on the development of a performance-based code. First published in 2000, the *International Code Council Performance Code*[39] takes a different approach than the performance-based codes and standards published by NFPA. First, unlike NFPA's performance-based codes and standards, which identify the fire safety goals and objectives and then allow for either performance-based design or the prescribed solution in a single document, the ICC's performance code is published separately. The effect of this is that a jurisdiction must separately adopt the code for it to be legally enforceable. If it is not legally adopted, it may be used as reference, but the jurisdiction may not be permitted to enforce it.

As with NFPA's performance-based codes and standards, the *International Code Council Performance Code* provides goals, objectives, and performance criteria, although the ICC uses different terminology. For example, *goals,* as defined by NFPA, are called *objectives* by ICC; *objectives* are called *functional statements;* and *performance criteria* are called *performance requirements.* However the *International Code Council Performance Code* does not specifically identify fire scenarios or explicit performance criteria. Instead, a matrix is provided that qualitatively identifies the acceptable performance as a function of the magnitude of the design event and the importance of a building (Figure 3.10.3).

Design events are classified as "small," "medium," "large," or "very large." Similarly, buildings are classified into four performance groups. Acceptable performance is classified based on the level of tolerable damage as "mild," "moderate," "high," or "severe."

The performance groups reflect the value of the building or facility to the community. Certain storage facilities might be classified as performance group I (the lowest level of importance), whereas hospitals and emergency treatment facilities would probably be classified as performance group IV. A mild impact would correspond to a minor number of mild injuries, whereas a severe impact would be a large number of significant injuries or a high probability of a fatality. A small design event might be a fire originating in a trash can, whereas a very large event might be an event such as an explosion. Decisions regarding the importance of a building, the severity of impact, and the level of tolerable damage are left to the designer and the AHJ.

Canada's Objective-Based Code

In 2005, Canada published its first "objective-based" code.[40] Canada's objective-based code is divided into three divisions, labeled A, B, and C. Division A contains performance requirements, in the form of *objectives* and *functional statements.* (The Canadian codes use similar terminology to the *International Code Council Performance Code.*) Division B contains acceptable solutions; that is, the code's prescriptive design option. Division C contains the administrative provision of the code. It is envisioned that the requirements in Division A will not change significantly with future code revisions, whereas the requirements in Division B will be revised, as is the case with most prescriptive codes.[41]

		INCREASING LEVEL OF PERFORMANCE → PERFORMANCE GROUPS			
		Performance Group I	Performance Group II	Performance Group III	Performance Group IV
Magnitude of Design Event (INCREASING MAGNITUDE OF EVENT ↑)	Very large (very rare)	Severe	Severe	High	Moderate
	Large (rare)	Severe	High	Moderate	Mild
	Medium (less frequent)	High	Moderate	Mild	Mild
	Small (frequent)	Moderate	Mild	Mild	Mild

FIGURE 3.10.3 Maximum Level of Damage to Be Tolerated Based on Performance Groups and Design Event Magnitudes (Source: Table 303.3, from the 2006 *International Code Council Performance Code for Buildings and Facilities.* Copyright 2006. In Canada's objective-based code, each prescriptive provision is tied to an objective and functional statement. Code users would identify which portions of a building will be designed according to a performance basis and which will follow the prescriptive requirements of the code. The portions of the building that are to be designed using the prescriptive requirements of the code would have to meet the provisions in Division B, whereas portions of the building that are designed according to a performance basis would have to meet the objectives and functional statements in Division A.

The performance-based approach of Canada's objective-based code is similar in concept to using equivalency provisions contained within wholly prescriptive codes, although it is not necessary for code users to interpret the intent of prescriptive provisions. The intent is provided by the objectives and functional statements that are tied to the prescriptive provisions.

The overall concept put forth by the Canadian code has similarities in form to that of NFPA. A single regulation identifies the overall goals and objectives. Compliance can then be achieved using either the prescriptive provisions documented in the regulation or a formalized performance-based option.

SUMMARY

The performance-based design concept for fire safety continues to gain momentum across the globe. Government agencies encourage the use of engineering approaches. Fire protection engineers are increasing the application of nontraditional methods in their designs. An increasing number of code and fire officials are being asked to make decisions about fire safety designs based on performance-based approaches. Researchers continue to improve and develop new tools and data. Code developers revise codes to better address the concept. But what is performance-based design really about? Is it about minimizing the cost for fire safety in buildings and increasing design flexibility? Is it about addressing voids in current regulations? Or is it about embracing new technologies? In part, the performance-based concept encompasses all these notions. However, it must also extend beyond them.

The creation of more functional buildings at reduced cost is certainly a desirable goal. However, fire safety is about safety. Cost savings and design flexibility should be considered valued by-products in the application of performance-based design. Overall, the application of new technologies and advances in our understanding of fire safety should produce more effective and reliable fire safety solutions.

Developing regulations that better support performance-based design is only a starting point. Implementation of performance-based design into everyday practice requires more than a rewrite of existing codes and standards. Major efforts to evaluate fire models and test methods are essential, as are efforts with legal issues and education.[42] Success requires cooperation and coordination by all concerned interests.

In the end, performance-based design should provide more answers than questions about fire safety. Once a performance-based design has been implemented and the building has been built, will the building owner and the broader community feel more confident about the building's safety features? More importantly, how can they be certain?

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on performance-based codes and standards for fire safety discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 1, *Uniform Fire Code™*
NFPA 13, *Standard for the Installation of Sprinkler Systems*
NFPA 72®, National Fire Alarm Code®
NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria, and Large Spaces*
NFPA *101®, Life Safety Code®*
NFPA 101A, *Guide on Alternative Approaches to Life Safety*
NFPA 301, *Code for Safety to Life from Fire on Merchant Vessels*
NFPA 550, *Guide to the Fire Safety Concepts Tree*
NFPA 551, *Guide for the Evaluation of Fire Risk Assessments*
NFPA 555, *Guide on Methods for Evaluating Potential for Room Flashover*
NFPA 805, *Performance-Based Standard for Fire Protection for Light Water Reactor Electric Generating Plants*
NFPA 909, *Code for the Protection of Cultural Resource Properties—Museums, Libraries, and Places of Worship*
NFPA 914, *Code for Fire Protection of Historic Structures*
NFPA 5000®, Building Construction and Safety Code®

SECTION 3

Chapter 11

Overview of Performance-Based Fire Protection Design

Frederick W. Mowrer ■ Eric R. Rosenbaum

Chapter Contents

Performance-Based Design Defined
Performance-Based Fire Protection Design Process
Time as a Performance-Based Design Parameter
Deterministic Hazard Versus Probabilistic Risk Assessment
Performance-Based Design Case Study
Developing Fire Scenarios and Design Fires

Key Terms

design fire scenario, deterministic hazard assessment, fire safety goals, occupant characteristics, performance-based design, probabilistic risk assessment, trial design

Engineering design is the process of selecting and orienting basic design elements to serve functional performance objectives within the constraints imposed by cost, technology, and safety. Design elements may include materials, components, products, assemblies, systems, or subsystems, depending on the application. The suitability of a design element for a particular application is determined by analysis. Different analyses use different properties or attributes of design elements to measure expected performance. Design elements selected for use must demonstrate acceptable performance based on the different analyses. In this context, all engineering design is, by definition, performance-based.

The concept of performance-based fire protection design is at least as old as the discipline of fire protection engineering. When the first sprinkler systems were developed in the mid-1800s, they were designed to meet the performance objective of automatic fire suppression in buildings with the constraints that such systems be installed at reasonable cost using technology available at the time. As with many engineered systems, these early sprinkler systems were redesigned, largely through trial and error as well as adverse loss experience, to improve their efficiency as well as their reliability. Other fire safety systems have similar development histories, as do many other engineered systems.

Although the concept of performance-based fire protection design has been around for a long time, the term *performance-based* has taken on a more specific meaning within the fire safety community in recent years. The term *performance-based* has become widely used internationally to distinguish emerging scenario-based methods of quantitative fire hazard analysis and fire risk assessment from traditional "prescriptive" regulatory approaches to fire safety. Within a performance-based design framework, desired outcomes are normally expressed in terms of specific fire safety goals, objectives, and performance criteria to be achieved. Within the traditional prescriptive framework, the analysis and design of building fire safety occur largely within the context of building code compliance, which does not explicitly demonstrate achievement of fire safety goals, objectives, or performance criteria. In a prescriptive environment, fire safety goals and objectives are generally implicit rather than explicit.

Over the past two decades, considerable progress has been made in the areas of performance-based fire protection analysis, design, and regulation. A number of guidance and regulatory documents have been published internationally that address the performance-based fire protection design process. Some of these documents include the following:

- *Comprehensive Fireproof Building Design Methods, Volume 1, Regulations for Comprehensive Design for Fire Prevention,* published by the Architectural Center of Japan in 1989[1]
- *Fire Engineering Design Guide,* first published by the Centre for Advanced Engineering at the University of Canterbury in Christchurch, New Zealand, in 1994, with the second edition published in 2001[2]

Frederick W. Mowrer, P.E., is an associate professor in the Department of Fire Protection Engineering at the University of Maryland. At the time this chapter was prepared, Professor Mowrer was the chair of the Technical Steering Committee of the Society of Fire Protection Engineers and the chair of the Research Advisory Committee of the NFPA Fire Protection Research Foundation.

Eric R. Rosenbaum, P.E., is director of architect and engineering services at Hughes Associates, Inc., in Baltimore, Maryland. Mr. Rosenbaum is the chair of the Society of Fire Protection Engineers Task Group on Performance-Based Analysis and Design.

- *Fire Engineering Guidelines,* published by the Fire Code Reform Centre in Australia in 1996[3] and the *Fire Safety Engineering Guidelines* published by the Australian Building Codes Board in 2001
- *Fire Safety Engineering in Buildings, Part 1: Guide to the Application of Fire Safety Engineering Principles,* Document DD240, published by BSI in the United Kingdom in 1997[4]
- *Fire Safety Engineering—Parts 1 through 8,* ISO/TR 13387, published by the International Organization for Standardization in Geneva, Switzerland, in 1999[5–12]
- *SFPE Engineering Guide to Performance-Based Fire Protection,* published jointly by the Society of Fire Protection Engineers and the National Fire Protection Association in the United States in 2000[13], with the second edition published in 2007
- *International Fire Engineering Guidelines,* produced in 2005 through a collaboration among the Australian Building Code Board, the Department of Building and Housing in New Zealand, the International Code Council in the United States, and the National Research Council of Canada

These documents present similar processes for the performance-based design of building fire safety. This chapter takes advantage of the processes documented in these publications to present an overview of performance-based fire protection design.

See also Section 1, Chapter 3, "Codes and Standards for the Built Environment"; Section 3, Chapter 7, "Fire Hazard Analysis Techniques"; Section 3, Chapter 8, "Fire Risk Analysis"; and Section 3, Chapter 10, "Performance-Based Codes and Standards for Fire Safety."

PERFORMANCE-BASED DESIGN DEFINED

Before considering the performance-based fire protection design process, it is useful to consider what distinguishes performance-based design from other design approaches. The *SFPE Engineering Guide to Performance-Based Fire Protection* (hereafter referred to as the *SFPE PBD Guide*) defines performance-based design as follows:

> An engineering approach to fire protection design based on (1) established *fire safety goals and objectives;* (2) deterministic and probabilistic analysis of *fire scenarios;* and (3) *quantitative assessment* of design alternatives against the fire safety goals and objectives *using accepted engineering tools, methodologies, and performance criteria.* [Emphasis added]

In comparison with prescriptive design, performance-based fire protection design has the following distinguishing features:

- Performance-based design is based on the specification of quantitative and physically meaningful *performance criteria* that can be used to evaluate the achievement of fire safety goals and objectives.
- Performance-based design is based on analysis of the dynamics of anticipated *fire scenarios.*
- Performance-based design is based on quantitative assessment of fire scenarios using accepted *engineering tools and methodologies,* which typically include some form of enclosure fire model.

Ultimately, the goal of performance-based fire protection design is to demonstrate, through appropriate engineering analyses, that an acceptable level of fire safety will be achieved under a comprehensive set of anticipated or foreseeable conditions of use. The adequacy and reliability of performance-based design depend in large part on the adequacy of the performance criteria selected, the comprehensiveness of the fire scenarios anticipated, and the accuracy of the engineering tools and methodologies used for analysis.

PERFORMANCE-BASED FIRE PROTECTION DESIGN PROCESS

The process of performance-based fire protection design can be considered in terms of a number of distinct steps. The *SFPE PBD Guide* outlines these steps in the flowchart illustrated in Figure 3.11.1.

Define Project Scope

The first step in the performance-based design process is to define the scope of a project. The *SFPE PBD Guide* identifies the following issues associated with defining the scope of a project:

- Constraints on the design and project schedule
- The stakeholders associated with project
- The proposed building construction and features desired by the owner or tenant
- Occupant and building characteristics
- Intended use and occupancy of the building
- Applicable codes and regulations
- The project management and delivery method

The various stakeholders must understand and agree on these issues at the outset to ensure that a performance-based design (PBD) meets their needs and interests. A stakeholder is an individual or other representative who has an interest in the successful completion of a project for financial, safety, or other reasons. Possible stakeholders include, but are not necessarily limited to, the following:

- Building owners, managers, and operations and maintenance personnel
- Tenants and other occupants
- Design team
- Construction team—construction managers, general contractors, subcontractors
- Authorities having jurisdiction (AHJ)—fire, building, insurance
- Accreditation agencies
- Emergency responders
- Peer reviewers

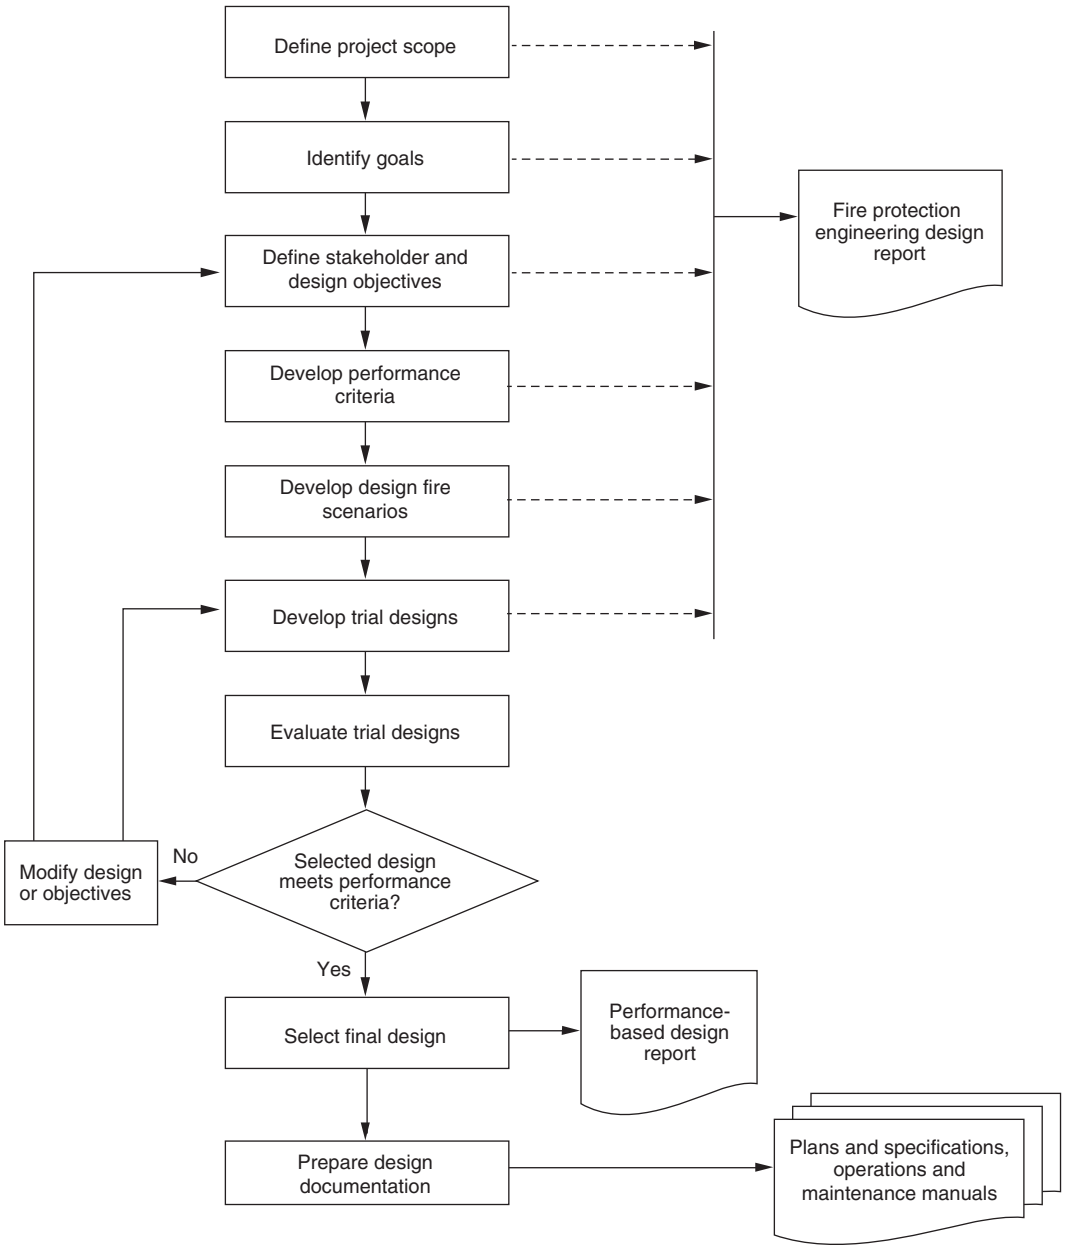

FIGURE 3.11.1 Steps in the Performance-Based Fire Protection Design Process (Source: *SFPE Engineering Guide to Performance-Based Fire Protection,* 2007, Figure 3-2)

Because the scope of many projects is limited, it is essential that the project boundaries be clearly defined and documented during this step so that all stakeholders clearly understand what will, and what will not, be addressed by the PBD. A clear definition of project scope is particularly important for the designer undertaking a PBD to avoid the potential for future misunderstandings and liabilities that might arise during the construction and use of a building.

Identify Fire Safety Goals

Once the project scope has been defined, the next step in the PBD process is for the various stakeholders to identify and for the fire protection engineer to document the fire safety goals of the design. These are the general goals to be achieved by the performance-based design. Fire safety goals may include levels of protection for people and property, or they may provide for continuity of operations, historical preservation, or environmental protection, among others. Fire protection generally has the following four interrelated fundamental fire safety goals:

1. *Provide life safety* for the public, for employees and other occupants, and for fire fighters; minimize fire-related injuries and prevent undue loss of life.
2. *Protect property,* minimizing damage to property from fire and fire protection measures (e.g., protect building,

contents, and historical features from fire and exposure to and from adjacent buildings).
3. *Provide for continuity of operations* (i.e., protect the organization's ongoing mission, production, or operating capability), minimizing undue loss of operations and business-related revenue due to fire-related damage.
4. *Limit the environmental impact* of fire and fire protection measures.

Not all of the above goals are relevant to all projects; the relevance depends on the scope of the project. One purpose of identifying fire safety goals is to help focus stakeholders on the overall fire protection concepts being developed so that all stakeholders are clear on what goals are and, of equal importance, are not being addressed by a given design. Another purpose is simply to document the fire safety goals to be achieved by the design. Although fire safety goals serve this important purpose, they do not provide sufficient detail to evaluate whether specific fire safety objectives will be achieved by a proposed design. This determination requires a more detailed description of objectives and performance criteria.

Define Stakeholder and Design Objectives and Develop Performance Criteria

The evaluation of fire safety objectives generally requires the specific stakeholder and design objectives to be defined and detailed performance criteria to be developed. Performance criteria are quantitative measures, usually in the form of threshold damage or injury levels, that reflect the intent of the design objectives. In general, some criteria address life safety whereas other criteria address damage thresholds for property. Life safety criteria generally address tenability and survivability of fire-induced atmospheres in terms of thermal effects, toxicity, and visibility through smoke. Property criteria may include thermal damage thresholds, structural integrity, smoke damage, and fire spread, among others. Some examples of fire safety goals and associated stakeholder objectives, design objectives, and performance criteria are provided in Table 3.11.1 for each of the fire safety goals described above.

Develop Design Fire Scenarios

After the performance criteria have been established, the next step in the performance-based design process is to develop design fire scenarios. In this context, a fire scenario is a set of conditions that defines the development of a fire and the spread of combustion products through a building. The fire, building, and occupant characteristics at the time of a fire need to be considered in order to define different fire scenarios because these characteristics all interact with each other and influence a fire scenario.

The fire characteristics describe the history of anticipated fire development and generally include consideration of the following:

- Ignition sources and materials first ignited
- Incipient fire development
- Flame spread and fire growth
- Flashover and fully developed fire conditions
- Fire burnout, decay, and extinction

Fire development in buildings is strongly dependent on enclosure and ventilation effects as well as on the installed fire protection features, so the building characteristics must be considered as part of the fire scenario development.

Building Characteristics. The building characteristics describe the physical features, contents, and ambient environment of a building. The building characteristics of interest for fire safety include the following:

- Architectural features, including space layout
- Structural features
- Building services and processes

TABLE 3.11.1 Examples of Fire Protection Goals, Stakeholder Objectives, Design Objectives, and Performance Criteria

Fire Protection Goals	*Stakeholder Objectives*	*Design Objectives*	*Performance Criteria*
Minimize fire-related injuries and prevent undue loss of life	No loss of life outside of the room or compartment of fire origin	Prevent flashover in the room of fire origin	COHb level not to exceed 12% Visibility greater than 23 ft (7 m)
Minimize fire-related damage to the building, its contents, and its historical features and attributes	No significant thermal damage outside of the room or compartment of fire origin	Minimize the likelihood of fire spread beyond the room of fire origin	Upper layer temperature no greater than 392°F (200°C)
Minimize undue loss of operations and business-related revenue due to fire-related damage	No process downtime exceeding 8 hours	Limit the smoke exposure to less than would result in unacceptable damage to the target	HCl no greater than 5 ppm Particulate no greater than 0.5 g/m^3
Limit environmental impacts of fire and fire protection measures	No groundwater contamination by fire suppression water runoff	Provide a suitable means for capturing fire protection water runoff	Impoundment capacity at least 1.20 times the design discharge

Source: *SFPE Engineering Guide to Performance-Based Fire Protection,* 2007, Table B-3.

- Operational characteristics
- Fire protection systems
- Emergency response characteristics
- Environmental factors

These building characteristics affect the growth and spread of fire as well as the movement of combustion products, so they need to be considered in the identification of possible fire scenarios.

With respect to fire development, the primary building features influencing a fire scenario include the following:

- Floor area and volume of the fire enclosure
- Flammability properties of room lining materials, furnishings, and other contents
- Number, type, and location of natural ventilation pathways
- Type and operating characteristics of mechanical HVAC systems
- Type and operating characteristics of automatic fire detection and suppression systems
- Thermophysical properties of enclosure boundaries and the fire endurance characteristics of enclosure boundaries and structural elements

Occupant Characteristics. Occupant activities can also influence fire development; therefore they need to be considered in the development of fire scenarios as well. Occupants can influence fire development in a number of ways, including the following:

- Occupants can accidentally or intentionally contribute to the ignition of fires.
- Occupants can open or close doors and windows to influence the potential for fire and smoke spread.
- Occupants can detect and suppress fires, particularly during the incipient stage of development.

Occupant characteristics also influence how occupants are affected by a fire and how they respond to fire-induced conditions. Some of the important characteristics influencing human behavior in fire include the following:

- Number and distribution of occupants
- Alertness, physical and mental capabilities
- Physical and physiological condition
- Role, commitment, familiarity, and social affiliation

Some of these occupant characteristics relate to the decision-making capabilities of occupants, some to their mobility, and some to their susceptibility to smoke.

Design Fire Curves. One of the most important factors to recognize and consider in the development and evaluation of fire scenarios is the transient nature of building fires. Because fire is a transient process, it affects a building and its occupants and operations in different ways at different stages. Differences of minutes or even seconds can mean the difference between the success or failure of a fire protection strategy. Consequently, in a performance-based design analysis, time is always one of the key design parameters. With respect to the development of design fire scenarios, this time dependency is normally addressed by the development of one or more design fire curves that describe the anticipated heat and smoke release rate histories of the design fire scenarios.

Design fire curves typically have some or all the stages illustrated in Figure 3.11.2. The initiating event is ignition. Following ignition, there may or may not be an incipient period of little or no growth, depending largely on the type and intensity of the ignition source and on the nature of the first fuel ignited. For example, a smoldering fire ignited by a cigarette in upholstered furniture may exhibit a relatively long incipient period, whereas a flaming fire involving the same upholstered furniture may not. Following ignition and the incipient period, if it occurs, most fires of any consequence undergo a period of growth to a maximum size. To a large extent, the rate of fire growth and the peak heat release rate distinguish relatively hazardous fire scenarios from less hazardous scenarios.

Once the fire reaches its peak heat release rate, it may continue to burn at approximately this rate for some period of time, depending on how much fuel is available to burn. This period of relatively steady burning is frequently called the fully developed stage. The final period, typically called the decay stage, occurs when the available fuel starts to become depleted. Some fires are already starting to burn out by the time they reach their peak heat release rate; these fires tend to exhibit heat release rates with distinct peaks, rather than plateaus. The area under the design fire curve represents the total energy released by the fire (see Figure 3.11.2).

In many respects, construction and quantification of design fire curves make up the most difficult, as well as the most important, aspect of the performance-based design process. Design fire curves are important because they govern the rate of hazard development as well as the ultimate magnitude of hazard development. Selection of a design fire curve that does not accurately portray the expected fire development will result in predictions of fire-induced conditions that are either too severe or too mild. This selection can result in designs that are either inadequate or uneconomical. Ideally, actual fire test data representative of the design fire scenario would be available and would be used to develop design fire curves, but in most cases such specific data are not available. In these cases, engineering judgment is needed to characterize and select appropriate design fire curves

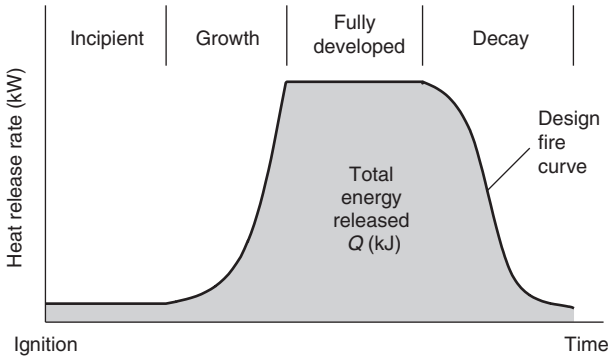

FIGURE 3.11.2 Stages of Design Fire Curves

based on the types, quantities, and configuration of available fuels, including initial and secondary fuels. It is important for all stakeholders to understand the bases for the selection of design fire curves and agree to the selection. To the extent that this selection may impose a need for administrative controls on the potential fuels within a building, these administrative controls need to be documented and enforced.

Develop and Evaluate Trial Designs

The steps of developing and evaluating trial designs are intended to consider how the various fire protection features (fire safety subsystems) will interact to provide the desired level of fire safety in a building. The fire safety subsystems considered in the *SFPE PBD Guide* include the following:

- Fire initiation and development
- Spread, control, and management of smoke
- Fire detection and notification
- Fire suppression
- Occupant behavior and egress
- Passive fire protection

These categories for fire safety subsystems are not unique; they are similar to the categories used to describe fire safety subsystems in a number of the international performance-based fire protection design guides listed at the beginning of this chapter.

Fire Initiation and Development. The fire initiation and development subsystem addresses the probability that ignition will occur as well as the rate of fire development and smoke release if ignition does occur. This subsystem is related directly to the design fire scenario and the design fire curves addressed in the previous section. Treating fire initiation and development as one of the fire safety subsystems helps to emphasize that the selection and placement of interior finishes and contents are an important part of the overall fire safety of a building. This aspect of fire protection design, controlling the fire source through product selection, is too often overlooked in favor of other fire protection strategies, such as fire detection and suppression, rather than being considered in conjunction with these other strategies.

Spread, Control, and Management of Smoke. The smoke management subsystem addresses the hazards resulting from the production and movement of smoke and the methods that can be used to control these hazards. These methods generally include the reduction of smoke generation through the control of materials that produce large quantities of smoke or by suppression, the extraction of smoke by natural or mechanical ventilation, and the containment of smoke by construction, often in combination with mechanical pressurization.

Fire Detection and Notification. The fire detection and notification subsystem addresses both the means used to detect a fire and the means used to notify building occupants and emergency responders of the presence and location of a fire. The fire detection element addresses the response of humans and automatic detection devices to the various fire signatures released during a fire.

Fire Suppression. The fire suppression subsystem addresses the means used to extinguish or control a fire. This subsystem includes automatic suppression systems, such as automatic sprinkler systems, as well as manual suppression systems, including fire department suppression operations. The impact of suppression systems and activities on fire development would be considered part of this subsystem.

Occupant Behavior and Egress. The occupant behavior and egress subsystem addresses the means used to protect occupants from the harmful effects of fire. In general, this protection means the design of an egress system that permits occupants to evacuate a building before untenable conditions develop.

Passive Fire Protection. The passive fire protection subsystem addresses the structural stability of a building as well as the fire resistance of enclosure boundaries to prevent the spread of fire between rooms of a building.

Develop Documentation

One of the most important aspects of performance-based fire protection design is documentation. Documentation is needed for the decisions made and analyses developed during the design process as well as for the duties and responsibilities of the stakeholders to ensure the ongoing conformance of the building's operation with the performance-based design basis. The *SFPE PBD Guide* identifies the following types of documentation:

- Plans and specifications
- Fire protection engineering design brief
- Performance-based design (PBD) report
- Operations and maintenance (O&M) manual

Plans and specifications are basically the same in performance-based design as in other design methods; they are intended to communicate important design information, particularly geometric data and information regarding acceptable materials and methods of construction, to the owner's representatives, to contractors, to AHJs, and to other stakeholders. The other three types of documentation are somewhat specific to performance-based design. The design brief is intended to summarize the performance criteria and analysis methods to be used to evaluate trial designs. The PBD report is intended to document thoroughly the performance-based design and its bases; the O&M manual is intended to help ensure that all the components of a PBD are in place and operating properly. Of central importance is documentation of the changes in use, occupancy, or operation of a building that should trigger a reevaluation of the building's fire safety.

TIME AS A PERFORMANCE-BASED DESIGN PARAMETER

As was noted previously, time is a key parameter in performance-based fire protection design. Most meaningful fire parameters are functions of time. For example, the physical hazards of fires are measured in terms such as fire growth rates, flame spread rates, heat release rates, smoke release rates, heat fluxes, and

burning duration—all functions of time. Similarly, the response of buildings, occupants, and fire protection systems to different fire scenarios can be considered in terms such as fire endurance periods, evacuation times, and fire detection and suppression response times. Consequently, time is an appropriate parameter to use for the quantitative evaluation of different fire scenarios and fire protection strategies.

There are two competing time scales that need to be considered, one associated with hazard development and the other with hazard mitigation. In this context, a successful fire protection strategy is one in which the time to the onset of unacceptable hazardous conditions is longer than the time to successful hazard mitigation for all relevant fire scenarios. This concept is illustrated in Figure 3.11.3.

The hazard development time scale shown in Figure 3.11.3 denotes two relevant times: $t(\dot{Q}_{crit})$ and $t(\dot{Q}_{crit})$. The first of these, $t(\dot{Q}_{crit})$, represents the time when a critical heat release rate is achieved. For example, this time might be the heat release rate needed to cause flashover of an enclosure. The second relevant time, $t(\dot{Q}_{crit})$, represents the time when a critical total quantity of heat or smoke has been released. For example, this time might be when sufficient carbon monoxide has been released to develop an untenable atmosphere. The time to critical hazard development will be based on the fire scenario and the design fire curve.

The hazard mitigation time scale shown in Figure 3.11.3 denotes three relevant times: t_{det}, t_{sup}, and t_{FR}. The detection time, t_{det}, denotes the time when a fire will be detected. The detection time will depend on the fire scenario, the design fire curve, and the types and locations of fire detection devices. The suppression time, t_{sup}, denotes the time when fire suppression is initiated. The suppression time will be equal to the detection time plus the time needed to initiate suppression once the fire is detected. For a wet-pipe sprinkler system, the suppression lag should be nil, and the suppression time will be the same as the detection time. For a dry-type sprinkler system, the suppression lag may be as much as 60 seconds for systems conforming to the requirements in NFPA 13, *Standard for the Installation of Sprinkler Systems*. For manual suppression, the suppression lag may be tens of minutes because the suppression lag includes the times needed for alarm verification and for fire department notification, response, and setup at the fire scene. The fire resistance time, t_{FR}, is the fire endurance period for the enclosure boundaries under the fire exposure conditions. For successful fire confinement, the fire resistance time must be longer than the duration of fully involved fire conditions.

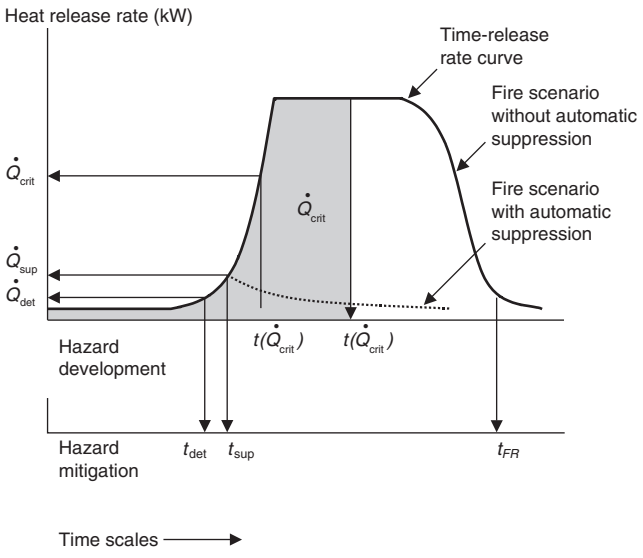

FIGURE 3.11.3 Time Scales Associated with Fire Hazard Development and Mitigation

To make practical use of this concept, the stakeholders need to agree on the performance criteria to be used and the design fire scenarios to be considered in order to evaluate when unacceptable hazard conditions are expected to develop.

All unwanted fires cause some damage and present some hazard. To permit quantitative assessment of fire mitigation strategies, a threshold level of tolerable or acceptable damage or hazard must be established. The time to the onset of unacceptable damage or hazard for a particular fire scenario depends on the following two factors:

1. The susceptibility to damage of the target being evaluated
2. The rate of development of the hazardous environment at the location of the target

If these two factors can be assessed quantitatively, they can yield either a time-dependent scale of damage or a critical time to damage onset. Damage to some targets may be related primarily to the total quantity of a fire signature, such as heat or smoke, released during a fire. This damage is represented as the area under the time-release rate curve (see Figure 3.11.3). Other targets may be damaged once a critical release rate is reached.

The relevant time scales to be compared depend on the type of fire safety analyses being performed. For life safety, the available safe egress time (ASET) must be greater than the required safe egress time (RSET). The available safe egress time is the time from ignition until the specified tenability criteria are exceeded at the location of interest. The required safe egress time is the time from ignition until the building or location of interest has been evacuated. Normally, a safety factor is added to the required safe egress time to provide for a margin of error. This concept is illustrated in Figure 3.11.4, which compares available safe egress time (ASET) and required safe egress time. Note that the required safe egress time includes a number of intermediate periods, including the time from ignition to detection, the time from detection to alarm notification, the time from alarm notification to recognition that an emergency exists, the time from recognition until movement begins, and, finally, the travel time for the exposed population to exit to a safe location. Each of these time periods needs to be evaluated through appropriate engineering analyses for each design fire scenario.

Time lines similar to the one shown in Figure 3.11.4 can be constructed to evaluate the performance of structural elements, fire barriers, and other targets that may be of interest for a particular application.

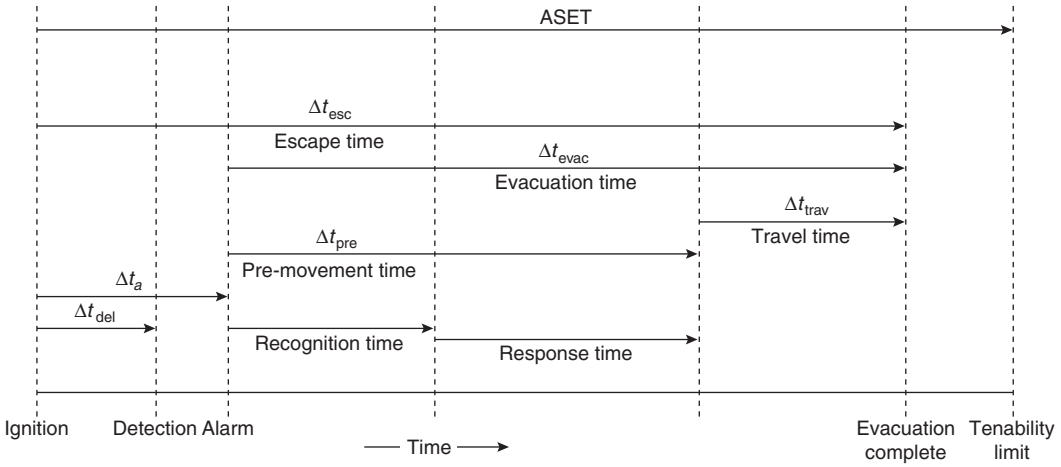

FIGURE 3.11.4 Example Time Line for Evaluation of Available Versus Required Safe Egress Times (Source: *Fire Safety Engineering in Buildings, Part 1: Guide to the Application of Fire Safety Engineering Principles,* Document DD240, BSI, 1997, Figure 2. DETERMINISTIC HAZARD VERSUS PROBABILISTIC RISK ASSESSMENT

Performance-based design is predicated on the specification of design fire scenarios and the evaluation of design alternatives. Two general approaches are available for this process: deterministic and probabilistic. Deterministic analyses consider only the consequences of specified fire scenarios, whereas probabilistic analyses consider the likelihood as well as the consequences of different fire scenarios. For example, a deterministic analysis could be used to assess the expected outcomes for a scenario with and without a properly operating sprinkler system but not the likelihood of each alternative.

Deterministic Hazard Assessment

In a deterministic analysis, a given set of input conditions always results in the same output predictions. Most fire dynamics and enclosure fire modeling calculations are deterministic. For most designs based on deterministic analysis, more than one fire scenario will be considered, even though the likelihood of the different scenarios is not explicitly addressed. For example, the performance-based option in the NFPA *101*®, *Life Safety Code*®, specifies eight required design fire scenarios without consideration of the likelihood of any of the specified scenarios.

Probabilistic Risk Assessment

In a probabilistic analysis, frequencies of occurrence are associated with design fire scenarios to yield the expected losses associated with each scenario. In this way, appropriate weights can be associated with different scenarios and different system reliabilities. A number of risk assessment tools can be used to aid the probabilistic analysis. Because time is a key parameter in fire scenarios, the event tree is a particularly useful tool for evaluating different possible outcomes at each stage of a fire scenario. The example fire event tree shown in Figure 3.11.5 illustrates the stages in fire development and typical factors that contribute to the probabilities at each stage of development.

The event tree shown in Figure 3.11.5 illustrates the concept of "defense in depth," which is widely used for building fire safety, particularly in the nuclear power industry. The defense-in-depth concept is based on the premise that the fire safety of a building should not rely exclusively on a single fire protection subsystem but should be based on a combination of subsystems in case one of the subsystems fails. The defense-in-depth concept has been used historically in building fire safety regulations, for example, through requirements for both automatic suppression and fire-resistive construction. With probabilistic assessment the costs and benefits associated with defense-in-depth applications can be appraised and optimized.

Analysis of the dynamics of different fire scenarios is not likely to differ significantly between deterministic and probabilistic approaches, but expression of performance objectives and criteria is likely to differ. For example, in a deterministic analysis the design objective may be to prevent flashover, whereas in a probabilistic analysis the design objective may be to demonstrate that the likelihood of flashover will not exceed 10^{-6}, or some other very small likelihood, per year. Conceptually, the risk-based probabilistic approach is more satisfying, but statistics are not always available to justify the probabilities needed for its application.

PERFORMANCE-BASED DESIGN CASE STUDY

The case study describes the application of performance-based design to a plan to address fire safety issues for a proposed per-

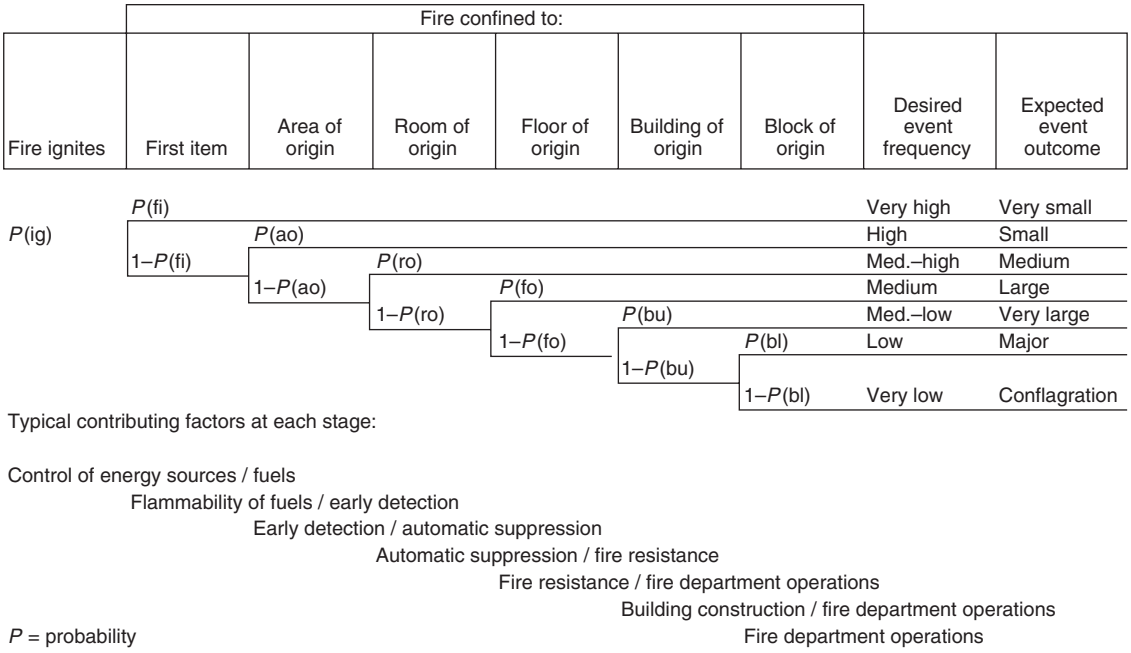

FIGURE 3.11.5 Example Fire Event Tree

forming arts center located in a large metropolitan area in the United States. The plan consisted of a comprehensive approach relative to managing a fire and exposures. As part of this fire safety plan, an alternative to smoke control for an atrium in the facility was developed.

The plan addresses fire safety by using performance-based design as documented in the *SFPE Engineering Guide to Performance-Based Fire Protection.*[13] The results of the analysis demonstrate how the *SFPE Engineering Guide* process works and provides a foundation for project stakeholders to achieve established fire safety goals.

Defining Project Scope

The example building features a large, approximately 150 ft (46 m) high, barrel-shaped glass atrium enclosing a large concert hall (more than 2000 seats) and a smaller theater (approximately 750 seats). Other uses in the building include meeting rooms, office space, and dining areas. The building is six stories high and occupies two city blocks with a footprint area of approximately 90,000 ft^2 (8360 m^2). The highest occupied level, a roof garden/terrace, is approximately 84 ft (26 m) high.

The stakeholders in the project include the owner, the authority having jurisdiction, the architect, the construction manager, the insurance company, the fire protection engineers, and other engineers responsible for designs of systems. Involvement of all of the stakeholders throughout the process is fundamental to the success of the project.

The building will be considered a mixed-use occupancy. Based on the height of the highest occupied level (i.e., the roof garden), the building was classified as a high-rise occupancy. The overall construction type of the building was determined to be protected noncombustible.

Under provisions of the applicable code, smoke control is required for all atria that connect more than two levels. The smoke control provided must maintain smoke to a minimum of 6 ft (1.8 m) above the highest level of exit access for a minimum duration of 20 minutes. Passive smoke control (i.e., no mechanical smoke control) is allowed by the code; however, an analysis must demonstrate that the smoke layer is maintained at least 6 ft (1.8 m) above the highest level of exit access for a minimum duration of 20 minutes. Therefore, the code criteria provide for safety by avoiding any smoke exposure to the occupants during an assumed exiting period. The code also allows alternative smoke control design approaches that achieve the goal of safe exiting of the building occupants. Based on the applicable code, smoke management (active, passive, or alternative) is required for the atrium of the building. An alternative approach for smoke control was developed for the proposed building that meets the intent of the code.

Identifying Goals

Goals establish the overall intent of the fire safety design. The goals were identified through discussions with stakeholders. Goals of the smoke management system include providing life safety and minimizing property damage. Compliance with the intent of the applicable code was also a goal. Unless the stakeholders agree the design meets the intent of the code, a building permit and certificate of occupancy may not be granted. These goals were modified, and other goals were developed as the project progressed. Maintaining the aesthetics of the design became a goal that all the stakeholders felt was important. Minimizing property damage by not allowing smoke to spread into surrounding areas was de-emphasized as a goal by the stakeholders.

Defining Objectives

The objectives define the engineering criteria needed to achieve the fire safety goals. Development of objectives required extensive communication among the stakeholders and an understanding of the proposed approach. The intent of the code smoke control requirements for atria is to provide for safe egress from the building and to prevent migration of smoke from or through the atrium to other areas. The stated requirements of the code require that the smoke layer be maintained above the occupants' heads. Therefore, occupants would not be exposed to smoke.

Controlling occupants' exposure to smoke is one way to provide life safety. Allowing occupants to be exposed to smoke, but limiting the concentration of combustion products in the smoke below hazardous levels is the methodology applied in this case study. A given fire size will produce varying volumes of smoke, depending approximately on the height of the space to the 5/3 power. As a result, much greater volumes of smoke are produced in tall, larger spaces than in smaller low spaces. However, the amount of particulate and energy produced is unchanged for a given fire size. A given fire size in a taller space contains a greater quantity of cool air, thus diluting the particulate-air mixture and reducing the effects of the energy input. Therefore, the relative hazard of the smoke produced by a given fire in a high ceiling space is less than that of a similar size fire in a low ceiling space. For detailed information on smoke management, see NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria, and Large Areas,* and Section 18, Chapter 3, "Smoke Movement in Buildings."

The analysis for the case study building utilizes the fact that occupants may be exposed to highly diluted smoke without being exposed to a hazard. Once stakeholders understood the difference and rationale for the proposed approach—that is, allowing immersion in smoke as long as it was not a hazard—acceptance of the ideas followed. In other words, the stakeholders recognized that occupants could be exposed to smoke, but not to a hazard. A hazard to the occupants was conservatively assumed to occur if hazard criteria were exceeded prior to 20 minutes or the time calculated to egress the building, whichever is greater. The hazard criteria were based on the toxicity, temperature, and visibility within the smoke layer. The limits on toxicity were based on tolerance limits for humans established in the fire science literature. Hazards of concern included carbon monoxide and oxygen depletion. Temperature exposures were also examined. As is most often the case in this type of problem, visibility issues tend to dominate the hazard analysis.

DEVELOPING FIRE SCENARIOS AND DESIGN FIRES

The *SFPE Engineering Guide* includes the following elements as part of a design fire scenario:

- Building characteristics
- Occupant characteristics
- Fire characteristics

Building Characteristics. The case study building characteristics include a large atrium space. The atrium space is approximately 362 ft (110 m) long and 178 ft (54 m) wide. The ceiling is a glass half-cylinder that has an outer radius of 89 ft (27 m). The height of the base of the half-cylinder is about 48 ft (15 m) above the ground floor. An enclosed theater and a concert hall are located in the atrium space, but separated by fire resistance rated construction. Both the concert hall and the theater are irregular shapes and were approximated as cuboids in the analysis. The theater was assumed to be 87 ft (27 m) long, 87 ft (27 m) wide, and 85 ft (26 m) tall. The concert hall was assumed to be 130 ft (40 m) long, 192 ft (59 m) wide, and 96 ft (29 m) tall. There are five levels open to the atrium space. All of the levels potentially have floor spaces where occupants or fires can be located within the atrium. The first floor (ground floor) was located at a zero elevation, the second floor at 21 ft (6.4 m) elevation, the third floor at 32 ft (9.8 m) elevation, the fourth floor at 55 ft (18 m) elevation, and the sixth floor (i.e., roof garden on top of the theater) at 84 ft (26 m) elevation. Figure 3.11.6 illustrates the proposed building in cross-section.

Occupant Characteristics. Occupant characteristics included the number, location, and capabilities of potential occupants. This analysis was based on design occupant loads calculated using the code criteria. The occupant loads were agreed on by the stakeholders as a conservative estimate of the potential occupancy of the structure. Occupants were assumed to be characteristic of the general public capable of attending an event.

Fire Characteristics. The code identifies a specific design fire based on the occupancies of the building for the analysis of atrium smoke control systems. The baseline fire is steady-state heat release rate. Therefore, a baseline fire as required by the code was included in the analysis. In addition, other design fire scenarios included anticipated fire scenarios developed by the stakeholders. Fire scenarios included furniture, kiosks, and displays located in the atrium on all levels open to the atrium. Sprinklers are not provided in high ceiling areas where fuel loads will not be sufficient to activate the system. Spaces adjacent to the atrium and not separated by fire resistance rated con-

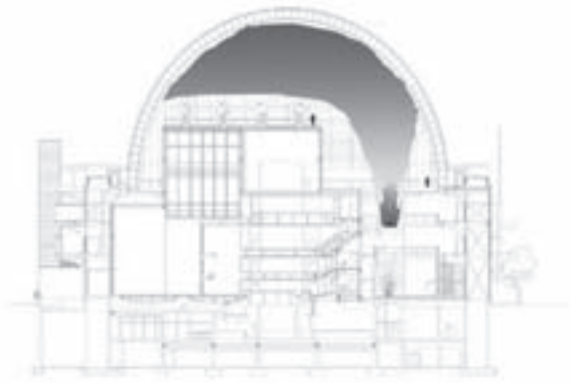

FIGURE 3.11.6 Cross Section of Proposed Performing Arts Center (Courtesy Hughes Associates Inc.)

struction have relatively low ceiling heights and are provided with automatic sprinkler protection. Therefore, fires in adjacent spaces were not evaluated. The composition of the fuel modeled in this analysis was also discussed with the stakeholders. The material properties of concern included the smoke yield, heat of combustion, and carbon monoxide yield.

Developing Trial Design

Trial designs define proposed alternative fire safety systems that address the hazard caused by the design fire scenario in order to provide the level of safety defined by the performance criteria. As the project design progressed, it became clear to all of the stakeholders that the preferred design for the smoke management system would rely on the vast size of the atrium to provide a safe haven for building occupants. This design recognized that the occupants would potentially be exposed to highly diluted smoke, and this would be acceptable. However, occupants could not be exposed to hazardous conditions. If it became apparent that relying on the size of the atrium would not provide an adequate level of safety, then alternative designs included installing a smoke exhaust at various levels in the atrium or installing a unique fire suppression system to limit fire size on the atrium floor.

Throughout the analysis, the stakeholders agreed on the approaches established. Prior to the design evaluation, an agreement on the proposed approach was recorded. The agreement consisted of documentation of meetings held to discuss the various aspects of the approach and all of the limitations and assumptions associated with the approach. All of the stakeholders understood the analysis was oriented toward establishing a fire safe approach with the first step to use the atrium volume and no emergency smoke exhaust.

Evaluating Trial Designs

Once the parameters of the evaluation had been established and agreed to by the stakeholders, the level of fire safety was evaluated. The evaluation process utilized a variety of fire models and calculations. Computer fire models were used to calculate the smoke layer properties (e.g., location, toxicity, temperature, visibility) as a function of time. Because of the limitations associated with individual modeling techniques, both zone fire models and hand calculations were used to estimate smoke layer location and composition. As further verification of the zone modeling, a smoke filling analysis was performed using computational fluid dynamics (CFD).

Due to the glass atrium construction and the potential environmental exposures, smoke stratification in the atrium was a concern. The ambient temperatures in the atrium were based on energy analysis performed by other stakeholders. The layer of hot air resulting from sun exposure to the glass roof may not allow a plume to penetrate, and, therefore, portions of the glass dome could not be utilized as a space for smoke to gather. Therefore, a smaller fire that would result in a weaker plume that would not penetrate the hot air layer might be a worse situation than a more intense fire. Stratification effects of the fire plumes were considered as part of the analysis.

A timed egress analysis was also performed to calculate the time required to evacuate the building in case of a fire. The time required to egress the building was compared to the progress and composition of the descending smoke layer to verify that tenable conditions were maintained for the duration of egress. The anticipated time to egress from the building was calculated based on a "hydraulic flow" type egress model. The basic assumption used in the hydraulic flow egress model is that the rate at which people pass through an exit component (i.e., exit flow) is based on the density of the group of persons entering the exit component. The exit flow assumption is similar in form for all types of exit components including stairs, doors, and corridors. The time to exit each floor incorporated such factors as the time to travel to an exit component, the time to wait for access to the exit component, the time to pass through the exit component, the time to descend through the building, and the time to wait in the queue before exiting the building. Several factors may delay the egress time, such as locating the exits (i.e., "way finding"), egress management activities (i.e., time for verification of alarms by building personnel), and inefficient exit use. Based on these influencing factors, a safety factor was applied to the calculated egress time.

Selecting Final Design

As a result of the evaluation, it was determined that life safety could be maintained utilizing the vast size of the atrium as a smoke reservoir. The atrium size limited the effects of a fire on the occupants of the atrium. Therefore, a large reservoir was utilized in lieu of mechanical smoke exhaust from the atrium. The evaluation demonstrated that, depending on the floor of the fire location, occupants might or might not be exposed to smoke. Where occupants were exposed to smoke, the smoke was highly diluted and did not create a hazard. Because the primary method to achieve fire safety was demonstrated to be adequate, the other trial designs were not evaluated.

One objective not addressed by the primary design was facilitating postfire operations by the fire department. The fire department's concern throughout the process was how it would clear smoke from the atrium if exhaust or openings were not provided in the glass barrel. Postfire ventilation by the fire department was facilitated by providing manually operated vents that allowed the fire department to exhaust smoke. The vents were provided high in the barrel as well as at the base of the barrel. Because of the unpredictability of the environment surrounding the building (e.g., wind and temperatures) and the low temperatures in the smoke layer, these vents were not utilized for automatic natural venting.

Because the final design did not prevent the hot upper layer's descent to floors open to the atrium, the possibility of smoke damage on floors open to the atrium exists. The stakeholders understood this limitation.

Preparing Design Documents

Documentation of the PBD process and the resulting final design was prepared and was reviewed by the stakeholders. Meetings were held to discuss the approach, assumptions, limitations and results. Limitations on fuel loads and space utilization were established in the process, and documented and approved by all of the stakeholders.

Observations

The *SFPE Engineering Guide* provides a methodology that was successfully utilized for the PBD of a smoke control system of a unique building. The performance-based design process included detailed analysis relating to the interaction of all the fire safety systems that were beyond the scope of this brief overview. Without understanding the means of egress, suppression and detection systems, and construction and other fire safety features in the structure, and without developing a comprehensive plan, a PBD may not adequately address all of the issues. The keys to the success of this process were the frequent, high-quality communications between the stakeholders and the initiation of the PBD early in the building design process. As a result of this analysis and the efforts of all the stakeholders, the fire safety goals of the project were achieved.

SUMMARY

The concept of performance-based fire protection design is not new. Fire protection engineers have been designing systems and subsystems to meet fire protection performance objectives and criteria within the constraints imposed by cost, technology, and safety for as long as such systems and subsystems have existed. In recent years, however, the term *performance-based fire protection* has taken on the more specific meaning associated with the design process outlined in this chapter. This process entails the quantitative assessment of different fire scenarios using appropriate computational methods and tools to determine whether specified performance objectives and criteria will be met by a proposed design.

The application of performance-based fire protection design demands a higher level of knowledge about building fire dynamics and fire protection system operating characteristics on the part of stakeholders than does traditional prescriptive design. Although this increased demand can impose additional costs on the design and review processes, it will also produce tangible and intangible benefits. One of these benefits is a better understanding of the expected consequences of fires in a building; another benefit, in many cases, will be reduced costs for fire protection. Whether the benefits of performance-based fire protection design will outweigh the costs depends on the particular application.

In closing this overview of performance-based fire protection design, it is important to emphasize that building fires are complex events, involving the interactions of the fire with the building and the people within the building. The range of potential interactions among the fire, the building, and the people gives rise to a large number of possible fire scenarios. It is not generally practical to evaluate every possible fire scenario, but it is important that the most significant scenarios, from either a hazard or a risk standpoint, are identified and evaluated.

Human Factors in Emergencies

Guylène Proulx

4.1 Human Behavior and Fire
4.2 Calculation Methods for Egress Prediction
4.3 Concepts of Egress Design
4.4 Techniques of Crowd Management
4.5 Strategies for Occupant Evacuation During Emergencies

Most of the *Fire Protection Handbook*® discusses, either directly or indirectly, how fire, systems, and structures behave in relationship to each other. This section focuses entirely on the role of human behavior in emergencies. More specifically, the section concentrates largely on how people discover fire and escape from fire and other emergencies. For the first time, the section also addresses the topic of crowd management, which is closely related to emergency evacuation.

Chapter 1, "Human Behavior and Fire," presents information that is as fundamental to fire protection as fire behavior. It also addresses the means by which people investigate "ambiguous threat cues" and decide that there really is a fire—namely, recognition, validation, definition, evaluation, commitment, and reassessment. Documented human behavior during several significant emergencies, including the Station Nightclub fire and events at the World Trade Center, are discussed.

Chapters 2 and 3 are particularly germane to anyone who uses or enforces NFPA *101*®, *Life Safety Code*®, or *NFPA 5000*®, *Building Construction and Safety Code*®, or who practices performance-based design. Chapter 2, "Calculation Methods for Egress Prediction," explains components of evacuation time, techniques for estimating evacuation time, and calculation methods for travel time, then discusses computer simulation and egress modeling. Chapter 3, "Concepts of Egress Design," reviews concepts that underlie the egress requirements, signage, and lighting in NFPA *101*.

Chapter 4, "Techniques of Crowd Management," is new to the *Fire Protection Handbook* and provides background information needed to fulfill the *Life Safety Code* requirement for trained crowd managers. The chapter reviews selected crowd disasters, explains the difference between crowd management and crowd control, presents a crowd disaster model, and explicates phases of crowd management.

The section closes with another new piece: Chapter 5, "Strategies for Occupant Evacuation During Emergencies." This chapter discusses occupant characteristics in the context of evacuation and compares total evacuation with the alternative strategies of defend-in-place, delayed evacuation, partial evacuation, phased evacuation, and zoned evacuation. The chapter also covers horizontal exiting, evacuation by elevator, preplanning, and nonfire emergencies.

Guylène Proulx, Ph.D., is a senior researcher at the Institute for Research in Construction at the National Research Council Canada, where she specializes in understanding human behavior in emergency conditions.

Chapter 1

Human Behavior and Fire

John L. Bryan

Chapter Contents

Awareness of the Fire
Decision Processes of the Individual
Behavior of Occupants
Disabled or Impaired Occupants
Fire Exit Drills

Key Terms

awakening, convergence cluster, Cook County Administration Building fire, decision making model, disabled occupant, evacuation, exit drill, health care facility, hotel, human behavior, MGM Grand fire, panic behavior, Station Nightclub fire, temporal-three signal, World Trade Center

How one reacts during a fire is related to the role assumed, previous experience, education, and personality; the perceived threat of the fire situation; the physical characteristics and means of egress available within the structure; and the actions of others who are sharing the experience. Postevent analysis of behavior has described actions as adaptive or nonadaptive, participative or inhibited, and altruistic or individualistic. Detailed interview and questionnaire studies over the last half century have established that instances of nonadaptive or panic-type behavior are rare, occurring under specific conditions. Most behavior in fires is determined by information analysis, resulting in cooperative and altruistic actions.

The earliest documented studies on human behavior in the United States involved capacity counts of the velocity of pedestrian movement for the New York City design of the Hudson Terminal Building in 1901.[1] The first edition of the National Fire Protection Association's *Building Exits Code* in 1927 (which eventually evolved into NFPA *101*®, *Life Safety Code*®) was developed from evacuation studies conducted during the decade since 1917. Classical evacuation studies involving railway terminals, subway stations, theaters, department stores, and federal government office buildings with both "normal" exiting flows and "fire-drill" exiting flows were conducted in the early 1930s and published in 1935.[1]

In England, the London Transit Board and other evacuation studies were conducted.[2,3] In the United States, during the 1940s and the 1950s, there was a lack of interest in studies on human behavior in fires. Even in fires that resulted in large loss of life, such as the Cocoanut Grove fire, dedicated human behavior studies of the responses of occupants were not conducted. An exception was the interview study of selected occupants of the Arundel Park fire in 1956, which verified the process of re-entry behavior by members of family groups.[4] The most productive period for research and publications in the United States on human behavior appeared to be from 1970 through the mid-1980s. The 5 year study and report of the National Commission on Fire Prevention and Control in 1973, entitled *America Burning,* provided a federal government focus on the national fire problem.[5] This report resulted in new and enhanced federal financial support for all facets of fire research including human behavior, even though the report envisioned the role of human behavior research being primarily applicable to the educational aspects of fire prevention. During the 1970s the National Bureau of Standards, through the Center for Fire Research, and the National Fire Protection Association were the primary sources for funding studies on human behavior in fire in the United States. Thus, studies resulted in an examination and development of the methods for investigating behavior of the occupants in fire situations in both the United States and United Kingdom. Funding was also provided for the United States and Japan Natural Resource Panel on Fire Research and Safety, which included the study area of human behavior in fires.[6–14]

The emphasis of the studies during this period was on defining human behavior in fire situations, including the examination of the then popular concept of "panic behavior" and an emphasis on the study of the evacuation process as it occurred in high-rise building fires. Characteristics of human behavior individually and within groups have been determined primarily by research studies in which individuals were interviewed by fire department personnel at the scene of the fire.[7,14] It must be recognized that an individual's behavior in a fire is affected by the variables of the building in which the fire occurs and by the appearance of the fire at the time of detection. For example,

Dr. John L. Bryan is professor emeritus of the Department of Fire Protection Engineering, College of Engineering, University of Maryland, and is currently a consultant in Frederick, Maryland.

response will vary if an individual smells smoke rather than sees flames or dark, acrid smoke completely obscuring a corridor. Variables of the fire protection provided for the building may also be critical to the individual's perception of the threat involved. Obviously, the most important individual decisions and behavior in life-threatening situations occur before the arrival of the fire department, in the early stages of the fire. Studies of health care facilities have indicated the importance of this early behavior:

> In the process of investigating these case studies we have come to believe that the period between detection of the fire and the arrival of the fire department is the most crucial lifesaving period in terms of the first compartment (the area in direct contact with the room of origin and the fire).[11]

Thus, the behavior of the individuals intimately involved with the initiation of the fire is critical not only for themselves but often for other occupants of the building. It should be recognized that the altruistic behavior observed in most fires, with occupants in the fire environment interacting in a deliberate, purposeful manner appears to be the general mode of reaction. The nonadaptive flight or panic-type behavioral reaction is apparently unusual in fires.

See also Section 4, Chapter 2, "Calculation Methods for Egress Prediction"; Section 4, Chapter 3, "Concepts of Egress Design"; and Section 20, Chapter 1, "Assessing Life Safety in Buildings."

AWARENESS OF THE FIRE

Obviously, the way an individual is alerted to the presence of a fire may determine the degree of threat perceived. With vocal alerting systems in buildings, variations in voice quality, pitch, or volume, as well as the content of the message, tend to provide threat cues.[15]

Awareness Cues

Proulx and Sime[16] in their study of evacuation drills in an underground rapid transit station found the use of directive public announcements with an alerting alarm bell most effective in creating an immediate effective evacuation. Ramachandran in his review of the research on human behavior in fires in the United Kingdom since 1969 summarized the effectiveness of alarm bells as awareness cues: "The response to fire alarm bells and sounders tends to be less than optimum. There is usually skepticism as to whether the noise indicated a fire alarm and if so, is the alarm merely a system test or drill?"[17]

Ramachandran[18] indicated that the development of "informative fire warning systems," which use a graphic display with a computer-generated message and a high-pitched alerting tone, has reduced the observed delay times in the initiation of practice evacuations. Cable[19] in his study of the response times of staff personnel to fire alarm signals in Veterans Administration hospitals found the greatest delay in response time with coded alarm bell systems. Kimura and Sime[20] in a study of the evacuation of two lecture halls by college students found that the lecturer's verbal instructions were the determining factor in students choosing to use the fire exit over the normal entrance and exit. Research literature developed from practice evacuations indicates that the use of verbal directive informative messages may be the most effective way to reduce delay in evacuation initiation.

However, note that if verbal directive messages conflict with other awareness cues, such as the odor or sight of smoke, occupants may question the credibility of the message and disregard the information. One of the few documented cases of this type of situation occurred in the South Tower of the World Trade Center on April 17, 1975. Lathrop[21] reported that the fire occurred in a trash cart in a storage area on the fifth floor, adjacent to an open stairway door that allowed smoke to infiltrate the ninth through twenty-second floors at approximately 9:04 a.m. Occupants of these floors moved into the core area of the building, and the building communications center monitoring the core lobby areas verbally directed the people in these areas to remain calm and return to their office areas at 9:10 a.m. Despite this announcement, occupants remained in the core lobby areas and became more concerned about smoke conditions. Thus, with occupants on the affected floors becoming more anxious, an evacuation message was announced at 9:16 a.m.

As Burns[22] reported, simultaneous occupant evacuations occurred in the explosion and fire of February 26, 1993, which severely affected both towers and the Vista Hotel of the World Trade Center. The explosion disrupted the Center's communications center, and the occupants, having experienced within minutes the explosion, loss of power, and smoke infiltration of the floors areas, evacuated without the established verbal directional announcements used in previous practice evacuations.

Fahy and Proulx in their questionnaire study of 382 trained fire warden personnel located in both towers of the World Trade Center at the time of the explosion and fire of February 26, 1993, found these personnel were alerted primarily in the following manner:[23]

> Respondents mentioned the following cues, either singly or in combination that something was occurring: hearing or feeling the explosion, loss or flickering of lights or telephones, smoke or dust, sirens and alarms, information from others, and people movement.

Temporal-Three Evacuation Signal

The temporal-three sound was mandated as the building evacuation signal in the 1995 edition of the National Building Code of Canada and in *NFPA 72®*, *National Fire Alarm Code®,* for all new buildings effective July 1, 1996. The temporal-three sound pattern was selected to allow the utilization of all the current types of signaling system devices. The temporal-three sound selection was a product of the Acoustical Society of America and the responsible code committees. The signal was subsequently adopted by ANSI with the standard S3.41, *Audible Emergency Evacuation Signal,* and by the International Standards Organization as ISO 8201, *Audible Emergency Evacuation Signal.* Figure 4.1.1 illustrates the temporal-three sound pattern characteristics as defined in *NFPA 72.*

It should be noted that *NFPA 72* also requires that the signal be continuous for a minimum time as follows:

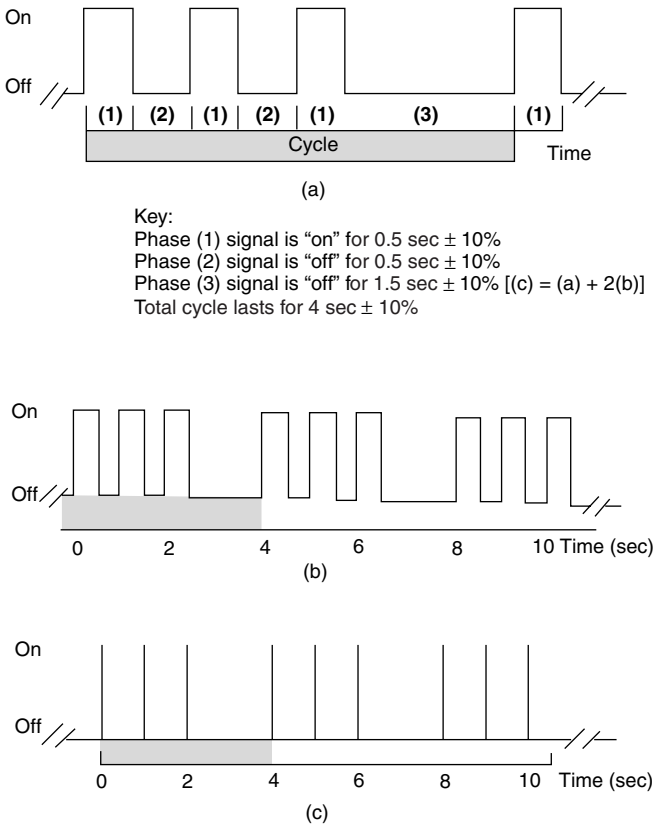

FIGURE 4.1.1 Temporal-Three Evacuation Signal (Source: *Life Safety Code Handbook,* National Fire Protection Association, Quincy, MA, 2006, p. 340)

The signal should be repeated for a period that is appropriate for the purposes of evacuation of the building, but for not less than 180 seconds.

The article by Proulx and LaRoche[24] describes the history of the selection of the temporal-three evacuation signal, but most importantly describes the details and the procedures implemented in their experimental study with 307 individuals relative to their recognition of the temporal-three sound as an emergency evacuation signal and their perceived "urgency" of the signal. The participants were provided with earphones containing the following recorded sounds: car horn, reverse alarm, buzzer, temporal-three (T-3) signal, bell, and slow whoop. The slow whoop was included due to its widespread use in the United States. The most widely utilized signaling device in Canada in institutional buildings was the bell. The presentation of the signals on each CD was varied with the temporal-three being first, third (middle), and sixth (last). The procedure in the study involved approaching the participants when they were alone and inactive in public buildings. The participant was asked to participate in a 5 minute sound recognition study. After listening to the CD each participant was asked three questions:

- Have you heard this sound before?
- What do you think this sound means?
- How urgent do you feel this sound is on a scale from 1 to 10?

Table 4.1.1 presents the results of this study.

It should be noted that of the 219 persons that indicated they had heard the temporal-three signal before, only 17 individuals or 6 percent of the participants correctly identified the signal. As indicated in this table the temporal-three signal had the least perceived urgency with a score of 3.97 on the scale of 1 to 10, with the bell and the slow whoop having the highest perceived urgency at 7.17 and 6.01. The authors of this study had the following critical conclusion concerning the temporal-three

TABLE 4.1.1 Participants' Response to Temporal-Three Signal

A. Number of Occupants Who Said They Had Heard Signal Before

Signal	*Participants (N = 307)*	*Recollection of Signal by Participants (Percentage of Participants)*
Car horn	297	97
Reverse alarm	280	91
Buzzer	249	81
T-3	219	71
Bell	177	58
Slow whoop	159	52

B. Number of Participants Who Correctly Identified Signal

Signal	*Participants (N = 307)*	*Correct Identification of Signal (Percentage of the Time)*
Car horn	302	98
Reverse alarm	218	71
Bell	155	50
Slow whoop	71	23
T-3	17	6
Buzzer	6	2

C. Perceived Urgency of Each Signal

Signal	*Urgency (as Rated by Participants on a Scale of 1 to 10, with 10 Indicating "Extremely Urgent")*
Car horn	4.93
Reverse alarm	5.60
Bell	7.17
Slow whoop	6.01
T-3	3.97
Buzzer	4.91

Source: Guylene Proulx and Chantal LaRoche, "Recollection, Identification and Perceived Urgency of the Temporal-Three Evacuation Signal," *Journal of Fire Protection Engineering,* Vol. 13, No. 1, 2003, pp. 67–82.

evacuation signal, which would apply to any emergency signal rather than an emergency communication:[24]

> The results of this study certainly dispute the assertion that the temporal content of the T-3 may be sufficiently urgent enough to trigger a general evacuation response. It is our opinion that an alarm signal, without any other cue, cannot convey a sufficient message of urgency to let people readily know that they are expected to evacuate a building. The response to the signal will still need to be learned, and probably still need to be prompted by voice communication instructions or by the behavior and directions given by staff. It cannot be expected that occupants will immediately start evacuation or relocation movement upon hearing the T-3 signal, more information will always be required to ensure occupant safe response during a fire incident in a public building.

Initial Means of Awareness

Most of the participants in residential occupancy studies were alerted initially to the fire by the odor of smoke. When the two categories "notified by family" and "notified by others" are combined, however, personal notification becomes the most frequently reported means of initial perception of fire, as indicated in Table 4.1.2.[7] The category "noise" includes noise from persons moving downstairs and through corridors, plus miscellaneous noise sources, including the breaking of glass and the arrival of fire apparatus.

Table 4.1.3 compares the means of awareness from participants of a British study[14] and those of a U.S. study.[7] The number of stimuli was reduced because the British study had fewer categories, and the U.S. responses have been adapted to the British categories. There was only one significant difference in the means of awareness between the two groups: 15 percent of the British participants became aware of the fire upon observing flame, contrasted with 8.1 percent of the U.S. participants.

Purser and Kuipers[25] studied 110 fire incidents with 210 occupants in residential buildings when the fire occurred. Table 4.1.4 presents the means of awareness for the occupants categorized with the occupant in the room of fire origin and when the occupant was not in the room of fire origin. The reader should compare the means of awareness presented in Tables 4.1.2 and 4.1.3 (1977 and 1972, respectively) with the means of awareness indicated in Table 4.1.4 of this study conducted in the early 2000s. It would appear the early means of awareness is still provided by the physical cues of the fire incident and verbal communication from other individuals.

Proulx and Fahy[26] in the study of the survivors' behavior in the terrorist aircraft attacks on the two World Trade Center towers on September 11, 2001, based on media accounts, indicated that 357 persons mentioned being alerted by the means presented in Table 4.1.5. The authors indicate the most frequent initial cue reported by 146 (69%) of the survivors in Tower 1 was building movement, feeling the building sway and tremble. The most frequent initial cue reported by 96 (66%) of the survivors in Tower 2 was the sight of fire, smoke, and debris from Tower 1. The authors note only 25 survivors (6%) who indicated building alarms in their media accounts.

A study one year later obtained information on the occupants' cues of awareness and their activities prior to movement or evacuation. The study involved 803 telephone interviews, 225 face-to-face interviews, and 5 focus group interviews with survivors and first responders, conducted by research personnel and designed and supervised by NIST.[27] In addition, the study of published data by Proulx and Fahy[26] was reviewed. The results of 440 telephone interviews indicating how survivors from World Trade Center 1 became aware of an unusual occurrence in their building are presented in Table 4.1.6. The data population of 440 consisted of approximately 55 percent of the 803 total telephone interviews of survivors from both buildings. Physical

TABLE 4.1.2 Means of Awareness of the Fire Incident (United States Studies)

Means of Awareness	*Participants*	*Percentage*
Smelled smoke	148	26.0
Notified by others	121	21.3
Noise	106	18.6
Notified by family	76	13.4

TABLE 4.1.6 How Survivors in WTC 1 Became Aware Something Was Wrong on September 11, 2001

Cue	*Percentage (N = 440)*
Felt something (building moving, impact, shaking, swaying)	63
Heard something (boom, crash, explosion, blast, roar, rumbling)	30
Other, including saw a plane, smelled jet fuel, fell down/fell off chair, warned by someone	7

Source: NIST WTC Telephone Survey Data, in Jason D. Averill et al., *Occupant Behavior, Egress, and Emergency Communications,* Federal Building and Fire Safety Investigation of the World Trade Center Disaster, NIST NCSTAR 1-7, National Institute of Standards and Technology, Gaithersburg, MD, Sept. 2005, p. 76.

cues of the aircraft striking the building consisted of 93 percent of the awareness cues to the occupants, as indicated by the following: "building moving, impact, shaking, swaying, boom, crash, explosion, blast, roar, rumbling."[27] The predominant activity of the survivors in World Trade Center 1 following their awareness of the unusual threatening cues, prior to initiating evacuation, was "Talked to Others," which would appear to be a "validation" action, as individuals were formulating their "definition" of the event, which was necessary for them to formulate their "evaluation" of a behavioral response.

The NIST telephone interviews of 363 survivors from World Trade Center 2 relating their means of awareness of an unusual occurrence in the buildings are presented in Table 4.1.7. When this table is compared with the means of awareness cues for the event in Table 4.1.6, the principal differences appear to be the cue of "Saw something (smoke or flames, plane, debris)" by 19 percent and "Warned by someone around me" by 13 percent.

TABLE 4.1.7 How Survivors in WTC 2 Became Aware Something Was Wrong on September 11, 2001

Cue	*Percentage (N = 363)*
Heard something (boom, crash, explosion, blast, roar, rumbling)	51
Saw something (smoke or flames, plane, debris)	19
Warned by someone around me	13
Felt something (building moving, impact, shaking, swaying)	11
Other, including contacted via telephone, lights flickered, news media	7

Source: NIST WTC Telephone Survey Data, in Jason D. Averill et al., *Occupant Behavior, Egress, and Emergency Communications,* Federal Building and Fire Safety Investigation of the World Trade Center Disaster, NIST NCSTAR 1-7, National Institute of Standards and Technology, Gaithersburg, MD, Sept. 2005, p. 76.

It is important to realize that 81 percent of the interviewees in World Trade Center 2 indicated they were aware of the event in World Trade Center 1, having been alerted by coworkers, telephone, or news media coverage. Thus, awareness data was obtained from all of the 803 telephone interviewees.

The factors of personnel in World Tower 2 being alerted by the event in World Trade Center 1 are more clearly observable in the Proulx and Fahy study of the published accounts of survivors relative to their "first cues of events within the towers" previously presented in Table 4.1.5 for survivors from both towers.[26] The identical increase in "Warning from others" and "Visual cues, saw fire, incoming plane, debris, smoke" is verified from the published accounts. The categories of "Contents movement" and "Smelled fumes or felt heat" were not indicated in the NIST study of awareness cues and may have been a feature of the telephone interviews, which are usually more highly structured.[27]

Awakening

A study of the NFPA-recommended smoke detector noise level of 75 dBA indicates that individuals with hearing impairments, those taking sleeping pills, or those on medication may require a detector noise level exceeding 100 dBA[28] (see *NFPA 72*). Flashing or activated lights are effective fire signals in occupancies populated primarily by hearing-impaired persons.[29] The 1981 edition of NFPA *101* for the first time permitted flashing of exit signs along with activation of an audible fire alarm system.

A study of 24 male subjects designed to determine whether they were awakened by a smoke detector's audible alarm signal and could identify fire cues found that the subjects slept through the alarm signals at a signal-to-noise ratio of 10 dBA and consistently failed to identify the awakening cue or radiant heat and smoke odor cues as fire warnings.[30] Other researchers have indicated that the alarm-signal-to-noise ratio is attenuated by physical surroundings.[31] A signal passing through a ceiling or a wall may be reduced by 40 dBA, whereas a signal passing through a door may be reduced by 15 dBA; in addition, the signal could be masked by a typical residential air conditioner noise level of 55 dBA.

Due to the vulnerability of many fire victims while sleeping, the capability of a fire alarm signal to awaken sleeping individuals is a critical variable in the design and application of an alarm system. Ball and Bruck have summarized research findings in Australia relative to the auditory arousal thresholds (AATs) of individuals in sleep stages relative to voice warnings/announcements and alarm signals in the following manner:[32]

- Sleepy individuals (defined as sleep latency = 5 minutes) and alert individuals (defined as sleep latency = 10 minutes) who have been deprived of sleep do not show the usual decline in AATs across the night.
- Sleep-deprived young adults will not reliably awaken to an alarm signal.
- Both the frequency of awakenings and the intensity of a stimulus required to induce awakening are related to age, with more frequent awakenings in response to lower-stimulus intensity as age increases.
- Individual differences account for more variability in AATs than sleep stage or age.

Human voice alarms have distinctive appeal in that they convey meaning and can also directly convey emotional significance. The research has found the following:[32]

- Individuals can successfully identify the emotion being conveyed when actors deliver signal words or phrases.
- The way in which signal words are spoken determines the believability, appropriateness, and most importantly, sense of urgency being conveyed.
- An increase in pitch of voice is equated with an increase in the perceived intensity of the emotion being conveyed, whether this emotion is positive or negative.
- Human voice alarms are perceived as more urgent and intelligible, than computer synthesized voice alarms, even when the computer generated sound has been manipulated to convey urgency.
- The female voice is perceived to be more urgent than the male voice.
- The level of urgency perceived varies for different signal words with "deadly" and "danger" perceived as more urgent followed by "warning," "caution," and "note."

Ball and Bruck collected a total of 1447 responses from 163 individuals with an estimated age range of 17 to 65, composed of staff and students at Victoria University, Melbourne, Australia. The responses to the question: "What sounds would draw your attention when sleeping?" are presented in Table 4.1.8. The responses to the question: "What sounds would you feel the need to investigate upon awakening?" are presented in Table 4.1.9. As shown, the study indicated the effectiveness of a signal expressing human emotion, which agrees with research that sleeping persons will respond to emotional sounds.

TABLE 4.1.8 What Sounds Would Draw Your Attention When Sleeping?

Top Fifteen Most Frequent Responses to Question 2 (*N* = 534)

Question	*Rank*	*Sound*	*Frequency*	*Percentage of Total*
What sounds would draw your attention when sleeping?	1	Child crying or calling out	38	7.1
	2	Loud voices	24	4.5
	3	Dogs barking continuously	22	4.1
	4	Baby crying	21	3.9
	4a	Sirens	21	3.9
	6	Telephone ringing	20	3.8
	6a	Alarms	20	3.8
	8	Alarm clock	16	3.0
	9	Smoke alarm	15	2.8
	10	Loud bangs	14	2.6
	11	Any loud sounds	13	2.4
	11a	Tapping on window or door	13	2.4
	11b	Footsteps	13	2.4
	11c	Glass breaking	13	2.4
	11d	Screaming	13	2.4
	11e	Sounds that do not belong	13	2.4
Total (*N* = 534)			289	54.1

Note: Table actually includes 16 responses due to the lowest ranked sounds being nominated an equal number of times.

TABLE 4.1.9 What Sounds Would You Feel the Need to Investigate on Awakening?

Top Fifteen Most Frequent Responses to Question 3 (*N* = 467)

Question	*Rank*	*Sound*	*Frequency*	*Percentage of Total*
What sounds would you feel the need to investigate upon awakening?	1	Child crying or calling out	31	6.6
	2	A disturbance in the house	29	6.2
	3	Sounds that do not belong	26	5.6
	4	Crying or screaming	22	4.7
	4a	Banging	22	4.7
	6	Glass breaking	21	4.5
	7	Dogs barking continuously	20	4.3
	8	Telephone ringing	18	3.9
	8a	Loud voices	18	3.9
	8b	Footsteps	18	3.9
	11	Alarm sounds	16	3.4
	12	Baby crying	15	3.2
	12a	Water dripping or rushing	15	3.2
	14	Smoke alarm	11	2.3
	14a	Door creaking or closing	11	2.3
Total (*N* = 467)			293	62.7

This set of sounds can be classified as follows:
Expressions of human emotion: sounds ranked 1, 4, 8b and 12a, giving a total of 86 responses (18.4%).
Manufactured alearting sounds: sounds ranked 8, 11 and 14, giving a total of 45 responses (9.6%).
Naturalistic alerting sounds; sounds ranked 2, 3, 4a, 6, 7, 8a, 8b, 12a, and 14a totaling 167 responses (35.8%).

Source: Michelle Ball and Dorothy Bruck, "The Salience of Fire Alarm Signals for Sleeping Individuals: A Novel Approach to Signal Design," *3rd International Symposium on Human Behaviour in Fire 2004,* Interscience Communications and University of Ulster, Belfast, UK, 2004, p. 308.

Bruck and colleagues have presented the following variables that may be significant factors in the arousal of children if the signal is significant to the children:[33]

- Ensuring the signal is not one that the child frequently hears while asleep to prevent habituation
- Increasing motivation to response through prior education/priming
- Including relevant content in the signal (e.g., using a verbal message about the fire)
- Including words with an emotional content
- Using a female voice to convey more urgency than a male voice
- Including the child's name as part of the signal

This study was conducted with children recruited by personnel at Victoria University in Melbourne, Australia. The children were all between 6 to 10 years of age. The signals were presented at the pillow of the sleeping subjects at 89 dBA ±3 dBA, with a duration of 3 minutes. Three studies were conducted. Study 1 involved a recording of the mother's voice with the message that there was a fire, they were to wake up now and go and investigate. The mother's voice message included the child's name once every 6 seconds. Study 1 also involved a female actor's recorded voice with the message of danger, there is a fire, and they must wake up now and go and investigate. All the voice messages were 30 seconds and connected to provide a 3 minute recording at 315 to 2500 Hz. In study 2 the children were exposed to a modified low-frequency temporal-three alarm at 500 to 2500 Hz. In study 3 the children were exposed to the Australian standard signal at 4000 Hz. Figure 4.1.2 presents the number of children who did or did not awaken to the four alarm signals in all three studies. Figure 4.1.3 presents the number and percentage of children who responded to the four alarm signals, with the time of the response categorized into 0–15 seconds, through 180 seconds. As indicated, the mother's voice woke 100 percent of the children, the actor's voice woke 94.4 percent, the low-frequency T-3 signal woke 96.4 percent, and the standard alarm woke 57 percent of the children. These authors suggested that alarm signals may be a critical factor, with the signals in the frequency of the human voice (2500 Hz or less) being more effective than higher-frequency signals.

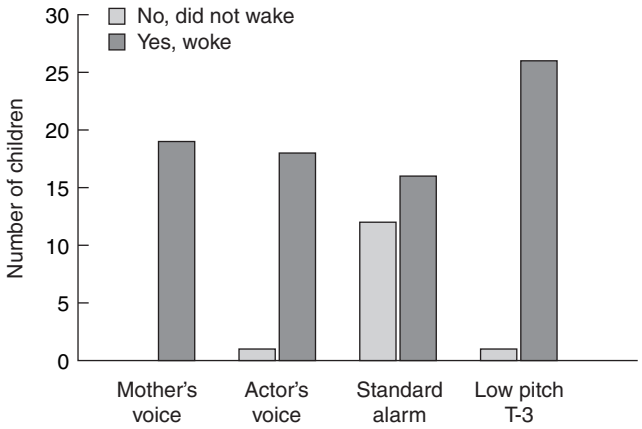

FIGURE 4.1.2 Number of Children Who Did or Did Not Awaken to the Different Alarm Signals Across All Three Studies (Source: D. Bruck et al., "The Effectiveness of Different Alarms in Waking Sleeping Children," *3rd International Symposium on Human Behaviour in Fire 2004,* Interscience Communications and University of Ulster, Belfast, UK, 2004, p. 284)

Ambiguous Threat Cues

The acknowledgment of ambiguous threat cues as signaling an emergency may be inhibited by the presence of other people. Recognition of this phenomenon resulted in an experiment involving college students (Figure 4.1.4).[34] While the students were completing a written questionnaire, the experimenter introduced smoke into the room through a small vent in the wall. If the students left the room and reported the smoke, the experiment was terminated. If the students did not report the presence

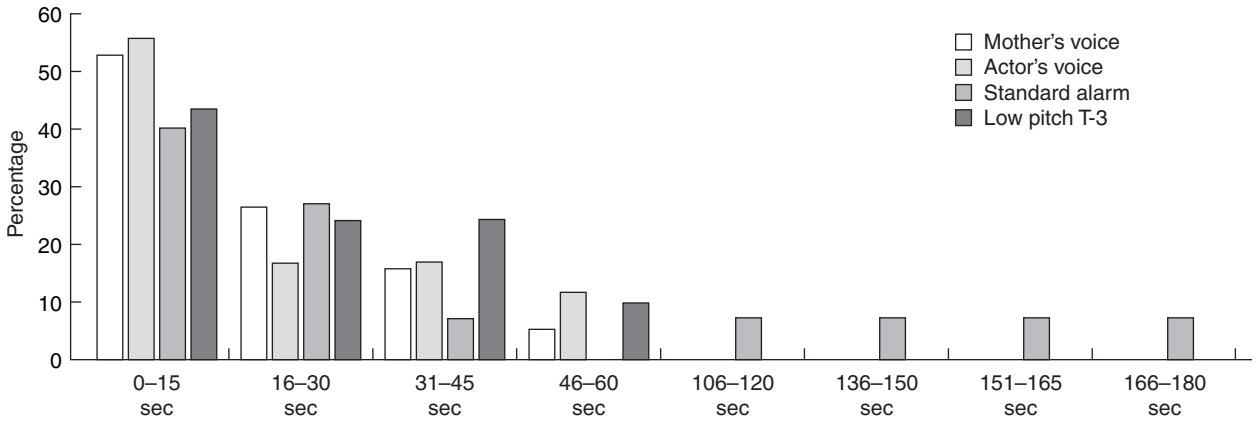

FIGURE 4.1.3 Percentage of Children Who Woke Within Different Time Categories to Different Alarm Signals (Source: D. Bruck et al., "The Effectiveness of Different Alarms in Waking Sleeping Children," *3rd International Symposium on Human Behaviour in Fire 2004,* Interscience Communications and University of Ulster, Belfast, UK, 2004, p. 285)

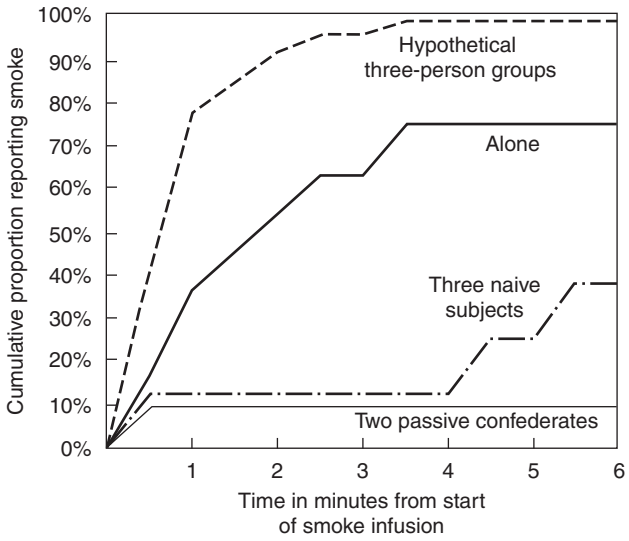

FIGURE 4.1.4 People's Inhibition of Smoke Cues (Source: B. Latane and J. M. Darley, "Group Inhibition of Bystander Intervention in Emergencies," *Journal of Personality and Social Psychology,* Vol. 10, No. 3, 1968, p. 218)

of the smoke within 6 minutes from the time they first noticed it, the experiment was considered complete. Students alone in the room reported the smoke in 75 percent of the cases. When two passive, noncommittal persons joined each student, only 10 percent of the students reported the smoke. When the experimental group consisted of three naive subjects, one individual reported the smoke in only 38 percent of the groups. Of the 24 persons involved in the eight naive-subject groups, only one reported the smoke within the first 4 minutes of the experiment. In the single-subject situation, 55 percent of the subjects reported the smoke within 2 minutes and 75 percent within 4 minutes.

The study reported that reaction to smoke was apparently delayed by the presence of other persons, with the median being 5 seconds for single subjects but 20 seconds in both the group conditions. These results undoubtedly reflect constraints that people accept regarding their behavior in public places. The performance of naive subjects in the passive-confederate situation was reported as follows:

> The other nine stayed in the waiting room as it filled up with smoke, doggedly working on their questionnaires, and waving the fumes away from their faces. They coughed, rubbed their eyes, and opened the window but did not report the smoke.[34]

It has been suggested that while trying to interpret the emergency potential of ambiguous threat cues, an individual is influenced by the reactions of others. Should these others remain passive and seem to interpret the situation as a nonemergency, the individual tends to modify his or her own interpretation according to this inhibiting social influence.[34] This behavioral experiment may help explain the reported tendency of people to disregard threat cues or interpret them as nonthreatening when they occur in places where there are many other people, such as restaurants, movie theaters, or department stores. These results may help explain the calls received by fire departments minutes or even hours after an incident is first detected. In the report of the Arundel Park fire,[4] several of the sample population indicated that when they entered the hall after observing the fire from outside the building, they warned their friends and suggested they leave but were laughed at, their warnings apparently disregarded.

Social inhibition, diffusion of responsibility, and mimicking have been indicated to be primarily responsible for the inhibition of adaptive and assistance behavior in emergencies. The inhibition of behavior in the early stages of a fire, when the cues are relatively ambiguous, may lead to nonadaptive flight behavior because the time available for evacuation has been expended. It is sometimes difficult to get the occupants of a building to evacuate because of social inhibition and diffused responsibility. The tendency to adopt cues for behavior from others is well documented in fires in restaurants, other public assembly occupancies, and hotels.

DECISION PROCESSES OF THE INDIVIDUAL

Seven processes have been identified that an individual may use in trying to structure and evaluate situational threat cues.[35] Six of these—recognition, validation, definition, evaluation, commitment, and reassessment—are presented in Figure 4.1.5. The seventh, a lattice involving the failure of successive defensives and a hierarchy of defenses, is not relevant to the decision process in fires.

Recognition

Recognition occurs when the individual perceives cues that indicate a threatening fire. The cues may be very ambiguous and

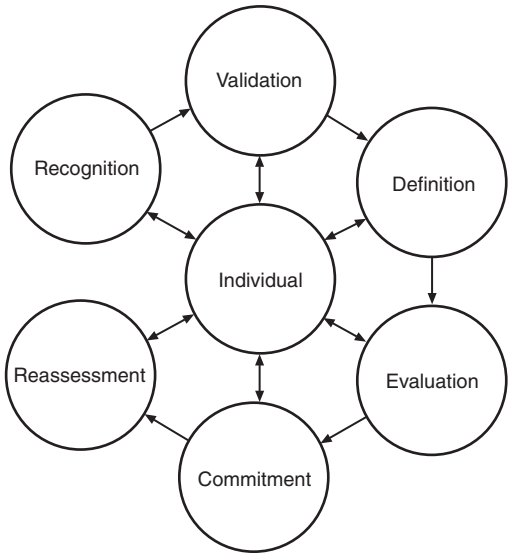

FIGURE 4.1.5 Decision Processes of the Individual in a Fire

not clearly indicative of a severe fire. However, the clues usually are continuous, with an increasing intensity due to the dynamics of flame, heat, and smoke production. It was also reported that an individual is predisposed to recognize threat cues in terms of the most probable occurrences, usually in relation to past experience and in the form of an optimistic wish. The optimistic wish aspect of the response may be a direct result of the individual's concept of his or her personal invulnerability.[35]

Threat recognition is important for fire protection. The adaptive action involved in the initiation of the fire alarm, the evacuation of building occupants, and the suppression of the fire may be delayed or postponed if individuals do not perceive the cues as indicative of a fire. The ambiguous nature of threat cues indicates that individuals who do not have specialized fire prevention or fire protection education and experience recognize only large amounts of smoke or sudden and threatening flames as indicative of a threatening fire.

Validation

Validation consists of attempts by an individual to determine the seriousness of the threat cues, usually by reassurance of the mild nature of the threat and its improbability. When the cues are significantly ambiguous, however, the individual tries to obtain additional information. In other words, the person is aware that something is happening but is not sure exactly what. This process of validation may be conducted by questioning other nearby individuals. Studies of the explosion of a fireworks plant in Houston, Texas, found that of the 139 persons interviewed, 85 individuals (or 61 percent of the population) obtained information on the source and nature of the explosion and smoke from someone they saw or from someone who telephoned and told them.[36] The presence of others during the threat recognition and validation process was found possibly to inhibit or influence the behavioral responses of the individual.

Definition

Definition essentially consists of an attempt by the individual to relate the information concerning the threat to some of the variables, such as the qualitative nature of the threat, the magnitude of deprivation of the threat, and the time context. The individual's stress and anxiety appear to be most severe before he or she has determined the situation's structure or meaning, because it is apparent that the situation requires interpretation. The individual's role (described at the end of the following section, "Evaluation") is one of the critical factors in the situation, relative to the personalization of the threat and the physical environment. The most important physical aspects in the definition process are the generation, intensity, and propagation of the smoke, flames, and thermal exposure.

Evaluation

Evaluation may be described as the cognitive and psychological activities required for the individual to respond to the threat. The individual's ability to reduce his or her stress and anxiety levels becomes the essential psychological factor. In the threat situation created by a fire, evaluation is the process involved in the decision to react by fight or flight. With evaluation, an initial decision to make an overt behavioral response is completed. Because of the time context of the generation and propagation of the fire, the mental processes up to and including the process of evaluation may have to be accomplished within several seconds.

Sime[37] emphasized the importance of the individual's perception of the time available for evacuation or to reach a refuge area as being the individual's estimation of the fire threat. He indicates that the "perceived time available" depends on the information and communication provided to the occupants concerning the fire's location and development. Variables of the physical environment are an important source of information for individuals involved in formulating adaptation, escape, or defense plans. Additional determinants may be the location of the individual relative to the egress routes, other people, the untenable effects of the fire, and the behavior of other individuals.

CASE STUDY: World Trade Center. NIST[27] in their studies of occupant behavior in the World Trade Center towers 1 and 2 provided some compilations of the activities of occupants prior to beginning their evacuation, including the following: information received and sought, the sources of help used, and the single reason to begin evacuation. Table 4.1.10 presents the activities of the occupants prior to evacuation in World Trade Center 1 and Table 4.1.11 present nine specific activities for the occupants of World Trade Center 2. A comparison of these two tables appears to indicate the occupants of World Trade Center 2 had a greater percentage of participation in the following activities: "Talked to others," "Gathered personal items," "Helped others," and "Searched for others." The percentages of occupants participating in the following activities were identical or almost identi-

Information about what had happened	57	81
Instructions to leave	28	17
Instructions to stay	17	12
Other, including information about what to do and to receive assistance in evacuation, do not know	13	13

Note: Total does not add up to 100 percent because respondents may have observed more than one event indicative of damage.

Source: NIST WTC Telephone Survey Data, in J. D. Averill et al., *Occupant Behavior, Egress, and Emergency Communications,* Federal Building and Fire Safety Investigation of the World Trade Center Disaster, NIST NCSTAR 1-7, National Institute of Standards and Technology, Gaithersburg, MD, Sept. 2005, p. 83.

cal (1% difference): "Talked on Telephone," "Moved between floors," and "Shut down computers." The only activity with a greater percentage of participation by occupants in World Trade Center 1 was the activity "Fought fire or smoke."

As can be seen from the comparison of the activities in the two tables, the rank order of the activities is identical except for the activity "Fought fire or smoke." It should be noted that World Trade Center 1 was struck by the aircraft at approximately 8:46:26 a.m. and survived 102:05 minutes, collapsing at approximately 10:28:31 a.m. World Trade Center 2 was struck at approximately 9:02:54 a.m. and survived 56:50 minutes, collapsing at approximately 9:59:04 a.m.[27]

The information received and sought by the occupants of World Trade Center 1 prior to their evacuation activity is presented in Table 4.1.12, and the identical activity for the occupants of World Trade Center 2 is presented in Table 4.1.13. A comparison of these two tables indicates the most information given and sought was "Information about what had happened." The information given and received in both towers for "Instructions to leave" was very similar, with a difference of only 2 percent in the information given. One of the greatest differences in the information given to the occupants was in the category of "Instructions to stay." In World Trade Center 1, 17 percent of the occupants were given this information, whereas in World Trade Center 2, 35 percent of the occupants were given this information, many over the building's public address system prior to the aircraft striking the second tower. An announcement is reported to have been made to occupants in World Trade Center 2 at 9:00 a.m. as follows:

> *There is a fire condition in WTC 1. WTC 2 is secure. Please return to your offices.*

At 9:02 a.m., a second announcement was reported as follows:

TABLE 4.1.13 Information Received and Sought Prior to Beginning Evacuation in WTC 2

Information Type	*Information Given (N = 77) (Percentage)*	*Information Sought (N = 64) (Percentage)*
Information about what had happened	65	92
Instructions to leave	26	17
Instructions to stay	35	13
Other, including information about what to do and to receive assistance in evacuation, do not know	10	5

Note: Total does not add up to 100 percent because respondents may have observed more than one event indicative of damage.

Source: NIST WTC Telephone Survey Data, in J. D. Averill et al., *Occupant Behavior, Egress, and Emergency Communications,* Federal Building and Fire Safety Investigation of the World Trade Center Disaster, NIST NCSTAR 1-7, National Institute of Standards and Technology, Gaithersburg, MD, Sept. 2005, p. 93.

> *May I have your attention, please. The situation is in Building 1. However, if conditions on your floor warrant, you may wish to start an orderly evacuation.*[27]

Remember, as indicated previously, World Trade Center 2 was struck by the aircraft at 9:02:54 a.m. Obviously, these contradictory buildingwide announcements may have been interpreted by some occupants as instructions to stay. The sources of help or assistance used by the occupants prior to their initiation of an evacuation are presented in Table 4.1.14 for the occupants of

TABLE 4.1.14 Sources of Help Used by Occupants Prior to Beginning Their Evacuation in WTC 1

Source of Help	*Percentage (N = 87)*
Coworker	48
Police officer/fire fighter	16
Floor warden	12
Manager/supervisor	13
Other/do not know	13
Stranger	8

Note: Total does not add up to 100 percent because respondents may have received help from more than one person.

Source: NIST WTC Telephone Survey Data, in J. D. Averill et al., *Occupant Behavior, Egress, and Emergency Communications,* Federal Building and Fire Safety Investigation of the World Trade Center Disaster, NIST NCSTAR 1-7, National Institute of Standards and Technology, Gaithersburg, MD, Sept. 2005, p. 84.

World Trade Center 1 and in Table 4.1.15 for the occupants of World Trade Center 2.

A comparative examination of these two tables indicates the greatest difference in the source of help is in the category of "police officer firefighter," with 16 percent of the occupants in World Trade Center 1 indicating this source of help and only 7 percent in World Trade Center 2. This difference could be a result of the difference in the initiation times of the two aircraft strikes. World Trade Center 2 was struck later, at 9:02:54 a.m., and collapsed quicker, at 9:50:04 a.m., surviving only 56:50 minutes; thus, emergency personnel had not reached as many floors in World Trade Center 2 as they had in World Trade Center 1. Proulx and Fahy[26] reported that 143 survivors reported seeing fire fighters in World Trade Center 1 and 26 reported seeing fire fighters in World Trade Center 2. The highest floor in World Trade Center 1 where survivors reported seeing fire fighters was on the 83rd floor. In World Trade Center 2 the highest floors in which fire fighters were reported seen was in the mid-level floors from the 43rd to the 76th.

Source: NIST WTC Telephone Survey Data, in J. D. Averill et al., *Occupant Behavior, Egress, and Emergency Communications,* Federal Building and Fire Safety Investigation of the World Trade Center Disaster, NIST NCSTAR 1-7, National Institute of Standards and Technology, Gaithersburg, MD, Sept. 2005, p. 95.

Table 4.1.16 presents the single reason given by the occupants of World Trade Center 1 to begin their evacuation, and Table 4.1.17 provides similar information for the occupants of World Trade Center 2.

A comparative examination of these two tables indicates that 26 percent of the occupants of World Trade Center 2 decided to initiate their evacuation from their observation of the fire and damage conditions of the situation following the aircraft strike in World Trade Center 1. It should be noted that an estimated 86 to 91 percent of the occupants in World Trade Center 2 initiated their evacuation before their building was struck by the aircraft.[27] The other single reasons the occupants indicated as their reason to begin evacuating which differed from occupants of World Trade Center 1 were "1993 experience (thought was a bomb)," and "WTC 2 building hit." The single reasons given by occupants of World Trade Center 1 to begin evacuating not specifically mentioned by World Trade Center 2 occupants

TABLE 4.1.17 Single Reason Given by Survivors to Begin Their Evacuation from WTC 2

Reason	*Percentage (N = 363)*
WTC 1 observations	26
Was told to evacuate	21
Afraid/felt danger	17
Friends/coworkers evacuated	11
1993 experience (thought was a bomb)	6
WTC 2 building hit	6
Other, including jet fuel, information seeking, evacuating the building, just felt like the right thing to do	7

Source: NIST WTC Telephone Survey Data, in J. D. Averill et al., *Occupant Behavior, Egress, and Emergency Communications,* Federal Building and Fire Safety Investigation of the World Trade Center Disaster, NIST NCSTAR 1-7, National Institute of Standards and Technology, Gaithersburg, MD, Sept. 2005, p. 94.

were "Building movement," "Saw debris," and "Saw smoke." The single reasons given by the occupants of both towers were "Afraid/felt in danger," "Was told to evacuate," and "Friends/coworkers evacuated."

During evaluation, an individual may decide to leave the building—flight—or to use a portable fire extinguisher—fight. During this time, he or she is particularly susceptible to the actions and communications of others. Thus, the individual may mimic the behavioral reactions of observed individuals, resulting in mass adaptive or nonadaptive behavior rather than selective, individualized behavior. The following situation at an auto sales and service agency in 1971 demonstrates what may have been an instance of mimicked behavior becoming normative group behavior:[38] About 10 p.m., the fire department received an alarm from a street fire alarm box. When fire fighters arrived, the 150 ft by 200 ft (46 m by 61 m) combination one-and-two-story building of wood frame and hollow block construction was well alight and nearly 300 spectators were watching the fire in 10°F (–12°C) weather. An investigation revealed the fire had been burning for about 90 minutes before the fire department was notified.

In studies of nonadaptive group behavior, the concept that this mode of behavior depends directly on the individual's perception of the reward structure of a situation has been developed.[39] People in a building who are confronted with a fire would probably initially perceive a reward structure that would encourage cooperative and adaptive behavior; in such cases, everyone should be able to reach and proceed through the available exits. However, the reward structure perceived by some individuals more remote from the egress routes could result in competitive behavior. Such individuals would perceive that cooperative behavior would make it impossible for them to reach an exit in time to escape the fire. Once the pattern of competitive behavior is initiated, the behavior pattern of the group may become one of intense individual competition for the escape routes.

In the evaluation process, an individual's cultural influences and assumption of a particular role may be very important in formulating defense or escape plans. It is believed that an individual playing a familiar role that is also suitable for the threat situation experiences less anxiety and responds with more adaptive behavior than an individual in an unfamiliar role confronted with an unfamiliar threat.

Jones and Hewitt[40] conducted detailed interviews with 40 occupants of a 27 story office building who had evacuated the building during a fire. It should be noted the fire occurred at 9:00 p.m. when the fire management plan was not in effect due to the building's reduced occupancy. In this situation it appeared that leadership and evacuation group formation were related to the occupants' fire training and their normal roles. The investigators found that relationship of the occupancy roles and normal or emergent leadership of occupants were critical factors in successful evacuation, with the following variables:

> The social and organizational characteristics of the occupancy, including what a person knows (or believes) of the situation, whether the person is alone or part of a group, the normal roles that people hold within the occupancy, and the organizational structure or framework. One factor that appears to be related to the chosen evacuation strategy of an occupant is the presence of leadership and the form which that leadership takes.

Horiuchi, Murozaki, and Hokugo[41] reported on a questionnaire study of 458 occupants of an 8 story office building involved in a fire incident. The researchers found significant differences between occupants who were familiar with the building and occupants attending training sessions who were unfamiliar with the building, relative to their actions, selection of evacuation routes, and effectiveness in exiting. The regular occupants of the building engaged in fire-fighting actions and alerted or assisted other occupants, whereas occupants unfamiliar with the building primarily engaged in evacuation.

Commitment

Commitment consists of the mechanisms the individual uses to initiate the behavior required to fulfill defense plans conceptualized in the evaluation process. This overt response to the threat of fire results in success or failure. If the response fails, the individual immediately becomes involved in the next process of reassessment and commitment. If the action succeeds, the anxiety and stress aspects of the situation are reduced and relieved, although the severity of the general fire situation may have increased.

Reassessment

Reassessment and overcommitment are the most stressful personal processes because previous attempts to adjust to the threat have failed. Thus, more intense effort goes into the behavior and the individual tends to become less selective in the choice of response. Encountering successive failures, the individual becomes more frustrated. The possibility of injury and risk increases with a greater activity level and with less probability of success, as was demonstrated in the Arundel Park fire, discussed later in the chapter. There, the number of those who selected windows as a means of escape increased as people became involved in their second escape attempts.[4]

In analyzing the behavior of an individual involved in the processes of recognition, validation, definition, evaluation, commitment, and reassessment, it must be remembered that these are dynamic processes. They are constantly being modified in relation to their magnitude, velocity, and intensity. A person's usual psychological and physiological activities will probably be below normal during the recognition process, when he or she is concentrating on perceiving the threat cues. During the process of validation and definition of the threat, adjacent members of the threatened population communicate overtly. The period of hyperactivity appears to occur initially during the process of commitment and to become intense during the process of reassessment and recommitment. Stress increases with each successive stage, as the primary motivation of the behavior is stress reduction. Appearance, proximity, propagation, time, and toxic gases of the fire threat also tend to predispose the individual to a higher level of activity, again depending on the individual's perception of these threat variables. During the process

of reassessment and recommitment, the individual's activity level may assume the hyperactive mode of frantic activity, or it may be expressed in the catastrophic state of complete physical immobility with a loss of ability to communicate coherently. These individuals appear to perceive the threat as above their level of adaptability. The stress is too severe, and they give up completely. Thus, they cease to make any attempt at an adaptive behavior and retreat totally from the situation through the mechanism of psychological withdrawal. These behavioral dynamics are presented in Figure 4.1.6.

Decision Making Models

Conceptual Model. A conceptual model of the individual's decision processes similar to some concepts previously discussed has been developed. Instead of the six processes described, only three have been used: (1) recognition/interpretation; (2) behavior, with either action or inaction; and (3) the outcome of the action, which involves the evaluation and long-term effect of the behavior.[6] Behavior evaluation is similar to the process of reassessing the decision model. Both the recognition/interpretation concept and the behavior concept involve factors critical to the decision processes. Experience and immediate circumstances have an impact on the recognition/interpretation concept. It has been emphasized that individuals in a fire may not know right away that they are involved in a fire and may not know where, in relation to their location, the fire is developing or where egress routes are located. A concept of a heuristic (i.e., experimental or provisional) systems model is presented in Figure 4.1.7.

The conceptual model just described has been modified into one involving three phases: (1) detection of cues, (2) definition of the situation, and (3) coping behavior. In addition, tentative determinants of the behavior have been developed, which increase the probability of detection and of fire suppression.[42]

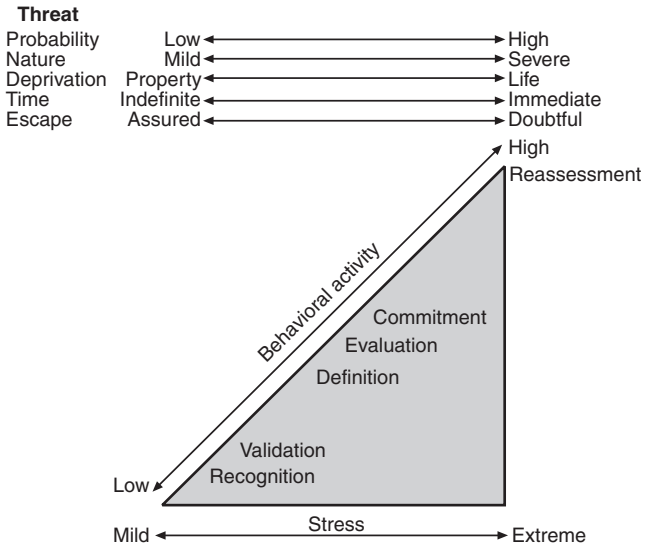

FIGURE 4.1.6 Dynamics of Behavioral Activity of the Individual

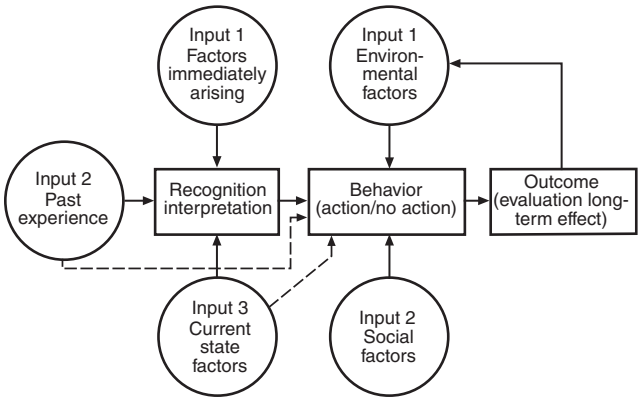

FIGURE 4.1.7 Preliminary Heuristic Systems Model of Behavior in Fires

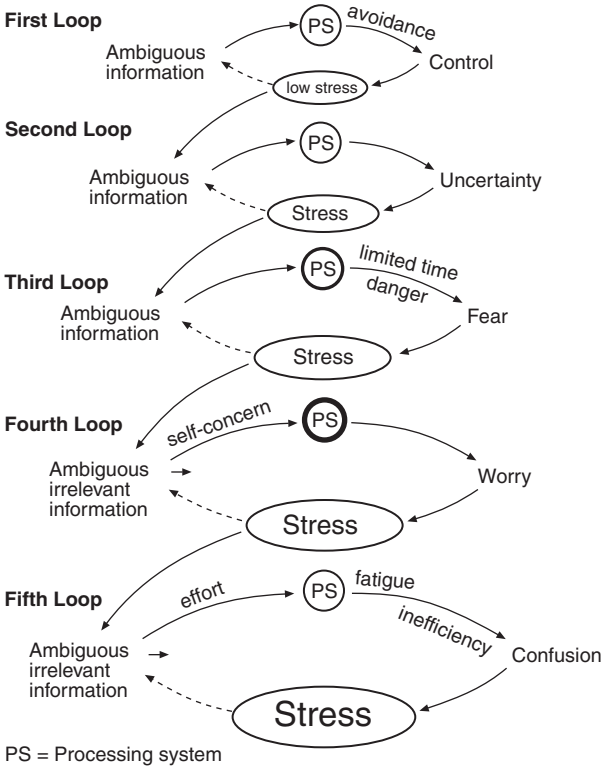

FIGURE 4.1.8 Stress Model of People in a Fire

Stress Model. Proulx[43] developed a stress model to demonstrate various levels of stress generation within an individual involved in the decision process during a fire incident. Figure 4.1.8 illustrates this stress model, which should be compared with the behavioral activity dynamics of the individual in a fire incident presented in Figures 4.1.6 and 4.1.7.

The left side of Figure 4.1.8 indicates the information the individual must process; the right side indicates the emotional state that results. Proulx describes the five loops in the stress model as follows:

1. The first loop starts with the perception of ambiguous information. This information is decoded in the processing system (PS in Figure 4.1.8) for interpretation. Given that the available information may not allow for a straightforward assessment of the situation, people will at first minimize or deny the situation. These defensive strategies of avoidance lead to an absence of reaction.

2. Although individuals may vary considerably in their appraisal of the same event, the repeated perception of ambiguous information will eventually generate a state of uncertainty, which will then induce a feeling of stress. Some time can be spent going repeatedly through the second loop.

3. The third loop is related to the interpretation of the situation as an emergency. The thicker line around the processing system expresses the pressure of the overload of information with which the person tries to deal at once. The fear felt by the person is a manifestation of a specific appraisal of the environment.

4. The fourth loop relates to the person's processing of irrelevant information and is represented by the very thick line around the processing system. This irrelevant information creates worry and more stress. The irrelevant information, created by the person, is caused by concern for his or her own performance in coping with the situation. Perceived feelings of arousal and fear, uncertainties regarding how to proceed with the problem, difficulties in interpreting what exactly is going on, and self-estimation of the efficiency of already applied actions become additional information to process.

5. The fifth loop supposes an investment of more mental effort to master the problem, momentarily reducing the pressure on the processing system, but resulting in fatigue and inefficiency manifested in a state of confusion.

Proulx indicates that definitive, valid, and directive information provided to occupants of a building in a fire incident most effectively reduces stress and thus tends to minimize response delays created in the first and second loops of the stress model.

Naturalistic Decision Model. Chubb[44] proposes that the model of the decision processes that fire department officers use in the incident command procedure be adopted as the decision process of building occupants in a fire situation. The decision model was developed from the theory of naturalistic decision making, which evolved from studies of decision makers in complex, time-critical situations. The critical variables of naturalistic decision-making theory appear to share many environmental and psychological features of fire situations involving building occupants. Chubb identified these critical variables:

- Ill-defined goals and ill-structured tasks
- Uncertainty, ambiguity, and missing data
- Shifting and competing goals
- Dynamic and continually changing conditions
- Real-time reactions to changed conditions
- Time stress
- High stakes
- Organizational goals and norms
- Experienced decision makers

Recognition-Primed Decision Model. Figure 4.1.9 illustrates the recognition-primed decision (RPD) model developed by Klein[45] from studies of fire department officers. Chubb correctly indicated this model's limitation when applied to building occupants. They lack the dynamic abilities—suitable training and previous experience—in building fires that fire officers have. Static abilities relative to building occupants' mental and physical capabilities also appear to be more varied and limited than those of fire officers. Chubb indicates that successful recognition-primed decision making depends on occupant training and practice of fire safety plans, with the decision support system in the building consisting of egress signs, emergency lighting, and vocal communication systems.

BEHAVIOR OF OCCUPANTS

A study involving 952 fires and 2193 individuals interviewed by fire department personnel at the scenes of fires in the United Kingdom found that the most frequent responses to fire involved evacuating the building, fighting or containing the fire, and alerting other individuals or the fire brigade.[14] An identical broad behavior categorization was found in a similar study, which involved interviewing 584 participants in 335 fires in the United States. Interviews were conducted by fire department personnel, who used a structured questionnaire at the scene of the fires.[7]

Purser and Kuipers[25] in their study of the 110 residential fire incidents previously discussed, also reported the sequence and frequency of people's actions as presented in Figure 4.1.10. This figure and the results of this study conducted in the early 2000s should be compared with Table 4.1.18, which concerns the first actions of participants involved in fires in Great Britain in 1971 and the United States in 1977, since the types and sequences of actions appear very similar. Table 4.1.20 also address initial responses, namely the first three actions of a U.S. population involved in fires in 1977. The authors of this report indicate the action of "investigate" was very common as a first action by 45 percent of their respondents and as a second action by 23 percent. These authors also report that actions such as "mitigate the fire," "help others," and "call for

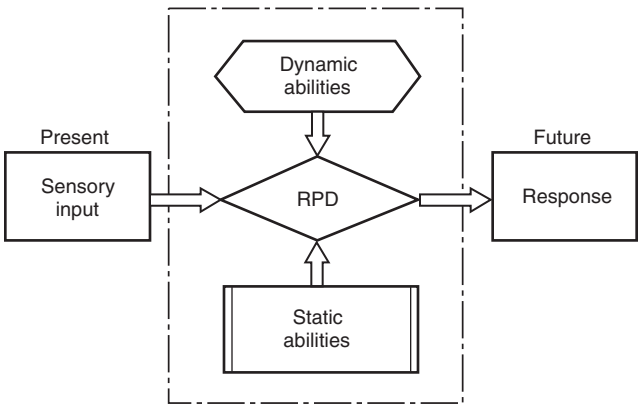

FIGURE 4.1.9 Recognition-Primed Decision Model

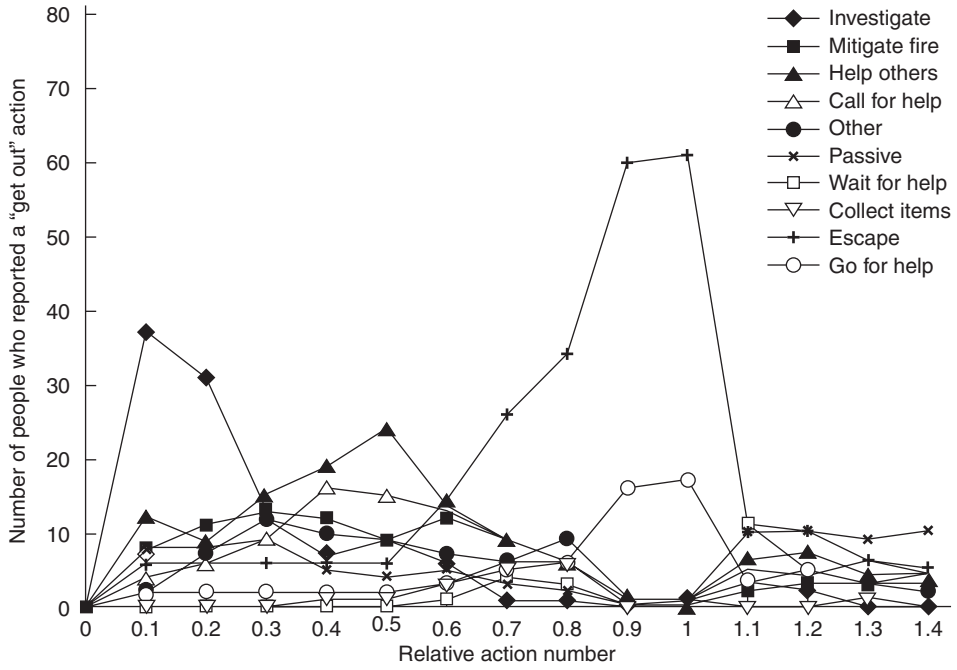

FIGURE 4.1.10 Frequency and Sequence of Actions Relative to Escape Action (Source: David A. Purser and Marion E. Kuipers, "Interaction Between Buildings, Fires and Occupant Behaviour Using a Relational Database Created from Incident Investigations and Interviews," *3rd International Symposium on Human Behaviour in Fire 2004,* Interscience Communications and University of Ulster, Belfast, UK, 2004, p. 452)

help" are in the middle of the actions sequence, and "escape" or "go for help" at the end of the usual sequence of four to five actions, although 50 percent of the occupants reported seven actions. "Call the fire brigade" was generally a fourth action, and "fight the fire" was usually occurring between the second and the sixth action. This study reported a similar cultural sequence of actions relative to the males and females found in the 1971 British study[14]and the 1977 U.S. study.[7] "Males were more likely than females to report 'investigate' or 'mitigate fire,' but less likely to report 'call or go for help' or 'remaining passive.'"

Comparison of the First Actions of British and U.S. Study Populations

Examination of initial behavioral responses to fire is presented in Table 4.1.18. Behavior of the individuals also varied by gender: males were predominantly active in fighting the fire, whereas females were predominantly concerned with alerting and helping others leave the building.

It should be noted that there were 10 statistically significant differences between the British and U.S. study populations. The U.S. study population was more likely to report five categories of first actions: "notified others," "got dressed," "got family," "left area," and "entered the building." A higher percentage of the British population reported as first actions "fought fire," "went to fire area," "closed door to fire area," "pulled fire alarm," and "turned off appliances."

Comparison of the Behavior of the British and U.S. Study Populations

The general classification of the three early actions for the British and the U.S. study populations alike were categorized as "evacuation," "re-entry," "fire fighting," "moved through smoke," and "turned back." Comparison of the two populations is presented in Table 4.1.19. There was a statistically significant difference between British and U.S. populations in every category except "moved through smoke."

Summary of the First, Second, and Third Actions of the Occupants

An interesting aspect of the U.S. study involves variation in the first, second, and third actions reported by participants. Table 4.1.20 presents the three actions for the group, totaling 584 individuals. "Notifying others" accounted for 15 percent of the first actions, but by the time of the third actions, it accounted for only 5.8 percent. A similar reduction in frequency can be observed for "searching for the fire." This activity decreases from 10.1 percent as the first action to 0.8 percent as the third action. The actions "got dressed" and "got family" also reduced in frequency with the progression from the first to the third action as time passed during the fire. In contrast, "left building," "fought fire," and "called fire department," increased in frequency from the first to the third actions.

Canter, Breaux and Sime[46] developed a decomposition diagram of the acts of 41 persons in 14 domestic fires. This study,

conducted in the United Kingdom, covers home fires, as do the studies by Wood[14] and Bryan[7] discussed previously. Figure 4.1.11 presents this decomposition diagram and should be compared with Tables 4.1.18 through 4.1.20. The sequence of the first, second, and third actions of the U.S. study population are generally similar to the sequence of actions in the decomposition diagram.

Summary of the First Actions of the Occupants, According to Gender

Differences between the first actions of the participants according to their gender have been examined. Table 4.1.21 presents the reported initial actions of the U.S. study population relative to the gender of the participants. Statistical differences between males and females are significant in the categories "searched for fire," "called fire department," "got family," and "got extinguishers." Male participants more frequently reported investigation and fire-fighting activities. For example, 14.9 percent of the males "searched for fire," as opposed to 6.3 percent of the females; 6.9 percent of the males "got extinguishers," as opposed to 2.8 percent of the females. Females more frequently reported warning and evacuation activities. For example, 11.4 percent of the females "called fire department" as their initial action, as opposed to 6.1 percent of the male participants. In relation to evacuation behavior, 10.4 percent of the females reported "left building" as the first action, contrasted with 4.2 percent of the male participants. The influence of cultural roles is probably indicated explicitly in the concern for other family

members—11 percent of the females "got family" as the first action, whereas only 3.4 percent of males engaged in this as an initial action. It should be noted that the second and third prevalent male actions of "searched for fire" and "got extinguishers" were equated to the female actions of "called fire department" and "got family."[7] This behavior has also been observed in health care and educational facility fires.

Behavior in Hotel Fires

Fire protection of high-rise buildings and their occupants was tested severely by the MGM Grand Hotel fire in Clark County, Nevada, on November 21, 1980,[47] and by the subsequent fire at the Las Vegas Hilton Hotel on February 10, 1981.[48] Both these hotel fires resulted in injuries and fatalities among guests. NFPA conducted an intensive questionnaire study of the guests registered in the MGM Grand Hotel on the evening of November 20 and morning of November 21, 1980.[49]

The MGM Grand Hotel fire was discovered by a hotel employee who entered the unoccupied deli-restaurant located on the casino level of the hotel at approximately 7:10 a.m. on November 21, 1980. As instructed, the hotel telephone operator immediately notified the Clark County Fire Department at approximately 7:17 a.m. The telephone operators were forced from their switchboard by the smoke immediately after they had made an announcement over the public address system, at approximately 7:20 a.m., to evacuate the casino area. The fire quickly reached flashover in the deli, immediately spread from east to west through the main casino area, and extended out the west portico doors on the casino level immediately following the arrival of the first fire department personnel.

An addition to the hotel was being constructed adjacent to the west end of the building, and construction workers helped warn and evacuate guests and assisted in fire fighting. The heat and smoke rapidly extended from the casino area through the seismic joints, elevator shafts, and stairways throughout the 21 residential floors of the hotel. The heat was intense enough on the 26th floor, a top floor, to activate automatic sprinklers in the lobby adjacent to the elevator shafts.

Due to the rapid early evacuation of the telephone staff, guests were not alerted by the hotel public address system or the local fire alarm system. Guests warned early in the fire, and those already awake and dressed, were able to escape before the smoke became untenable on the upper floors. Guests alerted later remained in their rooms or moved to other rooms, usually with other occupants. The fire itself did not extend above the casino level, except in a rather minor nature, into two guest rooms on the fifth floor. The fire resulted in 85 fatalities and injured 778 guests and 7 hotel employees. Seventy-nine body locations were documented: 18 on the casino level, 25 in guest rooms, 22 in corridors and lobbies, 9 in stairways, and 5 in elevators. The victims were found on the casino level and on the 16th and floors above, with the majority between the 20th and the 25th floors.

Table 4.1.22 presents the means by which the responding participants became aware of the fire incident within the hotel. It should be noted the hotel was protected with a fire alarm system of the presignal type, with manual stations only on the guest room floors; apparently, the system was never activated on the guest room floors. An examination of Table 4.1.22 indicates that similar to the means of awareness reported for residential fire incidents in single-family homes and apartments, 169 persons reported they were alerted by the awareness cue of seeing or smelling smoke, and 193 individuals indicated they were alerted by the actions of others involving: "Notified by others, people yelling, and a knock on the door."[49] From the questionnaires came statements that individuals evacuating the floors would knock on doors and yell out as they passed through the hotel corridors, realizing there had not been an alarm activation in the hotel, with many persons in their rooms at the documented 7:17 a.m. time that the fire department received a telephone alarm. It

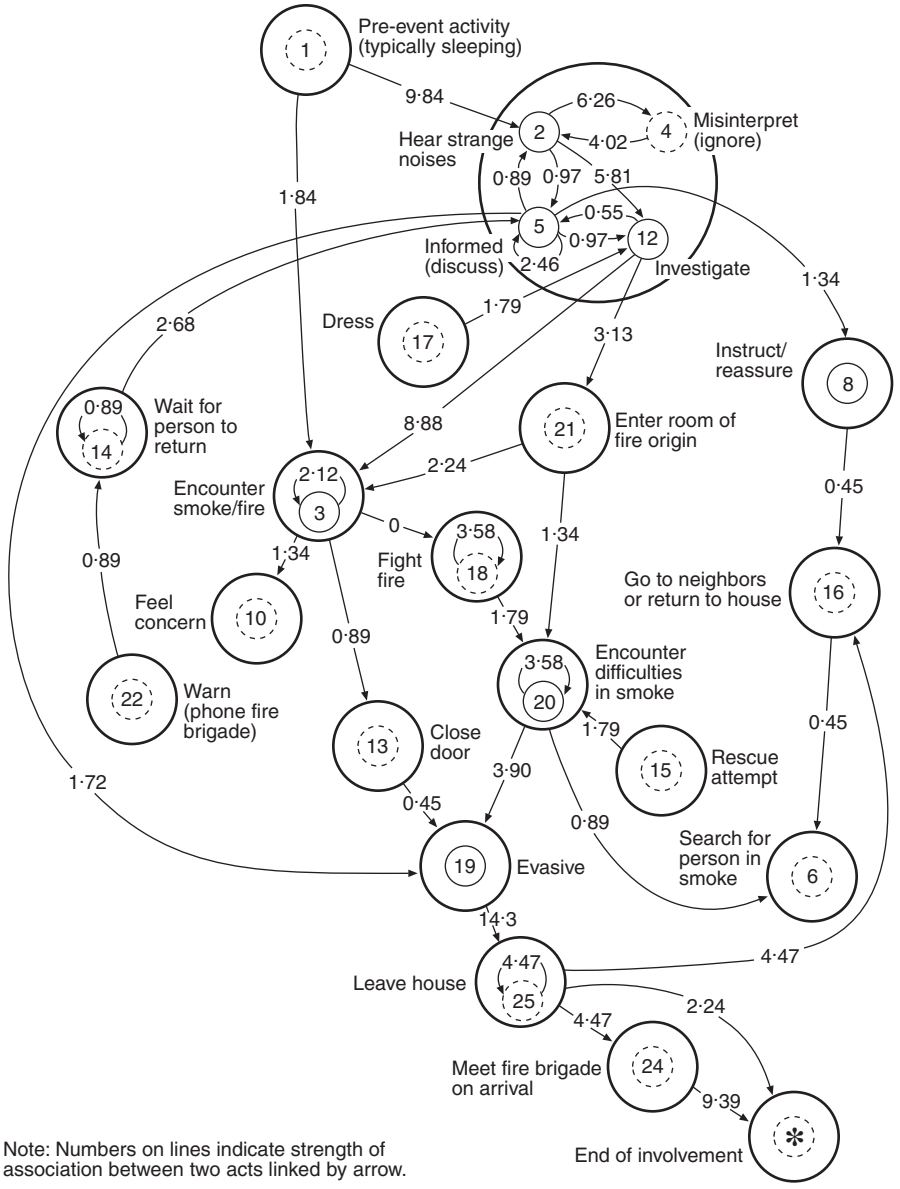

FIGURE 4.1.11 Decomposition Diagram—Domestic Fires

should also be noted that due to the extensive occupant notification actions 275 persons, or 51 percent of those reporting the time at which they became aware of the fire, indicated times between 6:30 a.m. and 7:15 a.m., all prior to the fire department notification. Figure 4.1.12 is a diagram of the guest floor of the MGM Grand Hotel that was used in the engineering study conducted by NFPA.[47]

Of the 9 victims found in the stairways, 2 were in stairway 1 at the extreme south end of the south wing on the 17th floor; 6 were between the 20th and 23rd floor in stairway 2 at the central end of the south wing; and 1 was found at the ground-floor level of stairway 4 at the extreme west end of the west wing. There are various estimates of the number of guests and fire department personnel who suffered injuries at the MGM Grand Hotel fire. Morris indicated that 619 people were taken to hospitals, and another 150 were treated at the Las Vegas Convention Center, where the survivors were transported from the hotel.[50]

The MGM Grand Hotel tragedy was a unique fire, especially from two aspects: (1) it was the second most serious hotel fire in U.S. history, surpassed only by the Winecoff Hotel fire in Atlanta, Georgia, on December 7, 1946, which killed 119; and (2) it was the first high-rise fire in the United States in which helicopters evacuated large numbers of people. About 300 were evacuated in this manner; the fire department rescued approximately 900 people by other means.

Shortly after the MGM Grand Hotel fire, NFPA prepared a 4 page, 28 item questionnaire that included the floor plan of the guest rooms. A total of 1960 questionnaires were mailed, and 554, or approximately 28 percent, of these were

returned. Of the respondents, 455 indicated a willingness to be interviewed.[51]

The age of the questionnaire population ranged from 20 to 84 years, with an average age of 45. The population consisted of 331 males and 222 females; one respondent did not indicate a gender. There were 103 guests who indicated they were alone at the time they became aware of the fire. The presence of other people, especially if they belong to the individual's primary group, appears to be a determinant of the response of many individuals in residential fires.[7] The initial five actions reported by the 554 guests, as elicited from the NFPA questionnaire study, are presented in Table 4.1.23.

Notice that the five most frequent first actions were "dressed," "opened door," "notified roommates," "dressed partially," and "looked out window." Guests reporting these actions were predominantly engaged in determining the degree of threat to themselves. Only 7.9 percent of the study population began or tried to begin their own evacuation with such actions as "attempted to exit," "went to exit," and "left room." A total of 16 individuals, or 2.9 percent of the population, initiated actions to improve the room as an area of refuge: "wet towels for face" and "put towels around door." The actions of the guests could be classified, in general, as evacuation actions or refuge processes. Actions relating to evacuation behavior appeared to be initiated early if the egress passages were clear of smoke or if the smoke was not perceived as personally threatening. If the smoke was

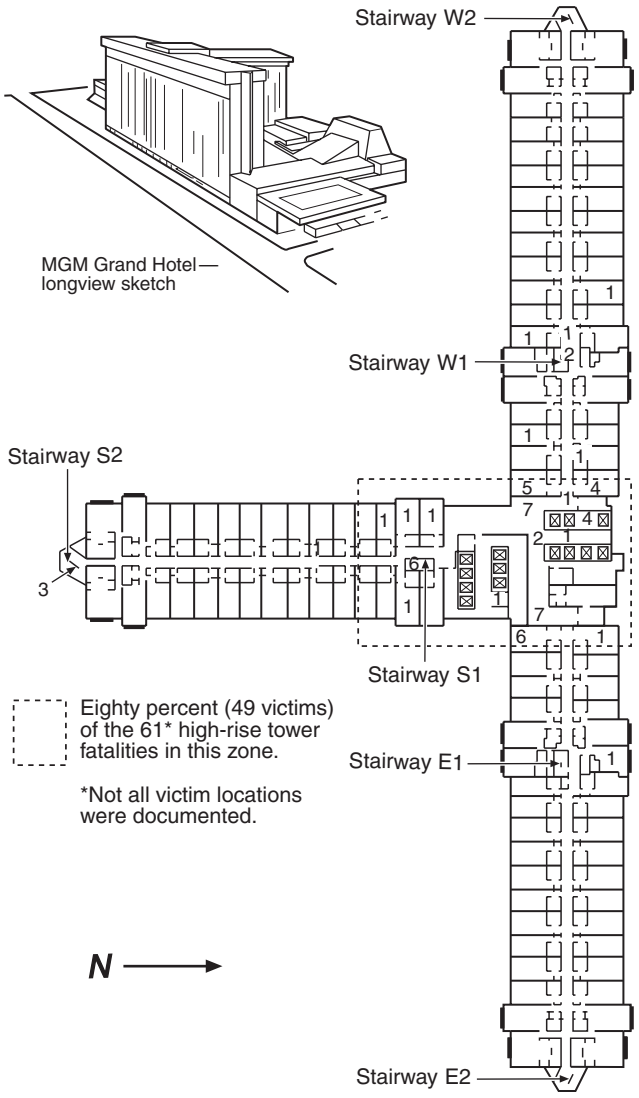

FIGURE 4.1.12 Residential Floor Diagram of the MGM Grand Hotel

heavy, however, the guests apparently decided to stay in their rooms or other rooms and to initiate actions to prevent smoke migration into the rooms of refuge.

Further examination of Table 4.1.23 shows that the five actions most frequently reported by guests as their second actions were "opened door," "dressed," "went to exit," "dressed partially," and "secured valuables." Approximately 19 percent of the study population reported dressing before initiating evacuation or refuge procedures.

The third actions of guests in the study population generally progressed to evacuation, attempted evacuation, and notification. Approximately 25 percent of this population was involved in evacuation actions, and approximately 10 percent attempted evacuations, as identified by the third actions of "attempted to exit" and "returned to room." The alerting and notification actions are identified as "notified occupants" and "notified other room."

The fourth actions of the guests in the study population indicate a progression to evacuation, attempted evacuation, and self-protection or room refuge actions. The most frequently reported fourth action was "went to exit"; approximately 16 percent of the population indicated that they did this. However, when one combines the guests involved in this action with those who "went down stairs," "went to another exit," "left hotel," and "left room," a total of 151 guests, or approximately 30 percent, were involved in evacuation as their fourth action. The process of forming convergence clusters was noted in this hotel fire. This action involved individuals clustering together in rooms they considered areas of refuge with individuals they usually characterized as strangers before the fire. The fourth actions of "went to other room" and "went to other room/others" are explicit indicators of the formation of convergence clusters.[51]

The fifth actions of the guests were primarily for self-protection and included improving the room as an area of refuge and evacuation behavior. The evacuation actions were "went downstairs," "left to exit," and "went to another exit." Involved in these evacuation actions were 175 individuals, or approximately 40 percent of the study population. Those unable to evacuate, and thus vitally concerned with refuge procedures, reported the fifth actions of "went to other room/others," "wet towels for face," "put towels around door," "broke window," "returned to room," "went to other room," "offered refuge in room," and "went to balcony." Approximately 40 percent of the fifth-action study population was involved in refuge procedures and self-protection actions.

Convergence Clusters

The phenomenon of convergence cluster formation was first noticed in a study of occupant behavior in a high-rise apartment building fire in 1979.[52] The clusters appear to involve occupants of the building who converged into specific rooms they perceived as areas of refuge. In the MGM Grand Hotel fire, guests tended to select rooms on the north side of the east and west wings and rooms on the east side of the south wing. In addition, guests reported that people had converged in the rooms with balconies and doors leading out to the balconies because of the ventilation, reduced smoke, improved visibility, and communication that the balconies offered. Guests who reported this behavior either estimated the number of persons in the room or connecting rooms, or they indicated only that "others" or "other persons" were present.[51]

Table 4.1.24 lists the rooms identified by guests as areas of refuge for numerous persons other than the original occupants. This table also presents estimates of the length of time that the clusters were maintained in the rooms—usually until the individuals were evacuated, or until the occupants were notified by fire or rescue personnel that evacuation was possible. Numbers in the two right-hand columns indicate the total number of persons in the clusters for the total number of rooms identified on the floor. The smallest number of people identified as a cluster was 3, and the largest was 53.

The greatest number of rooms used by convergence clusters and the largest population participating in convergence clusters

were located on the 17th floor of the hotel. No convergence clusters were identified by guests on the 6th, 21st, or 26th floors. The clusters appear to serve as an anxiety- and tension-reducing mechanisms for individuals confronted with a threatening situation. The action of "offered refuge in room," previously identified in the discussion of the fifth actions, is a positive indication of the occurrence of a convergence cluster.

In addition to the detailed human behavior study of the MGM Grand Hotel fire,[51] NFPA conducted a questionnaire study of guests' behavior in the Westchase Hilton Hotel fire in Houston, Texas, on March 6, 1982, in which 12 people died.[53,54]

Figure 4.1.13 presents the decomposition diagram for eight multiple-occupancy fires covering the actions of 96 persons.[46] These multiple occupancy fires in the United Kingdom involved hotel occupancies. A comparison of Figure 4.1.13 with Table 4.1.23 shows similarities between the five actions of the guests in the MGM Grand Hotel fire and the occupants' behavior in the British study

Guylène Proulx and her team at the National Research Council of Canada, studied human behavior in a fire in a 30 story apartment building in North York, Ontario, on January 6, 1995. The study was conducted by a mailed questionnaire sent to 349 apartments resulting in a return rate from 190 (54%) apartments. Table 4.1.25 identifies the "convergence cluster" information on this fire, identified by the researchers as "voluntary relocation." A total of 44 persons moved from one apartment to another during the fire. Of these occupants 26 (60%) changed floors before taking refuge in another apartment. Of these 26 occupants 16 (62%) indicated they had to find an area of refuge because of the smoke. It should be noted that on average occupants traveled 9 floors before accessing another apartment. It was reported that 18 (40%) of the 44 occupants involved in relocation did not change floors, only 3 of whom reported they relocated due to smoke; the remaining 15 were apparently motivated to join family members, friends, or neighbors. Of the 29 occupants who provided information on their relationship to the occupants of the relocated apartment,

21 indicated they did not know the occupants of the relocated apartment.[55]

The classic types of nonadaptive behavior in a fire ignore adaptive actions that might facilitate the evacuation of others or limit the propagation of smoke, heat, or flame. Nonadaptive behavior ranges from the single act of leaving a room of fire origin without closing the door, thus allowing the fire to spread throughout the structure and endanger the lives of all the occupants, to the more generalized behavior of fleeing from a fire without regard for others and perhaps injuring others in what is often termed "panic."

Nonadaptive behavior may be an omission, such as forgetting to close a door, or it may involve an action that, although well meaning, results in negative consequences. When the results of behavior are extinguishing the fire and eliminating the threat, the behavior may be said to be adaptive. However, the same behavior may be ineffective because the fire was more severe than first perceived. In such cases, the time spent trying to extinguish the fire might have been used more effectively to warn others and notify the fire department. Thus, some behavior that appears to be nonadaptive really is behavior that would have seemed most adaptive if it had been successful. Injuries people suffer in relation to a fire may be cues to their nonadaptive or risk behavior.

Behavior in a High-Rise Office Building Fire

The fire in the unsprinklered 36 story Cook County Administration Building on Friday, October 17, 2003, resulted in six fatalities and a dozen people injured. Proulx and Reid conducted a human behavior study using questionnaires to gain an understanding of the existing conditions in the building prior to the fire, past training and occupant awareness of the evacuation procedure, and occupant behavior and evacuation on the day of the fire.[56] Results show that although 85 percent of the survey respondents had received fire safety training, only 20 percent understood the phased-evacuation plan. There were only around 250 building occupants still in the building at the time of the fire; half of them used an elevator to exit. Unfortunately, the combination of locked doors that prevented re-entry on floors from the stairwells and fire-fighting activity taking place from the stairwell, were contributing factors to this tragedy.

The Cook County Administration Building located at 69 West Washington in Chicago, was built in 1964. The 36 story office building housed mainly Cook County offices, as well as a few other organizations. The floor area was approximately 17,000 ft^2 (1579 m^2). The central core common to all floors contained 16 passenger elevators. There were also 2 stairwells at the southeast and northwest corners, which traveled the full length of the building. The southeast stairwell had a smoke tower using a natural ventilation shaft. The doors between the stairwell and the tenant were permanently locked from the inside; once a person entered the stairwell they had to travel the full length of the stairwell to the ground floor lobby to exit. Re-entry was not possible on any floor and no access to the roof was available. The locked doors in the stairwells did not unlock upon alarm activation or power failure; these doors could be unlocked only with a master key. The building engineer held

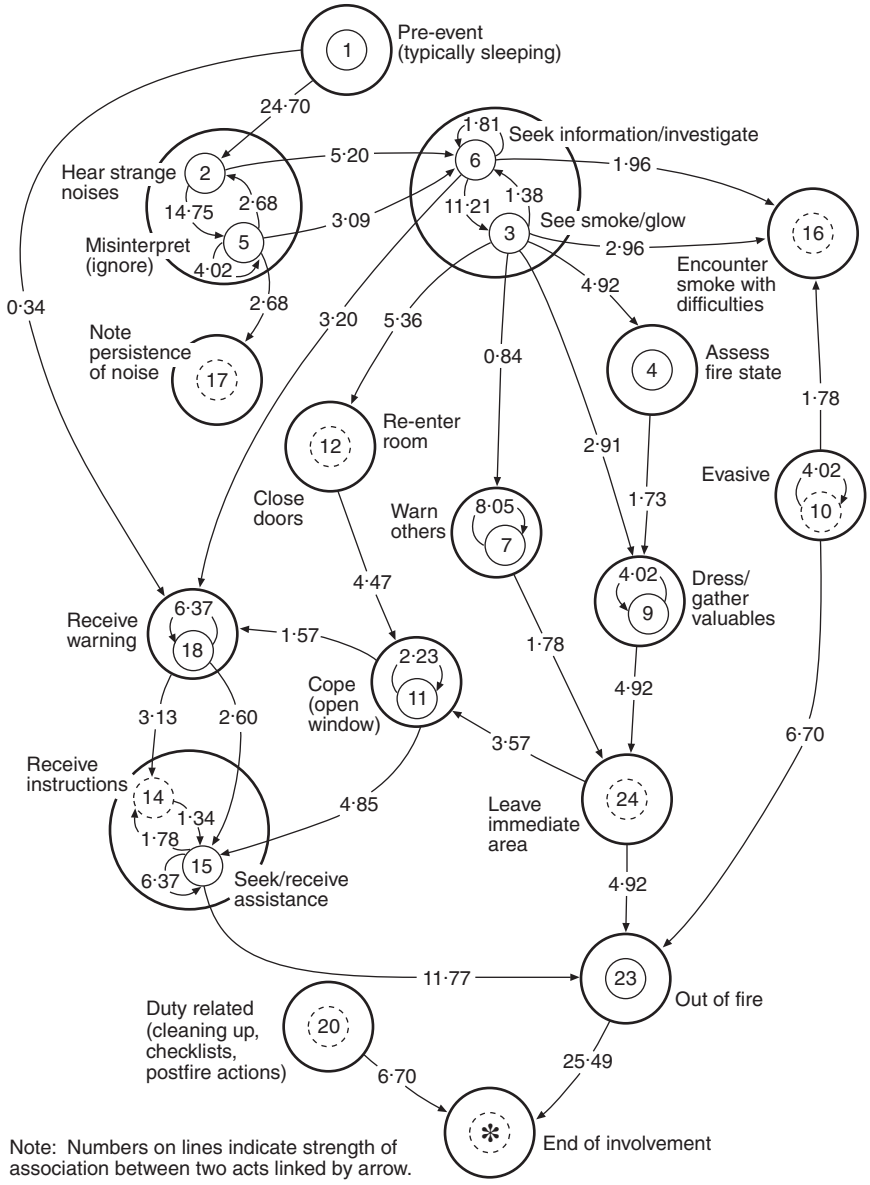

FIGURE 4.1.13 Decomposition Diagram for Multiple Occupancy Fires

one master key and another was kept in the security office on the third floor. Figure 4.1.14 illustrates the exterior of the Cook County Administration Building and the floor plan of the fire origin twelfth floor.

In total, 1862 surveys were distributed to employees. There were 551 surveys returned, which represents a return rate of 30 percent. Among the returned surveys, 462 were from occupants who worked in the building but were not present at the time of the fire. The remaining 89 responses were from occupants who were in the building at the time of the fire and provided information on their evacuation experience. The 89 surveys from respondents who were in the building at the time of the fire represented 40 percent of the occupants who were seen leaving the building on videotapes. Of these 89 respondents, 68 percent were female and 32 percent were male. The mean age of the respondents was 42.3 years (SD = 10.7). In the initial moment of the incident, the 89 respondents were evenly located throughout the building on different floors: 34 percent of the respondents were located on low-level floors, 33 percent were located on mid-level floors, and 33 percent were located on upper-level floors. This distribution of the respondents provides a very good overview of conditions throughout the building as perceived by the respondents.

Of the respondents, 38 percent first became aware of something unusual occurring by hearing a P.A. message, 28 percent became aware because they saw or heard others, 24 percent because they smelled something, and 10 percent because they saw something. Respondents were asked the time at which they

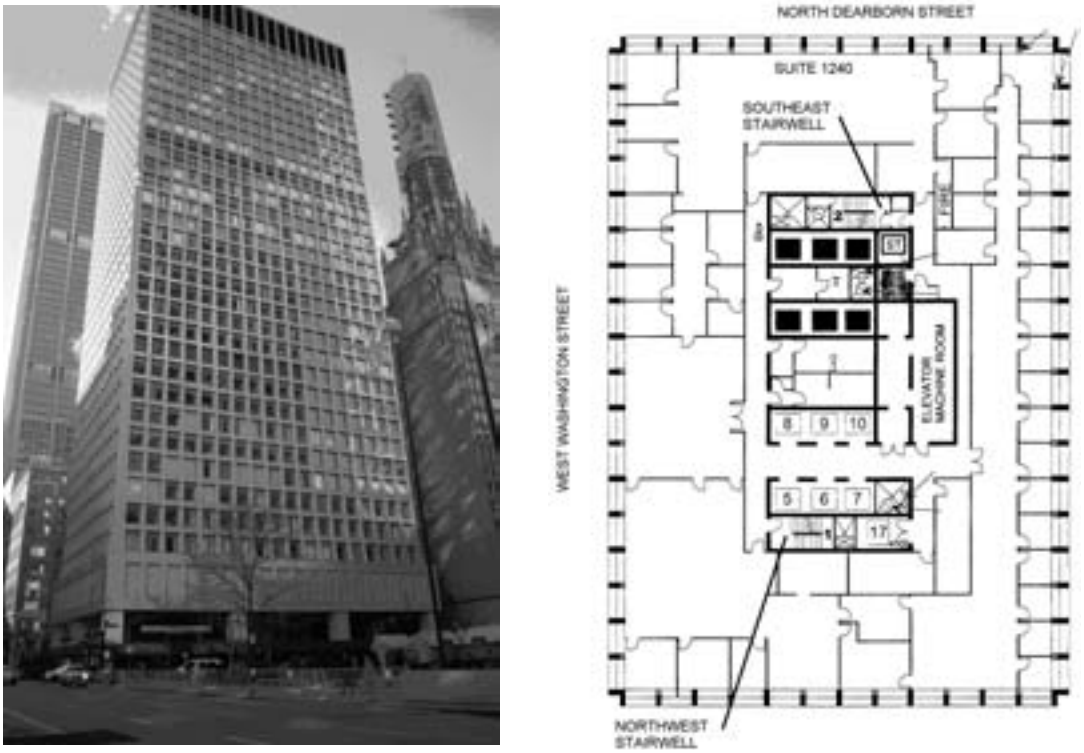

FIGURE 4.1.14 Cook County Administration Building and Twelfth Floor Plan (Source: G. Proulx and I. M. A. Reid, *Occupant Behavior and Evacuation During the Chicago Cook County Administration Building Fire,* Fire Research Program, National Research Council Canada, Ottawa, 2006, p. 4)

initially became aware that something unusual was happening. There was a marked tendency to round off the various reported times; therefore, the time analyses should be used with caution. The time reported by 25 percent was 5:00 p.m. For those who became aware of the incident via a P.A. message, the time ranged from 4:50 p.m. to 5:15 p.m., with most responses being at 5:05 p.m. Respondents were asked what they thought was happening in the initial moments. Of the 84 who responded to this question, 30 percent thought that there was a fire or emergency, 29 percent thought that there was a minor problem, 29 percent did not know what was happening, and 12 percent thought that it was a false alarm or a drill. When asked "How serious did you believe the situation to be at first?" respondents were provided with four categorized answers: "Not at all serious," "Only slightly serious," "Moderately serious," and "Extremely serious." It appears that initially, 36 percent thought that the situation was "Not at all serious," 28 percent thought that it was "Moderately serious," 22 percent thought that it was "Only slightly serious," and 14 percent thought the situation was "Extremely serious." Analysis showed that respondents' initial assessment of the situation significantly affected how serious they thought the situation was ($X^2 = 8.975$, $df = 3$, $p = 0.030$). This is shown in Figure 4.1.15.

When asked what factors motivated their decision to evacuate their floor, 88 percent of respondents provided one or more motivations for starting their evacuation. Motivations were coded under five factors as presented in Table 4.1.26. Respondents could mention one or several motivating factors, and in fact one-third of the respondents mentioned more than one factor. Overall, the most mentioned motivating factor was the perception of "fire cues," which are the smell or sight of smoke or flames. In second place was hearing one or more messages from the P.A. system, followed by being motivated to evacuate by other people. Another motivating factor was that it was time to leave for the day anyway. Finally, a small number were mo-

TABLE 4.1.26 Motivation to Start Evacuation

Motivation to Evacuate	*Respondents Who Mentioned*	*Percentage of Respondents Who Mentioned (of 78)*
Perceived fire cues	37	47.4
Heard P.A. message	24	30.8
Interaction or behavior of other occupants	21	26.9
Was leaving for the day	19	24.4
Concerned for own safety or danger	8	10.3

Source: G. Proulx and I. M. A. Reid, *Occupant Behavior and Evacuation During the Chicago Cook County Administration Building Fire,* Fire Research Program, National Research Council Canada, Ottawa, 2006, p. 12.

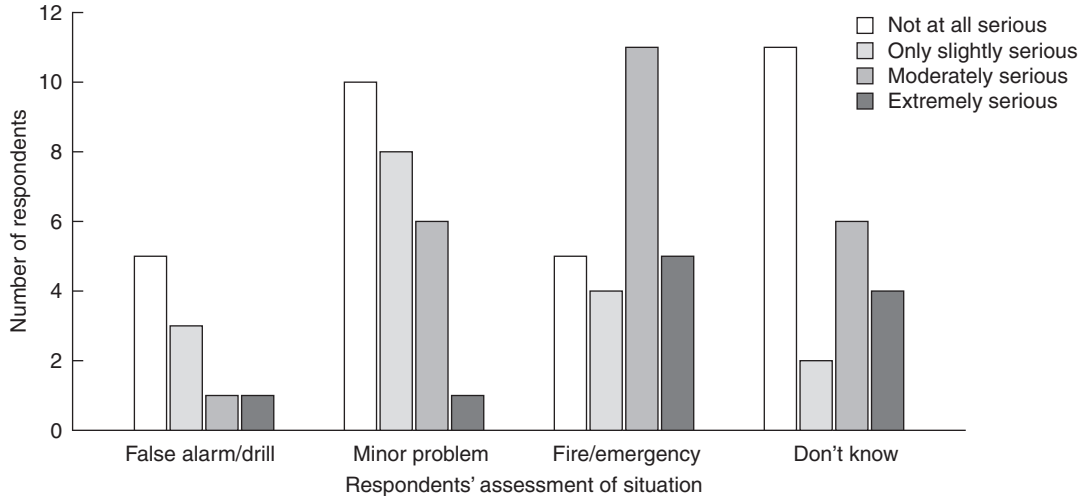

FIGURE 4.1.15 Initial Feelings About the Situation (Source: G. Proulx and I. M. A. Reid, *Occupant Behavior and Evacuation During the Chicago Cook County Administration Building Fire,* Fire Research Program, National Research Council Canada, Ottawa, 2006, p. 10)

tivated to evacuate because of a concern for their safety or the potential danger.

When asked if they left because someone told them to leave, 45 percent of the respondents gave a positive response. When asked who told them to leave, the survey provided 6 categories, as follows: 38 percent reported they were told to leave by a "Coworker," 24 percent by a "Supervisor," 22 percent by the "Message," 16 percent were told to leave by multiple persons (a combination of the above-mentioned choices), and no one reported being told to leave by a "Fire warden" or "Fire fighter." When they started to evacuate, 77 percent of the respondents were in a group of two or more. Half of the respondents waited for others before they left. Respondents were asked if they took anything with them when they left. Three categories were provided: "Personal effects," "Job-related material," and "Emergency equipment." A majority of the respondents, 71 percent, took personal effects, 7 percent took both personal effects and job-related material, 4 percent took job-related material, and 4 percent took emergency equipment when they left; 14 percent specified they took nothing. For respondents who took personal or job-related items, they took what they regularly took home for the weekend. Further, it can be seen from the security videos that most people exiting the building were wearing jackets. The approximate outside temperature at the time of the fire was 55°F (13°C). In addition, respondents from the day-care center located in the Bustle Building mentioned taking phone lists of the families of the children. Figure 4.1.16 presents the motivation of occupants to leave relative to their location in the building.

In total, 51 percent of the respondents attempted to use an elevator to evacuate. Such a high percentage of respondents attempting to use the elevator was rather unexpected considering that the building evacuation procedure and training recommended the use of stairwells and prohibited the use of elevators during a fire emergency. Further, signs located directly above the elevator call button, on every floor, indicated that "In Case of Fire, Elevators Are Out of Service." It should be noted that this information was not entirely correct, since the elevators did not have an automatic recall function and would continue to operate in a fire until manually or electronically recalled.

The high use of elevators to evacuate the building appears to be related to the time of the day; many people were leaving for the day and the weekend. Of those who mentioned that their motivation to evacuate was because they were leaving for the day, 95 percent (18 of 19 respondents) attempted to use the elevator. Of these 18 persons, most were aware that something unusual was happening; 11 had heard a P.A. message, 7 smelled

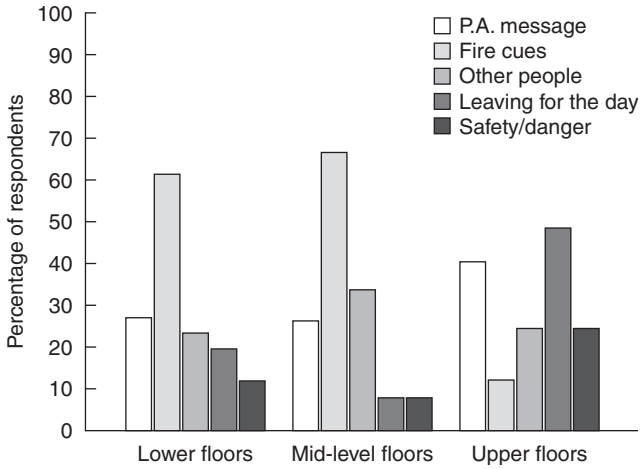

FIGURE 4.1.16 Motivation to Evacuate by Floor Level (Source: G. Proulx and I. M. A. Reid, *Occupant Behavior and Evacuation During the Chicago Cook County Administration Building Fire,* Fire Research Program, National Research Council Canada, Ottawa, 2006, p. 13)

smoke, 2 saw smoke, and 1 respondent heard a fire alarm on their floor prior to evacuating by elevator. Among the respondents that mentioned using the stairs as the appropriate evacuation procedure, 54 percent attempted to use the elevator to evacuate. Four of the individuals who reported using the stairs also mentioned that you should not use the elevator during an evacuation, but did attempt to use the elevator to evacuate. No statistical relationship was found between those attempting to use elevators and their floor level ($X^2 = 3.339$, $df = 2$, $p = 0.188$). A greater percentage, however, of those located on higher floors attempted to use the elevator; 62 percent of those located on upper floors versus 38 percent of those located on the lower floors attempted to use the elevator. Of those that used the elevator, all but one got off the elevator on the ground level floor.

Video cameras positioned on the ground floor lobby captured 223 occupants exiting the building from 5:00 p.m. until 5:35 p.m. These exiting occupants are shown as a continuous line in Figure 4.1.17. The number of occupants observed is shown on the right axis.

Also represented in Figure 4.1.17 are the exiting times of the survey respondents, calculated by adding the respondent estimated premovement time to the travel time from the time of initial awareness that something unusual was happening. The respondents exiting times range from 5:00 p.m. to 5:40 p.m., in 5 minute intervals. Exiting times are represented with bars for respondents that used the elevator or the stairs. The number of respondents is shown on the left axis.

The two sets of data presented in Figure 4.1.17, the video recordings and the respondent estimated times, show a similar pattern. It can be seen that a large proportion of the building occupants evacuated within 5 to 10 minutes of the first P.A. message issued. Initially, more occupants evacuated using the elevators whereas the stairs evacuees spread over a longer period of time.

Panic Behavior

One concept always discussed following a fire in which multiple fatalities occur, such as the Beverly Hills Supper Club fire,[57] is panic behavior. One classic definition of panic is

> a sudden and excessive feeling of alarm or fear, usually affecting a body of persons, originating in some real or supposed danger, vaguely apprehended, and leading to extravagant and injudicious efforts to secure safety.[58]

According to this definition, panic is a flight or fleeing type of behavior that involves extravagant and injudicious effort and is likely not to be limited to a single individual, but to be transmitted to and adopted by a group of people. From simulation experiments, a panic-type behavior reaction has been defined in the following manner: "A fear-induced flight behavior which is nonrational, nonadaptive, and nonsocial, which serves to reduce the escape possibilities of the group as a whole."[59]

The concept of panic is often used to explain the occurrence of multiple fatalities in fires even when there is no physical, social, or psychological evidence showing that competitive, injudicious flight behavior actually took place. The media and public officials often label various types of fire behavior as panic. The evidence accumulated from interviews with participants in the Beverly Hills Supper Club fire, and questionnaires completed by occupants, provided no evidence of the classic group-type of panic behavior with competitive flight for the exits.[60]

It has been said that panic as a concept is primarily a description rather than an explanation of behavior. The concept is used to support the introduction of requirements in fire and building laws or ordinances to provide for the fire safety of occupants. There also has been shown to be a difference between use of the concept to describe other persons' behavior in a fire and the use by someone engaged in the behavior to indicate

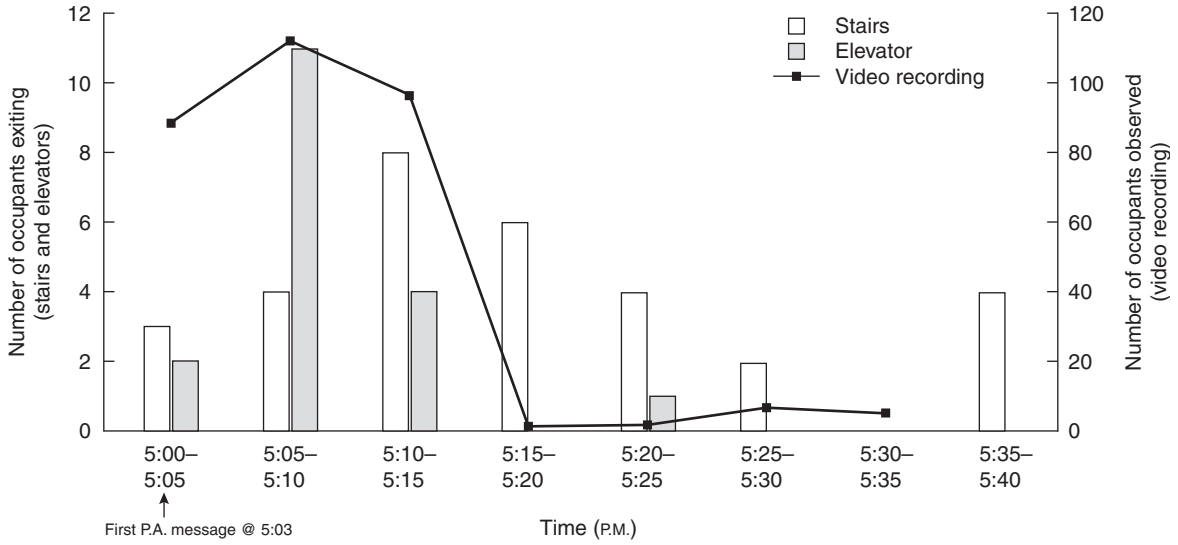

FIGURE 4.1.17 Number of Occupants Exiting the Building Between 5:00 p.m. and 5:40 p.m. (Source: G. Proulx and I. M. A. Reid, *Occupant Behavior and Evacuation During the Chicago Cook County Administration Building Fire,* Fire Research Program, National Research Council Canada, Ottawa, 2006, p. 18)

his or her own state of concern and anxiety.[61] Just because an individual identifies behavior as associated with panic does not necessarily identify the behavior as the classic panic-type response. The outcome of the behavior, as previously discussed, affects its labeling; the behavior of people in a fire is most likely to be misinterpreted when the outcome of the fire has been unfortunate.

The use of the concept of panic must be separated from use of the terms "anxiety" or "fear." The concept of self-destructive or animalistic panic responses to stimuli, such as the presence of smoke, has not been supported by the research on human behavior in fires. As has been pointed out, it is rare to have panic behavior in which the flight is characterized by competition among the participants, with resultant personal injuries.[7,14,15,60,62] In an interview study of 100 participants in single-family dwelling fires, no instances of panic behavior were found; primarily altruistic, helpful behavior was found instead.[63]

Ramachandran in his review of studies of human behavior in fires in the United Kingdom came to this conclusion about nonadaptive behavior:

> In the stress of a fire, people often act inappropriately and rarely panic or behave irrationally. Such behavior, to a large extent, is due to the fact that information initially available to people regarding the possible existence of a fire and its size and location is often ambiguous or inadequate.[17]

S. J. Blake, E. R. Galea, H. Westeng, and A. J. P. Dixon[64] conducted an analysis and review of media accounts of 250 survivors of World Trade Center towers 1 and 2 during the terrorist aircraft attacks of September 11, 2001. This study is very similar to the study previously considered by Guylène Proulx and Rita Fahy. In this study 124 survivors reported pre-evacuation behavior, 94 survivors (76%) reported one action, 19 survivors (15%) reported they left immediately with no pre-evacuation actions. The most frequent pre-evacuation action was "gather/provide information." These authors reported in their study the following account of nonadaptive behavior:[64]

> The extreme behavior action (which included the classic panic action or people behaving in an irrational manner) was only noted in 1/124 (0.8%) cases.

The Station Nightclub Fire

The most recent and one of the most deadly fires involving the occurrence of the classic type of panic behavior occurred in the Station Nightclub fire which occurred at approximately 11:09 p.m. on February 20, 2003, in West Warwick, Rhode Island.[65] This fire incident was also one of the most detailed videotaped fires since a television reporter/cameraman from station WPRI was on the premises filming when the fire was ignited by performers' pyrotechnics adjacent to highly combustible foam interior finish on the walls and the ceiling of the platform performance area. The fire resulted in 100 occupant fatalities and between 186 and 200 occupant injuries.

Figure 4.1.18 presents the interior dimensions of the club. Figure 4.1.19 presents the arrangement of the main entrance at the front of the building through which all the occupants were admitted, since the cashier's station was at the end of the entrance corridor. This area had a single door for egress indicated in the figure as 36 in. (0.9 m) in width.[65]

Although the videotape shows a crowd crush at the double exterior doors it appears from the investigation including the survivors accounts the primary crowd crush that denied access to the main exit was at the single door prior to the two main egress doors at the exterior of the building. The crowd crush occurrences at both locations had all the characteristics of the panic type of behavior defined by Schultz[59] as being a "fear-induced flight behavior which serves to reduce the escape possibilities of the group as a whole."

The investigation report provided the following analysis relative to the occupants egress behavior as follows:[65]

> The first patrons recognized the fire danger about 24 seconds after ignition of the foam; the bulk of the crowd began to evacuate shortly after that, around the time the band stopped playing (30 seconds).
>
> The rate of egress from the main entrance at the front of the building was primarily limited by the single doorway inside the vestibule, not the double doors visible from the outside.
>
> About two-thirds of the occupants appear to have attempted to leave through the single main entrance in the front of the building; many were unsuccessful.
>
> Prior to 1½ minutes into the fire, a crowd-crush occurred in the front vestibule which almost entirely disrupted the flow through the front exit. The precise event which led to the crowd-crush likely was related to the arrangement of the single interior door with merging streams of traffic and the pressure to escape the rapidly deteriorating conditions in the main area of the nightclub.
>
> Measurements of temperature, heat flux and gas species in a reconstruction of the platform area fire at NIST and computer models of the NIST experiment and the full nightclub suggest that the conditions around the platform, dance floor, sunroom and dart room would have led to severe incapacitation or death within about 1½ minutes after ignition of the foam for anyone remaining standing, and for not much longer even close to the floor.
>
> The number of building occupants at the time of the fire was reported by the *Providence Journal* to be 440.[65]

The NIST report[65] provided a total of 12 recommendations from the investigation and analysis of the Station Nightclub fire. The following recommendation addresses the human behavior factors that appeared to be critical in this fire incident:

> NIST recommends that research be conducted to better understand human behavior in emergency situations, and to predict the impact of building design on safe egress in fires and other emergencies (real or perceived) including the following:
>
> a. the impact of fire products (gases, heat, and obscuration) on occupant decisions and egress speeds

Re-Entry Behavior

The study of the 1956 Arundel Park fire was the first to document the phenomenon of re-entry behavior.[4] Some older codes and regulations affecting design of the means of egress appear to have been based on the assumption that pedestrian traffic only moves away from a fire and away from the area or floor of the building involved. However, the Arundel Park study indicated that approximately one-third of the survivors interviewed had re-entered the building.

Thus, it has become apparent that doors, stairways, and corridors will often be subjected to two-way movement of occupants and others. The occupant who, after leaving the building safely, turns around and re-enters is often completely aware of the fire in the building and of the specific portions of the building involved in fire and smoke propagation. Based on interviews with 61 persons, Table 4.1.27 presents the number of participants who re-entered Arundel Park during the fire. Note the reasons for the re-entry behavior and that those who re-entered were predominantly male.

The Arundel Park fire occurred in an assembly occupancy being used for a church-sponsored oyster roast, a family-type affair. Thus, the primary group cultural role of father or husband was apparently a critical variable in the re-entry behavior of the population interviewed and may have resulted in the fact that the re-entry participants were mostly male. It can reasonably be argued that re-entry behavior is not a nonadaptive behavior, since it is often used to assist or rescue persons remaining or believed to be remaining in the building. This type of behavior is often used by parents whose children are missing during a fire. The behavior is often undertaken in a rational, deliberate, and purposeful manner, without the emotional anxiety and self-doubt usually associated with nonadaptive behavior. However, re-entry behavior has been considered nonadaptive, since people going back into a burning building often hinder the efficient and effective evacuation of others through the same means of egress. The reasons elicited from participants in re-entry behavior in the Project People study[7] in the United States are presented in Table 4.1.28.

It would seem that 163 people from the total study population of 584, or 27.9 percent, engaged in re-entry behavior. The most popular reason given was to "fight fire," followed by "obtain personal property," "check on fire," "notify others," "assist fire department," and "retrieve pets." These six reasons accounted for approximately 73 percent of re-entry behavior. Table 4.1.29 compares the re-entry behavior of the British and U.S. study populations.

Note that all the reasons were significantly different, with the exception of the item "save personal effects." The re-entry reasons of the U.S. population were predominantly "save personal effects," "call fire department," "rescue pets," "notify others," "assist fire department," and "assist evacuation." The British population's re-entry reasons were predominantly "fight fire," "observe fire," "shut doors," "await fire department," and "fire not severe."

Occupant Fire-Fighting Behavior

Occupants who engaged in fire-fighting behavior were predominantly male, and this behavior now appears to be a culturally determined and expected aspect of the male role. However, it should be noted that, in the Project People[7] study of 335 U.S. fires, approximately 23 percent of the study population of 584 individuals were involved in occupant fire-fighting behavior. Of these, 37.3 percent were female. Of the 134 individuals who participated in fire-fighting behavior, 50 were female and 84 male. They ranged from a 7-year-old girl to an 80-year-old man. Distribution of the participants by gender and age is presented in Table 4.1.30. A plurality of those involved in fire-fighting behavior, or approximately 30 percent of the fire-fighting behavior population, were between 28 and 37 years old. A higher proportion of males than females reported "got extinguisher" and "fought fire," and this difference is statistically significant (Table 4.1.31).

Approximately 15 percent of the male population reacted by obtaining extinguishers. Similarly, approximately 26 percent of the male population fought the fire when they became aware of it, as contrasted with approximately 10 percent of the female participants. A higher proportion of women (33%) than men (26%) notified the fire department, as indicated in Table 4.1.31, but this difference is not statistically significant.

Occupant fire-fighting behavior appears most prevalent in occupancies in which the individuals are emotionally and economically involved—that is, in their homes or where such behavior is an assigned role as a result of training.[66] At some time during the fire, 285 individuals engaged in one of the six actions defined as fire-fighting behavior and 252 individuals participated in one of the four actions defined as notifying the fire department.

In the study of residential fires in Berkeley, California, 180 persons were involved in extinguishing and fire-fighting behavior. This study surveyed a population different from that of Project People, since the 1411 Berkeley households, with 208 fires, included fires not reported to the fire department; these accounted for approximately 80 percent of the total 208 fires. The majority of the unreported fires were extinguished by the occupants alone or with the help of neighbors.[67] Six percent of these fires self-extinguished; and 52 percent were extinguished by the individual who had started the fire. Thus, it appears that only the fires in the Project People study that were judged uncontrollable by the occupants resulted in notification to the fire department.

Similarly, approximately 85 percent of the fires in the National Fire Prevention and Control Administration National Household Survey[68] were not reported to the fire department.

In the Project People study, 107 of the 584 participants did not leave the building voluntarily after becoming aware of the fire. Their reasons for staying in the building are presented in Table 4.1.32.[7]

Fifty-two of the participants, or approximately 49 percent of the population, who stayed in the building reported that they remained because they wished to engage in fire control or fire-fighting activities. The other most frequent reasons were to notify others of the fire or because the occupant's way out of the building was blocked by smoke.

Occupant Movement through Smoke

Often related to fire-fighting behavior, and a definite component of evacuation behavior in many fires,[7,14] is the movement of occupants through smoke. The principal variables influencing an occupant's decision to move through smoke appear to be recognition of the location of the exit and thus of the travel distance, the appearance of the smoke, the smoke density, and the presence or absence of heat.[52–54] To achieve evacuation, occupants have moved through smoke, even for extended distances under conditions of extremely limited visibility at personal risk, and sometimes have been forced to turn back without completing the evacuation.[52,53]

Jin and Yamada[69] reported on a study involving 31 subjects (14 males and 17 females) traveling a maximum distance of 34.5 ft (10.5 m) in a corridor while exposed to smoke from smoldering cedar crib chips. The smoke extinction coefficient varied from

0.1 to 1.2 (m^{-1}). Subjects were also exposed to increasing heat from radiant heaters at the end of the corridor, where the mean temperature was 82°C. At five points in the corridor the subjects stopped and were asked mental arithmetic questions. Both walking speed in the corridor and mental arithmetic capability decreased as smoke density and radiant heat exposure increased.

Fahy and Proulx[23] in their questionnaire study of 382 employees in the 1993 World Trade Center explosion and fire found that 94 percent of the respondents in WTC 1 and 70 percent of the respondents in WTC 2 moved through smoke. In addition, the study reported that approximately 75 percent of these individuals turned back during their evacuation because of smoke, crowding, locked doors, breathing difficulty, fear, and poor visibility. It was also reported that some occupants continued to move through smoke, even when they perceived the smoke to be worsening and believed that they may have been moving toward the fire.

Proulx and Fahy[26] in their study of the media reports of occupant behavior in the World Trade Center terrorist aircraft attack of September 11, 2001, indicated that in WTC 1, 74 occupants (55%) reported "smoke" was the most frequent adverse condition; thus, it may be assumed they may have traversed through smoke conditions at some time in their evacuation. In WTC 2, 25 persons (44%) indicated "smoke" was an adverse condition, also implying some movement through smoke. Although smoke was reported as the most frequent adverse condition in WTC 1, in WTC 2 the most frequent adverse condition was "debris or collapse of a wall, ceiling or floor."

Table 4.1.33 compares the distance moved through smoke for the 1316 persons in the British study and the 322 persons in the U.S. study.

Reports by 60 percent of the British study population and 62.7 percent of the Project People participants indicated that they moved through smoke. It is thus apparent that building occupants will move through smoke in an evacuation process. An important variable may be the smoke density or the visibility distance of the occupants during the evacuation process.

Table 4.1.34 presents the visibility distance reported by the British and U.S. occupants as they moved through smoke while evacuating a building fire. They reported their movement through smoke under relatively high smoke density conditions, with visibility under 12 ft (3.7 m) for 64 percent of the British population and for 47.6 percent of the U.S. population.

Visibility distance for the British and U.S. populations at the time participants were forced to turn back is presented in Table 4.1.35. Comparison with Table 4.1.34 reveals that very few participants turned back when they could see more than 31 ft (9.4 m). The greater percentage of participants turned back at shorter visibility distances. When the visibility distance was below 12 ft (3.7 m), 91 percent of the British study population and 76.4 percent of the U.S. study population turned back (see Table 4.1.35).

Proulx[70] in the study of occupant response to a fire in a 25 story high-rise apartment building had 137 questionnaires returned, with 68 percent of the occupants over 60 years of age. Of the occupants, 114, or 83 percent, attempted to evacuate during the fire and 96, or 84 percent, of those attempting to evacuate moved through smoke. Of those moving through smoke, 45 percent indicated they could see "nothing at all" or "little," and 30 percent said they could see 12 to 15 m in the corridor. Of the 114 occupants who attempted to evacuate, 61, or 54 percent, were successful and 53, or 46 percent, were unsuccessful due to the smoke conditions in the stairs or corridors. Relative to the 53 unsuccessful occupants, 29, or 55 percent, returned to their own apartments and 24, or 45 percent, sought refuge in other apartments.

Heskestad and Pederson[71] have reported on five large "escape through smoke" experiments involving more than 300 persons with various way-guidance systems. In all of these ex-

periments, visibility was less than 3 m due to the induced smoke conditions. Two of the experiments involved the test situation modeled on a ship staircase and a ship or hotel corridor. One of these experiments involved an emergency training mock-up, one experiment used a corridor in a health care facility, and one experiment used portions of a passenger ferry. Variables measured during the experiments were the time for occupants to travel through the experimental facility with the number of incorrect decisions made during the travel. These experiments found that tactile and audible way-guidance systems appear to be as suitable as the visible systems in assisting movement by individuals through smoke.

Jin[72] has reported on numerous studies involving the effectiveness of guidance sign systems with human subjects in smoke environments. Improvements resulting from these experiments include a pictorial exit sign, flashing exit lights, and a flashing row of lights at floor level indicating the direction of egress travel. The flashing row of lights was effective in a smoke level of 1.01/m with the spacing of the lights at 0.5 m.

DISABLED OR IMPAIRED OCCUPANTS

Fire problems involving occupancies designed for permanently or temporarily disabled persons, such as nursing homes and hospitals, appear to be matched on the basis of building design, adequate staff training, and ability to protect the occupants in place until evacuation is possible. An extensive study of human behavior in health care facilities[66] indicated that the nursing staff performed their professional roles for their patients even when they were at risk.

The few fires studied involving disabled persons in occupancies other than health care facilities have primarily been in residential occupancies. In two of these cases, handicapped individuals were helped by other occupants to evacuate successfully. One instance involved a wheelchair user[51] and the other a blind person.[73]

Types of Impairment

Disabled people may have a variety of limitations that increase their risk in a fire: sensory problems, such as deafness and blindness; mobility problems that may entail the need for a wheelchair; and intellectual problems, such as mental retardation. Many handicapped persons with mobility problems also are concerned about their personal risk in high-rise office and residential buildings where the use of elevators is not allowed in a fire. In such situations, adequate areas of refuge must be provided for disabled, as well as able-bodied, occupants.[74]

In their reports of the explosion and fire in the World Trade Center on February 26, 1993, Isner and Klem[75,76] indicated that when the explosion occurred at approximately 12:18 p.m., normal power was lost and the emergency generators failed about 20 minutes later; all remaining power to the World Trade Center complex was disconnected at approximately 1:32 p.m. Thus, the simultaneous evacuations of both able and disabled occupants from towers 1 and 2 were conducted in darkness with varying smoke conditions in the stairways. These simultaneous evacuations may have involved the largest number of occupants and the longest evacuation times of any fire-induced evacuations of buildings in the United States.

Juillet,[77] in one of the first documented studies of this type, reported on the interview study of 27 occupants with disabilities evacuated from one of the two towers in the World Trade Center during the explosion and fire of February 26, 1993. The impairments of the interviewees included 14 with mobility impairments, 3 with sight or hearing impairments, 3 who were pregnant, 2 with cardiac conditions, and 7 with respiratory conditions. Juillet[78] indicated that the total disability population in both towers at the time of the incident was believed to be between 100 and 200 persons, approximately 100 of whom had been previously identified. The average evacuation time of the 27 study participants was 3.34 hours, with evacuation times reportedly ranging from 40 minutes to over 9 hours. The predominant means of evacuation was through the stairs with assistance from other evacuees or emergency personnel. The altruistic behavior seen in many fires involving large populations[51,53,77] appeared to have been exhibited in this fire in relation to the disabled occupants as reported by Juillet.

> However, in the absence of communications by authorities, they gladly accepted assistance—from colleagues and even from complete strangers—in evacuating. These caring groups of people who assisted the disabled protected their "charges" until they were safely evacuated and moved away from the building.[78]

The Fire Safety Engineering Research and Technology (SERT) Centre at the University of Ulster has completed the most extensive and detailed analytical and experimental studies of the evacuation capabilities of impaired individuals. Boyce, Shields, and Silcock conducted a series of studies in Northern Ireland to determine the number and characteristics of impaired persons who may be expected to frequent public buildings and

to determine the capabilities of these persons to complete an evacuation. The initial study determined the number and types of impaired persons expected to occupy public assembly occupancies.[79] This study found that 12 percent of the mobile population of Northern Ireland out in public are impaired persons and 2 percent of these impaired persons require assistance. Table 4.1.36 presents the number of impaired adults and children by their degree of mobility expressed as a percentage of the total mobile population.[80]

Table 4.1.37 illustrates the impaired persons in public who have experienced mobility difficulties as percentages of the total mobile population. Table 4.1.38 indicates the involvement of impaired persons in social and recreational occupancies relative to their degree of mobility.

Additional data presented in this study involved the frequency with which impaired persons go out in public. The prevalence of the type of impairment among the impaired population attending theaters, concert halls, motion picture theaters, sports stadiums, leisure centers, hotels, and lodging occupancies was reported. In addition, data was presented relative to the types of impairment among impaired adults who live in communal facilities and go out for meals and drinks and for adults who are employed. The perceived value of this information and data relative to the application of performance codes was stated in the following manner:

> The information provided in this analysis has important implications for characterizing building occupan-

cies. It establishes that public buildings are frequented by a significant number of disabled people and that the nature of their disabilities and how well they can be expected to evacuate without assistance during an emergency will be a function of the use of the building or part of the building. Characterizing buildings and characterizing occupants as required by performance-based codes, are not mutually exclusive activities, a fact that has not yet percolated through the design professions.[80]

Movement by People with Disabilities

The second study by Boyce, Shields, and Silcock[81] involved experimental observations and measurement of the movement of impaired persons on a horizontal corridor, inclined ramps, and stairs. Observations included the velocity of movement, rest periods required, assistance required, and the physical aids used relative to their degree of mobility impairment. There were 107 persons (54 males and 53 females, ages 20 to 85) who completed the horizontal corridor without assistance. The velocity of this population relative to their mobility impairment is presented in Table 4.1.39. Sixteen of the manual wheelchair users needed assistance to traverse the 50 m corridor at the 90° turn, 8 m from the starting point. Only 34 individuals were capable of participating in the stair movement studies involving ascent and descent travel, 30 without assistance and 4 with assistance, including three blind persons.

In general the movement velocity was slightly faster in descent travel on ramps, whereas on the stairs the ascent movement was faster, as indicated in a comparison of Table 4.1.40 and Table 4.1.41.

These authors indicated the following findings from these experiments:

> The abilities of disabled people cover a wide spectrum with respect to movement on horizontal and inclined planes. Given the significant differences in the capabilities of those using different mobility aids and the inherent differences in their spatial requirements, it is suggested that, for evacuation and modeling purposes, they be considered separately.
>
> Escape times are usually determined from characteristic travel speeds coupled with premovement times. From this study it is apparent that, for some disabled people, it may also be necessary to include periods of rest and time to negotiate changes in direction. This paper's findings should help designers derive characteristic times for disabled people traversing any typical escape route.

The detailed observations made during the movement studies suggest that, in designing accessible escape routes, more attention needs to be focused on the real, rather than the perceived needs of disabled people. Consideration should be given to the nature and position of support systems such as handrails, and the positioning of doors in escape routes, since these will influence the progress and the flight behaviors of some disabled occupants.[82]

Door Operation and Egress

The third study by Boyce, Shields, and Silcock[83] was an experimental study of door operation and egress with 104 mobility-impaired

persons (54 male and 50 female, ages 25 to 85). Impairments of the participants involved 5 using crutches, 28 using a walking stick, 8 using a walker, and 63 using no mobility aids. The time to negotiate a standard single-leaf door with a clear width opening of 750 mm for these individuals is presented in Table 4.1.42 with the type of door operation and the closer force on the door leaf.

In addition to mobility impairments, other critical impairments for this action involved 45 persons with a minor reaching and stretching impairment and 58 persons with a dexterity impairment. Table 4.1.43 presents the failure rates and the time to negotiate the door for the seven manual wheelchair users. The manual wheelchair users in general took more time to push the door open than to pull the door open. It also took these wheelchair users three to four times longer than the mobility-impaired persons to negotiate the door.

Signage

The fourth study by Boyce, Shields, and Silcock[84] was an experimental study to determine the ability of impaired persons

to locate and read three types of exit signs: nonilluminated, internally illuminated, and light-emitting diode (LED) signs. The signs were placed in a clear atmosphere in a room 2.3 m from the floor with a maximum viewing distance of 85 m. The distance from which participants were able to read the exit signs was measured, presented in Table 4.1.44. A total of 118 impaired persons participated in this study, including 25 persons with a sight impairment. The LED signs appeared to be the most visible and legible by the impaired persons with and without a sight impairment.

In a related study, Shields[85] observed that wheelchair users and mobile participants did not impede each other in evacuation progress and wheelchair persons did not impede each other. Mobility-impaired persons with walkers did impede wheelchair users.

Elevator Use

Klote, Alvord, Levin, and Groner[86] examined the design considerations needed to use elevators in tall buildings for the evacuation of disabled occupants. In the World Trade Center explosion and fire of 1993, the loss of power in both towers (including emergency power) trapped occupants in elevators in both buildings.

Burns[22] indicated WTC 1 had 99 elevator cars, many of them occupied. When one 6 ft × 8 ft (1.8 m × 2.4 m) car was opened, nine occupants were found unconscious. It was estimated that they had been exposed to the smoke in the shaft for approximately 2 hours at the ninth floor. Sherwood[87] reported that one 9 ft × 12 ft (2.7 m × 3.6 m) elevator car was stuck for 6 hours at the 41st floor of WTC 2 with 72 occupants (62 elementary schoolchildren and 10 adults).

NFPA *101* in the 1991 edition permitted the use of elevators with fire-fighter service from areas of refuge, which are also specified in this handbook. In 1997 the *Life Safety Code* permitted the use of a fire-fighter service elevator with special features to be used as a second means of egress from towers, along with specifications on the occupant load of the tower, the provision of automatic sprinklers, the egress arrangement, and capacity.

In the 1970s Pauls studied a number of evacuation drills in high-rise office buildings in Canada, which indicated that approximately 3 percent of the occupants were unable to use the stairs due to permanent or temporary conditions limiting their mobility.[88] The study population included occupants with heart conditions and individuals recovering from surgery, other illnesses, and accidents.

FIRE EXIT DRILLS

Determining when and what area to evacuate is probably the most important decision in a fire emergency. Any area at all affected by heat, flame, or smoke should be evacuated; in case of doubt, the entire building should be evacuated. Well-marked exits do not ensure life safety during an evacuation. Exit drills are necessary so that occupants will know how to make an efficient and orderly escape according to NFPA *101,* which contains detailed information on exit drills in individual occupancies.

Exit Drill Requirements and Procedures

Exit drills are required in schools, board-and-care facilities, and health care facilities, and are common in industries with high hazards. Employee training and drills are required in assembly, hotel, mercantile, and large business occupancies. Some form of exit drill should be conducted wherever or whenever possible to avoid confusion and ensure the evacuation of all occupants during a fire.[89] Personnel should be assigned to check exits for availability, search for stragglers, count occupants once they are outside the fire area, and control re-entry into the building before it is safe.

This re-entry behavior for rescue purposes of persons involved in fires should be noted. In a study of 335 fire incidents involving 584 persons, it was found that 163 persons, approxi-

mately 28 percent of the study population, re-entered the fire buildings following evacuation.[7] Approximately 10.5 percent of those persons who re-entered the buildings did so to alert or assist other persons.

The fire loss prevention and control management staff are responsible for planning exit drills. Plans should be discussed with both middle and line management to ensure understanding and cooperation. If there is no fire loss prevention and control manager, the plant, facility, or building manager should assume this responsibility or assign it to a staff member. After each exit drill, a meeting of the responsible managers should be held to evaluate the success of the drill and to solve any problems that may have arisen.

All employees should recognize the evacuation signal and know the exit route they are to follow.[90] On hearing the signal, they should shut off equipment and report to a predetermined assembly point. Primary and alternative routes should be established, and all employees should be trained to use either route.[90,91]

The problem with audible evacuation signals is the conditioning of the population within the occupancy to ignore the signal due to numerous false alarms. An investigation of an apartment building fire found that the alarm system actuation to initiate evacuation behavior was ignored by many of the building occupants due to the conditioning effect of numerous prior false alarms; 44 percent of the building occupants believed the alarm signal was a false alarm.[92]

When employees are assembled, the manager or supervisor of each area should account for all personnel. Missing employees should be immediately reported to the fire loss prevention and control manager and responding fire department personnel so that search and rescue efforts can be initiated. Only trained fire-fighting search and rescue personnel with adequate protective equipment should be permitted to re-enter an evacuated area.

One significant improvement to the traditional concept of fire drills in educational occupancies was suggested by a study of fire drills conducted in such occupancies.[93] The concept of smoke drills has been established, whereby the occupants are instructed to move through the simulated smoke areas in a crouched position. Students have transferred the smoke drill concept to fire incidents in residential occupancies, with effective results. Obviously, smoke drill training may be effective in a fire and should be used where applicable.

The timing of drills depends on the nature of the operation in the facility. Generally, drills conducted a few minutes before the lunch break have been found to minimize loss of time and production. The frequency of drills should be determined by the degree of hazard present and by the complexity of shutdown or evacuation procedures.

If a facility does not maintain a security organization that is responsible for daily inspection of emergency exits and designated evacuation routes, one employee in each area should be assigned this task. Maintenance of doors, panic hardware, exit lights, and emergency illumination should be given high priority, and repairs must be made without delay.

Research has found that for multistory office buildings, a trained group of floor wardens is the most effective means of monitoring the evacuation of occupants.[89] Adequate training for floor wardens or other personnel is necessary and must be specifically developed to include the procedures of the emergency evacuation plan for the facility. The most serious problem with using building monitors is the turnover of personnel due to employee transfers, reassignments, or resignations. Effective evacuation planning and preparation should assign specific responsibilities to staff positions (rather than individuals) within an organization. This ensures continuity of performance despite personnel changes.

The evacuation signal should be familiar to all employees. Vocal alarm systems (VAS)[94,95] reduce the need for employee perception and recognition of a signal, because the system provides vocal communication to the areas designated for evacuation. NFPA *101* first recommended the use of the VAS in assembly occupancies in 1981. An evaluation of VAS systems in nine buildings found that familiarity with the system compared with initial activation without prior familiarity did not significantly affect the egress behavior of populations.[87] In addition, the investigation determined the evacuation drills were valuable because they gave floor or area wardens an opportunity to rehearse their procedures. The use of an alerting tone in the frequency range of 2000–4000 Hz for the VAS is recommended prior to the verbal announcement, which should be specific for the audience and the facility.[90,95]

Health Care Facilities Drills

Fire drills in health care institutions are usually conducted as a part of the orientation program for new employees. Later, the drills are supplemented with in-service training for the staff personnel, including the emergency procedures. Fire drills in many facilities are conducted once a month on each shift. The training for the drills typically involves instruction and practice for the staff personnel in the various means of moving nonambulatory patients, procedures for alerting the facility staff, and the method of notifying the fire department. Once or twice a year, many facilities have fire departments provide training in the operation of portable fire extinguishers. Some fire departments actually provide staff personnel with experience in the operation of extinguishers on external fires.

However, most health care facilities prefer to train their personnel. The lecture method has been used to convey the essential features of the emergency plan to employees in health care facilities.[94] However, it was also found that the emergency plan in the facility studied was too general and ambiguous. Most health care facilities adopt the philosophy that it is the staff's responsibility to ensure the safe evacuation of patients initially to an area of refuge and then to the exterior if necessary. The control of the fire is limited to preventing the spread of heat and smoke by closing doors. This protects the occupants and inhibits or restricts the propagation of smoke and heat throughout the facility. Staff personnel have effectively evacuated numerous patients during fires or have protected the patients in their rooms by closing doors.[96]

A content and time evaluation of fire drill behavior by staff in six nursing homes concluded that a training program of the most modest type can produce changes in both knowledge and

behavior of evacuation and fire emergency procedures.[94] A total of 339 nursing home staff participated in the study that matched a group of 37 persons receiving the training with a control group of 49 persons not receiving the training. The high rate of personnel turnover, which appears to be rather typical in nursing home facilities, was noted. Following the presentation of the training program, staff members were evaluated by a written knowledge test, and their behavior was observed during the conduct of a drill of the emergency plan.

The evacuation process may be considered in four sequential phases: (1) the personnel supply phase, (2) the patient preparation phase, (3) the patient removal phase, and (4) the rest and recovery phase.[97] This approach focuses on the occupants in the fire-threatened area and the patients in or adjacent to the fire area. Removing immediately threatened patients and closing doors to the room of fire origin and to adjacent patient rooms would be compatible with this four-phase approach to evacuation. A detailed report on the fire evacuation organization, training, and drills involved in a 502-bed acute-care teaching hospital with 2500 employees has been published.[98]

In 1985, NFPA *101* included a new chapter devoted to the fire protection and life safety requirements for board-and-care facilities. That chapter now requires the evaluation and classification of the population of existing facilities according to their evacuation capability.

Evaluating Fire Drill Plans

The ultimate evaluation of fire drill and emergency plans has two factors: (1) performance of the occupants in a fire, and (2) effectiveness of the behaviors used in accordance with the fire drills or the fire emergency plan. In a World Trade Center fire incident report,[21] building occupants tended to seek verification of their beliefs about the threat of fire by physical clues, primarily smoke in the occupants' area. The report also indicated public address messages were not sufficient to alleviate spontaneous evacuations when occupants saw smoke on their floor. Further, occupant evacuation was reported (9th through 22nd floors) due to the perception and concern that a valid fire threat existed. In actuality, the fire did not require such an extensive evacuation.

Successful evacuation of personnel from the two floors above and below a fire in a 28 story high-rise college dormitory has been reported.[99] To allow free evacuation flow of the occupants down the stairways and allow fire department personnel to move up the stairs, stairs have been marked for occupant and fire department movement. The fire department movement stair has a red circle, 6 in. (152 mm) in diameter on the door; it is also utilized for ventilation. The occupant stair is marked with a 6 in. (152 mm) green circle.

In the safe evacuation of 190 guests during a high-rise hotel fire, 110 guests were assisted by the fire department. The success of the evacuation was made possible by the hotel employees' fire safety education and practice of evacuation procedures.[100]

Figure 4.1.20 correlates human response to cues, decision making, and movement as variables of individual behavioral response during fires.

SUMMARY

The Society of Fire Protection Engineers *Human Behavior in Fire, Engineering Guide*[101] summarizes the variables that are related and may be determinants of an individual's behavior in a given fire. Occupant characteristics include not just individual physical, cultural, and psychological characteristics but also other factors of the occupant's primary group relative to the occupational/cultural setting of the fire. The fire environmental impact includes the evaluation of the susceptibility of the occupants to the heat, flames, smoke, and toxic gases created by the fire incident relative to the locations of the fire effects and the occupants within the confines of the building, structure, or at an unconfined fire incident.

Behavior in fires can be understood as a logical attempt to deal with a complex, rapidly changing situation in which minimal information on which to act is available. It is suggested that the goals of codes should be "reoriented to increase the likelihood of informed decisions being made by people in fires."[102] Examination of behavior in the Beverly Hills Supper Club fire led to the recommendation that "fire safety education should consider and be based on people's erroneous conceptions about distance being related to safety, and the time needed to escape from a fire emergency."[103] More than a decade of detailed systematic research on human behavior in fires has resulted in the following consensus[61] on the behavior of most persons:

> Despite the highly stressful environment, people generally respond to emergencies in a "rational," often altruistic manner, insofar as is possible within the constraints imposed on their knowledge, perceptions, and actions by the effects of the fire. In short, "instinctive panic" type reactions are not the norm.

The relationship between the physical and social environment in which behavior occurs is complex. The situation is complicated by the individual's perception of ambiguous fire cues, which is primarily influenced by the person's relevant training and previous fire experience, if any. It must be recognized that fire cues are a product of a rapidly changing dynamic process that is constantly altering the decisions of the building occupant.

This dilemma has been summarized: "What is an appropriate action at one stage may be quite inappropriate a minute later."

Chapter 2

Calculation Methods for Egress Prediction

Rita F. Fahy

Chapter Contents

Components of Evacuation Time
Estimating Evacuation Time
Calculation Methods for Travel Time
Computer Simulation and Modeling of Egress Design

Key Terms

delay time, disabled occupants, egress, evacuation, evacuation time, occupant characteristics, pre-evacuation activity time, reaction time, Station Nightclub fire, time to notification, travel time

The evaluation of an engineered design requires a balanced comparison of predicted fire conditions and realistic evacuation predictions. Over the past decade or so, fire safety engineers have worked with, and developed confidence in, a range of calculation methods for the prediction of fire conditions. Researchers working in the area of human behavior in fire have begun to make real progress in the collection of data necessary for this analysis and in the development of predictive tools that will be comparable to those used to predict the growth and spread of fire and its effects.

Performance building and fire codes allow designers to use innovative building materials and concepts often not encouraged or even permitted in existing prescriptive codes, which can result in more cost-effective and creative designs. But this openness to innovation requires the designer to then demonstrate that the design is safe. For a design to be shown to be "safe," the designer must demonstrate that the time needed to move people to a safe location will be less than the time predicted when fire effects will have a potentially lethal impact on any occupant.

Time available to escape (ASET) > Time needed to escape (RSET)

ASET is defined as the time interval between fire ignition and the time at which conditions become untenable and occupants are unable to move to a location of safety, and RSET is defined as the time period required for an occupant to travel from his or her initial location to a location of safety. The location of safety can be a temporary refuge or can be a location completely free from danger. Fire safety design is a two-sided problem that requires fire safety engineers and the enforcement community to have knowledge in the use of both fire models and egress and human behavior models. Currently, fire safety engineers are very well trained in predicting fire growth and the spread of fire effluents in a structure. The focus of a fire safety design appears to favor this component of the fire safety problem. But it is crucial that the complexity and importance of the egress/behavior component never be underestimated or short-changed and that a balance between both components be maintained.

For their part, building and fire officials (the enforcement community) need to evaluate designs presented in their jurisdictions that will use various computer models or other calculation methods to demonstrate both the time necessary and the time available for occupant evacuation. They may need guidance on how to judge the appropriateness of methods, data, and assumptions used in these evaluations, particularly in the egress portion of analyses.

Members of both user groups must balance the two sets of escape time calculations in order to produce a meaningful result.

See also Section 4, Chapter 1, "Human Behavior and Fire"; and Section 4, Chapter 5, "Strategies for Occupant Evacuation During Emergencies."

Rita F. Fahy, Ph.D., is manager of NFPA's fire databases and systems.

COMPONENTS OF EVACUATION TIME

The *evacuation time* for an individual is the entire span of time that elapses from the ignition of the fire until the occupant emerges from the building or arrives at a location of safety. It consists of four components, all of which must be taken into consideration:

- Time to notification
- Reaction time
- Pre-evacuation activity time
- Travel or movement time

The first three components are often grouped together and referred to as "delay time" or "premovement time."

$$\begin{aligned}\text{Evacuation time} &= \text{Delay time} + \text{Travel time}\\ &= \text{Time to notification} + \text{Reaction time}\\ &\quad + \text{Pre-evacuation activity time}\\ &\quad + \text{Travel time}\end{aligned}$$

It is very important that engineers not underestimate the contribution that delay time can make to total evacuation time. Studies of evacuation drills in apartment buildings have shown that, on average, travel time makes up less than 25 percent of the average total time to evacuate.[1] In office evacuations, however, delay times can be extremely short, and the largest proportion of total evacuation time is accounted for by travel time. Therefore, the selection, estimation, or calculation of premovement times is extremely important to obtain valid results.

Time to Notification

In the evaluation of an engineered building design, evacuation time begins when ignition occurs. Some period of time, the time to notification, will elapse before conditions develop to the point where an alarm sounds or where people begin to sense the cues of the fire itself. The fire cues that reach occupants can be the sight or smell of smoke, heat, the sight of flames, the sound of glass breaking, or the sound of an alarm signal from a smoke alarm, a heat detector, or a sprinkler system. The time to notification can be modeled, or it could be estimated if necessary using expert judgment.

Fire growth and smoke transport models can be used with detector/sprinkler activation models to estimate this period of time. Some models that can be used include ASET,[2] which estimates the temperature and position of the smoke layer in the room of fire origin; DETACT,[3] which models heat detection and sprinkler activation; BREAK1,[4] which estimates time until glass breaks; or FDS (Fire Dynamics Simulator)[5], which predicts the transport of heat and smoke from a fire.*

Reaction Time

Reaction time is the time it takes an occupant to perceive the alarm or fire cue and decide to take action. For example, if a person is asleep when the smoke alarm sounds, it will take some period of time for the person to wake up, to identify the sound as the smoke alarm, and to decide to leave. There is currently no generally accepted modeling technique available for reaction time. The time used in an analysis may depend on observations (data) or expert judgment. An appropriate reaction time will depend on whether the person is awake or asleep, on his or her hearing ability, mental capacity, age (baby/child/adult), and so on. Some findings on sleep inertia in young adults awakened by smoke alarms have been published in recent years.[6] Studies have also looked at the ability of smoke alarms to awaken children and intoxicated adults.[7,8]

Pre-Evacuation Activity Time

Pre-evacuation activity time includes the time that elapses while the occupant is preparing to leave or seek refuge. Pre-evacuation activities involve all of the activities in which an occupant will engage from the time when he or she makes the decision to leave until the time he or she actually starts to travel toward an exit or an area of refuge. These activities may vary by occupancy. For example, hotel occupants might stop to pack their bags before they leave their rooms, whereas office workers may take time to shut off equipment and lock files. In an industrial setting, there may be a procedure that must be followed to safely shut down the plant's operations. To some degree, pre-evacuation activities can be reduced or eliminated through education or training. As with reaction time, there are no generally accepted modeling techniques available for pre-evacuation activity time, and the time used in an analysis may depend on observations (data) or expert judgment.

In reality, reaction time and pre-evacuation activity time are often considered together. In data collection exercises, it is generally not possible to separate the two time components, and the results will be reported as a single, combined time from notification to the time that movement toward the exit begins. Some of the data on pre-evacuation delays that have been obtained from postfire behavior studies and evacuation drills will be presented later in this chapter.

Travel Time

Travel time is the final component in the calculation of evacuation time. It is defined here as the time to move to a location of safety. There are various calculation or estimation techniques available for travel time. Some simple calculation methods can be found in FPEtool,[9] which is available from the National Institute for Standards and Technology (NIST) in the United States. These are based on some of the hand calculation methods described later in this chapter.

ESTIMATING EVACUATION TIME

For evacuation modeling, several types of data are needed, either as model inputs or as considerations for the designer in setting up an analysis of a building design. A major data category that overarches the components of evacuation is occupant factors. Occupant factors include the characteristics of the people who would be expected to populate a building, whether on a perma-

*The mention of these models does not represent or imply an endorsement of the models or the organizations that developed them.

nent or transient basis. These factors include age, agility, commitment to the task at hand, familiarity with the building, level of training in what to do in emergencies, and many others.

More specifically, to calculate evacuation time, data are needed on delay times and travel times for a range of occupancy types. What types of delays should be expected, and how long they may last, is very often a function of the characteristics of the occupants. Likewise, travel times will be impacted by the characteristics of the occupants.

Factors Related to Delay Times

Delay times, also referred to as premovement time, initial response time, or time to start, can last from a few seconds to several minutes or more. It is important to remember that during this period of delay, people might be simply ignoring available cues, or they might be engaged in pre-evacuation activities as discussed earlier. As described previously, delay time includes time to notification, reaction time, and pre-evacuation activity time.

Several factors can result in variations in delay times. These factors, which are also related to the characteristics of the occupants, include the following:

- Effectiveness of different cues
- Effectiveness or training
- Time of day, weather, and so on

Alarm devices use different sounds and, as a result, there can be confusion among building occupants as to what the sound is that they are hearing. And the alarm itself does not give people information as to what actions they should take. When building occupants hear an alarm, will they know if it is a burglar alarm or a fire alarm? Will they know if they should evacuate, or wait for further instructions? Voice communication systems, on the other hand, can convey information to building occupants and can decrease delay times by telling people what the situation is and what they are expected to do and how they should do it.

Training has been shown in studies to decrease delay times.[10] Trained building occupants can be expected to know where the closest exits are, should be able to recognize the alarm signal and know what to do, and could be expected to have shorter delay times. In buildings such as theaters and shopping centers, where the building occupants are not expected to be familiar with the alarms and exits, trained staff can reduce delay times significantly by directing occupants to the nearest exits immediately on hearing an evacuation signal.

Time of day and weather can have an impact on premovement delays. People may be reluctant to leave a building during a storm, in cold weather, or during the night. People may need extra time in winter to dress themselves and small children warmly.

Various characteristics of the occupants can also impact delay times. People with hearing impairments may not hear or interpret the sound of an alarm as quickly as people without impairments. People with mobility impairments may be slower to prepare themselves to evacuate or move to another location in the building. People who are engrossed in an activity may be too preoccupied to hear an alarm or warnings from other occupants, and then may be reluctant to leave what they are doing to take any protective actions.

Available Data on Delay Times

There are two principal sources of data on delay times: postfire survey questionnaires and videotaped observations from drills. Each method of data collection has its own advantages and disadvantages. Postfire survey questionnaires provide a method to collect information from real fires. However, it is very difficult for people to accurately estimate timelines for events in the past, particularly for traumatic events. Another problem is the subjectivity of the observations. For example, when people are asked to describe the thickness of smoke they traveled through or the duration of events, there is often a wide disparity in the descriptions among people who were in the same space at the same time. Videotaped observations allow the collection of very precise timelines, occupant densities, and travel flows in corridors and through doorways; however, the building occupants are not operating under any threat, and it is not clear to what degree observations from a fire drill will provide a good estimate of delay times or travel speeds in real fires. A third alternative method that has been mentioned recently is the use of video recordings from security cameras operating during a fire incident. Although the existence of such recordings has been mentioned, no data from the tapes have been reported yet in the literature. Some news footage of fires and evacuations in progress has been recorded in recent years. Examples include the Station Nightclub fire in Rhode Island in 2003 and the football stadium fire in Bradford (UK) in 1985.

Until behavioral models exist that can accurately predict the activities and behaviors of occupants before they begin to leave a building, it will be necessary for a designer evaluating an engineered design to provide an estimate of the duration of time those activities will require. Although a database of "accepted values" does not yet exist, there are summaries of delay times observed in several evacuation drills and actual fires available in the literature.[11]

One such summary report is based on five case studies that involved two sets of evacuation drills in apartment buildings, one set of office building drills, an actual apartment building fire and a fire in a megastructure complex.[12] The five case studies were part of an ongoing data collection project on human behavior in fire conducted at the National Research Council of Canada. These studies uncovered a broad range in the delay times that can occur and provided an indication of some of the factors that can result in delays. The times observed in these studies cannot be taken at face value as the "correct" times a designer should use, but they do provide an indication of the range of times that exists in real-life situations.

The main factor influencing delay times in the evacuation drills was the audibility of the alarm system. The evacuation drills in apartment buildings took place during two research projects and involved seven mid- and high-rise buildings. In the two mid-rise apartment buildings where the performance of the alarm systems was described as "good," the average time for occupants to begin evacuation was 2.82 minutes. For the two mid-rise apartment buildings with alarm system performance

described as "bad," the average delay time increased to 8.92 minutes.

Alarm system performance in two of the high-rise apartment buildings was described as "good," but the average delay time in those evacuations was quite different: 2.80 minutes in one and 5.32 minutes in the other. This discrepancy pointed out another factor that can significantly influence delay time—the weather. Since it was snowing at the time of one of the high-rise evacuation drills, the occupants took the time to dress warmly before leaving their apartments, adding approximately 2.50 minutes to the mean delay time. Overall in the apartment drills, the shortest average delay time for a building was 2.50 minutes and the longest was 9.70 minutes. Clearly, then, the delay time selected by a designer in the calculation of total evacuation time can greatly impact the final result and must be chosen with care.

The short delay times observed in the two office building evacuation drills demonstrated the combined effect of "good" alarms, training of occupants, and the use of fire wardens to assist in the evacuation. The delay times in the two drills averaged 0.60 minute and 1.05 minutes.

The activities most frequently reported in postdrill questionnaires were gathering valuables, getting dressed, and notifying others. To these activities, the participants in the residential drills had added: looking in the corridor, finding children, finding pets, and moving to the balcony.

A building designer must be cautious when using delay time data from evacuation drills as input to an evacuation model, as drills might underestimate the amount of time an occupant will delay. Although one might expect that occupants will move more quickly in an actual fire, it often takes longer, while the occupants attempt to sort through ambiguous cues and determine whether or not they really need to act.[13]

The postfire human behavior study provided important evidence that evacuation might take longer in an actual fire than in a drill. The fire started on the fifth floor of a 30 story building at approximately 5:00 a.m. on a winter morning. Six building occupants died in two stairwells while attempting to evacuate. The building occupants who participated in this study filled out questionnaires 2 to 3 weeks after the fire. Because of the time that elapsed between the fire and the survey, the occupants often rounded off the times they reported, but the study still provided important information on the range of time between various activities and events. Although the respondents in this study reported delays in beginning evacuation that ranged from 0 to 12 hours, close to half of the occupants attempted to leave within the first hour of becoming aware of the fire. And because no one above the fire floor who started evacuating after 5:30 a.m. was able to reach ground level on his or her own, the activities of the occupants in the first hour are of most interest. The average delay time for occupants who started to evacuate in the first hour was 10.50 minutes.

The human behavior study of the megastructure complex involved the explosion and fire that impacted the two 110 story World Trade Center towers in New York City in 1993. Building occupants had been trained, as had the occupants in the office drills mentioned previously, but in this case they were trained to wait on their respective floors for instructions. Since the emergency control center was destroyed in the explosion, the fire alarm system did not sound and no messages were transmitted. Occupants were forced to rely on ambiguous cues to alert them to the incident. Since the explosion was closer to the base on one tower, cues in that tower were somewhat less ambiguous than in the other. The delay times reported for the tower closer to the blast ranged from 0 to 4.08 hours, with a mean time of 11.03 minutes and a median time of 5.00 minutes. For the other tower, the delay times ranged from 0 to 3.08 hours, with a mean time of 25.40 minutes and a median time of 10.00 minutes.

Additional data need to be collected before a database exists that will provide precise estimates suitable for use, directly, in evacuation modeling. This set of studies illustrates, however, the variation that exists among different types of occupancies, between occupancies of the same type, and between drills and actual incidents, as well as the role of alarm effectiveness, training, and weather.

It is important to mention that the delay times described here are mean times. The distribution of delay times shown in Figure 4.2.1 is typical, with most times relatively short, but with a long tail that can stretch to infinity (representing building occupants who never leave the building during the incident). The data in Figure 4.2.1 comes from a fire drill in a one-story department store.[10] A fire safety engineer or building designer must take into consideration the actual distribution of delay times in evaluating an engineered design.

As mentioned earlier, some of the data collected has been summarized in a recent paper that proposed a database of travel speed and delay time data.[11] The delay time data from that paper can be found in Table 4.2.1.[14–25] The studies represented in this table involved hotels, office buildings, department stores, and a training facility. The user is cautioned to refer to the source documents for the full context of the experiments and incidents before applying the data to his or her application; otherwise, important differences between the evacuations that were the source of the data and the design being evaluated will be missed, and the resulting analysis could be completely invalid.

Factors Related to Travel Time

Travel time is a function of travel speed and distance to the exit and will vary among occupants. Evacuation models handle the calculation of travel time in various ways. Some evacuation models require the user to set a travel speed that will apply to all occupants throughout the evacuation, but this method does not take into account the effect of crowdedness, which will slow the travel speed of the occupants and increase their travel and total evacuation time. Another problem is that a uniform travel speed does not take into consideration the differing abilities of the building's occupants.

Travel time is to some degree a function of exit choice, because exit choice will determine travel distance. Buildings can be designed with multiple exits in the hope that people will use the closest exit in an emergency and thereby reduce their evacuation time. It has been shown time and again, however, that people tend to use the exit with which they are familiar, even if there is a closer emergency exit.[26] Without training, or instructions from trained staff, it may not be appropriate to assume that people will take the shortest route out of a building.

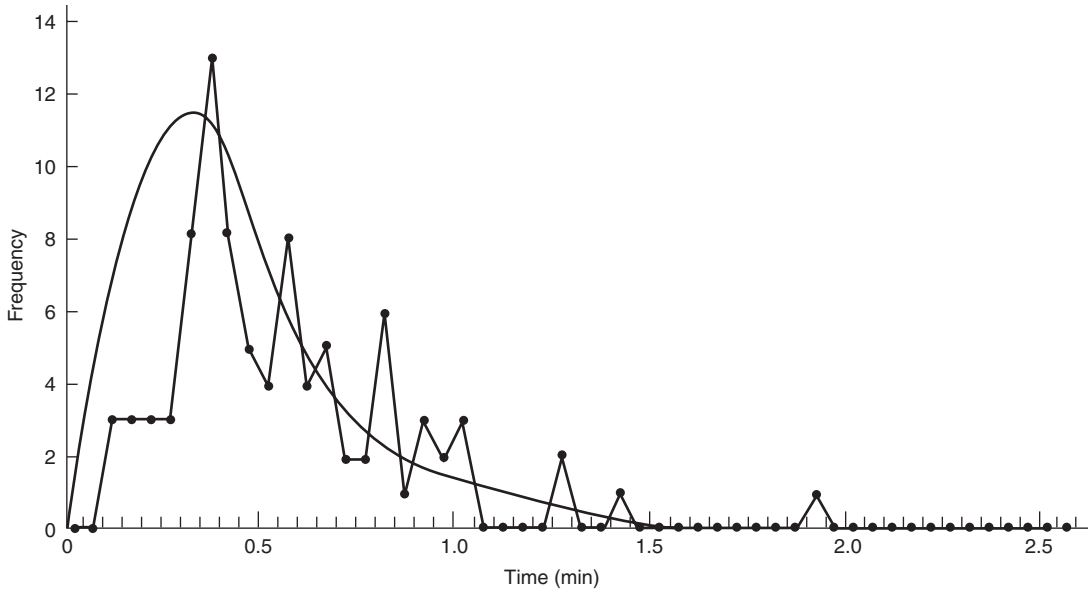

FIGURE 4.2.1 Experimental and Theoretical Premovement Times in a Department Store Evacuation

Other occupant characteristics impact both delays and travel time, but until very recently much of the necessary data to calculate their effects were not available. One important characteristic for which data have not been readily available is mobility, but a series of papers on the characterization of occupants of buildings, with particular emphasis on disabled occupants, was published in 1999. The series of papers covered the following:

- Prevalence, type, and mobility of disabled people
- Capability of disabled people to move horizontally or on an incline
- Capability of disabled people to negotiate doors
- Capability of disabled people to read and locate exit signs

The first paper documents a study that was done in Northern Ireland to estimate the number of disabled people who leave their homes and should be expected to use a variety of public buildings.[27] The study also looked at what percentage of the mobile population consists of the mobility impaired as well as to what degree those who use public places are disabled, concentrating on disabilities that would influence a person's ability to escape a fire. According to this study, almost 8 percent of the total mobile population has a mobility impairment of some sort and 0.14 percent use a wheelchair. The study also looked at the use of public buildings by people with disabilities and found that approximately 40 percent of mobility-impaired adults frequent theaters and sports facilities, almost 60 percent stay in hotels, almost 30 percent are employed, and approximately 50 percent frequent eating and drinking establishments. The paper also presents detail on the frequency of use of public spaces and degree of mobility (whether or not they require assistance). A design team should be able to calculate, using the data presented in the paper, the proportion of building occupants likely to have a mobility impairment. Other types of disabilities that impact the ability to evacuate are also detailed, including dexterity, reaching and stretching, seeing, hearing, and mental abilities.

The second paper in the series provides important data on the travel speed of a mobility-impaired population on horizontal paths, ramps, and stairs, with and without assistance.[28] For those traveling without assistance on horizontal paths, the mean speed for the mobility-impaired group was 2.62 ft/sec (0.80 m/sec), compared to 4.10 ft/sec (1.25 m/sec) for those not mobility impaired. The mean travel speed for the mobility impaired varied by type of aid required, from 1.87 ft/sec (0.57 m/sec) for walker users to 3.12 ft/sec (0.95 m/sec) for those who did not use an aid. Electric wheelchair users had a mean travel speed of 2.92 ft/sec (0.89 m/sec) whereas manual-wheelchair users had a mean speed of 2.26 ft/sec (0.69 m/sec). Travel speed data are also presented in the paper for movement on ramps, up and down stairs, and around corners. Information on the study participants' use of travel paths included observations on the amount of space used by people as they made their way along corridors or on stairs, the use of handrails, and difficulties negotiating stairway landings. An important added consideration covered in this paper is the rest time that many participants required while negotiating the 164 ft (50 m) paths and the recovery time required by those who completed the 164 ft (50 m) distance without stopping.

The third paper in the series looks at the ability of disabled people to use doors.[29] The data in the paper include the percentage of mobility-impaired participants who could not negotiate doors with various closing forces and the time needed to negotiate doors of various closing forces, overall and by type of aid used. The authors conclude in this paper that the travel times predicted for disabled building occupants must include the time needed to negotiate doors.

The fourth and final paper in the series looks at the ability of disabled people to locate and read exit signs.[30] The study

evaluated three types of exit signs—nonilluminated signs, internally illuminated signs, and light emitting diode (LED) signs. The paper presents data on the distances required by those with and without vision disabilities to locate and read exit signs and concludes that LED signs are the most visible and legible. The study did not, however, evaluate the ability of the participants to locate and read signs in the presence of distractions such as contrasting colors and smoke.

When an engineered design is being developed for public assembly properties, the design team must consider the characteristics of a population that accurately reflects the expected user population. This set of papers describes research on disabled groups in Northern Ireland. Whether or not it is reasonable to extrapolate the results to the rest of the world, this research provides data that begin to answer critical questions about the population at risk in public places. A Japanese study of users of two new shopping centers reported similar travel speeds for people with difficulty walking.[31] This study also reported average walking speeds for various other categories of occupants as well as the proportion of building users who reported difficulties in walking and using stairs. The observed walking speeds are shown in Table 4.2.2. Walking speeds were not reported for the small number of people who used wheelchairs or walking aids, who had visual impairments, or who were injured.

Similar data must be collected for the full range of occupancy types. A great deal of data on travel speeds has been collected and reported in the literature for a long time. To put the reported data into the correct context, it is important to note the factors that can result in variations in movement speed. These include crowd density; the mobility, age, and other characteristics of the occupants; the presence of family groups; the presence of smoke; and lighting and other design features. As the density of the crowd increases, the ease and speed of movement decrease until the crowd is moving at a shuffling pace. Family groups will attempt to stay together and will move at the speed of the slowest person. The presence of smoke can slow people down, or it can cause them to change directions or ultimately to stop their evacuation. Low lighting can slow people, particularly on stairs, and the evenness of the exit path and the roughness or smoothness of the walls along the exit path can also impact travel speeds.

Additional data on travel speeds have been summarized in a recent paper.[11] The data collected include the following types of occupancies: transport terminals, apartment buildings, assembly properties, industrial buildings, and hotels. Data for both able-bodied and mobility-impaired subjects are also available. The summary data from that paper are shown in Table 4.2.3.[32–35] Again, the user is cautioned to refer to the source documents for the full context of the experiments and incidents before applying the data to his or her application.

CALCULATION METHODS FOR TRAVEL TIME

Calculating the travel time for an individual alone is a fairly straightforward exercise: travel time will be the product of travel distance and walking speed. Calculating the travel time for a crowd of occupants is more complex. There are three fundamental characteristics of crowd movement: density, speed, and flow. Density of a crowd is defined as the number of persons per unit area (e.g., 2.0 persons/m^2). Density can also be expressed

TABLE 4.2.2 Average Walking Speeds and Standard Deviation for Various Categories of Users of Two Shopping Centers[31]

User Category	*Average Walking Speed (m/sec)*	*Standard Deviation (m/sec)*	*N*
Adult with difficulty walking			
Older adult walking very slowly	0.83	0.20	21
Adult with walking disability	0.78	0.19	8
Pregnant woman	0.79	0.12	4

*This person traveled at this speed for a distance of 4.9 m.

as the area per person (e.g., 0.5 m^2/person). Speed is the time rate of motion of the occupants, usually expressed in meters per second. Flow is the rate at which people pass a particular point, such as a doorway per unit of time (e.g., 2.0 persons/sec). Along with path width, the three characteristics of crowd movement are related as follows:

$$\text{Flow} = \text{Speed} \times \text{Density} \times \text{Width}$$

As mentioned in the previous section, speed is a function of density. The more people there are in a space, the more slowly they move, until eventually they reach the point where they are at a shuffling speed. Flow and density have a more complex relationship. At low densities, the rate of flow is small, as there are few people in the stream. Flow rates again are slow at high densities where there is little movement. Optimal flow is achieved at a density of approximately 2.0 persons/m^2. For details on the derivation of this value, the reader is referred to the *SFPE Handbook of Fire Protection Engineering*.[36]

There are several different approaches to calculating egress time. Flows through doors or corridors can be calculated. Walking speeds can be calculated or can be used as input to models to calculate evacuation time. These methods can be simple enough to do by hand or can be carried out by computer models that may incorporate other behavioral factors.

Empirically Based Evacuation Time Equations

Figure 4.2.2 presents a comparison of observed evacuation times for tall buildings with derived equations for the prediction of total evacuation time.[37–39] Pauls's data[39] are based on measurements obtained from 29 evacuation drills, primarily in office buildings ranging from 8 to 21 stories high. Pauls observed evacuation times varying from approximately 10 sec/story for buildings with small populations to approximately 20 sec/story for buildings with large populations. The evacuation equations

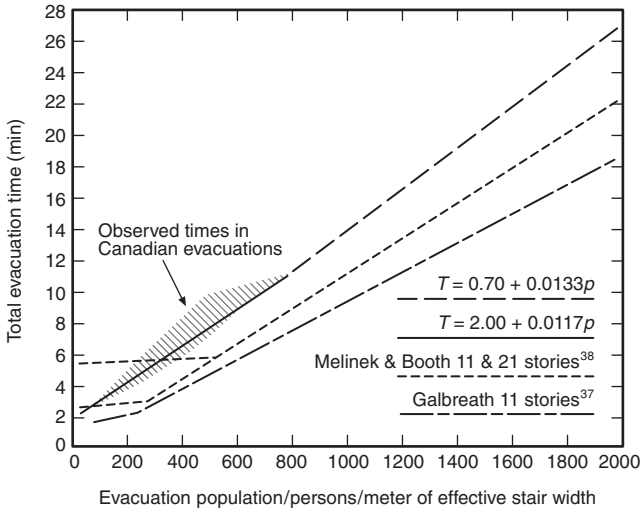

FIGURE 4.2.2 Predicted and Observed Total Evacuation Times for Tall Office Buildings

indicated in Figure 4.2.2 were developed from these observed evacuation times. The first equation,

$$T = 0.70 + 0.0133p$$

is to be applied to predict evacuation times in buildings with large populations exceeding 800 persons/m^2 of effective stair width. T is the minimum time (min) to complete an uncontrolled total evacuation by stairs, and p is the actual evacuation population/m of effective stair width, measured immediately above the discharge level of the stair.

It should be recognized that "effective stair width," as used by Pauls, is defined in the following manner:[39]

> This empirically based model describes flow as a linear function of a stair's effective width—the width remaining once the edge effects are deducted (150 mm or 6 inches from each wall boundary and 90 mm or 3.5 inches from each handrail centerline). It takes into account the propensity of people to sway laterally—especially when walking slowly in a crowd—and therefore to arrange themselves in a staggered traditional unit-width model based on presumed static dimensions of people's shoulders.

The second equation in Figure 4.2.2,

$$T = 2.00 + 0.0117p$$

is to be applied when the population/m of effective stair width is less than 800 persons.

Pauls[39] also examined the relationship between the speed of evacuation and the density on the stairs during the uncontrolled total evacuation, as indicated in Figure 4.2.3. It should be remembered that this movement would be in the vertical, downward direction.

Hydraulic Flow Calculations

The estimation of modeled evacuation time uses a series of expressions that relate data acquired from tests and observations to a hydraulic approximation of human flow.[40] Although the expressions indicate absolute relationships, there is considerable variability in the data. Figure 4.2.2 shows a typical relationship between the source data and the derived equation. The equations and relationships presented in the following paragraphs can be used independently or collectively to solve a complex egress problem. Such a coordinated collection of equations is demonstrated in the sample problem.

Effective Width, W_e. Persons moving through the exit routes of a building maintain a boundary layer clearance from walls and other stationary obstacles they pass. This clearance is needed to accommodate lateral body sway and assure balance.

Discussion of this crowd movement phenomena is found in the works of Pauls,[41] Fruin,[42] and Habicht and Braaksma.[43] The useful (effective) width of an exit path is the clear width of the path less the width of the boundary layers. Figures 4.2.4 and 4.2.5 depict effective width and boundary layer. Table 4.2.4 is a listing of boundary layer widths. The effective width of any portion of an exit route is the clear width of that portion of an exit route less the sum of the boundary layers.

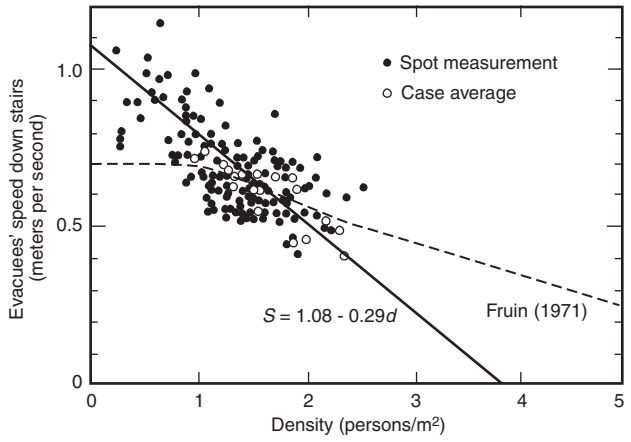

FIGURE 4.2.3 Relation Between Speed and Density on Stairs in Uncontrolled Total Evacuations

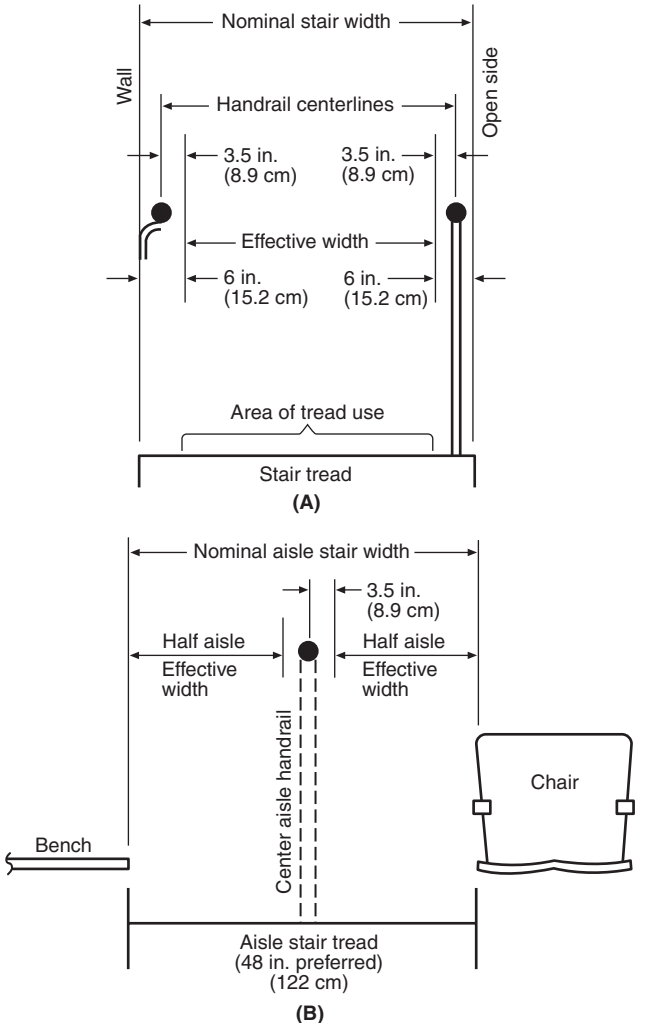

FIGURE 4.2.4 Measurements of Effective Width of Stairs in Relation to Walls, Handrails, and Seating

TABLE 4.2.4 Boundary Layer Widths

Exit Route Element	Boundary Layer *in.*	*cm*
Stairways—walls or side of tread	6.0	15
Railings, handrails*	3.5	9
Theater chairs, stadium benches	0.0	0
Corridor, ramp walls	8.0	20
Obstacles	4.0	10
Wide concourses, passageways	Up to 18	46
Door, archways	6.0	15

*Where handrails are present, use the value if it results in a lesser effective width.

Clear width is measured as follows:

1. From wall to wall in corridors or hallways
2. As the width of the treads in stairways
3. As the actual passage width of a door in its open position
4. As the space between the seats along the aisles of assembly arrangement
5. As the space between the most intruding portions of the seats (when unoccupied) in a row of seats in an assembly arrangement

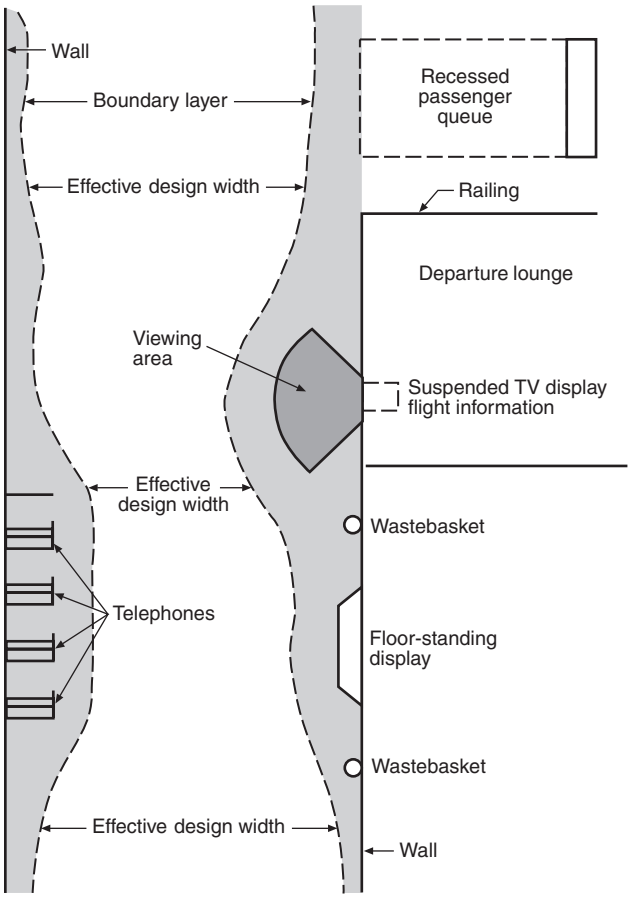

FIGURE 4.2.5 Public Corridor Effective Width

The intrusion of handrails is considered by comparing the effective width without the handrails and the effective width using a clear width from the edge of the handrail. The smaller of the two effective widths then applies. Using the values in Table 4.2.4, only handrails that protrude more than 2.5 in. (6 cm) need to be considered. Minor midbody height or lower intrusions such as panic hardware are treated in the same manner as handrails. Where an exit route becomes either wider or narrower, only that portion of the route has the appropriate greater or lesser clear width.

Density, *D*. Density is the measurement of the degree of crowding in an evacuation route and is usually expressed in persons/unit area. The calculations in this chapter are based on density expressed in persons/ft^2 (or persons/m^2).

Unless information on the dispersion of occupants indicates otherwise, the density of the first exit element (aisle, corridor, ramp, etc.) is based on all of the served occupants. This calculation will demonstrate the capacity limits of the route element and produce a value representing the maximum capacity of the element.

However, if the egressing population is widely dispersed, in terms of reaching the exit route element, the calculation is based on an appropriate time step. At each time increment, the density of the exit route is based on those who have entered the route minus those who have passed from it.

The density factors in subsequent portions of the egress system are determined by calculation. The calculation methods involved are contained in the section on transitions.

Speed of Exiting Individuals, *S*. The evacuation speed of a group is a function of the population density. The relationships presented in this section have been derived from Fruin,[42] Pauls,[41] and Predtechenskii and Milinskii.[44]

If the population density is less than about 0.05 person/ft^2 (0.54 person/m^2) of exit route (20 ft^2/person [1.85 m^2/person]), individuals will move at their own pace, independent of the speed of others. If the population density exceeds about 0.35 person/ft^2 (3.8 persons/m^2), no movement will take place until enough of the crowd has passed from the crowded area to reduce the density.

Between the density limits of 0.05 and 0.35 person/ft^2 (0.54 and 3.8 persons/m^2), the relationship between speed and density can be considered as a linear function. The equation of this function is

$$S = k - akD \tag{1}$$

where

S = Speed along the line of travel

D = Density (persons/unit area)

k = Constant, as shown in Table 4.2.5, where
- $k = k_1$ and $a = 2.86$ when calculating speed in feet per minute and density in persons per square foot
- $k = k_2$ and $a = 0.266$ when calculating speed in meters per second and density in persons per square meter

TABLE 4.2.5 Constants for Equation 2, Evacuation Speed

Exit Route Element		k_1	k_s
Corridor, Aisle, Ramp, Doorway		275	1.40

7.5	10	196	1.00
7.0	11	212	1.08
6.5	12	229	1.16
6.5	13	242	1.23

Note: 1 in. = 25.4 mm.

Table 4.2.5 shows evacuation speed constants.

Figure 4.2.6 is a graphic representation of the relationship between speed and density. The speeds determined from Equation 2 are along the line of movement; for stairs this is along the line of the treads. Table 4.2.6 provides convenient multipliers for converting vertical rise of a stairway to a distance along the line of movement. The travel on landings must be added to the values derived from Table 4.2.6. The maximum speed occurs when the density is less than 0.05 person/ft^2 (0.54 person/m^2). These maximum speeds are listed in Table 4.2.7.

Within the range listed in Tables 4.2.5 through 4.2.7, the evacuation speed on stairs varies approximately as the square root of the ratio of tread width to tread height. There are not sufficient data to appraise the likelihood that this relationship holds outside this range.

Specific Flow, F_s. Specific flow, F_s, is the flow of evacuating persons past a point in the exit route/unit of time/unit of effective width, W_e, of the route involved. Specific flow is expressed

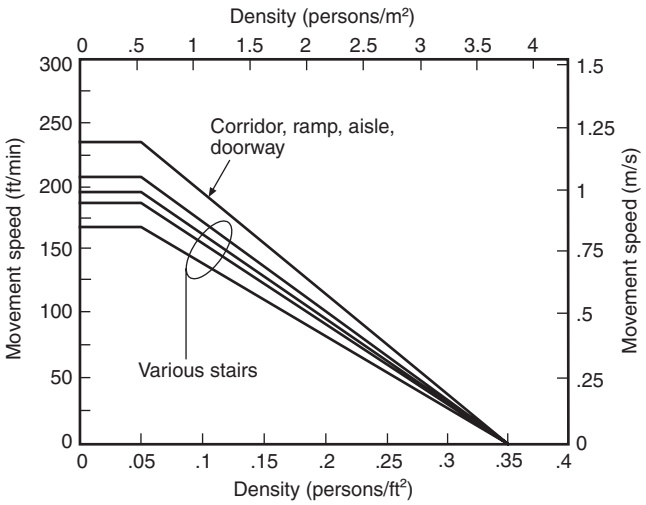

FIGURE 4.2.6 Evacuation Speed as a Function of Density. $S = k - akD$, where D = density is persons/ft^2 and k is given in Table 4.2.5. Note that speed is along line of travel.

TABLE 4.2.6 Conversion Factors for Relating Line of Travel Distance to Vertical Travel for Various Stair Configurations

Stairs Riser (in. [mm])	*Tread (in. [mm])*	*Conversion Factor*
7.5 (190)	10.0 (254)	1.66
7.0 (178)	11.0 (279)	1.85
6.5 (165)	12.0 (305)	2.08
6.5 (165)	13.0 (330)	2.22

in persons/min/ft of effective width (if the value of $k = k_2$, from Table 4.2.5) or persons/sec/m of effective width (if the value of $k = k_2$, from Table 4.2.5). The equation for specific flow is

$$F_s = SD \tag{2}$$

where

F_s = Specific flow

D = Density

S = Speed of movement

F_s is in persons/min/ft^2 when density is in persons/ft^2 and speed is in ft/min; F_s is in persons/sec/m^2 when density is in persons/m^2 and speed is in m/sec.

Combining Equations 1 and 2 produces

$$F_s = (1 - aD)kD \tag{3}$$

where k is as listed in Table 4.2.5.

The relationship of specific flow to density is shown in Figure 4.2.7. In each case the maximum specific flow occurs when the density is 0.175 person/ft^2 (1.9 persons/m^2) of exit route space. Maximum specific flows are associated with each type of exit route element; these are listed in Table 4.2.8.

Calculated Flow, F_c. The calculated flow, F_c, is the predicted flow rate of persons passing a particular point in an exit route.

The equation for actual flow is

$$F_c = F_s W_e \tag{4}$$

TABLE 4.2.7 Maximum (Unimpeded) Exit Flow Speeds

7.0 (178)	11 (279)	187	0.95
6.5 (165)	12 (305)	196	1.00
6.5 (165)	13 (330)	207	1.05

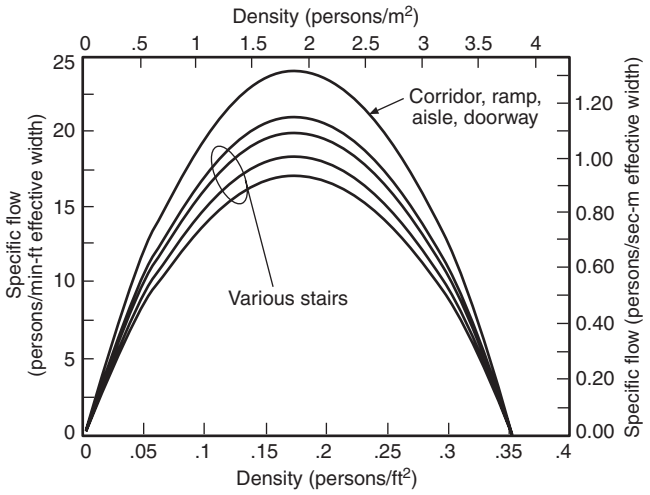

FIGURE 4.2.7 Specific Flow as a Function of Density

where

F_c = Calculated flow

F_s = Specific flow

W_e = Effective width

Combining Equations 3 and 4 produces

$$F_c = (1 - aD)kDW_e \tag{5}$$

F_c is in persons/min when $k = k_1$ (from Table 4.2.5), D is in persons/ft^2, and W_e in ft.

F_c is in persons/sec when $k = k_2$ (from Table 4.2.5), D is in persons/m^2, and W_e in m.

Time for Passage, T_p. Time for passage, T_p, that is, time for a group of persons to pass a point in an exit route, can be expressed as

$$T_p = P/F_c \tag{6}$$

TABLE 4.2.8 Maximum Specific Flow, F_{sm}

Exit Route Element	Maximum Specific Flow: *Persons/ min/ft of Effective Width*	Maximum Specific Flow: *Persons/ sec/m of Effective Width*

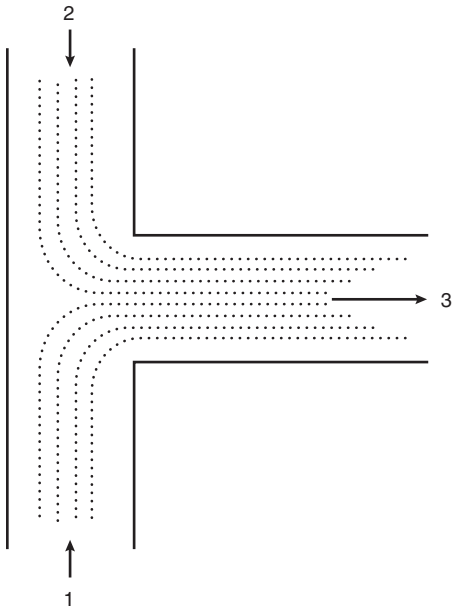

FIGURE 4.2.8 Merging Egress Flows

where T_p is time for passage (T_p is in minutes where F_c is persons/min; T_p is in seconds where F_c is persons/sec). P is population in persons.

Combining Equations 5 and 6 yields

$$T_p = P/(1 - aD)kDW_e \tag{7}$$

Transitions. Transitions are any point in the exit system where the character or dimension of a route changes or where routes merge. Typical examples of points of transition include the following:

1. *The point where two or more exit flows merge.* For example, the meeting of the flow from a cross aisle into a main aisle that serves other sources of exiting population. It is also the point of entrance into a stairway serving other floors (Figure 4.2.8).
2. *The point where a corridor enters a stairway.* There are actually two transitions: one occurs as the egress flow passes through the doorway; the other as the flow leaves the doorway and proceeds onto the stairs.
3. *Any point where an exit route becomes wider or narrower.* For example, a corridor may be narrowed for a short distance by an intruding service counter or similar element. The calculated density, D, and specific flow, F_s, differ before reaching, while passing, and after passing the intrusion (Figure 4.2.9).

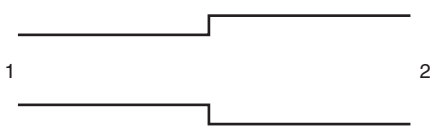

FIGURE 4.2.9 Transition in Egress Component

The following rules apply to determining the densities and flow rates following the passage of a transition point:

1. The flow after a transition point is a function, within limits, of the flow(s) entering the transition point.
2. The calculated flow, F_c, following a transition point cannot exceed the maximum specific flow, F_{sm}, for the route element involved multiplied by the effective width, W_e, of that element.
3. Within the limits of rule 2, the specific flow, F_s, of the route departing from a transition point is determined by the following equations:
   (a) For cases involving one flow into and one flow out of a transition point:

$$F_{s(\text{out})} = F_{s(\text{in})} W_{e(\text{in})} / W_{e(\text{out})} \tag{8a}$$

   where

$F_{s(\text{out})}$ = Specific flow departing from a transition point

$F_{s(\text{in})}$ = Specific flow arriving at a transition point

$W_{e(\text{in})}$ = Effective width prior to a transition point

$W_{e(\text{out})}$ = Effective width after passing a transition point

   (b) For cases involving two incoming flows and one outflow from a transition point, such as that which occurs with the merger of a flow down a stair and the entering flow at a floor:

$$F_{s(\text{out})} = \{\lfloor F_{s(\text{in})\text{-}1} W_{e(\text{in})\text{-}1} \rfloor + \lfloor F_{s(\text{in})\text{-}1} W_{e(\text{in})\text{-}2} \rfloor\} / W_{e(\text{out})} \tag{8b}$$

   where the subscripts (in-1) and (in-2) indicate the values for the two incoming flows.
   (c) For cases involving other merger geometries, the following general relationship applies:

$$\lfloor F_{s(\text{in-}1)} W_{e(\text{in-}1)} \rfloor + \cdots + \lfloor F_{s(\text{in-}n)} W_{e(\text{in-}n)} \rfloor = \lfloor F_{s(\text{out-}1)} W_{e(\text{out-}1)} \rfloor + \cdots + \lfloor F_{s(\text{out-}n)} W_{e(\text{out-}n)} \rfloor \tag{8c}$$

   where the letter n in the subscripts (in-n) and (out-n) is a number equal to the total number of routes entering (in-n) or leaving (out-n) the transition point.
4. Where the calculated specific flow, F_s, for the route(s) leaving a transition point, as derived from the equations in rule 3, exceeds the maximum specific flow, F_{sm}, a queue will form at the incoming side of the transition point. The number of persons in the queue will grow at a rate equal to the calculated flow, F_c, in the arriving route minus the calculated flow leaving the route through the transition point.
5. Where the calculated outgoing specific flow, $F_{s(\text{out})}$, is less than the maximum specific flow, F_{sm}, for that route(s), there is no way to predetermine how the incoming routes will merge. The routes may share access through the transition point equally, or there may be total dominance of one route over the other. For conservative calculations, assume that the route of interest is dominated by the other route(s). If all routes are of concern, it is necessary to conduct a series of calculations to establish the bounds on each route under each condition of dominance.

EXAMPLE: This example uses stairs of U.S. conventional size and is therefore presented in English units. Consider an office building (Figure 4.2.10) with the following features:

1. There are nine floors, 300 ft × 80 ft.
2. Floor-to-floor height is 12 ft.
3. There are two stairways, located at ends of building (no dead ends).
4. Each stair is 44 in. wide (tread width) with handrails protruding 2.5 in.
5. Stair risers are 7 in. wide; treads are 11 in. high.
6. There are two 4 ft × 8 ft landings per floor of stairway travel.
7. There is one 36 in. clear width door at each stairway entrance and exit.
8. The first floor does not exit through stairways.
9. Each floor has a single 8-ft-wide corridor extending the full length of each floor. Corridors terminate at stairway entrance doors.
10. There is a population of 300 persons/floor.

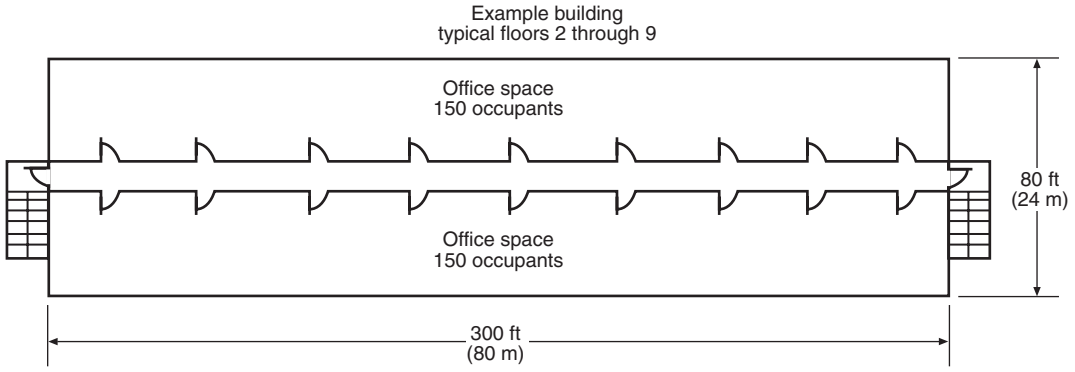

FIGURE 4.2.10 Floor Plan for Example

SOLUTION A—FIRST-ORDER APPROXIMATION

1. *Assumptions.* The prime controlling factor will be either the stairways or the door discharging from them. Queuing will occur; therefore, the specific flow, F_s, will be the maximum specific flow, F_{sm}. All occupants start egress at the same time. The population will use all facilities in the optimum balance.
2. *Estimate flow capability of a stairway.* From Table 4.2.4, the effective width, W_e, of each stairway is 44 – 12 in. = 32 in. (2.66 ft). Also, the effective width, W_e, of each door is 36 – 12 = 24 in. (2 ft). The maximum specific flow, F_{sm}, for the stairway (from Table 4.2.8) is 18.5 persons/min/ft effective width. Specific flow, F_s, equals maximum specific flow, F_{sm}. Therefore, using Equation 4, the flow from each stairway is limited to 18.5 × 2.66 = 49.2 persons/min.
3. *Estimate flow capacity through a door.* Again from Table 4.2.8, the maximum specific flow through any 36 in. door is 24 persons/min/ft effective width. Therefore, using Equation 4, the flow through any door is limited to 24 × 2 = 48 persons/min. Since the flow capacity of the doors is less than the flow capacity of the stairway served, the flow is controlled by the stairway exit doors (48 persons/stairway exit door/min).
4. *Estimate the speed of movement for estimated stairway flow.* From Equation 1, the speed of movement down the stairs is 212 – (2.86 × 212 × 0.175) = 105 ft/min. The travel distance between floors (using the conversion factor from Table 4.2.6) is 12 × 1.85 = 22.2 ft on the stair slope plus 8 ft travel on each of the two landings, for a total floor-to-floor travel distance of 22.2 + (2 × 8) = 38.2 ft. The travel time for a person moving with the flow is 38.2/105 = 0.36 min/floor.
5. *Estimate building evacuation time.* If all of the occupants in the building start evacuation at the same time, each stairway can discharge 48 persons/min. The population of 2400 persons above the first floor will require approximately 25 minutes to pass through the exit. An additional 0.36 minute travel time is required for the movement from the second floor to the exit. The total minimum evacuation time for the 2400 persons located on floors 2 through 9 is estimated at 25.4 minutes.

SOLUTION B—MORE DETAILED ANALYSIS

1. *Assumptions.* The population will use all exit facilities in the optimum balance; all occupants start egress at the same time.
2. *Estimate flow density, D, speed, S, specific flow, F_s, effective width, W_e, and initial calculated flow, F_c, typical for each floor.* Divide each floor in half to produce two exit calculation zones, each 150 ft long. Determine the density, *D,* and speed, *S,* if all occupants try to move through the corridor at the same time, that is, 150 persons moving through 150 ft of an 8-ft-wide corridor.

$$\text{Density, } D = 150 \text{ persons}/1200 \text{ ft}^2 \text{ corridor area} = 0.125 \text{ person/ft}^2$$

From Equation 1, speed, $S = k - akD$.

From Table 4.2.5, $k = 275$.

$$S = 275 - (2.86 \times 275 \times 0.125) = 177 \text{ ft/min}$$

From Equation 3, specific flow, $F_s = (1 - aD)kD$.

$$F_s = [1 - (2.86 \times 0.125)] \times 275 \times 0.125 = 22 \text{ persons/ft effective width/min}$$

From Table 4.2.8, the specific flow, F_s, is less than the maximum specific flow, F_{sm1}; therefore, F_s is used for the calculation of calculated flow.

From Table 4.2.4, the effective width of the corridor is 8 – (2 × 0.5) = 7 ft.

From Equation 5, calculated flow, $F_c = (1 - aD)kDW$

$$F_c = [1 - (2.86 \times 0.125)] \times 275 \times 0.125 \times 7 = 154 \text{ persons/min}$$

Note: At this stage in the calculation, calculated flow, F_c, is termed "initial calculated flow" for the exit route element (i.e., corridors) being evaluated because the calculated flow rate can be sustained only if the discharge (transition point) from the route can also accommodate the indicated flow rate.

3. *Estimate impact of stairway entry doors on exit flow.* Each door has a 36 in. clear width. From Table 4.2.4, effective width, W_e, is 36 – 12 = 24 in. (2 ft).

From Table 4.2.8, the maximum specific flow, F_{sm}, is 24 persons/min/ft effective width.

From Equation 8,

$$F_{s(\text{door})} = [F_{s(\text{corridor})}W_{e(\text{corridor})}]/W_{e(\text{door})}F_{s(\text{door})} = (22 \times 7)/2 = 77 \text{ persons/min/ft effective width}$$

Since F_{sm} is less than the calculated F_s, the value of F_{sm} is used. Therefore, the effective value for specific flow is 24.

From Equation 4 the initial calculated flow is $F_c = F_sW_e = 24 \times 2 = 48$ persons/min through a 36 in. door.

Since F_c for the corridor is 154 whereas F_c for the single exit door is 48, queuing is expected. The calculated rate of queue buildup will be 154 – 48 = 106 persons/min.

4. *Estimate impact of stairway on exit flow.* From Table 4.2.4, effective width, W_e, of the stairway is 44 – 12 = 32 in. (2.66 ft).

From Table 4.2.8, the maximum specific flow, F_{sm}, is 18.5 persons/ft effective width.

From Equation 8, the specific flow for the stairway, $F_{s(\text{stairway})}$, is 24 × 2/2.66 = 18.0 persons/ft effective width. In this case, F_s is less than F_{sm}, and F_s is used.

The value of 18.0 for F_s applies until the flow down the stairway merges with the flow entering from another floor.

Using Figure 4.2.6 or Equation 3 and Table 4.2.5, the density of the initial stairway flow is approximately 0.146 person/ft^2 of stairway exit route.

From Equation 1, the speed of movement during the initial stairway travel is 212 × (2.86 × 212 × 0.146) = 123 ft/min.

From Solution A, the floor-to-floor travel distance is 38.2 ft. The time required for the flow to travel one floor level is 38.2/123 = 0.31 min (19 sec).

Using Equation 4, the calculated flow, F_c, is 18.0 × 2.66 = 48 persons/min.

After 0.31 minute, 48 × 0.31 = 15 persons will be in the stairway from each floor feeding to it. If floors 2 through 9 exit all at once, there will be 15 × 8 = 120 persons in the stairway. After this time, the merging of flows between the flow in the stairway and the incoming flows at stairway entrances will control the rate of movement.

5. *Estimate impact of merger of stairway flow and stairway entry flow on exit flow.* From Equation 9, $F_{s\,(\text{out-stairway})} = \{[F_{s\,(\text{door})} \times W_{e\,(\text{door})}] + [F_{s\,(\text{in-stairway})} \times W_{e\,(\text{in-stairway})}]\}/W_{e\,(\text{out-stairway})} = [(24 \times 2) + (18 \times 2.66)]/66 = 36$ persons/ft effective width

   From Table 4.2.8, F_{sm} for the stairway is 18.5 persons/min/ft effective width. Since F_{sm} is less than the calculated F_s, the value of F_{sm} is used.

6. *Track egress flow.* Assume all persons start to evacuate at time zero. Initial flow speed is 177 ft/min. Assume that congested flow will reach the stairway in 30 seconds. At 30 seconds, flow starts through stairway doors. F_c through doors is 48 persons/min for the next 19 seconds. At 49 seconds, 120 persons are in each stairway, and 135 are waiting in a queue at each stairway entrance door.

   Note: Progress from this point on depends on which floors take dominance in entering the stairways. Any sequence of entry may occur. To set a boundary, this example estimates the result of a situation where dominance proceeds from the highest to the lowest floor.

   The remaining 135 persons waiting at each stairway entrance on the 9th floor enter through the door at the rate of 48 persons/min. The rate of flow through the stair is regulated by the 48 persons/min rate of flow of the discharge exit doors. The descent rate of the flow is 19 sec/floor.

   Thus,

at 218 sec (3.6 min)	All persons have evacuated the 9th floor.
at 237 sec (4.0 min)	The end of the flow reaches the 8th floor.
at 401 sec (6.7 min)	All persons have evacuated the 8th floor.
at 420 sec (7.0 min)	The end of the flow reaches the 7th floor.
at 584 sec (9.7 min)	All persons have evacuated the 7th floor.
at 603 sec (10.1 min)	The end of the flow reaches the 6th floor.
at 767 sec (12.8 min)	All persons have evacuated the 6th floor.
at 786 sec (13.1 min)	The end of the flow reaches the 5th floor.
at 950 sec (15.8 min)	All persons have evacuated the 5th floor.
at 969 sec (16.2 min)	The end of the flow reaches the 4th floor.
at 1133 sec (18.9 min)	All persons have evacuated the 4th floor.
at 1152 sec (19.2 min)	The end of the flow reaches the 3rd floor.
at 1316 sec (21.9 min)	All persons have evacuated the 3rd floor.
at 1335 sec (22.3 min)	The end of the flow reaches the 2nd floor.
at 1499 sec (25.0 min)	All persons have evacuated the 2nd floor.
at 1518 sec (25.3 min)	All persons have evacuated the building.

COMPUTER SIMULATION AND MODELING OF EGRESS DESIGN

Simulation modeling may be appropriate for problems that would otherwise require costly, time-consuming, and tedious manual effort; those that cannot be solved through experimentation because of high costs or unacceptable risks to human participants; and for which past experience, intuition, or available data do not provide the proper insight.[45]

Types of Evacuation Models

Three types of evacuation models are currently available:

- Single-parameter estimation models
- Movement models
- Behavioral simulation models

Single-Parameter Estimation Models. Single-parameter estimation models are generally used for simple estimates of movement times. They can be hand calculations or simple computer models (e.g., flow times based on widths of exit paths or travel times based on distances).

Movement Models. Movement models generally handle large numbers of people in a network flow. This type of model, often referred to as a hydraulic model, treats occupants like water in a pipe or ball bearings in a chute. They tend to optimize occupant behavior, with all occupants moving at the same speed, with perfect knowledge of the building's layout and exit routes. These models often do not include any delay times before occupants begin evacuation. Such models can be useful in benchmarking designs; if the calculated overall evacuation times using this type of model are insufficient for safe evacuation, then the actual evacuation time in a real fire will certainly be insufficient.

Behavioral Simulation Models. Behavioral simulation models consider more of the variables related to occupant movement and behavior. They treat occupants as individuals with unique characteristics. Occupants can move at different speeds in reaction to the conditions in their surroundings. Because they are tracked individually, their exposure and reaction to toxic conditions while evacuating can be estimated by some of these models or by tenability or toxicity models that analyze the

simulation results. This type of model allows a more realistic simulation, but there are concerns with their use related to the lack of available data that would allow the prediction of human behavior in fire. In choosing a model, the user has to understand the underlying assumptions and be sure that those assumptions are appropriate to the analysis at hand.

Computer simulation and modeling have become important tools in designing adequate means of egress under a variety of occupancy and structural conditions. Evacuation modeling has become particularly important in recent years since standards-making organizations around the world have developed performance-based options for fire protection design. The evaluation of an engineered design requires, for a range of fire scenarios, a comparison of the fire effects predicted for each scenario with the results of an evacuation model that will predict where and for how long people will be dispersed throughout a structure. The occupants' potential exposure to the effects of a fire will determine whether or not a design is acceptable.

History of Evacuation Modeling

Evacuation modeling has a long history. In one study of the critical variables for fire safety in relation to buildings used to house the elderly, the problem of fire development and evacuation as a time-structured problem was considered.[46] This study analyzed the variables related to the occurrence and spread of fire relative to the population's ability to reach an area of refuge from the effects of the fire. The study established the variables for the fire on a continuum of a "critical time" and the parameters for the survival of the occupants on a continuum of a "reaction time."

The definition adopted for critical time is the time elapsed from the start of the fire to the attainment of intolerable levels. The definition for reaction time is reported as the amount of time used by the occupant to react to the fire and to achieve safety by evacuating the fire area or by obtaining a place of refuge from the effects of the fire. Thus, within the framework of these definitions, both the parameters of the problem of the human behavior factors involved in a fire in a building and the variables of the problem are considered. This conceptualization of a critical time for fire development within a building and of the reaction time required for occupants to perceive and respond to the fire threat, either by evacuation or movement to an area of refuge, has been studied thoroughly. It resulted in multiple computer models of this essential egress behavior since Caravaty and Haviland's study in 1967.[46]

A computer model that simulated the movement of people during evacuation through the floor of fire origin was developed in the mid-1970s.[47] This Markov-based model focused on the movement of people through a fire floor from the time of alarm until their safe exit or until they became casualties of the fire. Six variables affecting their movement were identified:

1. Objective location of the threatening stimuli in time and space
2. Occupants' prior knowledge of effective egress routes
3. Occupants' perception of the location and severity of the threat
4. Occupants' perception of available alternatives
5. Occupants' threat-reducing experiences prior to the current movement decision
6. The interjection of sudden interpretations to the occupants' goal-directed behavior

A modeling technique was developed in the early 1980s that appeared to have potential for comparing the evacuation behavior of occupants assisted by trained personnel with evacuation without assistance.[48] This model determined the escape potential from an area of a building based on a deterministic approach with a computer algorithm, and it evaluated the effects of fire growth and smoke movement on occupants as they try to egress. Occupant evacuation was simulated with evaluation of the effects of the egress design, the density of the occupants in the means of egress, the congestion at door or other restrictions, and the effects of the combustion products on occupants.

The concepts of critical time and reaction time as originally formulated by Caravaty and Haviland[46] were adapted into a determination of the available safe egress time (ASET) model.[2] This model is a mathematical procedure for simulating the conditions that develop between the time of fire ignition and the onset of untenable conditions for human occupancy. It was developed to evaluate the evacuation plans and procedures within a specific building.[2] This model required input data on the physical dimensions of the building areas, the means of egress, and the specified evacuation routes with the number and location of the occupants. The model provided an estimated average evacuation time and an estimated total evacuation time.

Building network evacuation models similar to the model of O'Leary and Gratz[49] were developed that evaluate the egress environment within the building and the characteristics of the population relative to density and location.[50] The models predicted evacuation flows and times, and identified queuing problems. The model was validated with evacuation data from high-rise federal office buildings and college dormitories.

An analytical queueing network model (QNM) was also developed to be used in the analysis of a building design relative to the suitability of the egress system.[51] This model provided estimates of the evacuation times, the average queue lengths along egress routes, potential impairments, and total egress probability.

The improvement and use of computer models for evacuation analysis in the late 1980s were examined and reviewed by Watts.[52]

During the 1990s, development of evacuation models accelerated. Fahy[53] developed a FORTRAN model called EXIT89 to predict evacuation times for high-rise buildings. This evacuation model was designed to work with two of the subprograms of HAZARD I,[54] FAST, and TENAB to estimate the hazard to the occupants from the modeled fire incident. It calculates the occupants' movement along the shortest evacuation routes or user-defined "familiar" routes and the queuing of the occupants along these routes. The walking speeds in this model are derived from the occupant densities values developed by Predtechenskii and Milinskii.[44] The model has been further developed over the following decade to incorporate a range of real-life features, such as the presence of disabled occupants, premovement delays, choices in exit route selection, counterflows, and so on.[55]

In recent years, improvements in computer technology have allowed a new generation of computer models that take advantage of the power of computers today and the sophistication of newer software tools. Many of these models are analogous to the CFD models of fire development. Rather than using network-node descriptions of a building, these models describe the building space as a mesh, or grid, and use complex spatial analysis and computer-generated route-finding techniques. Rather than jump from node to node, as simulated occupants will appear to do in a network model, occupants will move from "tile" to "tile" in the grid that overlays the floor plan. This allows a more precise location of occupants throughout spaces.

The current generations of models all include the phenomena that EXIT89 sought to address. Some of the new models also include additional phenomena, but there are always tradeoffs between the completeness and detail of the models and the implied magnitude of data requirements. It is not clear that the net predictive power or accuracy is improved if simplified representations requiring limited data with moderate uncertainty are replaced by elaborate, highly sophisticated representations requiring enormous databases with large associated uncertainty and a heavy reliance on subjective estimation to compensate for a lack of field data. In short, the range of choices has expanded greatly over the past several years, but the value of simpler models has not been diminished.

Due to the variation in techniques used for modeling evacuation, it is not possible to present the equations used. For that level of detail, the reader is referred to the documentation for the particular model of interest. And, as the available list of evacuation models grows, it would not be feasible to list the models here. No truly objective comparison has been undertaken of the range of evacuation models currently available, but a brief overview of many of the currently available programs can be found in the literature.[56–59] The degree to which behavior is simulated varies extensively among available models. Care must be taken in choosing a model. The complexity of some models implies a greater predictive capability, but the scarcity of data available on behavior means that a great number of assumptions are embedded in the models, and the appropriateness of those assumptions is critical in evaluating the validity of a model's results.

Chapter 3–14 of the *SFPE Handbook of Fire Protection Engineering,* 3rd edition, "Emergency Movement," includes guidance on the selection of evacuation models. A list of questions the user should be able to answer about the model selected for analysis is provided.

SUMMARY

It is critically important in estimating the time to evacuate a building that attention be paid to more than the travel time necessary to clear spaces. The total time to evacuate a building, or to bring occupants to a location of safety, must include delay times before movement or refuge actions begin. Whether the estimates are based on data or on calculations, and regardless of whether the calculations are done by hand or by computer, a valid total evacuation time estimate cannot be estimated without consideration of time to start. The characteristics of the building occupants and of the building itself will govern the choice of appropriate delay time estimates, as well as the calculation of travel times.

Chapter 3

Concepts of Egress Design

James K. Lathrop

Chapter Contents

Fundamentals of Design
Life Safety Code®
Influences on Egress
Definition of the Term "Means of Egress"
Capacity of Means of Egress
Egress Facilities and Arrangements
Egress Lighting and Exit Signs
Alarm Systems
Emergency Egress and Relocation Drills
Maintenance of the Means of Egress

Key Terms

egress width, exit, exit access, exit discharge, hazard of contents, human factors, *Life Safety Code*®, means of egress, movement of people, NFPA *101*®, *NFPA 5000*®, occupant load

Means of egress and their design should be based on an evaluation of a building's total fire protection system and an analysis of the population characteristics and hazards to the occupants of that building. The means of egress design should be treated as an integral part of the total system that provides reasonable life safety from fire.

This chapter covers the fundamental concepts of good egress design that are the basis for NFPA *101*®, *Life Safety Code*®, and *NFPA 5000*®, *Building Construction and Safety Code*®. NFPA *101* governs good practices to provide life safety features in existing buildings and structures and features that can be designed as integral parts of new construction to provide reasonable safety to occupants in fires. *NFPA 5000* addresses new construction only, but covers life safety from many hazards in addition to fire. The components of good means of egress are discussed in some detail, with their functions and relationships in the total concept of proper egress design. Computer modeling and simulation to assist the egress design process also are discussed.

See also Section 4, Chapter 1, "Human Behavior and Fire"; Section 4, Chapter 2, "Calculation Methods for Egress Prediction"; Section 4, Chapter 5, "Strategies for Occupant Evacuation During Emergencies"; and Section 20, Chapter 1, "Assessing Life Safety in Buildings."

FUNDAMENTALS OF DESIGN

The approach to designing means of egress first requires a familiarity with the reactions of people in fire emergencies. These reactions can differ widely, depending on the physical and mental capabilities and conditions of building occupants. The psychological and physiological factors affecting the use of exits during emergencies are being identified and measured in research studies. Dr. John L. Bryan discusses in detail behavioral response to fire and smoke in Section 4, Chapter 1 of this book.[1]

Patterns of movement of people, singly and in crowded conditions, must also be understood. In buildings used as schools or theaters housing highly mobile occupants, for example, there are certain reproducible flow characteristics from persons exiting the buildings. These predictable flow characteristics have fostered computer simulation and modeling to aid the egress design process. However, no number of practical exit facilities can prevent injury or loss of life if the occupant egress flow is inhibited or prevented by the building itself, by personnel, or by fire and smoke conditions. An in-depth review of movement of people by Proulx can be found in Section 3, Chapter 13 of the *SFPE Handbook of Fire Protection Engineering,*[2] as well as in "Emergency Movement" by Nelson and Mowrer in Section 3, Chapter 14, of the same document.[3]

Human Factors

The design and capacity of doors, passageways, stairways, and other components in the total means of egress are related to the physical dimensions of the human body. The tendency of people to avoid bodily contact with others should be recognized as a major factor in determining the number of

James K. Lathrop, FSFPE, is vice-president of the firm Koffel Associates of Elkridge, Maryland, and Niantic, Connecticut. He is a member of the Technical Committees on Fundamentals, Board and Care Occupancies, Residential Occupancies, and NFPA's *Uniform Fire Code*™. He is also an alternate on the Technical Committee on Furnishings and Contents and the Technical Committee on Fire Tests. He is chair of the Technical Committee on Means of Egress and the Technical Committee on Pyrotechnics.

persons who will occupy a given space at any given time. Given a choice, people usually automatically establish "territories" to avoid bodily contact with others.

Studies have shown that most adult men measure less than 20.7 in. (520 mm) across at the shoulder, with no allowance for additional thicknesses of clothing.[4] A "body ellipse" concept is used to develop the design of pedestrian systems. The major axis of the body ellipse measures 24 in. (609 mm), whereas the minor axis is 18 in. (457 mm). This ellipse equals 2.3 ft^2 (0.21 m^2), which is assumed to help determine the maximum practical standing capacity of a space.

The movement of persons results in a swaying action that varies from male to female and, depending on the type of motion, varies with movement on stairs, on level surfaces, or in dense crowds. Body sway has been observed to range 1½ in. (38 mm) left and right during normal free movement. Where movement is reduced to shuffling in dense crowds and to movement on stairs, a total sway range of almost 4 in. (101 mm) has been observed. In theory, this indicates that a total width of 30 in. (762 mm) would be required to accommodate a single file of pedestrians traveling up or down stairs.[5]

Crowding people into spaces where less than 3 ft^2 (0.28 m^2) of space per person is available under nonemergency conditions may create a hazard. When the average area occupied per person is reduced to 2¾ ft (0.25 m^2) or less, contact will be unavoidable. Needless to say, under the psychological stresses imposed during a fire, such crowding and contact could contribute to crowd pressures, resulting in injuries. When a queue occurs because of an artificial, temporary situation or because of some permanent design feature, crowd control becomes difficult, and the well-being of individuals is threatened.

Factors Affecting Movement of People

There are several factors that determine how quickly people may pass through the means of egress.

In level walkways an average walking speed of 250 ft/min (1.26 m/sec) is attained under free-flow conditions, with 25 ft^2 (2.3 m^2) of space available per person. Speeds below 145 ft/min (0.73 m/sec) show shuffling, which restricts motion. Figure 4.3.1, adapted from *Research Report No. 95* of the London Transport Board,[6] shows the rate of speed reduction for space concentrations of less than 7 ft^2 (0.65 m^2) per person. Speeds of less than 145 ft/min (0.73 m/sec) result in shuffling, and, finally, a jam point is reached with one person every 2 ft^2 (0.18 m^2). The possibility of a significant nonadaptive behavior exists whenever egress movement is restricted, and the problem becomes urgent under fire exposure conditions, especially when there is more than one person every 3 ft^2 (0.28 m^2).

Calculations of flow rates using velocity (ft/min [m/sec]) and density (persons/ft^2 [m^2]) will reveal flow (persons/min/ft [persons/sec/m] of width), which increases as the pedestrian area decreases. The flow increases will continue until forward movement becomes restricted to the point that the flow begins to drop. Interestingly, observations of flow rates in one study noted the same flow rate sometimes occurred even though walking speeds of people were significantly different. Investigation revealed that the rate of decrease in speed, accompanied by an increase in density, results in uniform flow rates over a wide range of conditions.

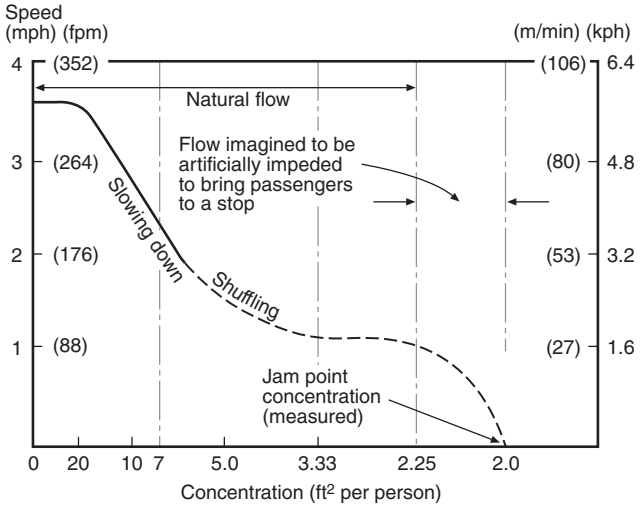

FIGURE 4.3.1 Speed in Level Passageways (SI units: 1 ft/min = 0.305 m/min; 1 ft^2 = 0.093 m^2)

A study of passageways indicates that for passageways over 4 ft (1.2 m) wide, flow rates are directly proportional to width. The London Transport Board *Research Report No. 95*[6] determined the flow rate in level passages to be 27 persons/min/ft (1.5 persons/sec/m) of width. Travel down stairways was determined at 21 persons/min/ft (1.2 persons/sec/m) of width, whereas upward travel was reduced to 19 persons/min/ft (1.1 persons/sec/m) of width. Where the width of a footway is less than 4 ft (1.2 m), the flow rate depends upon the number of possible traffic lanes. Absolute maximum flow rates occur when approximately 3 ft^2 (0.28 m^2) is occupied per person, which is applicable to both level walkways and stairs. In observed and measured evacuations, however, it has been empirically determined that the maximum flow rates down stairs in high-rise buildings occur when from 4 to 5 ft^2 of space (0.37 to 0.46 m^2) is occupied per person, as shown in Figure 4.3.2.[5] When flow in opposite directions takes place in a passageway up to the point where the two flows are of equal magnitude, there is no significant reduction in total flow below that which would be predicted on the basis of unidirectional flow in the same passageway.

Further, flow can be 50 percent greater in short passageways less than 10 ft (3.05 m) long than through a long passageway of the same width. Minor obstructions within a passageway do not appear to have a significant effect on flow. Within a 6-ft (1.82-m) wide passageway, there is no effect on flow rates when a 1 ft (0.35 m) projection is introduced. A 2 ft (0.61 m) projection resulting in a 33 percent reduction in width reduces the flow rate by approximately 10 percent. A major obstruction, though, such as that which occurs at a ticket booth or turnstile, may interrupt the movement of people and reduce flow rates.

Corners, bends, and slight grades up to 6 percent are apparently not factors in determining flow rates. A slight reduction in speed does occur, but the flow rate is maintained by an increased concentration of persons.

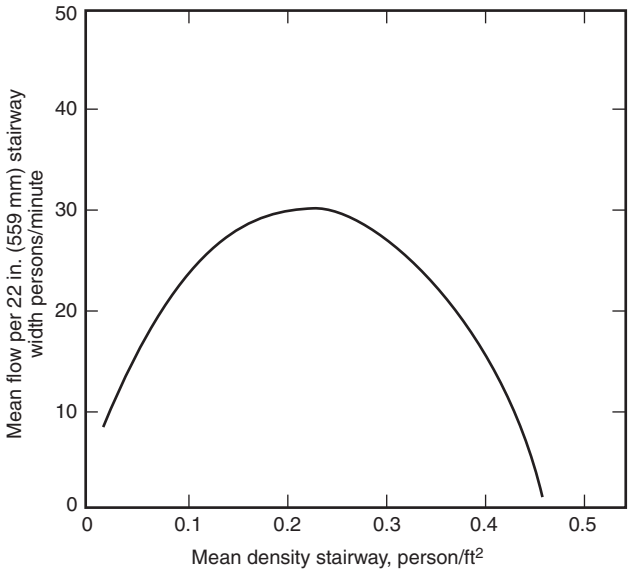

FIGURE 4.3.2 Effect of Density on Flow Down Exit Stairways in Evacuations of High-Rise Office Buildings[5] (SI units: 1 ft^2 = 0.093 m^2)

A center handrail or mullion, which may divide a passageway into narrower sections, can further reduce the capacity of the passageway. The observed capacity of a 6-ft (1.82-m) wide stairway reveals a reduction from 130 to 105 persons/min after installation of a center handrail.

Except for the very young and the very old, age does not appear to be a significant factor in determining travel speed. Studies have shown a significant reduction in walking speeds for persons over 65 years of age. Studies have further revealed that a 40 percent increase is possible in the normal walking speed, which tends to discount this factor as a major influence on flow rates.[4]

For additional information see Section 3, Chapter 13, of the *SFPE Handbook of Fire Protection Engineering*.[2]

Methods of Calculating Egress

Two major principles are used to determine the necessary egress width. They are based on anticipated population characteristics identified with a specific occupancy.

The Flow Method. This method uses the theory of evacuating a building within a specified maximum period of time. Flow rates were traditionally set at 60 persons per 22 in. (559 mm) width/min through level passageways and doorways. In older editions of NFPA *101* this 22 in. (559 mm) width was referred to as 1 "unit" of exit width. Credit was given only for whole or half units, a half unit being 12 in. (0.3 m). The unit of exit width is no longer being used in most model codes. The flow method most commonly used today is based on so much width of an egress element per person served. For example 0.2 in. (0.5 cm) per person for a door or other level egress component is what is used by the *Life Safety Code* and the *International Building Code*. Table 4.3.1 provides the capacity factors used by the *Life Safety Code*.

TABLE 4.3.1 Capacity Factors

	Stairways (Width per Person)		Level Components and Ramps (Width per Person)	
Area	*in.*	*mm*	*in.*	*mm*
Board and care	0.4	10.0	0.2	5
Health care, sprinklered	0.3	7.6	0.2	5
Health care, nonsprinklered	0.6	15.0	0.5	13
High-hazard contents	0.7	18.0	0.4	10
All others	0.3	7.6	0.2	5

Source: Table 7.3.31, NFPA *101*, 2006 edition.

Pauls's[7] effective stair width concept advocates the consideration of only the portion of the stair used in effective movement by the occupants, as observed in functional and practice evacuations. This width is established with 6 in. (150 mm) clearance from each side wall of the stair. Figure 4.3.3 illustrates the flow time in seconds relative to the effective stair width per person and the units of width.

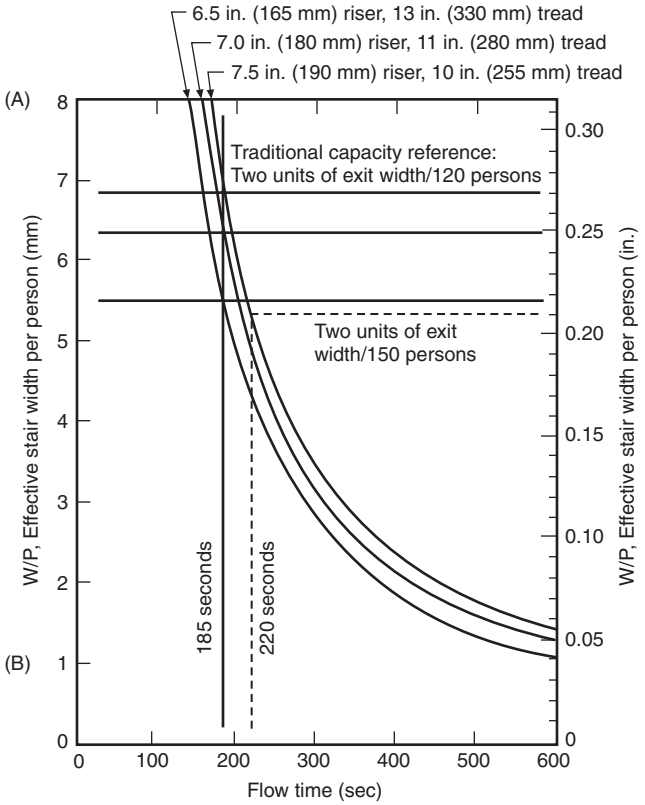

FIGURE 4.3.3 Relationship between Effective Stair Width and Units of Exit Width per Person and Flow Time for Three Stair Geometries[7]

The Capacity Method. This method is based on the theory that sufficient numbers of stairways should be provided in a building to adequately house all occupants of the building without requiring any movement, or flow, out of the stairways. In theory, assuming a stairwell provides a safe and protected area for all occupants within the protective barrier created by the stairway enclosure, evacuation of the building may then be more leisurely, permitting people to travel at a rate within their physical ability. The capacity method recognizes that evacuation from high-rise buildings is physically very demanding. Further, evacuation of a health care facility is likely to be slow. Thus, design criteria are established to permit holding occupants within exits or areas of refuge. The capacity method is not recognized in most model codes. However, codes do recognize areas of refuge. For example, the *Life Safety Code* does mandate that most health care occupancies have smoke compartments into which patients can be moved without having to evacuate the building.

Application

The capacity and flow methods may both be applied to efficient egress design, depending on specific circumstances. Where people are expected to be physically or mentally sick, aged, asleep, or incapacitated in any way, evacuation and use of the flow method can be augmented with the capacity method. Unless using a performance-based design, most model codes do not recognize the use of the capacity method alone.

There is little time between an alert and the use of an exit in assembly occupancies, and maximum flow rates that cause reductions in the area used by each person may result in reduced traffic flows. On the other hand, the staff supervision of children in an educational setting, coupled with their familiarity with the surroundings, their presumed high physical capabilities, and their experience with a program of drills should allow rapid evacuation times. Pauls has reviewed the historical and current literature relative to the principles of people movement, exit width determination, and the design of the means of egress.[8]

Design of Means of Egress

Designing a means of egress involves more than numbers, flow rates, and densities. Safe exit from a building requires a safe path of egress from the fire environment. The path is arranged for ready use in case of emergency and should be sufficient to permit all occupants to reach a safe place before they are endangered by fire, smoke, or heat. Proper egress design permits everyone to leave the fire-endangered areas in the shortest possible time with efficient exit use. If a fire is discovered in its incipient stage and the occupants are alerted promptly, effective evacuation may take place.

Maximum permitted evacuation travel distances are related to the occupant characteristics, occupant alertness, and building fire protection. The less capable people are to move, the less alert they are (such as sleeping), and the less protected a building is (such as no automatic sprinkler protection), the shorter the permissible travel distance.

Depending on the physical environment of the structure, the characteristics of the occupants, and the fire detection and alarm facilities, fire or smoke may prevent the use of one means of egress. Therefore, at least one alternative means of egress remote from the first is essential. Provision of two separate means of egress is a fundamental safeguard, except where a building or room is small and arranged so that a second exit would not provide an appreciable increase in safety. There are fewer or no advantages to separate means of egress if there is travel through a common space or use of common structural features that result in the loss of the two distinct and physically separate means of egress.

One example of a "common" structure is a multistory building where scissors stairs are used. These are two stairs enclosed within a common shaft, separated by a partition common to both stairs. Scissors stairs are sometimes used to provide the required exit capacity while minimizing the loss of valuable floor space. Where a set of scissors stairs is the only means of egress when two remote exits are required, the fundamental principle of two separate means of egress design may be violated. If the common partition between the stairs fails, it would result in the simultaneous loss of both exits during a fire, leaving no alternative means of egress. With scissors stairs, the validity of the two separate means of egress, therefore, depends on the design characteristics and construction of the common partition (Figure 4.3.4).

In some proposed egress designs, all the exits discharge through a single lobby at street level, even though this procedure results in egress travel through a common space. This design philosophy presumes that the lobby may be considered a safe area for all future egress needs during the life of the building. Where two remote means of egress are required, this type of egress design is not permitted by the *Life Safety Code* or by most model building codes.

NFPA *101* limits openings in exit enclosures to those necessary for access to the enclosure from normally occupied spaces and for egress from the enclosure. Penetration of enclosures by ducts or other utilities constitutes a point of weakness and may result in contamination of the enclosure during a fire and should not be permitted. Furthermore, it is not good practice to use exit enclosures for any purpose that could interfere with their value as exits. For example, exit stair enclosures should not be used for storage or any other use not associated with egress or areas of refuge for mobility impaired persons.

Provisions for handicapped persons is an important consideration in the design of an emergency means of egress from a building. A 32 in. (813 mm) doorway is considered the minimum width to accommodate a person in a wheelchair. Since handicapped employees or visitors may be found in all types of buildings, special life safety considerations are indicated. NFPA *101* contains several additional provisions to protect mobility-impaired individuals. It also must be noted that mobility handicaps are not the only type of handicap needing to be addressed. Hearing and sight impairments, along with certain mental disabilities, must be considered.

LIFE SAFETY CODE®

NFPA *101,* introduced in 1927 and revised and reissued in successive editions, is developed by several committees under the

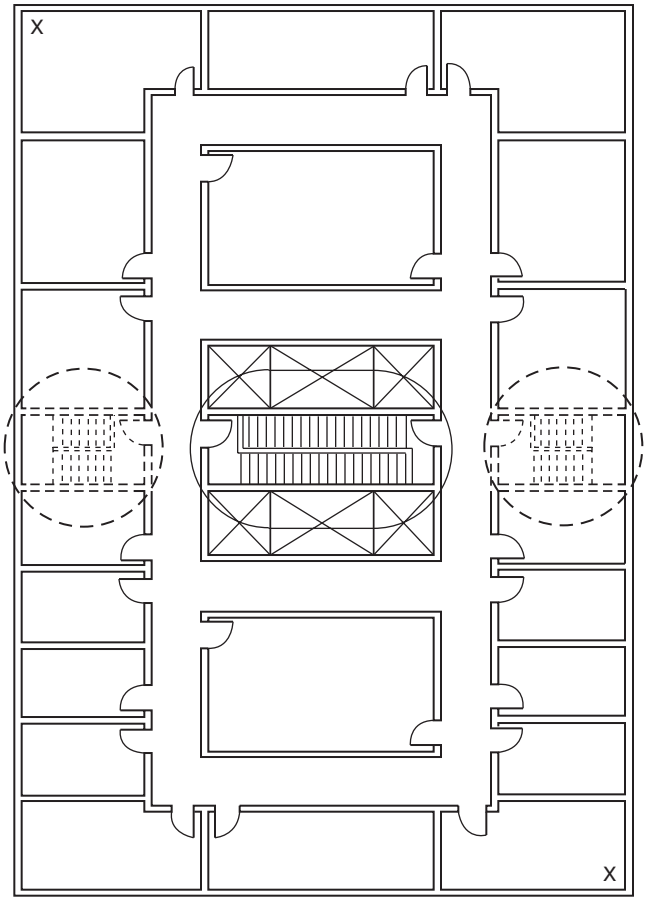

FIGURE 4.3.4 Advantages and Disadvantages of Scissors Stairs versus Conventional Stairs. This set of scissors stairs provides the same degree of remote exit doors as the circled stairs shown by dotted lines—travel distance for all occupants is the same, even if the dotted exit stairs were located at opposite corners as denoted by the cross marks. Space is saved; however, the integrity of the separation of the two scissors stairs is in question.

oversight of the Technical Correlating Committee on Safety to Life, a representative group dedicated to safety of life from fire. NFPA *101* is primarily concerned with the control of conditions that threaten the lives of individuals in building fires. This objective is different from fire protection provisions in building codes, which are concerned with the preservation of property in addition to the preservation of life. In 2000, NFPA announced its intent to write a building code. The first edition of *NFPA 5000®*, *Building Construction and Safety Code®*, was published in 2003. The provisions for means of egress in *NFPA 5000* are written by the same committees that write NFPA *101*. Because of this, the discussion here will address NFPA *101*. It is equally applicable to *NFPA 5000* when dealing with new construction.

Adequate means of egress alone are not a guarantee of life safety from fire. They do not protect an individual whose own carelessness causes a threat to life, such as setting his or her own clothes on fire. Neither do sufficient means of egress alone provide adequate protection in occupancies such as hospitals, nursing homes, prisons, assisted living facilities, and mental institutions, where occupants are confined or are physically or mentally unable to escape without effective and immediate assistance. NFPA *101* does recognize such situations and provides life safety measures, including low-flame-spread and reduced-smoke-producing materials for interior finish. In addition, automatic sprinkler and smoke management systems called for by NFPA *101* are designed to restrict the spread of fire and smoke and thus help to defend the occupants within an area of refuge until they are able to use the exits or until the fire has been extinguished.

In general, saving building occupants from a fire requires the following, all of which are identified in NFPA *101*:

1. Sufficient number of properly designed, unobstructed means of egress of adequate capacity and arrangement
2. Provision of alternative means of egress for use if one means of egress is blocked by fire, heat, or smoke
3. Protection of the means of egress against fire, heat, and smoke during the egress time determined by the occupant load, travel distance, and exit capacity
4. Subdivision of areas by proper construction to provide areas of refuge in those occupancies where total evacuation is not a primary consideration
5. Protection of vertical openings to limit the operation of fire protection equipment to a single floor
6. Provision of detection or alarm systems to alert occupants and notify the fire department in case of fire
7. Adequate illumination of the means of egress
8. Proper marking of the means of egress and the indication of directions
9. Protection of equipment or areas of unusual hazard that could produce a fire capable of endangering the egressing occupants
10. Initiation, organization, and practice of effective drill procedures
11. Provision of instructional materials and verbal alarm systems in high-density and high-life-hazard occupancies to facilitate adaptive behavior
12. Use of interior finish materials that prevent a high flame spread or dense smoke production that could endanger egressing occupants

Figure 4.3.5 illustrates some of the principles of exit safety.

NFPA *101* recognizes that full reliance cannot be placed on any single safeguard, because any single protective feature may not function due to mechanical or human failure. For this reason, redundant safeguards, any one of which will result in a reasonable level of life safety, should be provided. NFPA *101* also recommends the special protection of hazardous areas and specifies where automatic sprinkler, detection, and other protective systems are required.

NFPA *101* is used widely as a guide to good practice and as a basis for local laws or regulations. It differs from building codes since it generally provides little distinction among the different classes of building construction. However, where total

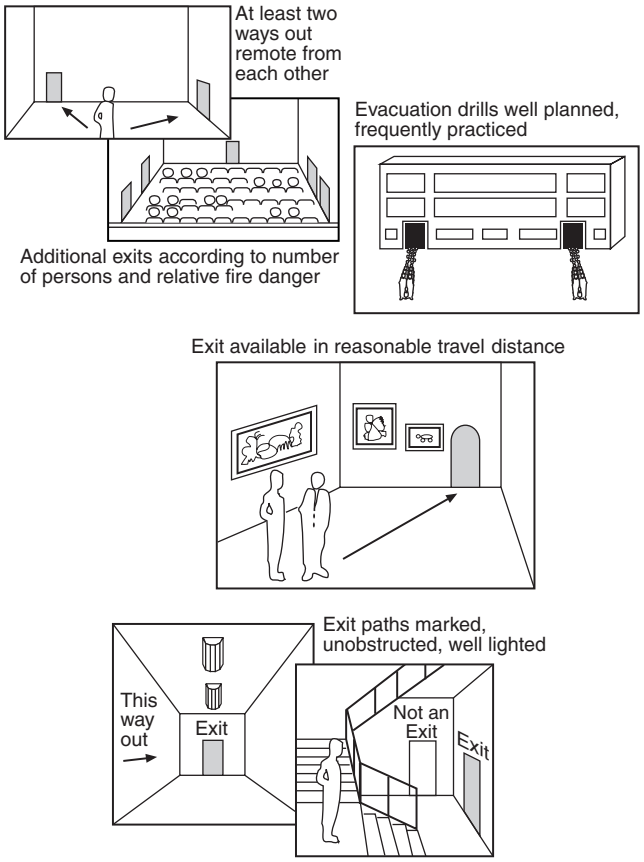

FIGURE 4.3.5 Principles of Exit Safety

evacuation of a building is not practical, due either to the occupant characteristics or the building environment, the construction type becomes an important variable and should be considered.

NFPA *101* also recognizes that all habitable buildings contain sufficient quantities of combustible contents to produce lethal quantities of smoke and heat.[9,10] In addition, casualty studies have established that the toxic properties of smoke are the principal hazard to life,[11] and this hazard is recognized in NFPA *101*.

NFPA *101* is intended to be applied to both new and existing buildings and is designed to provide a reasonable level of life safety from fire in both types of buildings. The authority having jurisdiction is given considerable latitude in achieving conformance with existing buildings. Each existing building represents a special situation that requires individual attention for the most effective and economical method of achieving a reasonable level of life safety.

The claim that buildings constructed many years ago according to all the legal requirements are sufficiently safe now should not necessarily be accepted. If the cost of reasonable life safety is judged to be prohibitive, the occupancy or the structure should be changed or prohibited because there is no justification for subjecting building occupants to an unreasonable level of peril from a fire.

There may be a variety of differing opinions as to what constitutes reasonable life safety from a fire in any given case. It is not possible to guarantee occupants 100 percent life safety from a fire; beyond certain conditions, a building becomes hazardous to the life safety of the occupants in a fire. How should the authority having jurisdiction establish the minimum conditions? NFPA *101* provides guidance for such decisions with the help of studies of major-loss-of-life fires,[12,13] fire development research,[10,14] personnel evacuation,[15–17] and human behavior.[1,18]

NFPA *101* examines the various occupancy populations according to their perceived life safety hazard, which includes psychological and sociological variables in addition to the physiological and environmental factors. These occupancy classifications are assembly, educational, day care, health care, ambulatory health care, detention/correctional, residential, residential board and care, mercantile, business, industrial, and storage. Additional provisions for special-purpose and high-rise structures are also included.

Separate and distinct means of egress provisions are made for each occupancy classification, with the various occupancy subgroups included. These classifications, based on the perceived hazard to life safety from a fire, often differ from older building code occupancy classifications. For example, mercantile and office occupancies were often grouped together in previous editions of building codes. However, there appears to be an increased hazard to life in mercantile properties, resulting from the displays of combustible merchandise, the greater density of the population, and the transient character of most of the occupants. These factors are not usually found in office and educational buildings, which have a relatively low combustibility content, a lower population density, and normally alert occupants who are in the building daily and presumably have the opportunity to familiarize themselves with the means of egress through functional use and evacuation drills.

INFLUENCES ON EGRESS

Influence of Hazard of Contents

An evaluation of the hazard of the building contents must take into account the relative probability of the ignition of combustibles, the spread of flames and heat, the probable smoke and gases expected to be generated by the fire, and the possibility of a fire-related explosion or other structural failure endangering occupants. The degree of hazard is usually determined by the flammability or toxicity of the contents and by the processes or operations conducted in the building. Most NFPA *101* requirements are based on the exposure created by contents with an ordinary hazard. Special requirements for areas with high-hazard contents usually consist of special protection systems, isolation of the hazard area via fire-rated construction, reduced travel distances, and additional means of egress.

To assist in evaluating the contents hazards, NFPA *101* establishes three classifications of contents: (1) low-, (2) ordinary-, and (3) high-hazard. They are discussed next. These should not be confused with the classifications established by NFPA 10, *Standard for Portable Fire Extinguishers,* or NFPA 13, *Standard*

for the Installation of Sprinkler Systems, nor with those established by some model building codes.

Low-Hazard Contents. These are contents of such low combustibility that no self-propagating fire can occur in them. Consequently, the only probable danger requiring the use of emergency exits will be from smoke or from fire from some external source. These are extremely unusual. The storage of sheet metal without combustible packing is one example.

Ordinary-Hazard Contents. These are contents that are liable to burn with moderate rapidity and to give off a considerable volume of smoke. This class includes most buildings and is the basis for the general requirements of NFPA *101*.

High-Hazard Contents. These are contents that are liable to burn with extreme rapidity or from which explosions are to be feared in the event of fire. Examples are occupancies in which flammable liquids or gases are handled, used, or stored; in which combustible dust explosion hazards exist; in which hazardous chemicals or explosives are stored; in which combustible fibers are processed or handled in a manner that produces combustible flyings; and similar situations.

Influence of Building Construction and Design

A building of fire-resistance-rated construction is designed to permit a burnout of contents without structural collapse. Fire-resistance-rated design does not ensure the life safety of the occupants of such buildings.[12,18] However, the ability of a structural frame to maintain building rigidity under fire exposure is important to the maintenance of the fire resistance protection of exit enclosures. Where a 2-hour fire-rated exit enclosure is required, a fire-resistance-rated structural frame capable of withstanding stresses imposed by fire for a similar period is also necessary. It is inconsistent to provide a 2 hour exit enclosure in a building with a structural frame rated at less than 1 hour, for example, unless special construction precautions are taken to prevent structural failure of the building from adversely affecting the protective construction of the exit enclosures.

The protection of vertical openings is one of the most significant factors in the design of multistory buildings, from the standpoint of life safety and exit design. Because of the natural tendency of fire to spread upward in a building, careful attention to details of design and construction are required to minimize this effect. One of the greatest hazards to life safety results from fires that start below the occupants and the means of egress, such as in basements or on the level of exit discharge. Similarly, fires in multistory buildings may result in smoke spread into enclosed exits before evacuation.[12,13,18] Conversely, escape from fires that occur above the occupants is relatively simple, provided sufficient warning is given and adequate means of egress are available.

The influence on the life safety of the occupants by the materials used in building construction depends primarily on whether the materials will propagate flame, support combustion, or create dense amounts of smoke when exposed to a fire initially involving the building contents. Some materials used as insulation, for example, could contribute to rapid flame development and dense smoke production spread. Masonry walls enclosing a wood-frame interior provide no increased occupant life safety compared with a total wood-frame structure.

Exit requirements are based on buildings of conventional design. Unusual buildings, such as those without windows or those with unopenable windows, call for special consideration. Windows provide a number of advantages in a fire. Windows allow occupants to see rescue operations in progress and allow occupants to communicate visually with rescue personnel. They also provide a means of access to the building by fire department personnel for rescue and fire fighting. Operable windows provide the additional advantage of access to fresh air, the potential ability to communicate orally with rescue personnel, and potential use for escape. Although it might be possible to break fixed windows to provide those same advantages, this poses several problems. First, falling glass presents a hazard to fire fighters outside; next, if the broken window permits smoke to enter, it cannot be closed as an operable window can; and last, depending on the type of glass and its thickness the window may be very difficult to break. Automatic sprinklers are considered a primary requirement for life safety in windowless buildings, buildings with unopenable windows, and underground structures.

Influence of Interior Finish, Furnishings, and Decorations

The rapid spread of flame over the surface of walls, ceilings, or floor coverings may prevent occupant use of the means of egress. In general, NFPA *101* limits the flame-spread index classification of interior finish materials on walls and ceilings to a maximum of 200, based on the results of tests conducted in accordance with NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials,* also known as ASTM E84. Lower ratings are prescribed for the interior finish materials used in exits and in exit access corridors. Materials classified as having a lower flame-spread index are also required in certain areas in individual occupancies. A fire-retardant coating may be used on existing interior finish materials to reduce the rate of flame spread. In areas protected with automatic sprinklers, the use of materials with higher flame-spread index classifications sometimes is permitted. Table 4.3.2 summarizes the interior finish requirements contained in NFPA *101* for the various occupancy classifications. NFPA *101* also recognizes NFPA 286, *Standard Methods of Fire Tests for Evaluating Contribution of Wall and Ceiling Interior Finish to Room Fire Growth.* Any material that passes this test, based on the pass-fail criteria contained in NFPA *101,* can be used anywhere in a building.

Floor coverings are evaluated by NFPA *101,* through the use of NFPA 253, *Standard Method of Test for Critical Radiant Flux of Floor Covering Systems Using a Radiant Heat Energy Source,* also known as ASTM E648. Two classes of floor coverings are established: Class I finishes, with a minimum critical radiant flux of 0.45 W/cm^2, and Class II finishes, with a minimum critical radiant flux of 0.22 W/cm^2.

Furnishings and decorations—particularly furnishings—play an increasingly important role in loss of life by fire.

TABLE 4.3.2 Interior Finish Classification Limitations

Occupancy	*Exits*	*Exit Access Corridors*	*Other Spaces*
Assembly—new			
>300 Occupant load	A	A or B	A or B
	I or II	I or II	
≤300 Occupant load	A	A or B	A, B, or C
	I or II	I or II	
Assembly—existing			
>300 Occupant load	A	A or B	A or B

Class C stores	A, B, or C	A, B, or C	A, B, or C
Business and ambulatory health care—new	A or B	A or B	A, B, or C
	I or II		
Business and ambulatory health care—existing	A or B	A or B	A, B, or C
Industrial	A or B	A, B, or C	A, B, or C
	I or II	I or II	
Storage	A or B	A, B, or C	A, B, or C
	I or II		

Notes:
1. Class A interior wall and ceiling finish—flame spread 0–25, (new applications) smoke developed 0–450.
2. Class B interior wall and ceiling finish—flame spread 26–75, (new applications) smoke developed 0–450.
3. Class C interior wall and ceiling finish—flame spread 76–200, (new applications) smoke developed 0–450.
4. Class I interior floor finish—critical radiant flux, not less than 0.45 W/cm^2.
5. Class II interior floor finish—critical radiant flux, not more than 0.22 W/cm^2 but less than 0.45 W/cm^2.
6. Automatic sprinklers—where a complete standard system of automatic sprinklers is installed, interior wall and ceiling finish with a flame spread rating not exceeding Class C is permitted to be used in any location where Class B is required and with a rating of Class B in any location where Class A is required; similarly, Class II interior floor finish is permitted to be used in any location where Class I is required, and no critical radiant flux rating is required where Class II is required. These provisions do not apply to new detention and correctional occupancies.
7. Exposed portions of structural members complying with the requirements for heavy timber construction are permitted.

*See corresponding chapters of NFPA *101* for details.

Source: Table A.10.2.2, NFPA *101,* 2006 edition.

Decorations can be treated with a flame retardant. Furnishings, on the other hand, are difficult to control and regulate as a fire hazard, since they are not attached to, or part of, the building construction or of the interior finish materials. Furnishings are moved, refurbished, and replaced. However, there are now test procedures for measuring the combustibility of upholstered furniture and its susceptibility to ignition.[19] Two NFPA standards address furniture combustibility: NFPA 260, *Standard Methods of Test and Classification System for Cigarette Ignition Resistance of Components of Upholstered Furniture;* and NFPA 261, *Standard Method of Test for Determining Resistance of Mock-Up Upholstered Furniture Material Assemblies to Ignition by Smoldering Cigarettes.* ASTM E1590, *Standard Method for Fire Testing Mattresses,* assesses heat release of mattresses and bedding. If the *Life Safety Code* regulates upholstered furniture or mattresses, the restriction will be found in the appropriate occupancy chapter. Few occupancies have such regulations, and even those occupancies limit the restriction to new upholstered furniture and mattresses. The U.S. Consumer Products Safety Commission (CPSC) also has a standard for evaluating the ignitability of mattresses.[20] A number of fires have been documented in which severe conditions resulted from fire involvement of only a few furnishing items.[9,10,14]

Influence of Psychological and Physiological Factors on Egress

The psychological and physiological conditions of the occupants must be considered, in addition to the physical configuration factors of the building, in planning means of egress. Studies indicate people usually behave adaptively and often altruistically in the stress of a fire.[21,22] A heterogeneous collection of persons under the influence of alcohol or drugs, as may be present in an assembly occupancy, may pose a greater probability of nonadaptive group behavior, with a competitive flight, panic-type behavior the likely result. Historically, this type of nonadaptive behavior has been documented, although studies indicate that the phenomenon is rare and depends on unique, predetermined conditions involving both the population and the physical environment of the structure.[21–23]

In some cases, evacuation procedures and the creation of areas of refuge within high-rise buildings encourage occupant movement upward within the building. The effectiveness of this concept has not been completely validated in actual fires. Because of the orientation of some people toward total evacuation and escape from the building, it is possible that they may attempt to evacuate a building in the conventional "down and out" approach despite instruction to the contrary.[22] This is even more problematic since the September 11, 2001 World Trade Center disaster.

Evacuation procedures in federal high-rise office buildings, as directed by vocal alarm systems, have continually obtained the selective movement of personnel in both upward and downward directions.[15] In two serious high-rise office building fires in São Paulo, Brazil, the occupants moved upward to the roof when their downward movement was inhibited by smoke and heat.[12] In the MGM Grand Hotel fire in Las Vegas, Nevada, in November 1980, there also was upward movement in the stairways to the roof and to rooms on upper floors when downward travel was made untenable by smoke and heat.[13,21] It should be noted that rarely have successful helicopter rescues from the roof been performed. Roof-mounted structures, antennas, and similar items make close approach difficult. In a significant fire, thermal updrafts make approaching the building hazardous. Buildings properly built and maintained in accordance with codes such as the *Life Safety Code* should not need such drastic measures.

All exits need to be conspicuously marked, because people are likely to be unfamiliar with the various exits from an area under fire conditions and thus neglect alternate means of egress. It is also important that the means of egress from a building be used as a matter of daily routine, so the occupants will be familiar with their location and operation. NFPA *101* requires that the main exit of assembly occupancies, which also serves as the entrance, be sized to handle at least half of the total occupant load of the building. Some assembly occupancies are now required to have a main exit that can accommodate two-thirds of the occupant load. This is a result of the Station nightclub fire in West Warwick, Rhode Island, where 100 people died.

There are three critical parameters in the effective use of the zoned evacuation of personnel to areas of refuge within a building:[24]

1. Proper construction to provide compartmented areas that are protected from the effects of fire and smoke
2. An effective verbal alarm system giving clear and comprehensive instructions, with provision for originating on-scene instructions from the fire department[15]
3. Effective evacuation drills to familiarize the occupants with the way the system functions

It has been advocated that occupants in fire-resistant, compartmented buildings used as hotels, motels, apartments, dormitories, hospitals, and other health care facilities should stay in their rooms rather than evacuate, because the rooms are the most adequate area of refuge.[25] In general, this method has not been adopted by NFPA *101* or by model building codes. However, the concept of areas of refuge is used by NFPA *101* extensively in occupancies such as health care as well as detention and correctional facilities and also to protect occupants with mobility impairments in all occupancies. In occupancies such as health care, ambulatory health care, and detention and correctional occupancies, NFPA *101* has mandatory provisions for smoke compartmentation to limit the need to move occupants off the story of fire origin. In new construction of any occupancy, buildings that are not protected by automatic sprinklers are required to provide "accessible means of egress" which in multistoried buildings usually means areas of refuge. NFPA *101* provides various ways of providing areas of refuge. The two most common areas of refuge are oversized exit stair landings or subdivision of the story by horizontal exits or smoke barriers.

Influence of Fire Protection Equipment

It is unsuitable to rely totally on manual or automatic fire-extinguishing systems in place of adequate means of egress, because fire-extinguishing systems are subject to both human and

mechanical failure. In addition, building areas may become untenable for human occupancy before the fire-extinguishing systems are effective. Under no condition can manual or automatic fire suppression be accepted as a substitute for the provision and maintenance of proper means of egress. However, NFPA *101* does provide significant alternative methods of compliance for buildings protected by automatic sprinkler systems. In addition, automatic sprinkler systems and various automatic detection systems are often installed in existing buildings to compensate for problems with the means of egress.

Where a complete standard system is installed, automatic sprinklers are sufficiently reliable to have a major influence on life safety. In addition to providing an automatic alarm of fire, they quickly discharge water on the fire before smoke has spread dangerously. Although automatic sprinklers should never be used in place of adequate means of egress, they are recognized in various ways by NFPA *101*. When total automatic sprinkler protection is provided, NFPA *101* permits increased travel distance to exits, the use of interior finish of greater combustibility, reductions in corridor requirements, and, in some occupancies, the use of combustible construction in situations where it would otherwise be prohibited. Provisions for areas of refuge are significantly easier to comply with in buildings protected throughout by automatic sprinklers. Sprinklers are particularly valuable in dealing with problems in existing buildings.

Automatic fire detection, or fire alarm, systems are valuable in notifying building occupants of a fire so they may evacuate promptly. Automatic fire detection systems only provide a warning of fire and do nothing themselves to suppress or limit the spread of fire and smoke. An automatic fire detection system is not a substitute for adequate means of egress.

Smoke detection systems can be useful to help mitigate problems in existing buildings. They can be especially useful where earlier egress may help solve problems, such as existing excessive common paths of travel, dead ends, and travel distance.

DEFINITION OF THE TERM "MEANS OF EGRESS"

NFPA *101* and most of the U.S. model building codes use the term "means of egress." A means of egress is a continuous path of travel from any point in a building or structure to a public way that is in the open air outside at ground level. Egress consists of three separate and distinct parts:

1. *Exit access.* Portion of a means of egress that leads to the entrance of an exit.
2. *Exit.* Portion of a means of egress that is separated from the area of the building from which escape is to be made by walls, floors, doors, or other means that provide the protected path necessary for the occupants to proceed with reasonable safety to the exterior of the building. An exit may comprise vertical and horizontal means of travel, such as exterior doors, protected stairways, ramps, and exit passageways.
3. *Exit discharge.* Portion of a means of egress between the termination of the exit and a public way.

Figure 4.3.6 illustrates the relationship among these three parts of an exit in a building.

The Exit Access

The exit access may be a corridor, aisle, balcony, gallery, room, porch, or roof. The length of the exit access establishes the travel distance to an exit, an extremely important feature of a means of egress, because an occupant might be exposed to fire or smoke during the time it takes to reach an exit. The average recommended maximum travel distance is 200 ft (61 m), but this distance varies with the occupancy, depending on the fire hazard and the physical ability and alertness of the occupants (Table 4.3.3). The travel distance must be measured from the most remote point in a room or floor area to an exit.

In most cases, the travel distance can be increased if the building is completely protected with a standard supervised automatic sprinkler system.

A dead end is an extension of a corridor beyond an exit or an access to exits that forms a pocket in which occupants may be trapped. Since there is only one direction of travel to an exit from a dead end, a fire in a dead end between the exit and an occupant prevents the occupant from reaching the exit. Another problem with dead ends is that while traveling toward an exit in a smoky atmosphere, an occupant may pass by the exit and walk into the dead end. This requires return travel, which adds distance, and therefore time, to reach the exit. In good egress

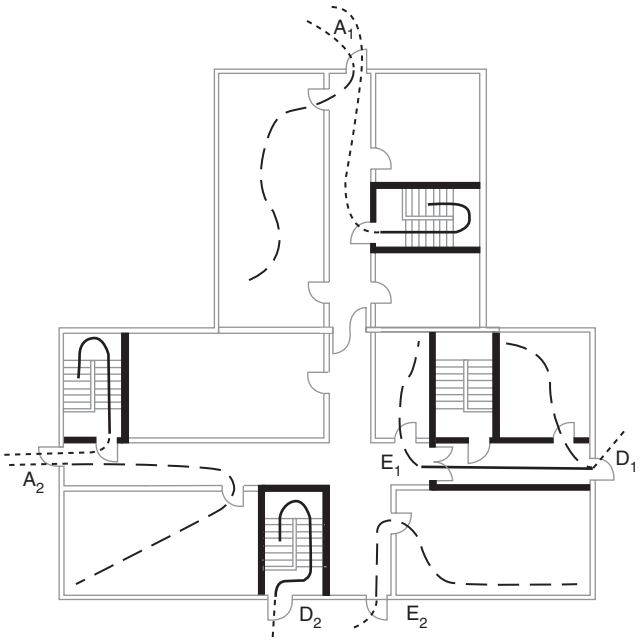

FIGURE 4.3.6 Examples of Exit Access, Exit, and Exit Discharge. To the occupant of the building on this level, the doors at A_1, A_2, E_1, and E_2 are exits. To the person emerging from the exit enclosures doors D_1 and D_2 are exit discharge doors. Exit access is denoted by dashed lines. Exit discharge is denoted by dotted lines. Solid lines are within the exit.

designs, dead-end corridors are not used. However, NFPA *101* permits dead ends in most occupancies, within reasonable limits (see Table 4.3.3). Two examples of dead-end corridors are illustrated in Figure 4.3.7.

The width of an exit access should be at least sufficient for the number of persons it must accommodate. In some occupancies, the width of the access is governed by the character of activity in the occupancy. One example is a new hospital, where patients may be moved in beds or in gurneys. The corridors in the patient areas of the hospital must be 8 ft (2.4 m) wide to allow for a bed to be wheeled out of a room and turned 90°.

A fundamental principle of exit access is the provision of a free and unobstructed way to the exits. If the access passes through a room that can be locked or through an area containing a fire hazard more severe than is typical of the occupancy, the principles of free and unobstructed exit access are violated.

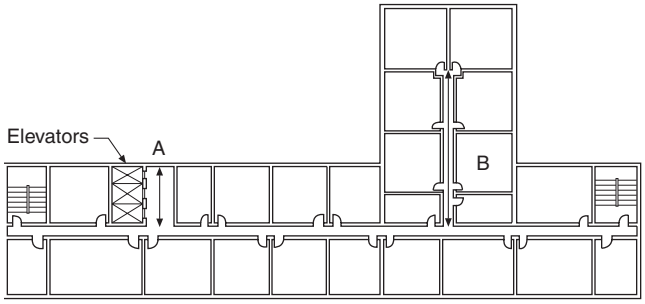

FIGURE 4.3.7 Two Examples of Dead-End Corridors. A shows an elevator lobby that has no exit at the far end, thereby forming a dead-end corridor. B is a "classic" dead-end corridor.

The floor of an exit access should be level. If this is not possible, small differences in elevation may be overcome by a ramp and large differences by stairs. Where only one or two steps are necessary to overcome differences in level in an exit access, a ramp is preferred, because people may trip in a crowded corridor and fall on the stairs if they do not see the steps or notice that those in front of them have stepped up or down.

The Exit

The types of permissible exits are doors leading directly outside at ground level or through a protected passageway to the outside at ground level, smokeproof enclosures, protected interior and outside stairs, exit passageways, enclosed ramps, and in existing buildings, enclosed escalators or moving walkways. Elevators are not accepted as exits; however, they can be used to provide a way of removing mobility-impaired individuals from areas of refuge. NFPA *101* also recognizes elevators for very limited use as a second exit for limited-access towers such as FAA control towers. Research is currently being conducted in an attempt to make elevators more usable for egress purposes. See Figures 4.3.8 and 4.3.9 for illustrations of some common types of exit arrangements.

The specific placement of exits is a matter of design judgment, given the specifications of travel distance, allowable dead ends, common path of travel, and exit capacity. NFPA *101* states

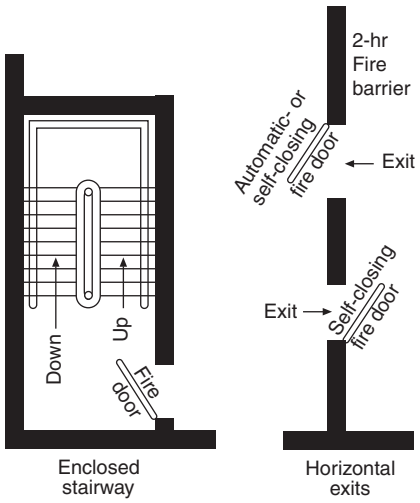

FIGURE 4.3.8 Plan Views of Types of Exits. Stair enclosure prevents a fire on any floor from trapping the persons above. A smokeproof tower is better, as it opens to the air at each floor, largely preventing the chance of smoke in the stairway. A horizontal exit provides a quick refuge and lessens the need for a hasty flight down stairs. Fire-rated doors must be arranged to be self-closing or automatic-closing by smoke detection.

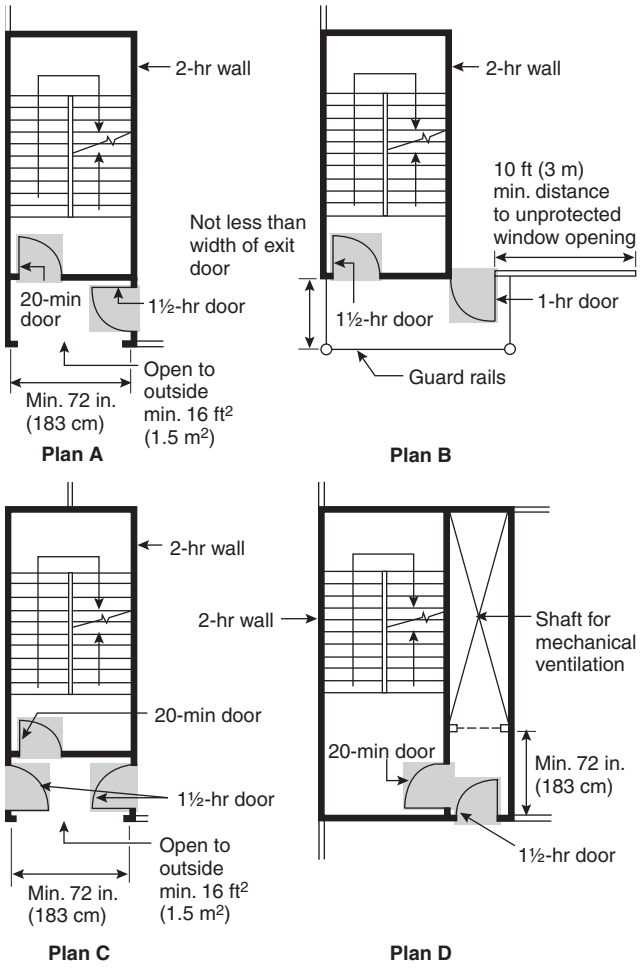

FIGURE 4.3.9 Four Variations of Smokeproof Enclosures. Plan A has an open-air vestibule opening from a corridor. Plan B shows an entrance by way of an outside balcony. Plan C could provide a stair entrance common to two areas. In Plan D, smoke and gases entering the vestibule would be exhausted by a natural or induced draft in the open air shaft. In each case, a double entrance to the stair tower with at least one side open or vented is characteristic of this type of construction. Pressurization of the stair tower in the event of fire provides an attractive alternate for tall buildings and is a means of eliminating the entrance vestibule.

that exits must be remote from each other, thus providing two separate means of egress so located that occupants can travel in either of two opposite directions to reach an exit. This concept is important when it is necessary for occupants to leave a fire or smoke-contaminated area and move toward an exit. If occupants have no choice but to enter the fire area to reach an exit, it is doubtful whether they will be able or willing to do so.

The Exit Discharge

Ideally, all exits in a building should discharge directly to the outside or through a fire-resistance-rated passageway to the outside of the building. NFPA *101* permits a maximum of 50 percent of the exit stairs to discharge onto the street floor. The obvious disadvantage of this arrangement is that if a fire occurs on the street-level floor, it is possible for people using the exit stairs discharging there to be discharged into the fire area. If any exits discharge to the street floor, NFPA *101* therefore requires that such exits discharge to a free and unobstructed way to the outside of the building, that the street floor be protected by automatic sprinklers, and that the street floor be separated from any floors below by construction having a 2 hour fire resistance rating.

Discharging an exit to the outside is not necessarily discharging to a safe place. If the exit discharges into a courtyard, an exit passageway must be provided from the courtyard through the building so that the occupants can get away from the building. If the exit discharges into a fenced yard, the occupants must be able to get out of the yard to get away from the building. If the exit discharges into an alley, the alley must be of sufficient width to accommodate the capacity of all the exits discharging into it, and any openings in the building walls bordering the alley should be protected to prevent fire exposure to the occupants proceeding through the alley.

When exit stairs from floors above the street floor continue on to floors below the street floor, occupants evacuating the building may miss the exit discharge door to the street level, continue down the stairway, and enter a floor below the level of exit discharge. Therefore, NFPA *101* requires a physical barrier or other effective means at the street floor landing to prevent evacuees from passing the level of exit discharge.

CAPACITY OF MEANS OF EGRESS

The capacity of exits is calculated using a capacity factor provided in NFPA *101*. This capacity factor is given as in./person (cm/person) and varies with the occupancy (see Table 4.3.1). The total exit capacity for each component of the means of egress, such as doors, stairs, ramps, corridors, and so on, is calculated based on its clear width. For example, one 34 in. (86 cm) clear-width door in an office occupancy would have an exit capacity of 170 persons (34 in. ÷ 0.2 in./person = 170 persons [86 cm ÷ 0.5 cm/person = 172 persons]). The reason for these variations in exit capacity factors is to establish a consistent total evacuation time in different occupancies, based on the physical ability, mental alertness, age, and sociological roles of the occupants. In occupancies where people are housed for care, the time taken to reach exits will be greater than in some other occupancies, and so the exits must be sufficiently wide to allow nonambulatory occupants to egress and to prevent any waiting to get into the exit.

Occupant Load

Occupant load, or the number of people to be expected in a building or an area within a building at any time for whom exits must be provided, is determined by the actual anticipated occupant load but not less than that number obtained by dividing the gross area of the story or the net area of a specific portion of the building by the area in ft^2 (m^2) projected for each person. The amount of floor area projected for each person varies with the occupancy (Table 4.3.4). These figures are based on actual counts of people in buildings and on reviews of architectural plans. In some situations, the maximum number of people in a building above the calculated occupant load can be determined at the design stage, in which case this number should be used in the design of the exits. A typical example is an assembly occupancy in which fixed seating is installed. Counting the number of seats provided, and calculating the standing or waiting areas by the occupant load factor, would obviously give a more accurate figure than multiplying a ft^2 (m^2)/person figure by the net floor area.

Computing Required Egress Width

To compute the minimum required egress widths from the individual floors of a building, the following steps are necessary:

1. Calculate the floor area, either net or gross, whichever is applicable.
2. Determine from NFPA *101* the estimated number of ft^2 (m^2)/person, or occupant load factor.
3. Divide the number of ft^2 (m^2)/person (occupant load factor) into the floor area to determine the minimum number of people for whom exits must be provided for that floor; use this calculated occupant load or the actual occupant load, whichever is *higher*.
4. Measure the clear width of each component in the means of egress.
5. Determine the capacity factor from NFPA *101* for each exit component for the appropriate occupancy.
6. Divide the clear width of each exit component by the capacity factor to determine the egress capacity for each component.
7. Determine the most restrictive component in each egress system.
8. Determine the total egress capacity for the story.
9. Ensure that the total egress capacity equals or exceeds the total occupant load.

In multistory buildings, the egress capacity for each story is calculated separately. In other words, the capacity of the stairs need only be wide enough to serve each floor, but it must not be less than the minimum width required by NFPA *101*. It must also be noted that the required egress capacity cannot be decreased in the direction of egress travel.

Street-floor exits may require special treatment, depending on the occupancy. Some occupancies require that street-floor

Notes:
NA = Not applicable. The occupant load is the maximum probable number of occupants present at any time.
[a]All factors are expressed in gross area unless marked "net."
[b]For the purpose of determining occupant load in mercantile occupancies where, due to differences in grade of streets on different sides, two or more floors directly accessible from streets (not including alleys or similar back streets) exist, each such floor is permitted to be considered a street floor. The occupant load factor is one person for each 40 ft^2 (3.7 m^2) of gross floor area of sales space.
[c]For the purpose of determining occupant load in mercantile occupancies with no street floor, as defined in 3.3.239 of NFPA *101,* but with access directly from the street by stairs or escalators, the floor at the point of entrance to the mercantile occupancy is considered the street floor.
[d]For any food court or other assembly use areas located in the mall that are not included as a portion of the gross leasable area of the mall building, the occupant load is calculated based on the occupant load factor for that use as specified in Table 7.3.1.2 of NFPA *101*. The remaining mall area is not required to be assigned an occupant load.
[e]The portions of the mall that are considered a pedestrian way and not used as gross leasable area are not required to be assessed an occupant load based on Table 7.3.1.2 of NFPA *101*. However, means of egress from a mall pedestrian way are required to be provided for an occupant load determined by dividing the gross leasable area of the mall building (not including anchor stores) by the appropriate lowest whole number occupant load factor from Figure 7.3.1.2(a) or Figure 7.3.1.2(b) of NFPA *101*.
Each individual tenant space is required to have means of egress to the outside or to the mall based on occupant loads calculated by using the appropriate occupant load factor from Table 7.3.1.2 of NFPA *101*.
Each individual anchor store is required to have means of egress independent of the mall.
Source: Table 7.3.1.2, NFPA *101,* 2006 edition.

exits be sized to handle not only the occupant load of the street floor but also the occupant load of the exits discharging to the street floor from floors above and below. In addition, in those occupancies where floors above and/or below the street floor are permitted to have unenclosed stairs and escalators connecting them with the street floor, the exits must be sufficient to provide simultaneously for all the occupants of all communicating levels and areas. In other words, all communicating levels in the same fire area are considered a single floor area for the purposes of determining the required egress capacity. This unified fire area factor can have a considerable effect on the sizing of the street-floor exits.

Should two or more exits converge into a common exit, the common exit should never be narrower than the sum of the widths of the exits converging into it.

Generally, the minimum number of exits is two. In certain limited situations, however, one exit may be permitted in some occupancies if there is a very low occupant load, low fire hazard, and a limited travel distance.

EGRESS FACILITIES AND ARRANGEMENTS

The following egress facilities are covered in NFPA *101*.

Doors

Doors should be side-hinged or pivoted swinging type and should swing in the direction of egress travel, except in small rooms. Horizontal sliding, vertical, or rolling doors are recognized for use as means of egress in some occupancies. In assembly occupancies, day-care centers, and schools, panic hardware should be installed on all egress doors equipped with latches that serve areas with an occupant load of 100 or more.

Where doors protect exit facilities, as in stairway enclosures and horizontal exits, they normally must be kept closed to limit the spread of smoke. If open, they must be closed immediately in case of fire. Although ordinary, fusible-link-operated devices to close doors in case of fire are designed to close in time to stop the spread of fire, they do not operate soon enough to stop the spread of smoke and are not permitted by NFPA *101*. At relatively low temperatures, smoke accumulation could continue and could reach untenable levels long before the fusible link melts, allowing the door to close.

Sometimes, people keep self-closing doors open with hooks or with wedges under the door. Doors also can be blocked open to provide ventilation, for the convenience of building maintenance personnel, or to avoid the accident hazard of swinging doors. The following measures have been provided in the NFPA *101* to alleviate this undesirable situation:

1. Doors that are normally kept open can be equipped with door closers and automatic hold-open devices that release the door and allow them to close when smoke detectors operate.
2. Doors that are normally closed can be equipped to open electrically or pneumatically when a person approaches the door, as long as smoke detectors are used to prevent the door from automatically opening when there is smoke in the area.
3. Doors that normally are closed can be opened and held open manually by monitors, as in schools.

Qualifications and limitations are applicable to each of these measures. One is that, in the event of electrical failure, the door must close and remain closed unless it is opened manually for egress purposes.

Another major maintenance difficulty with exit doors is the exterior door that is locked to prevent unauthorized access or for other reasons. NFPA *101* specifies that when the building is occupied, all doors must be kept unlocked in the direction of egress.

NFPA *101* allows a delayed releasing device on some egress doors, provided this is permitted by the requirements of the occupancy in question. Where the devices are allowed, the following provisions apply:

1. The building must be protected throughout by an approved and supervised automatic fire detection system or automatic sprinkler system.
2. The release devices are installed only in low- or ordinary-hazard areas.
3. The devices must unlock when the fire detection system or automatic sprinkler system operates.
4. The devices must unlock on loss of power.
5. The devices must initiate an irreversible process that will free the latch within 15 seconds whenever a force of not more than 15 lb (6.8 kg) is applied to the releasing device, and the door must not relock automatically. Operation of the releasing device must actuate a signal near the door.
6. A sign must be placed adjacent to the door that reads: PUSH UNTIL ALARM SOUNDS. DOOR CAN BE OPENED IN 15 SECONDS!
7. Emergency lighting must be provided at the door. Refer to NFPA *101* for more details and restrictions. Some of the occupancy chapters have further limitations.

NFPA *101* also provides "Access Controlled Egress Doors." The code spells out several limitations for these. One of the limitations included is that when an occupant approaches the door from the egress side, a sensor must unlock it.

Locks on a door that let people exit but not enter are satisfactory, but even this type of lock may not be satisfactory for security purposes. Possible measures to prevent unauthorized use of exit doors include the following:

1. An automatic alarm that rings when the door is opened
2. Visual supervision such as wired-glass panels, closed-circuit television, and mirrors, which may be used where appropriate
3. Automatic photographic devices to provide pictures of users

So-called exit locks, with a break-glass unit actuated by striking a handle with the hand, are not permitted by NFPA *101* unless installed in conjunction with panic bars. Otherwise, they do not comply with the NFPA *101* provision that reads: "A latch or other fastening device on a door shall be provided with a re-

leasing device having an obvious method of operation and that is readily operated under all lighting conditions."

Other types of break-glass locks and electrical controls for releasing exits from a central point are not permitted by NFPA *101*. The exception is an occupancy where controls may be necessary, as in health care or detention and correctional occupancies.

A single door in a doorway should not be less than 32 in. (813 mm) wide in new buildings and 28 in. (711 mm) in existing buildings. To prevent tripping, the floor on both sides of the door should have the same elevation for the full swing of the door.

Panic Hardware

Egress doors in assembly, day-care, and educational occupancies, such as schools or movie theaters, normally are equipped with panic hardware. Basically, panic hardware devices are designed to facilitate the release of the latching device on the door when a pressure not to exceed 15 lb (6.8 kg) is applied in the direction of exit travel. Such releasing devices are bars or panels extending not less than one-half of the width of the door and placed at a height not less than 30 in. (762 mm) or more than 44 in. (1.1 m) above the floor.

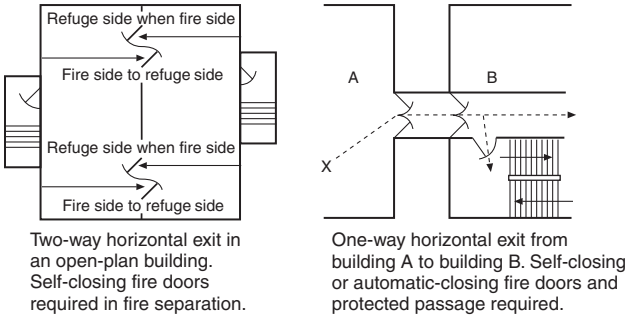
Panic hardware that has been tested and listed for use on fire-protection-rated doors is termed "fire exit hardware." If panic hardware is needed on fire-protection-rated doors, only fire exit hardware is to be used.

Panic hardware is available for use on single and double doors, with variations for rim-mounted hardware and mortise or vertical rod devices.

Horizontal Exits

A horizontal exit is a means of egress from one building to an area of refuge in another building on approximately the same level, or a means of egress through a 2 hour fire barrier to an area of refuge at approximately the same level in the same building that affords safety from fire and smoke. With a horizontal exit, it is obvious that space must be provided in the area or building of refuge for the people entering the refuge area. NFPA *101* recommends 3 ft^2 (0.28 m^2) of space per person, with the exception of health care or detention and correctional occupancies, where 6 to 30 ft^2 (0.56 to 2.79 m^2) of space is recommended. Horizontal exits cannot comprise more than one-half the total required exit capacity, except in health care facilities, where horizontal exits may comprise two-thirds of the total required exit capacity, and in detention and correctional facilities, where horizontal exits can comprise 100 percent of the total exit capacity. Horizontal exits have been applied universally in health care facilities where the evacuation of patients over stairs is slower and more difficult than taking them through a horizontal exit to a safe area of refuge. A horizontal exit arrangement within a single building and between two buildings is illustrated in Figure 4.3.10.

A swinging door in a fire wall provides a horizontal exit in one direction only. Two openings, each with a door swinging in the direction of exit travel, are needed to provide horizontal exits from both sides of the wall. Where property protection requires fire doors on both sides of the wall, a normally open, automatic, fusible-link-operated, horizontally sliding fire door may be used on one side, with a swinging fire door on the other.



Two-way horizontal exit in an open-plan building. Self-closing fire doors required in fire separation.

One-way horizontal exit from building A to building B. Self-closing or automatic-closing fire doors and protected passage required.

FIGURE 4.3.10 Types of Horizontal Exits

Stairs

Exit stairs are arranged to minimize the danger of falling, because one person falling on a stairway may result in the complete blockage of an exit. Stairs must be wide enough for two persons to descend side by side, thus maintaining a reasonable rate of evacuation, even though aged or mobility-impaired persons may slow the travel on one side. There must be no decrease in the width of the stair along the path of travel, since this may create congestion.

Steep stairs are dangerous. Stair treads must be deep enough to give good footing. NFPA *101* specifies a minimum 11 in. (279 mm) tread and a maximum 7 in. (178 mm) riser for new stairs. Landings should be provided to break up any excessively long individual flight. Continuous railings are now recommended for new stairs. New stairs more than 60 in. (1.5 m) wide should have one or more center rails. Beginning with the 2006 edition of NFPA *101,* new very tall buildings will be required to have wider stairs. If a stair serves a total of more than 2000 people there are more stringent width requirements to accommodate better flow (allowing for easier passing and for easier movement of mobility-impaired persons) as well as counter flow (allowing fire fighters with equipment up while occupants are evacuating).

Prior to 2006, two classes of stairs were permitted in NFPA *101* for existing buildings, with a single class of stairs for new stairs. There were Class A and Class B stairs for existing buildings. Starting with the 2006 edition the provisions for Class A stairs were deleted from the code and now there is one set of requirements for new and one for existing. The requirements are given in Table 4.3.5.

Stairs can serve as exit access, exit, or exit discharge. When used as an exit, they must be in an enclosure that meets exit enclosure requirements or outside the building and properly protected. Exit access stairs that connect two or more stories are vertical openings and must be protected as a vertical opening.

Stairways may be inside the building where NFPA *101* generally specifies protective enclosures. They also may be outside

TABLE 4.3.5 Requirements for New and Existing Building Stairs

	New Stairs	*Existing Stairs*
Minimum width clear of all obstructions except projections not exceeding 3½ in. (0.89 mm) at and below handrail height on each side	44 in. (1.12 m) 36 in. (0.91 m) where total occupant load of all floors served by stairways is less than 50	36 in. (0.91 m) 36 in. (0.91 m)
Maximum height of risers	7 in. (178 mm)	8 in. (203 mm)
Minimum height of risers	4 in. (102 mm)	—
Minimum tread depth	11 in. (279 mm)	9 in. (229 mm)
Minimum headroom	6 ft 8 in. (2.03 m)	6 ft 8 in. (2.03 m)
Maximum height between landings	12 ft (3.7 m)	12 ft (3.7 m)
Minimum dimension of landings in direction of travel	Stairways and intermediate landings shall continue with no decrease in width along the direction of exit travel. In new buildings every landing shall have a dimension, measured in direction of travel, equal to the width of the stair. Such dimension need not exceed 4 ft (1.22 m) when the stair has a straight run.	
Doors opening immediately on stairs, without landing at least width of door	No	No

if they comply with the requirements for exterior stairs and are arranged so that persons who fear heights will not be reluctant to use them, are not exposed to fire conditions originating in the building, and, where necessary, are shielded from snow and ice. Exterior stairs should not be confused with fire escape stairs (Figure 4.3.11). Exterior stairs as shown in the figure can be used in many types of occupancies, such as schools, motels, small professional buildings, and so on. Note that there are two means of egress, remote from each other, from the second-story balcony.

Construction details of stair enclosures involve the principles of limiting fire and smoke spread. Doors on openings from each story are essential to prevent the stairway from serving as a flue. In general, stairway enclosures should include not only the stairs, but also the path of travel from the bottom of the stairs to the exit discharge, so that occupants have a protected, enclosed passageway all the way out of the building. The stair enclosure should be of 1 hour construction when connecting three or fewer floors and of 2 hour construction when connecting four or more floors.

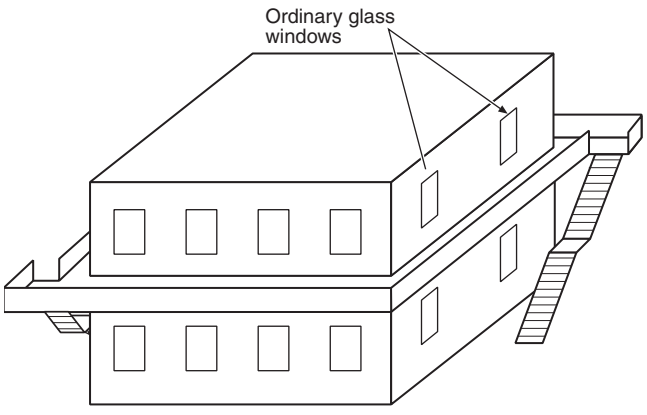


FIGURE 4.3.11 Outside Stairs Providing Direct Exits to the Outside for All Rooms in a Multistory Building. There are no interior corridors through which smoke and flame could spread.

Smokeproof Enclosures

Smokeproof enclosures provide the highest protected type of stair enclosure recommended by NFPA *101*. Access to the stair is only by balconies open to the outside air, vented vestibules, or mechanically pressurized vestibules, so that smoke, heat, and flame will not spread readily into the tower even if the doors are accidentally left open (see Figure 4.3.9).

Ramps

Ramps, enclosed and otherwise arranged like stairways, are sometimes used instead of stairways where there are large crowds and to provide both access and egress for nonambulatory persons. To be considered safe, exits ramps must have a very gradual slope.

Exit Passageways

A hallway, corridor, passage, tunnel, or underfloor or overhead passageway may be designated an exit passageway, providing it is separated and arranged according to the requirements for exits.

The use of a hallway or corridor as an exit passageway introduces some unique considerations. The use of these spaces for purposes other than exiting may violate fundamental design considerations. In an industrial situation, for example, the use of a gasoline-powered forklift in a corridor designated as an exit passageway would violate the principles of exit design.

NFPA *101* specifies that an exit enclosure should not be used for any purpose that could interfere with its value as an exit and is strictly limited by the code. Furthermore, penetration of the enclosure by ducts and other utilities may violate the protective enclosure.

Each opening in an exit enclosure introduces a point of weakness that could allow fire contaminants to spread into the exit and prevent its use. The typical corridor used as an exit with numerous door openings could result in fire contamination of the enclosure if a door fails to close and latch. The door openings in exit enclosures should be limited to those necessary for access to the enclosure from normally occupied spaces. Therefore, doors and other openings to spaces such as boiler rooms, storage spaces, trash rooms, and maintenance closets are not allowed into an exit passageway.

An exit passageway should not be confused with an exit access corridor. Exit access corridors do not have as stringent construction protection requirements as do exit passageways, because they provide access to an exit rather than being an extension and component of the exit. In Figure 4.3.6 the passage between E_1 and D_1 is an exit passageway.

Fire Escape Stairs

Fire escapes are, at best, a poor substitute for standard interior or exterior stairs. NFPA *101* only permits existing fire escapes in existing buildings; for some occupancies they are not allowed even for existing buildings. Existing fire escape stairs can be rebuilt, but new fire escapes cannot be installed on an existing building unless specifically approved by the authority having jurisdiction.

The same principles of design apply to fire escapes that apply to interior stairs, though requirements for width, pitch, and other dimensions are generally less strict. NFPA *101* gives the following criteria for fire escape stair design.

Fire escape stairs ideally extend to the street or to ground level. When sidewalks would be obstructed by permanent stairs, swinging stair sections designed to swing down under the weight of a person may be used for the lowest flight of the fire escape stairs. The area below the swinging section must be kept unobstructed so the swinging section can reach the ground. A counterweight of the type that balances on a pivot should be provided for swinging stairs; cables should not be used. Fire escapes that end on balconies above the ground level and provide no way to reach the ground, except by portable ladders or jumping, are unsafe.

Many persons who fear heights are reluctant to use fire escapes. As far as possible, design should provide a sense of security, as well as suitable railings and other details actually needed for safety. Fire escapes must be well anchored to building walls and kept painted to prevent rust.

Preferred access to fire escapes is through doors leading from the main building area or from corridors, never through rooms that may have locked doors except where every room or apartment has separate access to a fire escape. Although preferred access to fire escapes is by doors, windows may be used, in which case sills should not be too high above the floor. Windows should be of ample size, and, if insect screens are installed, they should be of a type that can be opened or removed quickly and easily. Decorative grilles or security bars should not be installed over windows that provide access to fire escapes.

Fire escapes can create a severe fire exposure to people if flames come out windows beneath them (Figure 4.3.12). The best location for fire escapes is on exterior masonry walls without exposing windows, with access to fire escape balconies by exterior fire doors. Where window openings expose fire escapes, fixed wired glass in metal sashes should be used. Where there is a complete standard automatic sprinkler system in the building, the fire exposure hazard to personnel on fire escapes is minimized.

In northern climates, outside fire escapes may be obstructed by snow and ice.

Escalators, Moving Walkways, and Elevators

In some occupancies, escalators may be recognized as egress in existing buildings. However, they are seldom installed in such a way that they would qualify as exits, and it is common to find escalator installations with unprotected floor openings. Escalators are not recognized as an acceptable component in a means of egress in new construction in any occupancy and in existing conditions in many occupancies.

Moving walkways also may be used as existing means of egress if they conform to the general requirements for ramps, if inclined, and for passageways, if level.

Elevators are not recognized as exits. However, elevators are permitted to be used, under limited conditions, to serve areas of refuge for the mobility impaired. The *Life Safety Code* also recognizes elevators, under very limited conditions, as the second exit from limited-access towers such as FAA control towers. As mentioned earlier, there is significant research being conducted in an attempt to develop ways to use elevators for egress.

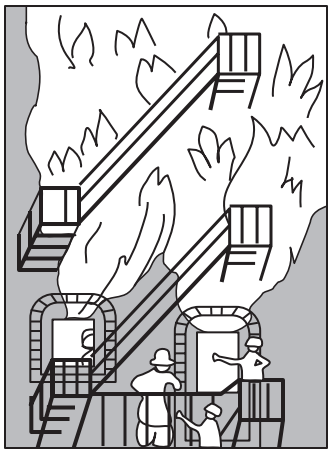

FIGURE 4.3.12 The Makeshift, Often Dangerous Aspect of Fire Escapes. Fire may make fire escapes useless as this picture, drawn from a photograph of an actual fire, shows.

Areas of Refuge

Since 1991, NFPA *101* has listed "areas of refuge" as a specific means of egress element. Although they are beneficial to all people, their primary purpose is for people with difficulty using stairs. All new buildings must address the issue of "accessible means of egress." In most new nonsprinklered multistory buildings, this will require some form of area of refuge. Figures 4.3.13 and 4.3.14 illustrate two methods for providing areas of refuge in nonsprinklered buildings.

Ropes and Ladders

Ropes and ladders generally are not recognized in codes as a substitute for standard exits from a building. This is proper since there is no excuse for permitting their use except possibly in existing one- and two-family dwellings where it is economically impractical to add a secondary means of escape. In this case, a suitable rope or chain ladder or a folding metal ladder may be suitable. However, the homeowner should recognize that aged, infirm, very young, and physically handicapped persons cannot use ladders and that, if the ladder passes near or over a window in a lower floor, flames from the window can prevent the use of the ladder.

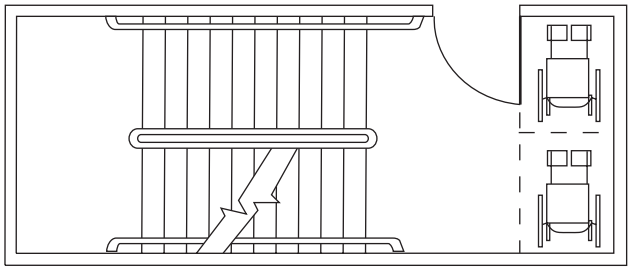

FIGURE 4.3.13 Exit Stair Used as an Area of Refuge. When stair landings are used as an area of refuge, the stairs are required to be 48 in. (122 cm) between handrails to accommodate carrying persons in wheelchairs.

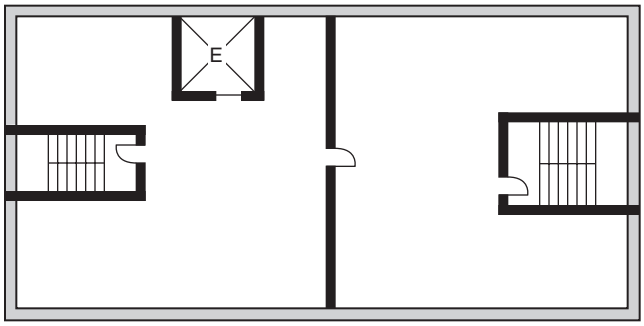

FIGURE 4.3.14 Areas of Refuge in Nonsprinklered New Construction. In this case the story is subdivided by either a horizontal exit or a 1 hour fire resistance rated smoke barrier. Each side of the barrier is an area of refuge for the other side. If the smoke barrier is used the stairs are required to be 48 in. (122 cm) between handrails to accommodate carrying persons in wheelchairs.

Windows

Windows are not exits. They may be used as access to fire escapes in existing buildings if they meet certain criteria concerning the size of window opening and the height of the sill from the floor. Windows may be considered a means of escape from certain residential occupancies.

Windows are required in school rooms subject to student occupancy, unless the building is equipped with a standard automatic sprinkler system, and in bedrooms and living areas in one- and two-family dwellings that do not have two separate means of escape. These windows are for rescue and ventilation and must meet the criteria for size of opening, method of operation, and height from the floor.

EGRESS LIGHTING AND EXIT SIGNS

Egress Lighting

In buildings where artificial lighting is provided for normal use, the illumination of the means of egress is required to ensure that occupants can evacuate the building quickly. The intensity of the illumination of the means of egress should be not less than 1 footcandle (10.77 lu/m^2) measured at the floor. It is desirable that such floor illumination be provided by lights recessed in the wall and located approximately 1 ft (30.5 cm) above the floor because such lights are then unlikely to be obscured by the smoke that might occur during a fire. In auditoriums and other places of assembly where movies or other projections are shown, NFPA *101* permits a reduction in this illumination for the period of the projection to values of not less than ⅕ footcandle (2.2 lu/m^2).

Emergency Lighting

NFPA *101* requires emergency power for illuminating the means of egress in many occupancies. For example, emergency lighting is required in assembly occupancies; in most educational buildings; in health care facilities; in detention and correctional facilities; in most hotels and apartment buildings; in Class A and B mercantiles; in business buildings based on occupant load and number of stories; in most industrial and storage buildings; and in underground or windowless structures subject to occupancy by more than 100 persons.

Well-designed emergency lighting using a source of power independent from the normal building service automatically provides the necessary illumination in the event of an interruption of power to normal lighting. The failure of the public utility or other outside electric power supply, the opening of a circuit breaker or fuse, or any manual act, including accidental opening of a switch controlling normal lighting facilities, should result in the automatic operation of the emergency lighting system.

Reliability of the exit illumination is most important. NFPA 70, *National Electrical Code*®, details requirements

for the installation of emergency lighting equipment. Battery-operated electric lights and portable lights normally are not used for primary exit illumination, but they may be used as an emergency source under the restrictions imposed by NFPA *101*. Luminescent, fluorescent, or other reflective materials are not a substitute for required illumination, because they are not normally sufficiently intense to justify recognition as exit floor illumination. However, such items are being used to supplement emergency lighting. And, as is discussed under exit signs below, code-compliant luminescent exit signs are now being manufactured.

Where electric battery-operated emergency lights are used, suitable facilities are needed to keep the batteries properly charged. Automobile-type lead storage batteries are not suitable because of their relatively short life when not subject to frequent recharge. Likewise, dry batteries have a limited life, and there is a danger that they may not be replaced when they have deteriorated.

If normal building lighting fails, well-arranged emergency lighting provides necessary floor illumination automatically, with no appreciable interruption of illumination during the changeover. Where a generator is provided, a delay of up to 10 seconds is considered tolerable. The normal procedure is to provide such emergency lighting for a minimum period of 1½ hours. Most health care occupancies have self-contained electric generating plants for emergency power supplies, not only for exit lighting but also for use in the event of failure of the public utility. Where such emergency electric facilities are provided, they may supply power for emergency exit lighting, as well as other critical areas of such buildings.

Exit Signs

All required exits and access ways must be identified by readily visible signs where the exit or the way to reach it is not immediately visible to the occupants. Directional "EXIT" signs are required in locations where the direction of travel to the nearest exit is not immediately apparent. The character of the occupancy will determine the actual need for such signs. In assembly occupancies, hotels, department stores, and other buildings with transient populations, the need for signs will be greater than in a building with permanent or semipermanent populations. Even in permanent residential-occupancy buildings, signs are needed to identify exit facilities, such as stairs, that are not used regularly during the normal occupancy of the building. It is just as important that doors, passageways, or stairs that are not exits but are so located or arranged that they may be mistaken for exits be identified by signs with the words "NO EXIT."

Signs should be so located and of such size, color, and design as to be readily visible. Care should be taken not to obscure the visibility of these signs with decorations, furnishings, or other building equipment. NFPA *101* does not make any specific requirement for sign color but requires that signs be of a distinctive color. Some local codes do specify exit sign color. NFPA *101* specifies the size of the sign, the dimensions of the letters, and the levels of illumination for externally illuminated signs. For internally illuminated signs, the code mandates compliance with UL 924, *Standard for Emergency Lighting and Power Equipment.* This performance-based standard provides methods to evaluate different types of exit signs, including luminescent signs.

Improvement in the physical marking of exits in an office occupancy with point-source, red or green strobe lights has been suggested. Placing corridor illumination on the walls close to the floor to provide effective illumination under smoke conditions, as is the practice in Japan, is a technique worthy of research.[26]

ALARM SYSTEMS

Fire alarm systems to alert occupants to leave the building are normally operated manually. The alarm-sounding devices themselves should be distinctive in pitch and tone quality from all other sounding devices, and the use of these devices should be restricted to evacuation notification. Vocal alarm systems have been developed and installed in many high-rise buildings.[14] NFPA *101* mandates voice alarm and communication systems in high-rise buildings. It is, of course, very important that all alarm system devices be distributed throughout a building so as to be heard effectively in every room above all other sounds. Visible, as well as audible, alarm devices are sometimes used in buildings. NFPA *101* permits flashing the exit signs with the activation of the fire alarm system. In new construction, visible alarms must be provided in addition to audible alarms in most instances. Advances in alarm technology, such as directional sounders, are now being used to assist people in finding the exits.

The proper maintenance of alarm systems is most important. Alarm systems should be supervised by a responsible person who will make the proper tests at specified intervals and will take charge of all alterations and additions to the systems.

EMERGENCY EGRESS AND RELOCATION DRILLS

Emergency exit and relocation drills are essential in schools and are desirable in every type of occupancy to ensure familiarity with the exits and their operation. In occupancies such as hospitals, nursing homes, hotels, and department stores, drills are usually limited to employee participation, without alarming patients, guests, or customers. Drills should be planned to get everyone out of the building or to an area of refuge in an orderly manner, as promptly as possible. Fire fighting is always secondary to life safety, and, in general, fire-fighting operations should not be started until the evacuation is completed, except in cases where trained fire departments conduct rescue and fire-fighting operations simultaneously.

Drills should be held at least once a month or more often, but not at regularly scheduled periods. Drills should occur on all shifts in an occupancy operated 24 hours a day. They should simulate typical fire conditions for the occupancy. Drills, both with and without warning, are beneficial.

School emergency egress and relocation drills are an exercise in discipline, not speed, though reasonably prompt evacuation of a building is important. Students and staff should not be permitted to stop to put on coats. No individuals should be

permitted to remain in the building, and no one should be excused from participating in the drill. The drill should include a roll call by class at designated assembly areas outside the building to make sure that no one has been left behind.

There also should be an established routine for a complete check of the entire building, including toilets, to make sure that no one has been left behind. All exits should be used in drills, but routes should be varied from drill to drill. Occasional drills should be held that simulate conditions of an exit blocked by fire or smoke. All drills should simulate the fire department notification procedure. For a more detailed discussion of fire exit drills, see Chapter 1 of this section.

MAINTENANCE OF THE MEANS OF EGRESS

The provision of a standard means of egress with adequate capacity does not guarantee the safety of the occupants in the event of an evacuation of any building. Means of egress that are not properly maintained can mean loss of life in a fire. Property managers usually assign definite responsibility for maintenance of mechanical and electrical equipment but may fail to do the same for the means of egress. As a result inspection authorities may find otherwise safe stairways used as storage for materials during peak sales or manufacturing periods. In apartment buildings, rubbish, baby carriages, and other obstructions are often found in stairway enclosures. Exit doors may be found locked or hardware in need of repair. Doors blocked open or removed from openings into stairway enclosures may permit rapid spread of smoke or hot gases throughout the building. Loose handrails and loose or slippery stair treads offer the dangerous probability that persons evacuating a building will fall in the path of others seeking escape. Maintaining the exit discharge free of the accumulation of ice and snow in climates subject to such weather is very critical. Maintaining the means of egress in safe operating condition at all times is as important to the prevention of loss of life as the proper construction of the building and the elimination of fire hazards.

SUMMARY

Providing adequate means of egress is a key fire safety issue in both new buildings and existing facilities. NFPA *101* provides in-depth coverage for providing adequate means of egress. For new construction, many of the issues are also covered in building codes, including *NFPA 5000.* This chapter only introduces the subject. To more completely understand the subject, both the NFPA *Life Safety Code® Handbook* and the *SFPE Handbook of Fire Protection Engineering* should be consulted.

Chapter 4

Techniques of Crowd Management

John J. Fruin

Chapter Contents

Overview of Crowd Management and Crowd Control
Crowd Disaster Model
Crowd Management Examples and Disaster Incidents
Crowd Management Phases

Key Terms

Chicago E2 nightclub incident, craze, critical occupancy, crowd control, crowd management, DuPont Plaza Hotel fire, egress, flight response, ingress, metering, pressure point, Station Nightclub fire

Crowds occur frequently for different purposes in a wide variety of venues. Entertainment and sporting events will attract thousands of spectators. Large numbers of passengers move through transportation terminals during peak periods, sometimes resulting in serious crowding when connecting services are disrupted. Major office and shopping complexes have large tenant and transient visitor occupancies. Special events such as parades and public demonstrations can attract many thousands of participants and observers. Usually these large gatherings of people occur without serious problems. Occasionally fires or other events, combined with venue or management deficiencies, precipitate a rapid concentration of people that results in multiple casualties.

This chapter defines the terms *crowd management* and *crowd control* and differentiates between the two. A crowd disaster model, patterned after the systems analysis method, forms a basis for evaluating crowd incidents. A sampling of crowd disasters, which illustrate aspects of crowd behavior, is followed by a description of the sequence of crowd management phases.

See also the following chapters with related topics: Section 4, Chapter 1, "Human Behavior and Fire"; Section 4, Chapter 2, "Calculation Methods for Egress Prediction"; Section 4, Chapter 3, "Concepts of Egress Design"; and Section 4, Chapter 5, "Strategies for Occupant Evacuation During Emergencies."

OVERVIEW OF CROWD MANAGEMENT AND CROWD CONTROL

Crowd Management and Crowd Control Defined

Crowd Management. *Crowd management* is defined as the planned movement and assembly of people.* Although the terms *crowd management* and *crowd control* are often used interchangeably, there are important differences. Crowd management involves the systematic assessment of all aspects of venue occupancy prior to use. It can be considered an adjunct to the life safety evaluation process, with greater concentration on the possibilities for extreme crowding and its potentially fatal consequences. Crowd management planning includes determination of expected number of occupants of a space, anticipated group behavior, assessment of the adequacy of assembly areas, means of both ingress and egress, processing procedures such as ticket collection and security screening, staffing requirements, and means of communication.

Crowd Control. *Crowd control* is defined as the restriction or limitation of group behavior.* Crowd control may be part of a crowd management plan or may occur as a reaction to a group problem. It can include extreme measures to enforce order, such as the use of force, threat of personal injury, or arrest. It may employ barriers that alter the space available for occupancy and patterns of group

*The definitions of crowd management and crowd control are based on composite opinions of various safety professionals who recognize the differences between the proactive preplanning of events and reactive control during the event itself.

John J. Fruin, Ph.D., is a traffic engineer specializing in pedestrian movement and safety. His background includes two degrees in transportation planning (traffic engineering) and two in civil engineering. He worked at the Port Authority of New York and New Jersey for 30 years and was a consultant to the Port Authority after retiring. His consulting experience has included the Who concert disaster investigation; the Dupont Plaza Hotel fire litigation; and circulation issues in transportation, museum, sports, and museum venues.

movement. Inappropriate or poorly managed control procedures may precipitate crowd incidents rather than prevent them. For example, reacting to a group of unruly persons at a rock concert, police herded these individuals into areas where there was no means of egress, causing some to jump off grandstands and be injured. Other crowd incidents have occurred where exit controls, or even locked exits, have prevented orderly egress. Compliance with codes does not ensure safe functioning of an extremely crowded venue.

Crowd Composition

Crowds can attract participants who come to observe and to enjoy an event peacefully, as well as predators in search of victims and people with other psychological, social, or political agendas. The crowd provides some with a cover to engage in hostile or aberrant behavior, or as an opportunity for theft, selling drugs, or solicitation.[1] As an illustration of criminal manipulation of a crowd, a team of pickpockets was observed by the author delaying train departures at a New York City transit station to purposely increase crowding in subway cars. They then boarded the train, pushed their way through the crowded car, picking pockets along the way, and fleeing at the next stop. Casualties have been caused by the failure of guard railings under crowd pressures and by the structural failure of ramps and bridges under the stress of heavy crowding, as illustrated in the railing failure noted in the Hillsborough Stadium disaster described later in this chapter.

Crowd Psychology

Psychologists have likened a crowd to a series of intermeshing behavioral cells. Each crowd cell is composed of a small group of surrounding people, with limited personal interaction and communication within it. The members of an individual cell have no broad view of what is occurring in the crowd mass. A dominant cell member may influence the behavior of others within the cell. There may be cell-to-cell communication, often with the spread of unfounded rumors and misinformation. Investigations of several major crowd incidents—for example, the Who concert described later—have shown that misinformation precipitated inappropriate reactions. Crowd situations show a lack of front-to-back communication. People in the rear of the crowd will continue to press forward, while those in front experience severe distress but are unable to communicate their plight. This situation is due in part to the differences in pedestrian densities between front and rear ranks of a crowd. Those in the rear are at densities that still permit movement, whereas those in front are immobile and under great pressure. The unpredictability of group behavior is a significant complication in crowd management planning.

Crowd Categories

Three general categories of potentially dangerous crowd situations have been identified: (1) critical occupancy, (2) flight response, and (3) craze.[2] All types of crowds, even relatively small gatherings, can quickly become dangerous if not carefully managed. For example, a number of eager young participants were injured at an Easter egg hunt when sponsors began throwing gifts out to them.

Critical Occupancy. Critical occupancy is the gradual accumulation and overloading of a pedestrian space, beginning at levels below 3 ft^2/person (0.28 m^2/person) until it reaches the plan view area of the human body of about 1.3 to 1.5 ft^2 (0.12 to 0.14 m^2). Critical occupancies can occur in transportation terminals during service disruptions, at public events, or at other venues where ingress and assembly are not controlled. Escalators, because of their continuous passenger delivery characteristic, have caused critical occupancy fatalities where the discharge end space is restricted. So-called "festival seating" events, at which there are actually no seats, aisles, or other assembly control features, can more easily result in critical occupancy conditions. In one sense, all fatal crowd incidents are the result of critical occupancy conditions, with the difference that flight and craze events involve sudden mass movement.

Flight Response. The flight response occurs where people are fleeing either from a real threat, such as a fire or explosion, or from a perceived, but otherwise nonthreatening, event. Flight responses may be labeled as panics and stampedes, but closer examination shows that rapid group movement away from the threat was a reasonable reaction. Later investigation of victim behavior may show that mutual cooperation and assistance existed within group cells, rather than the destructive nonadaptive behavior of a panic. Flight response fatalities may occur where egress facilities are overwhelmed by the sudden rush and are restricted or blocked. Flight response incidents may occur due to fire, explosions, power outages, structural failures, group altercations, police actions, severe weather such as hailstorms or tornadoes, and earthquakes.

Craze. A craze is a competitive rush to obtain some highly valued objective. Crazes may happen when spectators attempt to get closer to celebrities, gain entry into a popular event, or, more unfortunately, where food is being distributed to starving victims of a disaster. Craze fatalities can occur where ingress facilities such as doors, ticket collection, or other pedestrian movement elements in the path between the crowd and its intended objective are overwhelmed.

CROWD DISASTER MODEL

The primary elements involved in crowd disasters have been determined from personal experiences in dense crowds, studies of many major crowd incidents, and basic pedestrian traffic engineering principles. The elements provide a model for understanding the causes of crowd disasters, means of prevention, and possible mitigation of an ongoing crowd incident. The model is patterned after classic systems analysis elements of time, space, information, and energy, and modified to form the descriptive acronym FIST. The acronym itself is a useful reminder that any crowd situation is potentially dangerous. The meaning of the initial letters of the acronym is as follows:

F = *Force* of the crowd, which is sufficient to cause compressive asphyxia, bend or dislodge steel railings, and, when fully unleashed, nearly impossible to control

I = *Information* on which the crowd acts or reacts, real or perceived, true or false, any and all means of communication with the crowd, security, medical, and first responder personnel

S = *Space* involved in the crowd incident and all its related physical facilities, standing area, doors, stairs, corridors, and escalators

T = *Time* during which the crowd buildup occurs, duration of incident, scheduling, and other time-based factors such as processing rates of pedestrian facilities

Force

The physical and psychological pressures within crowds at maximum density are difficult to describe unless one has personally experienced them. When crowd density equals the area of the human body, individual control is lost as one becomes an involuntary part of the mass. The crowd mass becomes almost fluid, with shock waves propagated through it sufficient to lift people off their feet and propel them distances of 10 ft (3 m) or more. People may be literally lifted out of their shoes or have clothing torn off.

Intense crowd pressures, exacerbated by anxiety, can make it difficult to breathe. Compressive asphyxia from these pressures is the most common cause of crowd deaths, not the trampling usually reported in the press. Compressive asphyxia, a condition medically difficult to reverse, has occurred in people as others pile up on them as they fall. As evidence of the magnitude of forces involved, bent steel railings were discovered after several fatal crowd incidents (for example, in the Who concert disaster). This indicates that forces of more than 1100 lb (500 kg) occurred. The pressures are not due entirely to pushing, but are also the domino effect of people being forced off balance and leaning on those in front. It could be compared to the compression of a giant steel spring. The human shock waves that surge through the crowd are a combination of this domino effect and a collective muscular reflex to obtain breathing space. Persons falling during a crush will have others forced on top of them, pinning them down and if the pile is high enough, causing respiratory failure.

Casualties have also been caused (as indicated in the Hillsborough Stadium disaster) by the failure of guard railings under crowd pressures and structural failure of ramps and bridges under the stress of heavy crowding. Security personnel may attempt to control the crowd from the front, urging people not to push. However, this type of control can be ineffective because counterpressures in front ranks can cause falls farther back within the crowd, resulting in pileups. For example, in the Who concert, fatalities occurred about 30 ft (10 m) back from a wall, possibly indicating that those at the wall were "pushing off" and subjecting those in the fatal zone to pressure from both front and rear ranks.

Information

The lack of immediate, reliable, and authoritative information by both crowd managers and crowd participants can be a critical factor in crowd incidents. In the broad systems sense, information has many forms. It includes any and all means of communication, the sights and sounds affecting group perceptions, training and actions of personnel, signs, and even methods of ticketing. Crowd managers and control personnel require an instant and accurate view of levels of occupancy, movement, and the actions of a crowd. They must know the practical limitations and capacities of every facet of the venue. Crowd members need to be informed of the status of events and requirements for safe and orderly conduct. Tickets affect crowd behavior and movement by determining the numbers of people involved in an activity and specific points of entry, assembly, and exit. Information is considered to be one of the most important aspects of crowd management.

Space

Space encompasses all the physical facilities used for the assembly and movement of people. It includes the size and areas of standing and seating spaces, and the number and practical working capacities of corridors, ramps, stairs, doors, turnstiles, escalators, and elevators. The configuration of these facilities is also a consideration. For example, a confusing or circuitous alignment of egress facilities would be an impediment to orderly evacuation in a flight response incident, particularly if obscured by smoke or power and illumination failures. Deficiencies in the capacity and configuration of assembly and movement facilities are considered to be the primary cause of crowd disasters.

Time

Time is the duration of the crowding experience. It is a direct determinant of total movement capacity. Crowd incidents may begin with a rapid buildup of people at a point where practical capacity is exceeded and free movement is blocked. As a simple example of temporal effects, there are significant differences in the group experience during the longer ingress period before a sporting event, compared to the game end when all patrons wish to exit at once. During the exit sequence, facilities are used to near maximums, and dense crowding occurs. Time-based strategies can be used to manage the degree of crowding during some events. Major art exhibitions have reduced traffic peaking and venue crowding by time-of-arrival ticketing. These tickets stipulate a specific time block during which the ticket is valid.

Metering

Metering is a time-based crowd management and control technique used to control the arrival rate of persons at any "bottleneck" facility with limited capacity. Examples include stairs, narrow corridors, escalators, doors, ticket processing, and security screening locations. In California, a form of metering was applied by the Bay Area Rapid Transit (BART) system planners at the Oakland stadium pedestrian bridge connection to the adjacent transit station.* The bridge was purposely underdesigned so that bridge traffic flow rate equaled the passenger loading

*This information was based on a conversation with the then chief of planning design of the BART system

rate of the transit system trains. This form of crowd management avoids potentially dangerous crowding on transit platforms.

Metering must be carefully applied because it can cause waiting lines on the approaches to the metered facility. These approaches should be open and large enough to accommodate expected demands. Formalized queue lines are frequently used at the approaches to metered facilities.

Staff communication is a critical aspect of metering control. Personnel involved in metering control procedures should be in constant communication with each other and alert to any overcrowding problems and to stop movement. In the Oakland stadium example, a BART train service delay would require immediate notification of personnel at the pedestrian bridge entrance control.

CROWD MANAGEMENT EXAMPLES AND DISASTER INCIDENTS

A sampling of lethal crowd disasters in the critical occupancy, flight, and craze categories follows. Several historical lists of crowd disasters are posted on the Internet.*

Viewing Situations

Stalin's Funeral, 1953. Stalin's funeral in March 1953 is an example of a critical occupancy incident caused by ineffective crowd management and control procedures. Reportedly 3 million persons had gathered to view Stalin's body lying in state at the Hall of Columns near Moscow's Red Square. Side streets along the route to Stalin's bier were blocked by army tanks and trucks to control movement of the crowd. Police and military, some on horseback, beat people with clubs to further control the crowd, even as hundreds of people were fatally crushed against building walls and the parked tanks and trucks. This event is in sharp contrast to the management of the crowd at Pope John Paul II's lying in state.

Pope John Paul II, 2005. Approximately 4 million people came to view Pope John Paul II lying in state in April 2005. An orderly queue line was set up on the approaches to St. Peter's Cathedral, at times reaching 3 miles (5 km) in length. Some mourners waited as long as 15 hours for a few seconds of viewing. Security was a significant concern, not only because of the sheer magnitude of the crowd but also because of visiting heads of state, some unpopular, and potential terrorist acts. Thousands of security forces, taken from the ranks of police and fire departments across Italy, were called in for crowd control. At one point two large lines heading toward St. Peter's Square were gradually merged into one by alternately releasing 500 persons at a time. The entire route was observed by CCTV, and crowd status was constantly communicated to police. Approximately 18,000 people per hour viewed the pope, with ushers dividing the line in two at the bier and urging mourners to walk past quickly.

Viewing situations, whether for those described here or for museum exhibitions, have capacity limitations. The viewing frontage, or the number of observers either standing or walking, and their viewing times determine the rate of flow. The smallest picture in a museum exhibit can determine flow rates because of its limited viewing frontage. Functions such as ticket collection and security screening also restrict pedestrian traffic flow and crowd processing rates.

Sports Stadia

Hillsborough Stadium, Sheffield, England, 1989. Sports stadia have been the scenes of a number of critical occupancy crowd disasters around the world. The 1989 Hillsborough Stadium in Sheffield, England, is cited only because it is one of the most thoroughly investigated.[3] Overcrowding of a stadium terrace, lack of front-to-back communication, combined with a railing failure resulted in 96 deaths and more than 400 injured. In this incident a larger than anticipated turnout of fans for a semifinal cup event overwhelmed the turnstile processing capacity, causing a backed-up crowd outside the stadium. It was later estimated that it would have taken more than two hours to process the accumulated fans with the available turnstiles. Police decided to open the gates to the west terrace to avoid crowd rush problems that would have occurred with the start-up of the match. Detailed analysis of photographs before the railing collapse showed that average standee densities on the terrace steps were 8.4 persons per square meter (1.3 ft^2/person), varying from 7.5 persons to 10.0 persons per square meter (1.4 to 1.1 ft^2/person) in rear and front rows, respectively.

Stadia with reserved seating are less likely to experience crowd crush incidents, such as the one that occurred at Hillsborough, because this system results in balanced, predictable occupancy, and dispersed pedestrian points of entry and egress. Seat and aisle arrangements result in spectator densities of about 2 persons per m^2 (5 ft^2/person) in seated sections.

Stepped Terraces and Stairs

Stepped terraces and stairs of any type are inherently dangerous places to accumulate crowds. Several incidents that follow show the involvement of stairs in fatal crowd incidents. Stairs provide a narrow platform for standing, and any pressure from the rear can cause chain reaction falls and potentially lethal pile-ups. Stairs are often weak links in pedestrian traffic movement because of reduced capacity and difficulties in bypassing slower pedestrians.

City College of New York Gymnasium, 1991. Critical occupancy of a stair resulted in 9 deaths and 28 injured at the entrance to the City College of New York gymnasium in December 1991.[4] A celebrity basketball game, advertised on a local radio station, attracted a large crowd. The gym was quickly filled, and the code-compliant, outward-opening doors closed to prevent more entries. Police controlled the crowd on the streets

*The website for Crowd Dynamics Ltd. (http://www.crowddynamics.com) has a comprehensive list of incidents; the online encyclopedia *Wikipedia* (http://www.wikipedia.org) lists crowd disasters under the term "human stampedes"; stories on crowds by both BBC News and CNN often cite a history of incidents; http://www.crowdsafe.com is also a useful site.

outside the venue, but were unaware of what was happening inside. Those precariously queued on the stair were driven into the lower landing area, jamming into the closed doors and piling up against them.

Festival Seating Events

Festival seating events, actually general admission without the formalized control offered by reserved seats and aisles, consistently result in critical occupancy conditions. Fan exuberance combined with extreme densities in front ranks cause most of these incidents.

Pearl Jam Concert, Roskilde, Denmark, 2000. In June 2000, 9 persons were killed and more than 25 injured as the band Pearl Jam played at 1 of 7 stages in Roskilde, Denmark.[5] Roskilde is one of Europe's biggest annual outdoor music events. It was estimated that 50,000 people had congregated at the Pearl Jam venue. Band members became aware of the crush and implored the audience to step back. It is virtually impossible to reverse a crowd crush in progress by this method because those in front ranks, in the "crush zone," cannot move, while those in the rear sense no danger. Subsequent police investigation exonerated the band and music fair management and blamed actions of the crowd for the deaths. A police representative suggested changes that might have lessened the tragedy, including a shorter chain of command to stop concerts more quickly and possible better surveillance of the audience.

Security staff is relatively ineffective in festival seating events, relegated to standing around the perimeter of the audience, without direct crowd access. Persons becoming ill in a dense crowd must be "surfed" out of the venue, by being passed overhead by the audience to security personnel on the perimeter. Surfing itself can be dangerous in critical occupancy conditions if the "surfer" is dropped and then becomes a fall and pileup hazard. Some top performers contractually limit crowd controls because they want to "feel" the energy of their fans (from the stage, not in the audience). Performers will sometimes throw souvenirs such as T-shirts out into the audience, potentially inciting dangerous crowd movement; at other times last-minute cancellation of an event has led to crowd disorders. Venue owners and managers have the responsibility of controlling promoter and entertainer actions, consistent with the venue capabilities and audience safety.

Central Park, New York City.

Festival seating events in New York City's Central Park have been successfully managed for many years without serious incidents. The concert security staff use crowd barriers to create a clear center aisle approximately 12 ft (about 4 m) wide extending from the rear of the venue up to the stage. The center aisle serves multiple purposes, including observation of crowd behavior, removal of unruly persons, and provision of medical assistance if needed. Other venues have installed crowd access and safety zones along the front of the stage, with some extending the zone out into the audience in "T" and "H" configurations. These configurations require clear routes out of the crowd scene to a secure area where medical aid can be administered. Extra-large format (Jumbo-Tron) TV screens offer opportunities to quickly communicate with crowds, by showing crush conditions in the front of the venue. In indoor venues they provide an opportunity to inform spectators of exit locations, venue rules, and other safety information.

Flight Response Incidents

Flight response incidents are triggered by fires, explosions, or unusual weather events that are perceived as threatening personal safety. Misinformation has also caused flight response incidents when there is no real threat.

DuPont Plaza Hotel Fire, San Juan, Puerto Rico, 1986. The DuPont Plaza Hotel fire in San Juan, Puerto Rico, in December 1986 resulted in 98 deaths in the hotel casino.[6] The casino had a double door at the front entrance off the main lobby and a single door at the rear. The rear door was a short distance from the pool area and the nearby beach. Under normal circumstances, the casino could be evacuated in a few minutes. The fire, started by arsonists, began in a ballroom on the other side of a wide stair adjacent to the casino. Hotel staff became aware of the fire shortly after ignition and made futile attempts to extinguish it. Casino occupants were not made aware of the fire at that time. Within an estimated 12 minutes, the fire flashed over the stair and rapidly engulfed the casino. The flashover blocked the main entrance doors, leaving only the single rear door for escape. Had this door opened outward, instead of inward, many lives would have been saved because of its close proximity to the pool area. However, fleeing victims piled up against the door, jamming it shut. Virtually all the victims were found at this door (Figure 4.4.1).[7]

The incident illustrates the importance of rapid communication, and the design and maintenance of viable egress routes. The DuPont Plaza Hotel fire and a number of other hotel fires resulted in the passage of the Hotel and Motel Fire Safety Act of 1990 (PL 101-391). This law mandates that federal employees on travel must stay in public accommodations that meet certain minimum levels of safety, including (1) sleeping rooms equipped with hardwired smoke alarms in accordance with *NFPA 72®*, *National Fire Alarm Code®*, and (2) the installation of an automatic sprinkler system complying with NFPA 13, *Standard for the Installation of Sprinkler Systems,* or NFPA 13R, *Standard for the Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height,* as appropriate. The automatic sprinkler provision does not apply to accommodations that are three stories or less in height.

E2 Nightclub Incident, Chicago, 2003. In February 2003 a DJ dance at the E2 nightclub in Chicago resulted in 21 dead and 85 injured.[8] Occupancy estimates vary, but a fire department official stated that as many as 1500 persons were on the second floor of the popular club at the time. There was an altercation in the club and the promoter's security personnel used mace pepper spray in an attempt to quell it. The spray permeated the air causing some to choke. Rumors spread that it was a terrorist act using poison gas. The bulk of the crowd rushed toward a 54-in. (21.3-cm) wide stair that connected to the front entrance, exceeding its capacity. Critical occupancy of the stair resulted

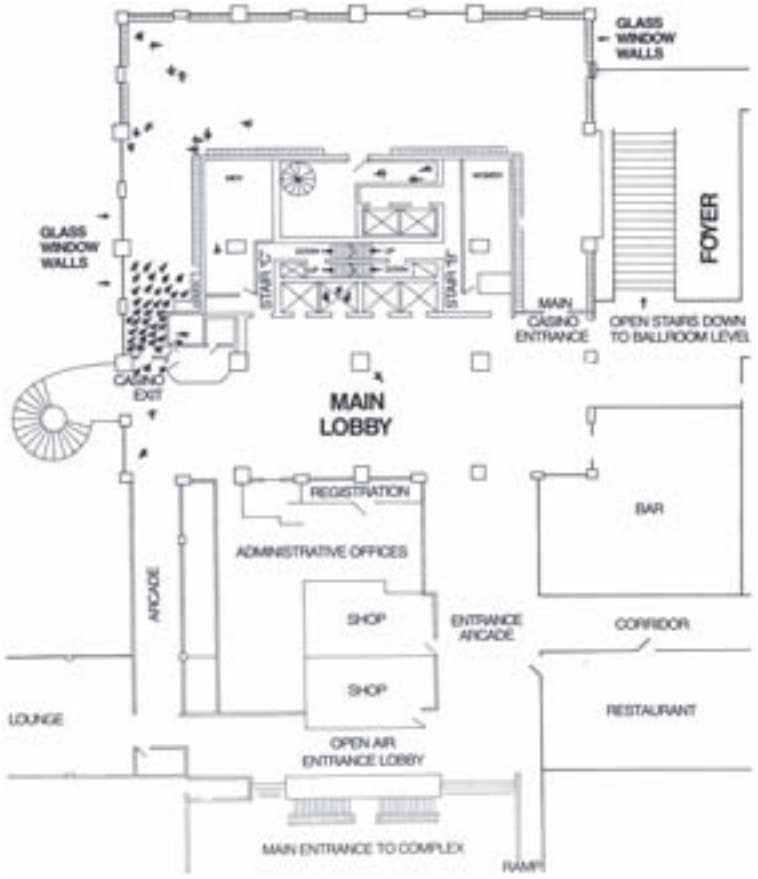

FIGURE 4.4.1 Location of DuPont Plaza Hotel Fire Fatalities on Casino Floor (Source: K. J. Thomas, "Investigation Report on the Dupont Plaza Hotel Fire, December 31, 1986, San Juan, Puerto Rico," *NFPA Investigation Report,* National Fire Protection Association, Quincy, MA, 1987)

in a pileup in the 11 ft by 12 ft (3.4 m by 3.7 m) entrance lobby below. One of the witnesses said it was not uncommon for mace to be used in clubs for control purposes. Had the rumors not spread, it is likely that only minor eye irritations and breathing discomfort would have resulted from security staff actions.

The Station Nightclub Fire, 2003. The Station Nightclub fire in West Warwick, Rhode Island, also in February 2003, resulted in 100 dead (Figure 4.4.2) and more than 180 injured.[9]

Pyrotechnics used by the heavy metal band Great White ignited soundproofing behind the stage and quickly spread. A fire official stated that the nightclub was fully involved within 3 minutes. For a brief moment some watched the fire, thinking it was part of the act, but then quickly realized the danger. Most headed for the front entrance, the typical escape route in many incidents, jamming it and blocking orderly egress. Those outside tried to extricate victims in the pileup, succeeding in rescuing some. Three other exits were functional at the time, but exit signs were obscured by smoke. There were reports of the victims attempting to aid each other in finding other exits, helping some to survive.

Quitab Minar Tower Blackout, New Delhi, India, 1981. A power failure resulted in 45 deaths, 27 of them children, in December 1981 at the Quitab Minar Tower in New Delhi, India.[10] The 800-year-old tower is a popular tourist attraction and museum. A blackout, combined with unfounded cries that the tower was falling, triggered a sudden flight of 300 to 400 people. The fatalities occurred on a narrow tower stair.

Craze Incidents

The Who Concert Disaster, Cincinnati, Ohio, 1979. The Who concert disaster in December 1979 at the Cincinnati, Ohio, Coliseum is an example of a craze.[11] A crowd of 18,000 young fans was gathered outside the Coliseum waiting to enter this general admission event. All seats were on a competitive first in–best seat basis. Many were waiting for hours with inadequate lavatory facilities. The opening of the gates was delayed until shortly before the scheduled time of the performance. The warmup band started playing, and the fans thought the concert had begun. Only two doors were open to permit entry. The crowd rush and pressures resulted in 11 deaths.

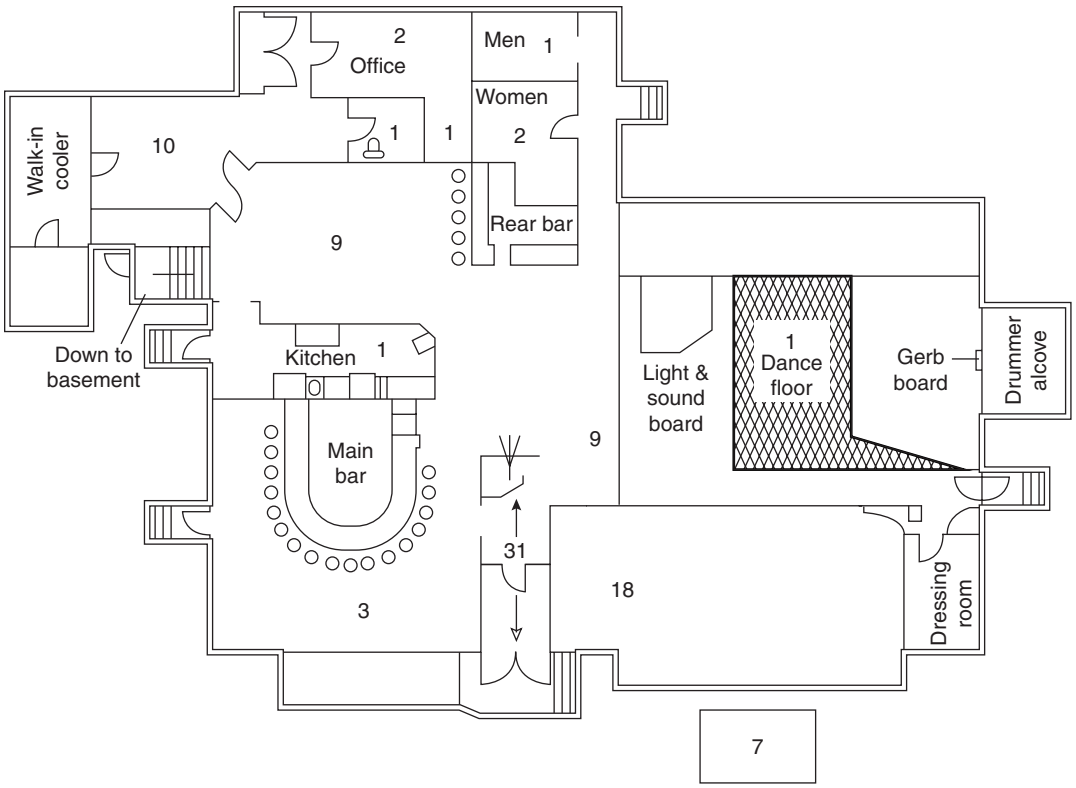

FIGURE 4.4.2 West Warwick, Rhode Island, Police Department Victim Location Diagram (Source: http://www.nist.gov/public_affairs/releases/Vol_I_NCSTAR2.pdf, Figure 5.54)

Sangju, South Korea, Concert Incident, 2005. The Who concert disaster scenario was replicated in October 2005 at a Sangju, South Korea, venue.[12] About 20,000 people had been waiting two hours for a free admission event featuring traditional Korean music popular among the elderly. The rush began when only one gate was opened, causing 11 deaths and injuring 72 others. The dead included 8 women aged 54 to 76, along with 3 boys aged 7, 12, and 14.

Minsk, Belarus, Incident, 1999. A crowd rush into a transit station in the Belarus capital, Minsk, in May 1999 killed 54 and injured more than 100.[13] About 2500 people had just left a concert when a hailstorm caused them to seek cover in the Nyamiha station. The incident happened in a tunnel leading to the station. Among those killed were 2 police officers, who died trying to control the crowd, and 42 teenage women.

Mecca, Saudi Arabia, Hajj Incidents. The vast multitudes of devout Muslims participating in Hajj at Mecca, Saudi Arabia, make it a monumental crowd management problem. More than 2 million people, the equivalent of the combined population of the cities of Boston and Philadelphia, participate in a series of symbolic rituals as part of the pilgrimage. There has been a series of crowd incidents over the years related to movement between the housing areas and the ritual site and during rituals at the site. Crowd deaths totaled 1426 in July 1990, 270 in May 1994, 180 in April 1998, 35 in March 2001, 36 in February 2003, 244 in February 2004, and 345 in January 2006.[14] After the 2004 incident, Saudi officials widened ramps leading to the ritual stoning of the devil where several crushes occurred, expanded the ritual area, added more emergency exits, and installed CCTV cameras. Reportedly, 60,000 security personnel are used for crowd control, or about 1 for every 40 pilgrims. Falling during the mass movement of pilgrims is a common cause of these incidents, with the following crowd unable to stop because of the pressures from behind.

CROWD MANAGEMENT PHASES

There are three phases in which crowd management principles should be applied: (1) venue design, (2) pre-event planning, (3) and the event itself, including ingress and egress. Crowd management objectives are to provide a safe, secure, and convenient environment, with the objective of preventing critical occupancy conditions and avoiding incidents that would precipitate sudden mass movement within the venue or to and from it.

Venue Design

Many architects and engineers give minimal attention to the movement of people in initial venue design beyond that required for compliance with local building code or permit requirements. Compliance with standards does not guarantee that a venue will function well during maximum occupancy or emergency

conditions. Designers have the responsibility of preparing the initial crowd management plan. Designing for crowd management requires that the projected maximum occupancy of a space, combined with expected behavioral factors, be correlated with the traffic processing capabilities of all corridors, stairs, ramps, escalators, elevators, and other related facilities.

Circulation "Tree" Diagram. A good management technique is to develop a circulation "tree" diagram, or schematic pedestrian traffic flow plan, to show how the expected occupancy of a space will be distributed among its various elements. For example, a circulation tree diagram for a stadium would schematically show the section capacities, aisle widths and capacities, vomitories, connecting hallways, entrance doors, numbers of turnstiles, capacities of queuing spaces, and so on. The circulation diagram is a useful tool for assessing actual venue performance under various conditions and pinpointing areas that are not performing as expected. The circulation plan can be further refined by using computer simulations of pedestrian traffic movement, queuing accumulations, and other parameters. Simulations offer the advantage of examining the performance of a venue for a wide variety of scenarios, including the impacts of extreme variations in venue occupancy; the timing of events; temporal changes in venue configuration; and number of turnstiles, doors, or other processing facilities[15,16] (Figures 4.4.3 and 4.4.4).

Movement Pathways. Movement pathways should be simple and direct, and not circuitous or offset from the normal straight line of sight. Arrangements that result in unbalanced use of egress or ingress routes, dead ends, or similar confusing and irregular pathway choices, are not acceptable. Dispersed and equally balanced ingress and egress points are preferred over a single centralized location. The influence of external facilities on the volume and patterns of movement within a venue must be considered. For example, the concentration of parking or transit operations on one side of a stadium will focus internal movement toward that side, resulting in unbalanced traffic demands. Signing should be used to identify functions such as ticketing, to clarify routes within the venue and also to identify external elements such as parking and transit.

Pressure Point Hazards. Pressure point hazards along movement pathways must be avoided. Pressure points are locations where a right angle change in the normal direction of movement or a confluence of traffic streams results in crossing conflicts and accident exposure. Pressure point incidents may result in ca-

sualties where there are inadequately guarded openings to lower levels, at stair approaches, and on landings at the discharge or outlet ends of escalators. Crowd pressures at such locations may result in people being pushed over guardrails or down stairs, or in the structural failure of the guardrails.

Determining Location of Crowd Management Center. The crowd management center location and its supporting communications should be determined early in design. Real-time information about the status of crowd conditions in large assembly spaces is critical. The center should provide a maximum view of the venue, supplemented by CCTV access to blind spaces, pressure points, and major movement pathways. The crowd management center requires full communications integration with all crowd management staff; local police, fire, and emergency medical services; and any on-site radio or television media staff. Provision should be made for location of extra-large format TV screens as a multipurpose means of communication.

Backup Standby Power. Backup standby power for lighting and communications must be included in the design. The New Delhi Quitab Minar Tower blackout crowd incident is an example of the confusion that can result from a lighting and communications failure. Public address systems tied only to primary power sources would be lost during a power outage, potentially when they might be needed the most.

Emergency Medical Facilities. Emergency medical facilities sufficient to handle routine accidents as well as potentially larger crowd incidents are necessary. Lives may be unnecessarily lost in large crowd incidents due to the lack of simple equipment such as stretchers, oxygen, and defibrillators. Many venues accommodate the population equivalent of a medium-sized city, requiring that the medical center be fully equipped to provide immediate skilled response to cardiac cases, spinal injury cases, and other similar emergencies. The means of communication with local hospitals and emergency medical services, their response times and capabilities, and their ability to handle a possible mass crowd disaster should be established.

Pre-Event Planning

Operational Plan. Pre-event planning for the movement and assembly of large groups of people involves the determination of projected levels of occupancy, volumes and pathways of movement, crowd densities, anticipated crowd behaviors, and appropriate staffing. If available, the designer's crowd management plan can provide basic information about movement and assembly capabilities of the venue. The operator has the responsibility of using these data, combined with knowledge of the characteristics of the group and expected behaviors, to develop the operational plan. The ideal operating plan establishes a continuing pattern of normal crowd management that will easily shift into an emergency mode if circumstances suddenly change.

General Admission Events. General admission events should be avoided because they introduce competition within groups to obtain favorable viewing positions. Reserved seating has been combined with festival seating areas to maximize attendance at some events. This combination can result in competition by those in reserved seating to move closer to the performers in the festival viewing area. This situation can precipitate confrontations with crowd control personnel and in some venues can result in accidents as patrons attempt to enter the festival sections forcibly and unsafely.

Staffing Levels. Staffing levels for crowd management in different venues depend on group size, whether the group simply moves through a space or will both move and assemble, and the expected behaviors of the group. There are three types of security staff, with different levels of responsibility. Security staff can consist of peer, or "T-shirt" personnel, who are limited more to ushering and have limited contact with the audience; uniformed venue personnel, with the power to remove disorderly persons and hold them in custody; and police officers, with full powers of arrest and use of force if necessary. Impulsive crowd movement by groups of as few as 30 people can result in falls and other crowd-induced injuries.

Staffing in large assembly spaces depends on the configuration of the venue and the type of event. A children's parade or circus is obviously much different from a rock concert or hotly contested sports event. Security staffing for a low-risk event could be as low as 1 person per 250 patrons and for a high-risk event, 1 per 50. For instance, the 2006 edition of NFPA *101*®, *Life Safety Code*®, requires at a minimum 1 trained crowd manager for every 250 occupants for new and existing assembly occupancies.

The number of ticket collectors and others processing the entry of patrons depends on projected peak arrival demands and the procedures required. A simple pass-through gate with no information exchange required can accommodate up to 60 patrons per minute. This rate will be cut in half if the ticket processor has to read and tear the ticket. When patrons require more involved instructions or information, entry processing rates can drop to 6 per minute. In venues in which there are "stop and frisk" procedures, entry processing may be reduced further. Individuals selected for more involved security screening should be quickly moved away from the main entry stream, in a space set aside for this purpose. Airport-type security, employing metal detectors and other types of screening, may be necessary at some public gatherings.

Staff training for crowd management is of vital concern. Frequently casual labor individuals are used as peer security employees at large events, with nothing more than vague instructions about controlling certain crowd behaviors. Even permanent staff may have limited training in crowd management, recognition of potentially dangerous crowd problems, and the handling of accidents and other emergencies.

During a study of door egress rates at a 16,000 seat arena, the author observed that a number of doors were chained and locked during the event as a means of controlling gate crashing. Crowd densities during a sudden emergency egress would make it impossible for the staff to gain access to these doors to unlock them. Training should include instructions on the basics of normal and emergency crowd movement and assembly; initial

handling of accident victims, altercations, and other crowd incidents; communications procedures and use of communications equipment; avoidance of actions that would incite or trigger dangerous crowd behaviors; and conduct and demeanor during an emergency. Personnel should be provided with a pocket guide to reinforce training guidelines and communications procedures.[17]

Weather Conditions. Weather conditions are a factor in open venues in areas where tornadoes, thunderstorms, hailstorms, or other similar meteorological events are common. The crowd manager in open venues has the responsibility of keeping abreast of local area weather, particularly when severe weather is predicted. The retaining of a private meteorological service for this purpose for larger public events and venues is advisable.

The Event

Communication failures are a common component of virtually all serious crowd incidents. Accurate and timely information is necessary to assure an appropriate response to developing situations before they reach critical phases. All security personnel should be connected to the central crowd management control center via handheld radios. Public address systems should be capable of reaching all areas of the venue, and instructions should be accurately phrased and understandable. Closed-circuit TV surveillance cameras should be situated to cover all blind spots, as well as a wide view of the event venue. A staff member should be constantly monitoring the situation from a control center and be prepared to pass on information to staff on site and to provide instruction to the crowd via the public address system. Extra-large TV screens are an excellent means of audience communication, but camera personnel must be included in the communications network and must understand what to record for crowd crush or other emergency incidents. Crowd managers should know how to communicate with first responders in an emergency and what their radio frequencies are. This information could prove valuable in assuring that appropriate equipment and numbers and type of personnel are dispatched to the site.

One aspect of September 11, 2001, that has not received much attention is that there were three subway transit stations in the World Trade Center (WTC) complex and two more nearby. These stations were capable of delivering many thousands of occupants into the complex within a few short minutes. Out of all the communication failures, there was one success: the NYPD stopped all the trains from entering the WTC, avoiding even more people on the scene.

SUMMARY

Crowds occur frequently in a wide variety of venues. Occasionally, a sequence of events precipitates a rapid concentration of people that results in multiple casualties. Crowd management is a planned program for the safe movement and assembly of people. Three categories of situations that have resulted in crowd fatalities include critical occupancy, flight response, and craze. A systems model of the primary elements involved in crowd disasters are embodied in the acronym FIST, with F standing for force, I for information, S for space, and T for time. To illustrate both the three categories and the four elements involved in crowd incidents, a number of crowd disasters are described. The role of crowd management in venue design, in pre-event planning, and during events is critical to ensure a safe, secure, and convenient environment and to avoid incidents that would bring about a sudden mass movement either within the venue or to or from it.

Chapter 5

Strategies for Occupant Evacuation During Emergencies

Daniel J. O'Connor ■ Bert Cohn

Chapter Contents

Occupant Characteristics
Total Evacuation Compared to Alternative Evacuation Strategies
Horizontal Exiting
Evacuating by Elevator
Preplanning for Fire Incidents
Nonfire Emergencies

Key Terms

area of refuge, area of rescue assistance, defend-in-place, delayed evacuation, elevator, horizontal exiting, occupant characteristics, partial evacuation, phased evacuation, total evacuation, zoned evacuation

As children, we learned in school that when the fire alarm signal is given, whether bells, horns, or strobes, we should immediately stop what we are doing and line up to evacuate the building by the nearest exit. We learned that if that route is blocked by smoke or fire, we must use an alternate exit. The school held fire drills so that if a real fire occurred, evacuation would be fast and orderly. The school preplanned not only for a possible fire but for other events as well, such as tornadoes, earthquakes, and other natural or man-made circumstances that could affect the students and teachers. For some events, we found refuge in the building, but fire situations invariably called for immediate and total evacuation to a place of safety outside.

The common evacuation drills experienced during our school years represent a total general building evacuation; that is, everyone evacuates (general) and they evacuate to a point completely outside the building. More recently, there has been growing recognition that the considerations of occupant characteristics, authority-figure influence, and building type can make a total general building evacuation a disproportionate or even dangerous response. If the building is very large or very tall, most people may be too far away to be in danger from even a large and growing fire, and the length of travel during evacuation may pose significant risks (e.g., falls) of its own. If the occupants are restricted or nonambulatory, there may be little likelihood that total evacuation can be accomplished ahead of the growing fire.

This chapter discusses a variety of evacuation strategies that may be appropriate for various occupancies. The conditions under which any one evacuation strategy should be used depend on the nature of the building and the occupant characteristics. The following examples outline some of the basic building and occupancy considerations that may impact the selection of an appropriate evacuation strategy:

- *Assembly buildings:* large and potentially dense population of occupants subject to the threat of a single fire incident
- *Low- and mid-rise residential:* sleeping occupants in buildings of combustible construction types with a higher risk of fire spread and total fire involvement
- *High-rise residential:* sleeping occupants in buildings generally of high degree of fire-resistive construction and floor-to-floor compartmentation
- *Health care facilities:* these are facilities in which occupants can be expected to require assistance from staff and are physically not capable of relocating down stairs or to the building exterior
- *Detention/correctional facilities:* occupants who cannot be released to the public space but must be relocated in the event of fire to adjoining secured zones

Daniel J. O'Connor, P.E., FSFPE, is vice-president of engineering for Schirmer Engineering Corporation in Deerfield, Illinois.

Bert Cohn, P.E., FSFPE, is senior project manager for the Chicago regional office of Schirmer Engineering Corporation.

- *Multistory or large-floor-area buildings:* buildings in which total or partial evacuation is possible, depending on the nature of the building fire protection features and occupancy
- *Very tall buildings:* buildings with large occupant loads and long total evacuation times (e.g., >1 hour)
- *Buildings with occupants with disabilities:* special provisions in the form of specific refuge areas or procedures for relocating occupants with physical or mental limitations may be necessary for a wide variety of buildings and occupancies
- *Critical operations buildings:* facilities housing personnel and functions that control critical processes or operations (e.g., air traffic control tower, power plant control room) in which early evacuation of key personnel would create large risks from unattended critical processes (e.g., crash of incoming aircraft, core meltdown and release of radioactivity)

OCCUPANT CHARACTERISTICS

The characteristics of occupants play an important role in selecting an appropriate evacuation strategy.

Consider the contrasts between two occupancy scenarios—a mid-rise office building and a low-rise nursing home. Generally, the mid-rise office building occupants are assumed to be alert, able-bodied occupants of various ages. Such occupants can be expected to comprehend emergency instructions and make decisions relative to their individual safety based on the emergency information in any fire incident. Additionally, office building occupants can readily move to the safety of exit stairs and down the stairs to the exterior of the building. These occupant characteristics are amenable to selecting a phased or total evacuation of such a mid-rise office building.

In contrast to the office building occupants is the scenario involving a low-rise nursing home facility. The occupants of such a facility exhibit characteristics that are significantly different than those of the office building occupants. First, the general population age is expected to be over 65 years, and the physical and mental capabilities are expected to be significantly diminished compared to the office building population. The presence of staff in a nursing home is a positive factor, yet it can be a difficult and ineffective undertaking for a few staff members to initiate and conduct a total evacuation of occupants in poor health and who may be sleeping. A total evacuation may, in fact, put nursing home residents at greater risk during a fire incident, given their inability to comprehend and follow instructions, slower walking speeds, and need for physical assistance if nonambulatory. Compared to the office building scenario, it is apparent that a rapid, effective total evacuation is not the best option for a nursing home scenario, and an alternative strategy to shelter nursing home residents from the effects of a fire may be better. Certainly, facility staff are expected to respond by evacuating or attempting rescue of those in near threat of the fire followed by relocating other residents to safe areas of the building.

TOTAL EVACUATION COMPARED TO ALTERNATIVE EVACUATION STRATEGIES

Total Evacuation

For most buildings, immediate and general evacuation of occupants to the street or other exterior place of safety in the event of fire is the accepted norm. This is the common practice for houses, hotels, dormitories, rooming houses, stores, restaurants, movie theaters, schools, and other low-rise structures. If a fire alarm system is installed, an automatic or manual alarm initiation starts the general evacuation signals. Where NFPA *101®*, *Life Safety Code®*, is accepted and subject to approval of the authority having jurisdiction (AHJ), a positive alarm sequence can provide a 3 minute window for investigation (2 minute delay in Residential Board and Care) before the general evacuation signal is given.

In most locations, total evacuation immediately or very soon after fire discovery is the most conservative and best response. Smaller buildings are less likely to have personnel trained to respond to and realistically evaluate the potential threat of an incipient fire. For fires in the home, the best procedure is to get everyone to safety as fast as possible, before making an attempt to fight the fire. Even calling the fire department is best done away from the home that is on fire.

Alternative Evacuation Strategies Defined

Immediate, total evacuation may not always be desirable or feasible. Health care and detention facilities may operate under conditions that prevent such evacuation, and the mechanics and time involved in totally evacuating very large or very high structures immediately following detection of a fire make delayed or phased evacuation a necessity. Several different but related concepts are recognized when immediate, total evacuation is not possible or desired.

Partial or Zoned Evacuation. Partial or zoned evacuation provides for immediate, general evacuation of the areas of the building nearest the fire incident. A partial evacuation may be appropriate when the building fire protection features assure that occupants away from the evacuation zone will be protected from the effects of the fire for a reasonable time. However, evacuation of additional zones may be necessary.

Phased Evacuation. Phased evacuation provides for immediate, general evacuation of the areas of the building nearest the fire incident with continuing, selective evacuation of all other building areas.

Delayed Evacuation. Delayed evacuation takes advantage of temporary holding places, typically known as *areas of refuge* or *areas of rescue assistance,* where occupants can remain in relative safety, albeit near the fire area, for a period of time before

evacuating the building, either by themselves or with assistance from emergency responders or others.

Defend-in-Place. The defend-in-place strategy recognizes that at times it is safer for occupants to remain in place within protected zones of a building than to evacuate the building.

Partial or Zoned Evacuation

Using a partial evacuation strategy will depend to a large extent on the building characteristics. Buildings built with distinct fire barriers, smoke separations, or horizontal exits or which have a high degree of floor-to-floor fire resistance are candidates for using a partial evacuation. These fire and/or smoke compartmentation features provide protection for those occupants outside of the affected fire area or floor. Those occupants located in the fire or smoke compartment of origin are subject to the greatest risk and, therefore, it is logical to focus on their evacuation and movement to safety (Figure 4.5.1). However, evacuating only those at immediate risk does not mean that the evacuation is completed. The circumstances of the fire incident, the nature of the occupants, and the assessment of fire conditions by the responding fire department will be factors in the decision to evacuate any additional zones.

Partial or zoned evacuation of a building may be an appropriate strategy in some facilities. A partial evacuation can avoid subjecting all occupants to a mass exodus event, which alone poses a set of risks to the occupants and can interfere with the efficient response of the fire department or other emergency responders. In all cases when a partial evacuation is the general strategy to be used, it is important that evacuation procedures address and account for additional and continued evacuation of building zones.

Phased Evacuation

Phased evacuation is total evacuation but not all at once. Occupants most likely to be affected by the fire incident are evacuated first, followed by others who are more remote from the fire incident. This is done to smooth the flow of people from the building. Everyone attempting to exit simultaneously from a high-rise building soon causes the stairways to be filled and will slow the evacuation from the portions of the building most affected by the incident.

Phased evacuation is accomplished most often by voice communication over fire alarm speakers. The initial evacuation may be done automatically as an alarm is received and can be for the fire floor and the floors immediately above and below or variations thereof. Subsequent evacuation is ordered by the fire department on a selective basis.

Delayed Evacuation and Areas of Refuge

For many buildings, a principal evacuation strategy may be generally applicable to the building population; however, there may be a small number of occupants having special needs or limitations that may require specific consideration or procedures to address needs for their safety.

In today's society local, national, and international laws as well as the general business community continue to strive to

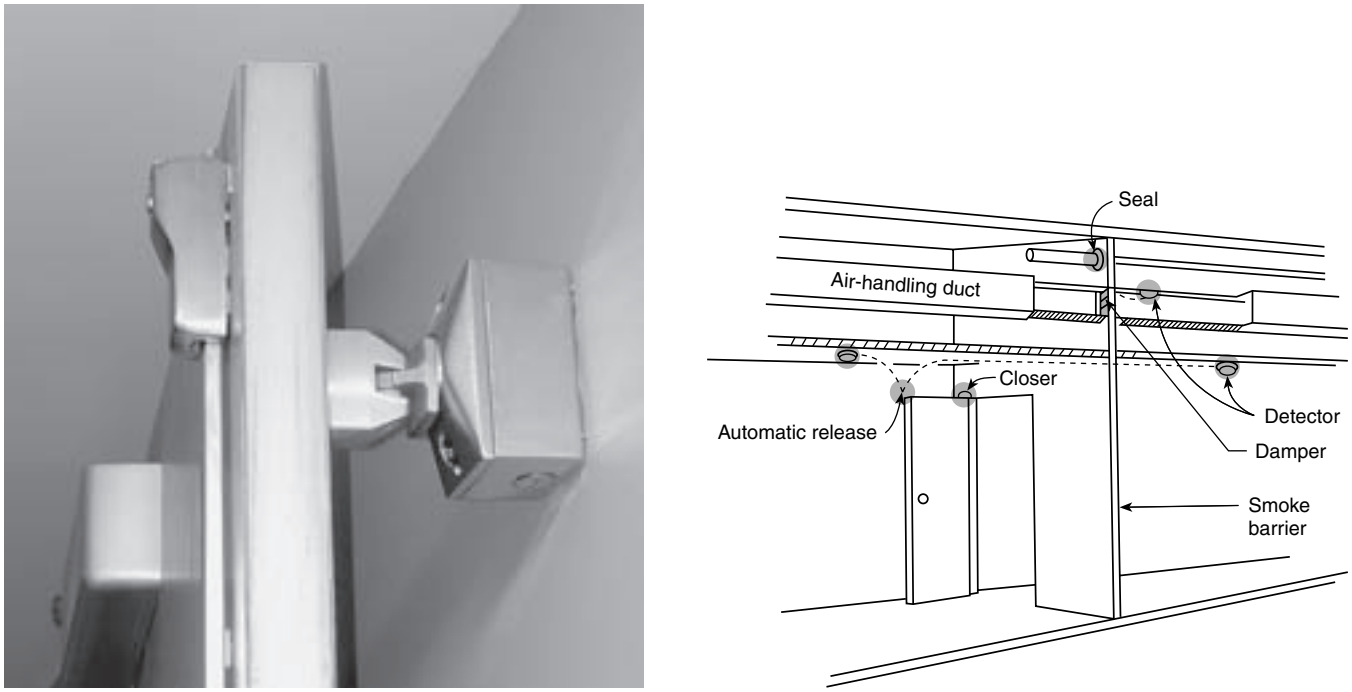

FIGURE 4.5.1 Magnetic Release for Door Barrier (left) and Typical Protective Measures for Smoke Barrier Penetrations (right) (Source: Exhibits 8.8 and 8.10, *Life Safety Code® Handbook,* 2006 edition)

provide employment, goods, and services to individuals who have a disability or impairment. Often these individuals will require special assistance in the event of a building evacuation. In the United States the Americans with Disabilities Act of 1990 (ADA) requires that policies and procedures for public accommodations address people with disabilities, which include individuals with one of the following impairments that could impact their evacuation from a building:

- *Mobility impairment:* includes slow walkers and wheelchair users
- *Visual impairment:* blind or difficulty with seeing the exit route or proceeding down stairs
- *Hearing impairment:* individuals whose deafness or limited hearing may preclude hearing and interpreting emergency evacuation instructions
- *Temporary impairment:* individuals who have been injured or are recovering from a serious medical condition
- *Medical condition:* individuals whose stamina or physical condition may inhibit their ability to egress (e.g., individuals with respiratory disorders, pregnant women)
- *Mental impairment:* individuals who may have difficulty implementing an appropriate emergency response, may become confused, or lose direction during an emergency

Depending on the nature of any given individual's disability, the level of evacuation assistance required will vary. In many cases the assistance needed may not be readily available and temporary relocation to an area of safety within a building as a delayed evacuation measure may be necessary.

NFPA *101* provides for temporary holding areas within buildings, protected from the immediate effects of a fire and, thus, allowing delayed evacuation. The definition of an area of refuge, from which evacuation can be delayed, has been expanded in recent years to include sprinklered buildings and reduced fire ratings.[1] In effect, NFPA *101* recognizes that immediate, total evacuation can be avoided where provisions are made within the structure to hold people while the situation is being assessed. By definition, an area of refuge is either (1) a story in a fully sprinklered building that has at least two accessible rooms or spaces separated from each other by smoke-resisting partitions or (2) a space within the path of travel leading to the outside, protected from other spaces by some means of separation or by virtue of its location. Two separated accessible spaces in a sprinklered building are not required for low-hazard occupancies, such as business and apartment buildings. Figure 4.5.2 illustrates a typical area of refuge.

Further explanation and expansion of the concept of an area of refuge to delay total evacuation is provided in the NFPA *101* Annex:[2]

> An area of refuge might be another building connected by a bridge or balcony, a compartment of a subdivided story, an elevator lobby, or an enlarged store-level exit stair landing. An area of refuge is accessible by means of horizontal travel or, as a minimum, via an accessible route meeting the requirements of ICC/ANSI A117.1, American National Standard for Accessible and Usable Buildings and Facilities.

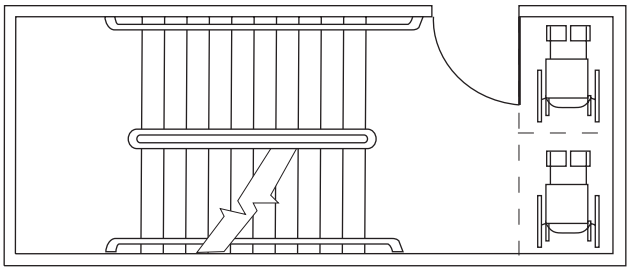

FIGURE 4.5.2 Exit Stair Used as an Area of Refuge (Source: Figure A.7.2.12.3.1, NFPA *101,* 2006 edition)

> This *Code* (NFPA *101*) recognizes any floor in a building protected throughout by an approved supervised automatic sprinkler system as an area of refuge. This recognition acknowledges the ability of a properly designed and functioning automatic sprinkler system to control a fire at its point of origin and to limit the production of toxic products to a level that is not life threatening.
>
> The requirement for separated rooms or spaces can be met on an otherwise undivided floor by enclosing the elevator lobby with ordinary glass or other simple enclosing partitions that are smoke resistant.

Defend-in-Place

As an alternative to total evacuation, a defend-in-place concept is recognized in NFPA *101*. An appendix paragraph[3] from the 1997 edition of NFPA *101* summarized the concepts that continue to be recognized under the 2006 edition of NFPA *101*.

> It is not always necessary to completely evacuate the building or structure to escape from a fire or other emergency. An area of refuge formed by horizontal exits, smoke barriers, other floors, or similar compartmentation often can serve as a place for the occupants to remain in relative safety until the emergency is over. In those occupancies where access to the exits is by way of enclosed corridors, particularly those occupancies with sleeping occupants, a single fire may block access to all exits, including horizontal exits and smoke barriers. In such cases, the occupants may achieve a greater degree of safety by remaining in their rooms.

An area of refuge becomes "defend-in-place" if fire control is achieved before it becomes necessary to order evacuation from spaces that are remote from the fire incident. The use of fire-resistive construction and fire partitions and the availability of horizontal exiting all can reduce the risk that the area of refuge will ever be sufficiently threatened that it must be abandoned for a total evacuation.

The defend-in-place concept has been used in apartment buildings of fire-resistive construction, where it can be safer to remain in the apartment than to attempt evacuation through a smoke-filled corridor and down several flights of stairs. Partitions between apartments and corridors typically have at least

1-hour fire resistance ratings, giving sufficient time for fire department response and phased evacuation as needed. Human behavior has been on several occasions cited as playing a major role in the fatalities and injuries of high-rise residential buildings in 1985 by Macdonald[4] and most recently in some detail by the works of Proulx.[5] Both authors' works have seriously questioned the appropriateness of evacuation of high-rise residential buildings, including hotels. Frequently during fires, occupants who stayed in their apartments or hotel rooms were safe and uninjured, whereas those who evacuated became casualties. Both conclude that occupants of residential high-rise buildings should use a stay-in-place approach, which then suggests a defend-in-place design philosophy.

Defend-in-place is not limited to fire-resistive construction. As stated earlier, NFPA *101* recognizes each floor of a fully sprinklered building to be a place of refuge from a fire on another floor. Thus, immediate evacuation is not necessary and evacuation may not be necessary at all. Except in rare cases, there is time for orderly, phased evacuation.

HORIZONTAL EXITING

Horizontal Exiting Defined

Evacuation from a building, as normally thought of, envisions everyone leaving the building for an exterior place of safety, either a street or a path that leads to a street. But evacuation can also be to another building, by first crossing an open space between the buildings or directly through a communicating opening in a common wall. This is horizontal exiting, and it does not have to be at ground level. Horizontal exits, whether across an open-air passageway or through a fire wall, can be on any or all levels of a multistory building. Horizontal exiting often is feasible within a building that has fire-resistive floors through the use of 2 hour fire partitions, as seen in Figure 4.5.3.

Benefits of Horizontal Exiting

Horizontal exiting can be very beneficial for defend-in-place situations where total evacuation is particularly difficult, such as health care facilities with nonambulatory patients and detention facilities that do not care to have inmates wander the streets. The space to which occupants evacuate via a horizontal exit must be large enough to house the population (in a cramped manner) and must have its own stairway or other exits leading to the exterior.

Besides the advantage cited earlier—of not having to evacuate occupants to the street or other exterior location—horizontal exiting permits same-level, faster evacuation from the location of a fire incident on upper stories of a building. The queuing delay common for stairway exiting is avoided, using the same exit widths in relation to stairways, and often horizontal exiting permits the elimination of one or more stairways, providing good financial benefit. Exiting capacity is calculated separately for each section, and credit is given for the horizontal exit (as a doorway exit) in both directions.

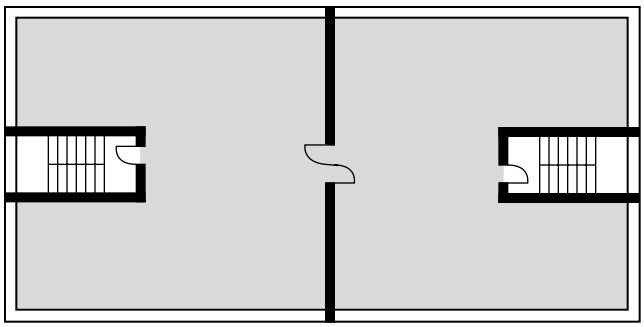

FIGURE 4.5.3 An Area of Refuge on Both Sides of the Wall Provided by a 2 Hour Fire Barrier Incorporating a Horizontal Exit (Source: Exhibit 7.70, *Life Safety Code® Handbook,* 2006 edition)

EVACUATING BY ELEVATOR

Disadvantages of Evacuating by Elevator

Following fire incidents in which people were trapped in elevators as elevators stopped at fire floors and would not allow elevator doors to close, building evacuation using elevators has become universally discouraged. The ubiquitous signage "Use Stairways in Case of Fire—Do Not Use Elevators" in elevator lobbies is the result. NFPA *101* does not accept elevators as exits (except in limited-occupancy towers) but permits them to be used for evacuation of mobility-impaired individuals.[6]

Beside the problem of the elevator being called to the fire floor by circuit malfunction, other problems with elevators during a fire have been cited,[7] including the following:

- Delays in elevators arriving may cause people to wait in an environment exposed to smoke, heat, or flames.
- Persons calling for elevators at the fire floor may expose additional persons to the fire by having a descending elevator stop at the fire floor.
- Large numbers of persons attempting to crowd into an elevator in an attempt to escape may prevent the doors from closing, trapping all at the fire floor.
- A power failure during elevator operation may cause people to be trapped between floors; emergency power can be ineffective if elevator cabling or machinery is affected.

Conditions for Elevator Evacuation

Despite the general adverse attitude, elevators can be very efficient in moving people out of upper floors of buildings, and they are almost a necessity for evacuating those unable to descend many flights of stairs unassisted. In fact, the use of elevators for emergency evacuation can be especially attractive in high-rise buildings and should focus on immediate assisted evacuation from the floor levels affected by a fire emergency. Each floor of a high-rise building can qualify as an area of refuge. Thus, limiting elevators to floors in most immediate need of evacuation can be done without endangering occupants on other floors.

To use elevators as a primary means of egress, so that they can be safely utilized for evacuation during a fire emergency, a

number of proposed requirements have been set forth by one author, a retired New York City fire officer:[8]

- The building should be fully sprinklered.
- Elevator shafts should be pressurized.
- Elevator lobbies should be enclosed and pressurized.
- Air intakes for pressurization of shafts and lobbies should be from a smoke-free source.
- Elevator lobbies should have smoke detectors.
- Elevator systems should be water resistant.
- Elevators should return to a designated level on a power failure.
- Elevators should have dedicated emergency power.
- Elevator lobbies should have direct access to a pressurized stairway.
- Elevator cabs and lobbies should have two-way communication with the fire command station.
- Elevator response during fire emergencies should be preplanned.

Whether all such conditions are needed to make elevator evacuation as safe as stairway evacuation is debatable, but several of the items are part of current code requirements. Elevator recall is common, and smoke detectors to actuate elevator recall tend to be provided for any new or retrofit elevator work. NFPA *101* allows elevators to be used for exiting from places of refuge provided the elevator is arranged for fire fighter service, power supplies are protected, and the shaft meets the requirements for a smokeproof enclosure.[9]

Fire Fighter Use of Elevators

Although not giving credit for elevators that are available for evacuation (except towers with limited occupancy), NFPA *101* recognizes elevators as a means of egress under certain conditions.[10] Under manual, in-car "fire fighter" control, elevators may be operated by trained emergency service personnel (e.g., building personnel or fire personnel) to assist in evacuation, particularly in high-rise buildings, in towers, or in deep underground spaces where travel over considerable vertical distance on stairs may require excessive physical effort. Stairways are intended to be used for the initial escape from the immediate area of danger, and elevators are permitted to be used to complete the travel to the street. Where stairway doors are locked against re-entry, as may still be permitted in existing buildings, re-entry to allow escape by elevators may not be an option. Even when emergency preplanning includes provisions for elevator evacuation, the presence of persons waiting at elevators may not be known by emergency service personnel.

Elevator systems, to be reasonably safe for emergency personnel, need basic safeguards that will also allow them to be used for controlled evacuation, and during the evacuation phase doing so necessitates primarily that elevator lobbies and shafts are kept free of smoke and heat and that power is maintained to the elevators.

A task group formed by the American Society of Mechanical Engineers (ASME A17) is conducting a hazard analysis and identifying the corrective measures to allow the use of elevators for egress of occupants as well as fire fighters. This renewed interest in the use of elevators for egress sprang from the recommendation following the NIST investigation into the World Trade Center disaster. The terrorist attacks and subsequent progressive collapse of the Twin Towers have resulted in renewed interest in being able to totally evacuate high-rise buildings if there is a fire of sufficient magnitude to threaten the structural integrity of the building.

In the early stages of a fire, smoke barriers with minimal fire resistance can provide a reasonable level of assurance against smoke filling of elevator shafts, and when elevator banks on the same level are separated by smoke or fire barriers, there is an even greater likelihood that at least one bank will be smoke-free for a considerable period of time. With a small likelihood of smoke filling and with reliable power and two-way communication between elevator lobbies and a fire command station, which also controls elevator operation, all available elevators can be dispatched to the floor needing immediate evacuation and returned nonstop to the lobby. A concept such as this will limit the number of persons who need to be evacuated by means of stairways from upper levels of high-rise buildings under most circumstances.

PREPLANNING FOR FIRE INCIDENTS

What is a "fire plan"? To some people it means a small-scale floor plan mounted on the wall in schools, hotels, and other places, showing where the fire exits are and possibly the fire extinguishers. What is really meant by the term is the preplanning document for fire emergencies. Often it is an emergency plan that covers other events as well (Figure 4.5.4). Every building, or complex of buildings, needs to preplan for emergencies—the single-family home, church, hospital, school, college campus, apartment building, or factory. When only a few people are involved, the preplanning can be informal, but for any place in which large numbers of people are present, a written plan covering fire and other emergencies is essential. NFPA 1600, *Standard on Disaster/Emergency Management and Business Continuity Programs,* has been recommended for disaster/emergency planning by the 9/11 Commission and has been adopted by the U.S. Department of Homeland Security as the National Preparedness standard.

General Guidelines for Fire Incidents

For fire incidents, the fire plan has to cover items such as who does what in case of fire (who calls the fire department, who initiates fire evacuation signals, who checks that all rooms have been cleared, etc.). The person or persons in charge may be designated as well as floor monitors or others with special duties during fire emergencies. The plan may call for periodic fire drills and prescribe how they will be conducted. Persons or agencies to be contacted should be set forth, including emergency telephone numbers. Prefire planning should include measures to assure that routes to fire exits are clear, exit doors can be opened in an emergency, and exit signage is maintained. If delayed evacuation procedures are permitted, the plan must set forth how evacuation will be accomplished and who will be responsible for ordering evacuation following the initial evacuation from the fire incident area. If there is a fire control center in

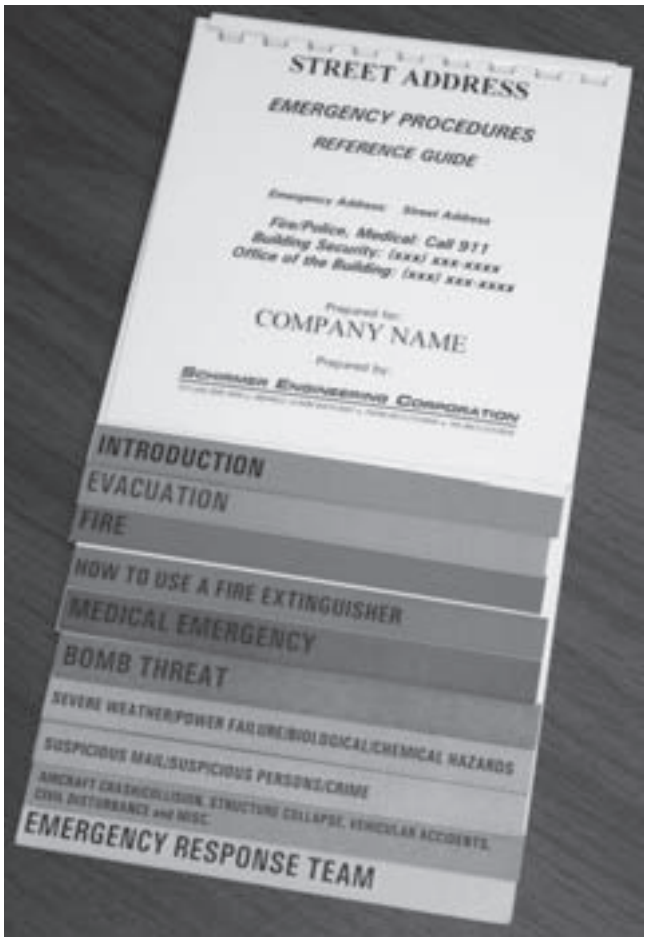

FIGURE 4.5.4 Sample Emergency Procedures Reference Guide (Courtesy Schirmer Engineering Corporation)

the building or there is two-way communication from areas of refuge, the plan must designate how communication with persons needing assistance will be accomplished and provide for the dispatch of trained personnel for rescue assistance (unless this function is clearly established to be the purview of the fire department).

Fire Drills

Periodically holding fire drills enhances the ability to safely evacuate the building under emergency conditions. Occupants become familiar with the alarm signals and know how to find designated exits. They learn the locations of alternate means of egress, such as emergency exit doors that are not normally used by building occupants. If the building has installed directional sounders, occupants familiarize themselves with their ability to guide them to the nearest exit.

School Evacuations

School Evacuations Under Terrorist Threat. Pulling a false fire alarm in a school in order to lure students outside so that they can be attacked has been tried, and it may happen again. The threat is slight, but suitable precautions should be taken when there is a viable threat, either when the school has received information of a possible terrorist attack or when local authorities have determined that there is a higher danger of such an attack. Currently, there are no good guidelines for measuring the comparative threat to the student body from fire versus terrorist attack in order to decide whether the risk to students from an assumed fire is less than the threat of killers waiting outside.

False Alarms and School Evacuations. False alarms for the purpose of disrupting classes is an ongoing problem in some schools, and the 3 minute delay prior to sounding alarm signals alluded to earlier in this chapter provides an opportunity for investigating the legitimacy of the alarm. Another successful method to reduce false alarms is to provide an approved cover over the device, which when raised sounds an audible alarm immediately, before there is an opportunity to pull the fire alarm. The *Life Safety Code* permits omitting manual fire alarm stations in schools when an automatic sprinkler system or automatic fire detectors have been provided.[11] In Chicago, schools are allowed to move manual fire alarm stations into classrooms to make them less accessible for malicious use.[12] Any of these methods can be successful in reducing the ability to initiate a false alarm solely for the purpose of achieving evacuation to an attack-vulnerable location.

Horizontal Exiting in Schools. When appropriate to the building and subject to approval of the AHJ, horizontal exiting, as previously described in this chapter, can avoid evacuation to the exterior of the building under most circumstances as long as the distance to the nearest horizontal exit from any point in the building is within the limits established by local code. Zoning of the fire alarm system is necessary so that evacuation signals sound only in the zone where the alarm was initiated. Sound preplanning and drills must be carried out to assure that all teachers and students feel comfortable with any scheme that does call for immediate evacuation to the outside upon a fire signal.

Aids to Evacuation from Fire

A number of manufacturers promote the sale of equipment or devices to help people escape from burning buildings, targeting high-rise buildings in particular. Among these items are rope ladders or similar escape devices that can be deployed from windows, escape hoods, escape suits fastened to cables, special chairs or slides for assisted evacuation on stairways, parachutes, and suspended rescue platforms. At the right place at the right time, such devices may provide for the evacuation of a few people who might otherwise be trapped. None are currently recognized by NFPA *101* or other generally accepted life safety standard.

Except for escape hoods, which can be issued to everyone in a building, none of the devices appears to provide the capacity to assist more than a minimal number of persons, and to do that they have to be located at the point at which people are trapped and from which the device is capable of reaching ground level in a safe manner. ASTM Committee E06 has established a subcommittee to develop standards for high-rise external evacuation devices to better define and evaluate device suitability.[13]

Escape hoods can provide a measure of protection from smoke and other toxic fumes, but whether they meet manufacturers' claims needs to be evaluated by independent testing under standardized conditions. Furthermore, the potential benefit of attempting to escape through otherwise intolerable smoke and heat conditions in a high-rise fire needs to be evaluated against remaining in a designated area of refuge until assisted evacuation can be provided.

Evacuation from rooftops by means of helicopters also has limited applicability and limited chances of success under the severe fire conditions under which it is most needed. Smoke, wind, and updrafts are deterrents to safe evacuation, and at best, only a few people can be rescued in this manner. Those who most require assisted evacuation may not be able to reach the rooftop, and they are better served by areas of refuge within the building.

NONFIRE EMERGENCIES

Although fire is the most common emergency consideration in buildings, other emergencies may be of greater potential threat and may require a different strategy for evacuation or no evacuation. Such emergencies include weather-related events or natural disasters, as well as man-made incidents. The following is a list of such events that may be a consideration for any given building depending on the geography, potential local building or site hazards, or building service outages:

- Earthquakes
- Tornadoes
- Hurricanes
- Flood events including heavy rain/melting snow, hurricane storm surge, tsunamis, mudslides, dam failure
- Volcanic eruptions
- Wildland or forest fires
- Building power outages
- Hazardous materials incidents

In contrast to a fire incident in a building, an event such as a tornado, earthquake, volcanic eruption, one of the flood scenarios, or a hazardous materials incident can pose an unanticipated and immediate threat to occupants in many if not most areas of a building. To escape the threat of fire in a building generally requires evacuation to the building exterior or specific fire refuge area within the building; however, the strategy for some of these events will require a different approach.

Commonsense guidance on procedures and safety measures can be found from a variety of sources. The Federal Emergency Management Agency, the National Safety Council, the American Red Cross, and the Building Owners and Managers Association International[14] provide Web-based literature and other guidance documents useful in preplanning for natural disaster and hazardous materials events. Some of the basics included in these sources follow. (See also Section 5, Chapter 3, "Disaster Preparedness Education.")

Earthquake

During an earthquake, building evacuation is not the appropriate strategy. Moving into or out of a building during an earthquake is not recommended, and occupants are best protected by relocating away from windows and glass constructions (partitions, skylights) to relative safety under desks or tables. Individuals on elevators should leave the elevator and find similar refuge as soon as possible.

Tornado

Tornado emergencies also would not require a building evacuation to the exterior; however, interior evacuation or relocation of occupants may be necessary. Occupants are best directed to seek shelter away from windows and glass, and relocate if possible to underground areas. In buildings lacking sufficient underground areas occupants should seek refuge in small rooms on the lowest floors of the building or find refuge in the most interior rooms away from doors and windows. Spaces with large-span flat roofs are most susceptible to roof collapse and should not be considered as areas of shelter. Evacuation instructions directing occupants to the designated areas of shelter in the building should be provided.

Other Natural Disasters

The impending threat from hurricanes, forest fires, volcanoes, and floods are often threats that are preceded by warnings through public information sources such as radio, television, and the Internet. Given that these events can be catastrophic to life and property, it is recommended that emergency procedures would allow for immediate building and site evacuation provided the warning time frame allows for major relocation of occupants. Procedures for such evacuations need to be in place well in advance, as the logistics may be time consuming, as in the case of buildings housing the elderly or disabled.

Hazardous Materials Incidents

Hazardous materials incidents are by nature unpredictable events that can impact the interior spaces of a building or expose a facility from an exterior location. The magnitude of a hazardous material event and the nature of the health threat can vary widely and the input of those familiar with the building hazards or expertise in hazmat incidents (e.g., fire department) is needed to develop a reasonable emergency response. Evacuation, relocation, or other protective measures may be needed. Getting the information and communicating protective measures to affected or potentially exposed building occupants are important aspects for handling any hazardous material incident.

SUMMARY

Occupant response strategies involve a number of considerations that include the building characteristics, the occupant characteristics, the criticality of building operations, and outside influences, such as weather, or in the case of schools the threat of violence. These many factors require that preplanning and procedures be established well in advance and can work to assure that occupants can be protected when an emergency scenario arises. Immediate evacuation in the event of an emergency may not be the appropriate response and the scenarios

for delayed evacuation should be reviewed and understood by building staff and occupants.

5.1 Principles and Techniques of Fire and Life Safety Education
5.2 Fire and Life Safety Education Messages
5.3 Disaster Preparedness Education
5.4 Media's Role in Fire and Life Safety Education
5.5 Reaching High-Risk Groups
5.6 Juvenile Firesetting
5.7 Using Data for Public Education Planning and Decision Making
5.8 Evaluation Techniques for Fire and Life Safety Education

Section 5 of the *Fire Protection Handbook*® addresses fire and life safety education, an activity that includes topics far beyond traditional school-based fire and burn safety programs. As the field of fire and life safety education becomes broader, it is also becoming more quantifiable, as seen in the two chapters dealing with data and evaluation. For this edition, the section includes two new chapters—one on educational messages and another on disaster preparedness education.

Chapter 1, "Principles and Techniques of Fire and Life Safety Education," applies educational fundamentals to fire and life safety education through topics such as principles of learning, the learning process, education models, and the importance of audience age and cultural background. The chapter also introduces the concept of message effectiveness.

Chapters 2 and 3 are new to the *Fire Protection Handbook*. The purpose of Chapter 2, "Fire and Life Safety Education Messages," is to expand on the concept of an appropriate fire or life safety message and to link the communication process to the effective application of a message. Sample fire safety messages developed through an NFPA demonstration project are introduced to illustrate one process of message development. Chapter 3, "Disaster Preparedness Education," provides examples of disasters and disaster-specific messages, and discusses the processes for identifying and analyzing community risks.

Chapter 4, "Media's Role in Fire and Life Safety Education," summarizes ways in which the news media and fire and life safety educators interact. Emergency scene public information and legal issues are among the chapter's contents.

Chapters 5 and 6 cover specific audiences. Chapter 5, "Reaching High-Risk Groups," presents considerations and techniques for reaching preschool children, older adults, low-income audiences, First Nations' populations, and people with disabilities. Chapter 6, "Juvenile Firesetting," outlines the characteristics of children involved in firesetting behavior, their motivation, and intervention strategies. The chapter also introduces the function of the Juvenile Firesetter Intervention Specialist (JFIS).

In its final two chapters, the section turns to the role of data and evaluation. Chapter 7, "Using Data for Public Education Planning and Decision Making," relates data to decisions that identify the major fire problems and target audiences, design an education program to address those problems with that audience, and deliver the right program to the right people. Chapter 8, "Evaluation Techniques for Fire and Life Safety Education," explains the evaluation process and highlights a hierarchy of evaluation measures.

Edward Kirtley, M.A., is with Fire Protection Publications at Oklahoma State University. He is the past chair of the NFPA Technical Committee on Professional Qualifications for Fire and Life Safety Educator.

Key Terms

curriculum development, domains of learning, education, educational methodology, five-step method of instruction, information, learning, learning environment, program (education), public fire and life safety educator, social marketing, target audience

Public fire and life safety education may be defined as "comprehensive community fire and injury prevention programs designed to eliminate or mitigate situations that endanger lives, health, property, or the environment."[1] Organizations whose personnel conduct fire and life safety education programs include fire departments, state or provincial fire agencies, schools, burn prevention and treatment organizations, city health departments, and corporate safety offices. Fire and life safety educators blend and apply seven distinct areas of expertise in their professional practice: (1) principles of education, (2) education techniques, (3) methods of coalition building, (4) presentation skills, (5) working with the media, (6) education program planning, and (7) education program evaluation. This chapter focuses on principles and techniques of education.

For further information, see the following chapters in Section 5: Chapter 2, "Fire and Life Safety Education Messages"; Chapter 3, "Disaster Preparedness Education"; Chapter 4, "Media's Role in Fire and Life Safety Education"; Chapter 5, "Reaching High-Risk Groups"; Chapter 6, "Juvenile Firesetting"; Chapter 7, "Using Data for Public Education Planning and Decision Making"; and Chapter 8, "Evaluation Techniques for Fire and Life Safety Education."

PRINCIPLES OF LEARNING FOR FIRE AND LIFE SAFETY EDUCATORS

Learning Defined

The terms *learning, education,* and *information* are related, but there are important differences among these three concepts.

Learning is knowledge gained through observation and study, resulting in a change of attitude or behavior.[2] Stated another way, learning cannot take place without change.

Education is the process of training, teaching, or instructing students in new skills. Training, teaching, and instruction all deal with preparing students for some kind of action or activity, such as driving a car, operating a machine, or testing a smoke detector. "How to do" something is at the core of education.

Information is facts, knowledge, or data. Information is the raw material of the new skills of education and the change of learning. For example, a presentation for the chamber of commerce on how to develop an occupant emergency plan for the workplace is an educational activity. It teaches a skill (i.e., how to develop an occupant emergency plan). Later, when the participants actually do their plans, a change has happened; that is, learning has taken place.

A presentation to the same group about how the community's Insurance Services Office (ISO) rating is set is a public information activity. Interesting facts have been shared. But the participants

Edward Kirtley, M.A., is the municipal programs manager at Oklahoma State University/Fire Service Training. He is a retired fire chief with over 25 years experience in the fire service and is the past chair of the NFPA Technical Committee on Professional Qualifications for Fire and Life Safety Educator.

do not have any new skills, such as how to use an ISO grading schedule.

It is important to differentiate between education and entertainment in public education. There are many programs used today in fire and life safety education that depend heavily on entertainment. Entertainment, unlike education, does not necessarily result in learning. The audience may enjoy the program and the program may result in an increase in awareness of fire safety issues, yet there is no change in behavior. This is an essential difference between an educational program and a program that focuses on entertainment. Although entertainment certainly has a place in fire safety education initiatives, it should not be confused with, nor promoted as, an educational program that results in learning (i.e., a behavior change). Note that changing a person's attitude—the way the individual feels about fire safe behavior—is an important step in changing behavior. The changed attitude is a necessary precursor to changed behavior.

Characteristics of Learning

For the practicing fire and life safety educator, the complex field of learning theory can be summarized in several points.[2]

1. Learning can be and often is a lifelong activity. Learning does not stop when school ends.
2. Changing attitude or behavior can be stressful. For example, it is uncomfortable to change a fire and life safety attitude from "My kids would never play with fire" to "I need to be more careful about where I put my cigarette lighter."
3. People learn at different rates and in different ways. How people learn is not related to intelligence.
4. Learning benefits from reinforcement. This characteristic argues against once-a-year fire and life safety education programs but is a strong argument for ongoing activity.
5. Effective learning benefits from support from the people who influence or control the students. In the workplace, supervisors should support an employee's new interest in keeping exits clear. Parents need to support a child's desire to install more smoke detectors.
6. Learning is enhanced when multiple senses are stimulated. Students need to *hear* words and *see* illustrations. Through props (such as burned items from a house fire) students *touch* and even *smell* the effects of fire. This characteristic of learning applies to adults as well as children, although great care should be taken in the use of potentially threatening props with children.
7. Learning is most effective when it is focused. In focused learning, the fire and life safety educator begins with an overview (e.g., "This morning we will learn what to do in case your clothes catch fire") and then explains the individual actions (e.g., how to "Stop, Drop, and Roll," how to cool a burn, and when to get medical attention).

Motivation and Learning[3]

Motivation is an essential step in the learning process. Educators have long realized the importance of motivation when attempting to create behavioral and attitudinal changes in the learner. Although several different models describe learner motivation, there are common elements in all the models.

First, the educator must establish a strong connection between the topic and the needs of the learner. This is commonly called the relevance of the topic. The learners must be able to see that the topic applies to their world. For fire and life safety topics the learners must understand that the risk applies to them. For example, an educator is delivering a presentation to parents (the target audience) of young children about the need for bicycle helmets. The educator must convince the parents that their children who ride bicycles, skateboards, and so on are at risk from injury if they crash without a helmet. This can be accomplished through the use of personal testimonies, injury statistics, anecdotes, or local news stories about a child being injured without a bike helmet.

Next, the educator must explain the benefit to the target audience of acting on the information. In other words, members of the target audience must believe they will benefit from changing their behavior or their beliefs about the topic. In the example above involving bicycle helmets, the parents must understand *and believe* they and their children will benefit from wearing the helmets; that is, their children will avoid a head injury from a bicycle crash. This can be accomplished with personal testimony, statistics, medical information, and so on. As with relevance, the greater the benefit for the learner the stronger the motivation to learn about the fire or life safety education topic.

A final component of motivation is the ability to act on the information, especially for adult learners. The learners must be able to take personal action with the information to be motivated to change. If they believe there is no way to act on the recommendations, they will not act. For example, consider the example of the bike helmets already discussed. Suppose that the target audience were low-income parents who could not afford bike helmets or who might not have access to them. The parents may clearly understand the need for helmets, and the benefits from them, but cannot act because of the monetary issue. In this case, the educator must provide a way for the learners to take action, for example, by providing the helmets to the children at little or no cost.

These two motivational issues must be addressed with every audience, regardless of age, if motivation for the topic is to be created. With younger children this will require a simple approach using basic language that is positive and does not frighten or intimidate the children. For adults, the educator must draw on the experiences of the audience and an understanding of their needs to create the motivation.

The Domains of Learning

Education is not based solely on fundamental human needs but is also based on audience needs. Audience needs are often described according to three domains of learning:

1. The *affective domain* involves how people feel about a situation and is the realm of values and opinions (e.g., whether or not they worry that their cigarette may have started a grass fire; whether they care about damage to wildlands).
2. The *cognitive domain* involves what people understand (e.g., how fast a grass fire is likely to grow).

3. The *psychomotor domain* deals with what people can do (e.g., how to dispose of smoking materials properly).

When developing a presentation, at least the affective and cognitive domains must be addressed during the presentation. With some behaviors and issues, information provided on the fire safety issue (cognitive domain) will result in a change in the learner's values (affective domain). In other cases, a learner's values or perception of the fire problem must be changed before the person is willing to receive information on the problem. In either situation, the affective and cognitive domains must both be addressed. If the presentation includes psychomotor skills such as crawling low under smoke, the psychomotor domain must be included in the presentation. This objective may require an opportunity for the learners to practice the skill or behavior.

Each domain can be related to specific kinds of educational needs (Table 5.1.1). As discussed later in this chapter, the domains of learning are very important to the process of writing educational objectives.

THE LEARNING PROCESS[3]

To be effective in creating behavior and attitude change in the learner, the educator must approach educational presentations with a sound understanding of how people learn—that is, the learning process (Figure 5.1.1). By understanding the learning process, educators can appropriately apply all the educational tools available to them. Although the learning process is basically the same for all audiences, the tools used will vary greatly based on the topic, the age of the learner, and amount of life experiences of the learner.

Steps

The first step in the learning process is for the learners to receive information about the topic. The information is received by learners through the senses—what they see, what they hear, and what they touch and experience. The more senses that are involved in this step the greater the likelihood that learning will occur.

Motivation. Part of this first step is also creating the initial motivation to learn about the topic. This has previously been discussed. It is important to remember that young or old, without the motivation, learning will not occur. This means the first few minutes of a presentation, when communication is initiated with the learner, are critical to the success of the overall learning experience.

TABLE 5.1.1 Education Needs and Learning Domains

Target Domain	*Audience Needs*	*Audience Situation*
Affective	Motivation	Does not value something
Cognitive	Information	Does not know something
Psychomotor	Skills	Cannot do something

Transfer to Short-Term Memory. The second step in the learning process is the transfer of the information into short-term memory (STM). STM is an area where information is initially sorted. It has a limited storage capacity, approximately six or seven bits of information or one "chunk" of information. When the information arrives in short-term memory, the learner's mind immediately begins searching for a connection with knowledge the learner already possesses that is similar to the new information. If a connection, or link, is made with existing knowledge, the information is then transferred to long-term memory. If the information is not connected, it is lost as more new information comes into STM, since STM can hold only six or seven individual bits of information.

Transfer to Long-Term Memory. The third step in the learning process is the transfer of information from STM to long-term memory (LTM). LTM is the storage area for all knowledge and skills the learner possesses. LTM is similar to a computer memory in that information is stored based on similar characteristics. These storage areas are called "cells." There may be a cell for colors, one for automobiles, one for birds, and so on. The more life experiences the learner has, the greater the number of cells that exist in LTM. As discussed above, a link must be established between the new information and a cell that already exists. If a cell does not exist, the educator must create a new cell for that type of information. This is especially important with presentations to preschool children. In all cases, the educator must actively and thoughtfully create the link for the learner through examples, stories, experiences, and so on.

Application. The fourth step in the learning process is application of new information so that transfer of learning occurs. By applying or practicing the new skills or knowledge, the learner strengthens the information in procedural memory, an element of long-term memory. Transfer of learning is the ultimate goal of the learning process. When transfer of learning occurs, learners are able to apply the new information—skills, knowledge, and attitude—to situations in their lives. Transfer of learning occurs through application of the new information or skills. In other

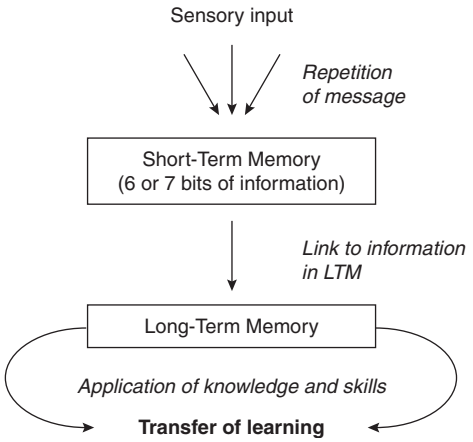

FIGURE 5.1.1 The Learning Process

words, transfer of learning occurs after the new information or skill has been practiced. For young children this means performing the behavior—for example, fire or life safety behavior—until it is mastered. For adults this can be accomplished through questions or activities and may even require actual practice with some skills, such as donning a bicycle helmet or placing a child in a car safety seat.

The amount of application required to achieve transfer of learning is determined by several factors. First, the developmental stage of the learner will influence the amount of application required. Young children can require more time for practice than will adults in most cases. Another factor is the life experience of the learner. Someone who has had experience with a fire or life safety behavior, for example, the use of a fire extinguisher, might well require less practice. Finally, the quality of the educational experience will affect the amount of application required. A high-quality experience that utilizes appropriate presentation techniques and applies learning theory will result in quicker transfer of learning.

It is important to understand that learners may know the correct action to take, but without transfer of learning, they may not be able to actually perform the action when the time comes. For example, children may know that if their clothes catch on fire, they are to "Stop, Drop, and Roll." However, if they have never applied or practiced "Stop, Drop, and Roll," they may not be able to do so if their clothes actually catch on fire.

Essential Elements

There are several essential elements from the learning process the educator should apply in every presentation to enhance transfer of learning:

1. The educator should present information so that multiple senses of the learner are used. This means adding at least visual and kinesthetic components so the learner sees, hears, and experiences the new information.

2. The educator must explain the relevance and benefit of the new information at the beginning of the presentation and reemphasize them throughout the remainder of the presentation when appropriate. The educator's job is more than just presenting good information; it also involves connecting with and, if necessary, changing the learner's personal values about fire and life safety. This approach means that the educator must overcome existing beliefs about safety, especially with learners who have extensive life experiences. This change in values can be accomplished only when the learner clearly understands the need to change (motivation), a process that begins with understanding the relevance and benefit of the new information.

3. The educator should present information in small amounts, such as six or seven bits of information or one psychomotor skill, and must then apply the information. This process of "present—apply" ensures that no information is lost between short-term and long-term memory. It also helps ensure that transfer of learning occurs.

4. The educator should create strong links between the new information or skills and the learner's current knowledge, skills, or experiences. This process is planned by the educator and is never left to chance. If that link is not created, the information or skill will be lost from short-term memory and the learning process will be stalled.

5. The educator should minimize the stress in the learning environment. This objective is especially critical for younger children. The educator should always use positive behaviors, should avoid the use of "don't," and should never scare or frighten the learners, as feeling afraid closes their minds to learning.

AGE AND LEARNING

People learn from cradle to grave. *How* people learn, on the other hand, changes throughout life. The twin factors of development stage and age determine how people learn throughout their lives. Generally, people pass through six development stages, as outlined in Table 5.1.2.[4]

Aging happens automatically, whereas psychological development happens only when the person is ready and when environmental factors (such as family, friends, school, and work situation) are right. Preschoolers, elementary school children, adolescents, adults, and seniors all learn very differently. In learning, age combines the influences of psychological/social/personal development with the effects of motor ability and communication skills. Being aware of how people learn at different ages is the first step in making sure that education programs and materials are "age appropriate."

Preschool Children

Children ages 3 to 5 grow and change more rapidly than any other fire safety audience. Some basic facts, though, will be true throughout the preschool years.

Basic Facts

1. Children ages 3 to 5 will learn fire and burn safety the same way they learn everything else—by seeing and doing.[5] What young children *do* will have a more lasting effect than what they *see*. For example, an adult will remember how to "Stop, Drop, and Roll" after seeing a demonstration. A preschool child must practice before learning happens.

2. What young children *see* is more influential than what they *hear*. A child will watch an adult find a lighter but will not remember the adult saying: "Always tell me when you find a lighter. Never touch a lighter."

3. Young children love repetition. Fire and life safety educators will need far fewer programs and activities for this group than for other audiences.

4. Young children have fewer experiences in the world than adults and, consequently, their understanding of the world around them is more limited. Using the right approaches with this audience is critical, because the wrong approach can be dangerous.

Children's Television Workshop (the producers of *Sesame Street*) studied how preschoolers would interpret fire and burn safety messages on television. Their findings also apply to nontelevised programs. Their findings include the following:[6]

TABLE 5.1.2 Developmental Stages and Implications for Education

Stage	*Characteristics*	*Educational Implications*
Stage 0, Blind trust	Develops only biologically; does not interact with surroundings	Too early for education
Stage 1, Focused on self	Responds out of fear; recognizes and begins to interact with surroundings; bases decisions on authority, obedience, and punishment	Wants to avoid the pain of burns; may fear punishment for fireplay
Stage 2, "Me and thee"	Responds out of need for personal gain; will satisfy needs of others for personal gain; bases decisions on "What's in it for me?"	Wants approval of others: for children, approval of fire fighters, teachers, and parents is important. Adults will seek approval of individuals who matter to them.
Stage 3, Group stage	Responds from a need for belonging and loyalty; accepts group rules as price for being part of the group; tries to meet group expectations	Responds to pressure from peers (whether children, adolescents, or adults) for fire safety; may respond to group pressure to be fearless
Stage 4, Group focus stage	Makes groups more abstract, does things "for the good of the order"; values social stability; accepts group rules for the good of other people	Responds to fire safety rules (such as bans on outdoor burning) and ordinances (such as smoke detector codes)
Stage 5, Interactive and independent stage	Regulates own behavior; negotiates for what the individual thinks is best	Will be fire safe only if it personally matters; may ignore rules that "don't apply to me"

1. Showing a dangerous activity, even while warning against it, is not recommended for preschoolers. *Children respond more to what they see than to what they hear.*

2. The extremely limited vocabulary of preschool children limits the fire and burn safety concepts that can be presented. "Hot" and "fire" will be understood, but "scald," "avoid," "prevent," "appliance," and "boil" are beyond preschoolers.

3. Young children have difficulty relating one event to another. "If/then" thinking or making choices (e.g., "If the door is hot, do not open it" or "Use your second way out") is simply more than many preschool children can do.

4. Young children view the world unpredictably. They may focus on one part of a program or story but ignore the rest. It is difficult for them to link the beginning and end of even the simplest story. Preschoolers do not necessarily link a problem and its solution.

Basic Techniques. Findings such as the above have very practical implications for fire and life safety educators. For example, "All fire safety messages should involve the two basic techniques by which preschoolers actually gain knowledge. By seeing an image, it is implanted; by doing, the action is learned. These two principles should guide fire safety messages for the preschool audience."[6]

Clearly, special care is needed in teaching safety to preschool children. Rather than develop their own, fire and life safety educators may prefer to rely on programs and materials such as the *Learn Not to Burn: Preschool Program*[7] and the *Sesame Street Fire Safety Resource Book.*[8]

A recent study at Oklahoma State University[9] indicates that any fire safety education message or behavior involving preschool children must address or consider three areas of development: physical skills, cognitive skills, and socioemotional skills. (The ability to relate to others and develop a healthy relationship with others in a group are examples of socioemotional skills.) Skills from all three areas must be utilized if teaching and learning are to be effective. For example, consider the behavior "crawl low under smoke." When teaching this behavior, the fire safety educator must consider if the individual child's physical development and skills allow him or her to crawl quickly through the obstacles found in most homes enroute to the exit. The child's ability to understand the behavior and the decisions necessary to perform the behavior also must be considered. A younger child of 3 or 4 years old may not be able to understand the behavior. Finally, the socioemotional development of the child must be considered. Does the child have the emotional ability to make decisions associated with the behavior, and then perform the behavior, under the stress of the fire situation?

All of these issues must be considered for every behavior taught to preschool-age children in order to ensure each individual child fully understands the expected behavior and is able to correctly make decisions and perform the behavior when required to do so in a fire situation.

Elementary School Children

The elementary school years are marked by steady physical, mental, and emotional growth. Considering physical growth, for example, "There are some marvelous happenings going on in the body, such as the shedding and erupting of teeth, the body's changing proportions. Along with the increase in height and weight, the internal organs—heart, kidneys, and liver—are increasing in their ability to function."[10]

Children ages 5 to 11 are probably the most frequent audience for fire and life safety education programs. Two strong trends in elementary education relate directly to fire and burn prevention: (1) *developmental learning* and (2) *comprehensive education.* Fire and life safety educators may need to tailor their approach and techniques to conform to these educational trends in elementary schools.

Developmental Learning.[11] University of Chicago educator Robert Havighurst identifies nine major groups of "developmental tasks" for elementary school children. Several of these tasks relate directly to fire and life safety:

1. *Physical skills.* Children become much more coordinated so that tasks that were impossible or difficult a short time ago—such as lighting a match—become possible or easy.
2. *Self-attitudes.* Children develop strong attitudes about themselves: their adequacy, personal hygiene and appearance, vulnerability, or safety.
3. *Social skills.* By elementary school age, children learn to get along with others, to make friends. Courtesy and other rules (including safety behavior) become important to them.
4. *Social roles.* Boys and girls become more interested in gender differences. Children this age are curious about—and want to follow—what society perceives as masculine and feminine roles.
5. *Academic skills.* Elementary school children learn a fantastic array of academic skills. In the mid-elementary years, abstract learning begins; speed reading, spelling, cursive writing, and higher math skills follow.
6. *Living concepts.* Concepts of everyday living (such as social, work, and civic issues) are included here.
7. *Values.* With the development of a conscience, children learn to distinguish between good and bad, right and wrong.
8. *Independence.* Between the ages of 5 and 11, children realize that adults are imperfect. As children spend more time away from their home, peers become more important.
9. *Social attitudes.* Feelings about home, religion, government, and other groups develop.

Fire and life safety programs that actually teach bigger areas, such as Havighurst's developmental tasks, have a far better chance of being taught in the classroom than a stand-alone fire safety effort. For example, consider the following:

1. Fire and life safety helps children develop positive *self-attitudes.*
2. A fire station tour teaches *social skills* (how the fire fighters live and work together), *social roles* (both men and women can be fire fighters), and *living concepts* (the fire service as a career), in addition to *self-attitudes* (learning about safety).

Comprehensive Education. An established strategy for teaching fire and life safety behaviors in schools is comprehensive education. Rather than being taught as a stand-alone subject, fire and burn safety is taught as part of a larger safety program or as part of a comprehensive health education program.

In many ways, fire and life safety education has been comprehensive education for many years. For example, for years fire departments have conducted baby-sitter programs that teach first aid and child care along with fire safety. Many fire safety educators include electrical safety, water safety, and citizen cardiopulmonary resuscitation (CPR) in their presentations. Many fire departments teach emergency response to hurricanes, earthquakes, or other natural disasters.

The National Fire Protection Association's *Risk Watch* program is an excellent example of a comprehensive education approach to fire and life safety education. *Risk Watch* addresses nine of the most critical or highest risk areas for children. The program was developed cooperatively with agencies that focus on the risk areas. The individual risk areas addressed include the following:

- Motor vehicle safety
- Fire and burn prevention
- Choking, suffocation, and strangulation prevention
- Poisoning prevention
- Falls prevention
- Firearms injury prevention
- Bike and pedestrian safety
- Water safety
- Natural disaster emergency response

Adolescents[12]

Knowing how adolescents develop and learn helps make the job of teaching them easier. Sowers[12] has observed:

> [Adolescents] live in the present and seem reluctant, even fearful, of looking too far beyond next weekend. Taking precautions in advance or being too concerned about the possible dangers that could harm them are not considered very important by most young people. This may be in part because teenagers characteristically have an "it-can't-happen-to-me" attitude, but the underlying reason may have more to do with appearing "babyish" or "nerdlike" to their friends than to any real sense of invulnerability.[12]

Of all the characteristics of adolescence, fire and life safety educators especially need to understand their developmental tasks and how adolescents learn.

Developmental Tasks. Adolescence is a bridge between childhood and adulthood. Becoming an adult is much more than going through puberty, learning how to drive, and deciding what to do after high school. Adolescence involves several developmental tasks that H. D. Thornburg listed in his landmark 1975 book, *Development in Adolescence*, as follows:

1. Develop conceptual thinking and problem-solving skills
2. Form more mature relationships with peers of both sexes
3. Achieve a masculine or feminine social role
4. Prepare for marriage and family life
5. Prepare for a career
6. Acquire a set of ethics to guide behavior
7. Develop civic competence and responsible community behavior

A major challenge for fire safety educators is to find ways to fit their message into the big picture of adolescent development. For example, a discussion about reporting who is pulling false alarms can be presented as ethics. The role of smoking in residential fire death can be taught in terms of responsibility toward others.

How Adolescents Learn. Adolescents have their own distinct learning style, especially when it comes to learning behaviors and attitudes (rather than facts). Ways that adolescents learn include the following:

1. *Direct experience.* Although direct experience with a fire or burn must be avoided, adolescents can have indirect experience with a fire or burn through fire department "ride-along" programs, serving coffee and donuts at the fire scene, or by volunteering at a burn unit or burn camp.
2. *Hypothetical projection.* Adolescents might think about how a fire would destroy their clothes or stereo or about how a burn injury would change their appearance.
3. *Role model emulation.* This involves following the attitudes and actions of role models. For example, young adolescents will observe whether their heroes smoke and how they dispose of their smoking materials.
4. *Instruction/demonstration.* This technique is particularly effective in teaching skills, such as changing a smoke detector battery or CPR.
5. *Rehearsal.* Through simulation, adolescents practice their response to emergencies.
6. *Teaching "best practice" to others.* For example, showing younger adolescents the safe use of portable fire extinguishers is a good test of how well the "teacher" can perform and gives a sense of competence.

Adults[3]

Adults as students reflect the many roles they have in life.

> They are parent, spouse, employer, employee, homeowner, renter, community worker, volunteer, child to their parents, hero to their children, and emotional and financial provider. They are expected to face the trials of the very young, the confusion of the teenager, the responsibility of adjusting to a changing world, and, somehow, balance their own desires and needs for relaxation and happiness.
>
> Adults appreciate the need for training and education for professional purposes. They also invest untold amounts of money and time in leisure activities. The task of the educator is to make fire safety just as worthy of their time, interest, and effort.[13]

When it comes to learning, adults are not simply "grown-up children." Instead, adults learn in specific ways. Although adults might not participate in formal education experiences on a regular basis, adults continue to learn in both formal and informal settings. General principles of how adults learn include the following:

1. *Adults need to know why they must learn something.* Establishing a need to know is the cornerstone of teaching adults. For the most part, adults feel that they need to know practical, nuts-and-bolts-type information. Being able to perform some task better is usually a strong motivator for the adult learner.
2. *Adults need to be self-directing.* Adults like to control their lives and make their own decisions. Similarly, adults like to control what and how they learn. In other words, adults are participatory—not passive—learners. Instructional methods that encourage participation include role play, debate, problem-solving discussion, demonstration, case discussion, coaching others, and skills-practice exercises.
3. *Adult learners bring their total life experiences into the learning environment.* Instructional methods that encourage participation take advantage of the experiences and knowledge of adult learners. However, adults may have already made up their minds about how fire safe they are—or want to be. Brainstorming exercises or group discussion may help keep minds open.
4. *Adults are task-centered learners.* Adults tend to center their learning around completing tasks, solving problems, or handling the way they live. Adults are, for example, much more interested in "writing better business letters" than in diagramming sentences or in "doing my time sheet right" than in addition.
5. *Adults have external and internal motivators to learn.* External motivators to learning include objectives such as getting promoted, getting a raise, or finding a job with better working conditions. For the most part, external motivators are visible or measurable. Internal motivators are related to the hierarchy of needs. They are usually invisible and impossible to measure.

Older Adults.[14] Older adults, senior citizens, seniors, the elderly, elders—perhaps no other group has so many names. Older adults are an important audience for fire and life safety education for two reasons: (1) older adults are the fastest-growing segment of the population, and (2) older adults have an unusually high risk of fire and burns.

When planning fire and life safety programs for older adults, remember to do the following:

1. Allow plenty of time. Like anyone else, older adults may get anxious if time appears short.
2. Count on a talkative audience and include a question-and-answer session.
3. Watch out for too much sunlight or glare in a room.
4. Darken the room, as possible, when using audiovisuals.
5. Keep the room at a steady, warm temperature.
6. Limit programs to 30 minutes.
7. Keep a low-pitched voice; speak slowly and clearly.
8. Use or design simple handouts. Avoid "busy" materials and fancy typography. Look for double-spaced materials.

For more guidance on working with older adults, see Section 5, Chapter 5, "Reaching High-Risk Groups."

EFFECTIVENESS OF MESSAGES

There has been surprisingly little research about what kinds of messages motivate people to be firesafe. The research that

does exist, though, gives clear direction to fire and life safety educators.

Negative Messages

A Study of Motivational Psychology Related to Fire Preventive Behavior in Children and Adults,[15] commissioned by the NFPA and completed in 1974, states:

> There is ample evidence that fear and threats of violence, unless continually maintained, have little long-term positive effect on behavior. People tend to tune out or suppress information which is disturbing or contrary to their belief or inclinations.
>
> People under threat or tension will seek to reduce that tension. Some will seek new information in order to act effectively. Others will block out that which is creating the tension. Therefore, fire prevention information should be directed toward positive motives which already exist within the recipient of the message.[15]

Positive Messages

The *Motivational Psychology*[15] study shifted the tone of fire and life safety education from negative to positive. Messages such as "Stop, Drop, and Roll" began replacing negative messages, such as "do not run if your clothes catch fire." The study also contributed to the development of the National Fire Protection Association's *Learn Not to Burn* programs. That study challenged the conventionally held view of the public's apathy about fire safety by concluding that people *do* care about fire safety, even though they might not know how to prevent or respond to fires. Based on interviews with people who had and had not experienced a fire, the study noted that "awareness of a fire as a powerful and potentially tragic force is not deeply buried in most people's consciousness." For both those who had and had not experienced a fire, "fire prevention awareness is increased when a person is responsible for others."

The association's research also included questions about how the public wanted fire safety information presented. The messages from the public were clear: Teach, don't preach. Do not scare us to death but make us think about fire safety. Give us information and if you can't make it interesting, at least make it short.[16]

A 1991 study by the American Red Cross about whether people took action to prepare for natural disasters after seeing slides of disasters reached conclusions that were similar to the Strother study.[15] Highlights from the American Red Cross report are as follows:

1. People remember more when they see disaster damage images in presentations.
2. Seeing disaster images does not encourage people to take action to get ready for a natural disaster.
3. Seeing disaster images discourages people from taking action.
4. After seeing disaster images, people were confused about what to do.
5. Avoiding or denying something unpleasant caused people not to take action among those who saw disaster images.
6. "Just not getting around to it" caused people not to take action among those who did not see the disaster images.[17]

FIRE AND LIFE SAFETY EDUCATION MODELS

Social Marketing[18]

Social marketing is a design approach to fire and life safety education that has begun to be used in the United States and South Africa. Social marketing has been used successfully by international health promotion agencies that work in foreign countries for many years. Social marketing applies proven commercial marketing techniques to health and safety problems that require long-term behavior change in the target audience. However, social marketing does not just rely on marketing principles for success. Principles and techniques from other disciplines such as sociology, education, psychology, and communications are incorporated into the social marketing framework. The critical element in social marketing is the paradigm that the needs and characteristics of the target audience are the basis for program decision making and design.

There are seven key concepts in social marketing. The concepts work together to bring about personal and social change in behavior resulting in reduced fire risk and risk from preventable injuries. The concepts are summarized as follows:

1. *Action is the objective.* The goal of every social marketing initiative is to change the risk behaviors of the target audience. By changing these personal behaviors and improving safety decision making, the risk from fire and injury is reduced. In social marketing awareness of the problem is not enough; the prize is the long-term change in behavior.

2. *The target audience is the focus of the initiative.* In many cases prevention experts, including fire safety educators, have designed prevention initiatives around *their perception* of the problem. Althouh this educator-centered approach has worked with white, middle-class issues, the approach has failed miserably with high risk audiences. The fire problem is based on the characteristics, norms, values, and habits of those people involved in the problem. Subsequently, the solutions must also reflect the characteristics, norms, values, and habits of those involved (i.e., the target audience).

3. *The target audience must believe the change in behavior is a positive exchange.* This concept is based on the willingness to trade one behavior, generally well established in the target audience, with a new behavior that will improve fire safety. For example, a parent or caregiver may have smoked in bed for 20 years. What does the new behavior (not smoking in bed) offer in exchange for quitting the old behavior? The fire safety educator must show that a positive exchange is possible and desired. In this example, the positive exchange is being safe from a potentially fatal bedroom fire versus the pleasure of having one last cigarette before going to sleep.

4. *The target audience is segmented into specific markets that share characteristics.* This is the opposite of the "one size fits all" approach to fire safety messages. In social marketing,

there may be several different groups identified in a single target audience. Each group has its own messages designed to change behavior. For example, a growing fire problem in the United States is the careless use of candles. There are several groups that should be targeted including teenagers and young adults who use candles for ambience, seniors who use candles for pleasant scents in the home, the poor who use candles for lighting, and so on. Each of these groups has specific reasons for using candles and each will respond to different approaches.

5. *The fire safety education campaign or initiative utilizes the four Ps of marketing: product, price, place, and promotion.* This is the traditional marketing principle that is employed by social marketing. The product involves the desired behavior, that is, what the target audience is being asked to do. Price involves what the target audience perceives it must pay, or give up, in the behavior exchange. It is critical that the price be considered from the target audience's perspective, not the perspective of the fire safety educator. Place is how the fire safety messages are disseminated to the target audience so that the messages are received and understood. Promotion is the means or strategy for convincing the target audience to take action, that is, that the exchange is worth the price of change.

6. *The competition to change the behavior is understood and addressed.* To the fire safety educator the need to change behavior is self-evident and little convincing is required. To the target audience in a social marketing initiative the need to change may not be so obvious, especially when there are competing behaviors. In short, the target audience may perceive strong reasons or justification to *not* change behavior. Consider the example of teenagers using candles. The new desired behavior is for teenagers to avoid using candles in their bedrooms. However, the norm for teenagers is to use a lot of candles when friends come over. The norm of social pressure to conform and fit in competes against the desired fire safety behavior.

7. *The initiative must be constantly monitored and be changed when needed.* The target audience and the environment in which behaviors occur are constantly changing. These changes include sociocultural norms, changes in services available to the target audience, and so on. The initiative or program must be constantly monitored to ensure the messages are correct, the four Ps still apply, behavior change is occurring, and fires and injuries are decreasing. When a change is noted, the initiative must be adjusted accordingly. Remember, the goal is *long-term* social and behavioral change resulting in lower fire and injury risk.

Health Belief Model[19,20,21]

Another useful model that is being used in the design of fire safety education programs and individual presentations is the health belief model. This model is used to explain what must occur for a person, generally an adult, to make the decision to change a safety-related behavior. In other words, the model explains what is involved in the decision making of typical adults when deciding to mount a smoke alarm in their house for the first time. The model was developed by the public health profession over many years of experience with health promotion initiatives. In 2005 the National Fire Academy incorporated the model into the fire and life safety education course *Changing American Family at Risk* because of its potentially positive impact on the success of fire safety education initiatives and programs. When presented with information on a fire and life safety behavior, a person may choose to adopt the new behavior if the following conditions are satisfied:

1. The person is aware that a problem exists due to current behavior.
2. The person understands the problem and the factors contributing to it.
3. The person believes he or she, or someone under his or her care, is personally at risk from the problem. In other words, the problem may actually happen to the person.
4. The person believes the benefits to change outweigh any barriers to do so. This belief is the same concept of the exchange in social marketing.
5. The person believes he or she is capable of successfully making the behavior change.
6. The person clearly understands what he or she must do to reduce the risk.
7. The person has an understanding and personal commitment to the reasons for changing the behavior.
8. The person has the resources and ability to successfully make the change in behavior.
9. The person receives positive feedback when the change is made.

By understanding these conditions must be present, the fire safety educator can build them into the program or presentation. For example, consider an initiative on mounting smoke alarms in the home. Based on the health belief model, the first step of the fire safety educator is to successfully inform the target audience that there is a problem; that is, they are at risk from fire or injury by not having a smoke alarm in their homes. This initial message must clearly explain the problem and the factors contributing to it.

Next, the message must be convincing *and compelling.* A message may clearly point out a problem and the need to take action *without compelling the target audience to take action.* The target audience must be compelled to take action and mount the smoke alarm. Part of this effort involves convincing the target audience that the benefits outweigh any barriers, they are capable of the behavior change, and the resources to make the change are readily available. In some cases accomplishing this goal may mean the fire department must make the smoke alarms available at no cost *or may require the department to go to the home and mount the smoke alarm.*

Once the change in behavior is made, there must be positive feedback to the person who has mounted the smoke alarm. Over the years a lack of positive feedback has been a problem with smoke alarms. For example, a fire safety presentation convinced a homeowner to go home and mount a smoke alarm. The homeowner mounted the alarm in the bedroom hallway right outside the bathroom. Every time someone took a shower the alarm sounded. The chronic false alarms were negative feedback and soon led the homeowner to remove or disable the alarm. This result could have been prevented by giving

the homeowner more explicit instruction on where to mount the smoke alarm so that false alarms would be eliminated or minimized.

CURRICULUM DEVELOPMENT

There are seven basic steps to curriculum development: (1) writing educational objectives, (2) developing a course outline, (3) developing a lesson plan, (4) selecting instructional methods, (5) choosing educational materials, (6) developing testing tools, and (7) allocating time to a subject.

Writing Educational Objectives

Educational objectives are sometimes called instructional objectives, behavioral objectives, or learning objectives. Regardless of what they are called, objectives answer the question: "What will happen as a result of the education program?"

Increasingly, objectives focus on what people can *do* after education, not on what they will *know* after education. For example, "the student will *show how to* change the battery in a home smoke detector" rather than "the student will *describe how to* change the battery in a home smoke detector," or "the student will appreciate the importance of changing the battery in a home smoke detector."

Objectives need to be realistic and measurable. Making objectives realistic is the responsibility of the educator. Making objectives measurable—so that students and programs can be evaluated—is also necessary. A standardized language and format for educational objectives help make them measurable.

Objectives are often written in a standardized format, originally developed by Robert F. Mager in his seminal book, *Preparing Instructional Objectives.*[22] This standardized format has three components:

1. The *performance* or behavior component of the objective describes what learners must be able to do to demonstrate what they have learned.
2. The *condition* component of the objective describes the conditions and resources available to the learner.
3. The *standard* or *criterion* component describes how well the action must be performed.[23]

Table 5.1.3 presents sample objectives for the affective, cognitive, and psychomotor domains of learning. Note that the affective objective deals with values (i.e., what is important). The cognitive objective covers understanding or knowledge. The psychomotor objective describes what the participant will be able to do. These three sample objectives are measurable.

Developing a Course Outline

The course outline is developed to meet the educational objectives and may be as straightforward as determining the sequence for teaching several lessons. For these instances, fire safety educators teach a single audience a single lesson and developing a course outline is not necessary.

Developing a Lesson Plan

A series of steps, known as the "five-step method of instruction," comprises the act of "teaching." The steps are (1) pretest, (2) preparation, (3) presentation, (4) application, and (5) evaluation. The steps of preparation, presentation, application, and evaluation will become part of the written lesson plan.

A lesson plan is a step-by-step guide for presenting a lesson. It outlines the material to be taught and the procedures to be followed in teaching the fire safety lesson. The lesson plan helps ensure efficient use of time and accurate coverage of the subject matter. When several fire and life safety educators are involved, the lesson plan helps ensure uniform teaching and helps avoid overlapping instruction.

The lesson plan guides how the students and educator spend their class time but does not dictate what will happen in class minute by minute. A lesson plan is *not* a script. A good lesson plan has some built-in flexibility—which is very valuable if, for example, the pretest reveals that the class already knows what the educator planned to teach but does not understand what the educator expected the class to already know.

Pretest. Pretests determine what the student/participant already knows (and doesn't know) before the fire safety education program. Pretests allow the public fire educator to customize the presentation to meet the needs of the individual participants.

In addition, pretests are useful tools for audience assessment. Some public fire educators use pretests as motivational

TABLE 5.1.3 Educational Objectives and Domains of Learning

Domain	*Sample Objective*
Affective (values, feelings, or opinions)	At the conclusion of the 30 min presentation on residential fire safety (condition), the adult participant will be able to state two factors (standard or criterion) that illustrate the importance of testing and maintaining smoke detectors (performance or behavior).
Cognitive (knowledge or understanding)	At the conclusion of the 30 min presentation on residential fire safety (condition), the adult participant will be able to describe three key steps (standard or criterion) in testing and maintaining smoke detectors (performance or behavior).
Psychomotor (skills)	At the conclusion of the 30 min presentation on residential fire safety and given a smoke detector for demonstration purposes (condition), the adult participant will be able to change the smoke detector's battery (performance or behavior) so that the detector alarms when tested (standard or criterion).

tools. Pretests can also provide students with an overview of what they will learn. Finally, pretests can serve as learning aids by providing questions for practice quizzes and by guiding individual study and review.

The most common type of pretest is the pencil-and-paper written test, although oral or performance tests are also used. Written or oral pretests are somewhat more convenient, simply because the entire class can take part in a written or oral pretest simultaneously. However, written or oral pretests do not assess psychomotor skills; for example, a score of 100 percent on a written pretest about home smoke detectors is no guarantee that the student can actually change the battery.

Generally, formal pretesting is not feasible with adult audiences and special events. Time constraints and the nature of the audience and venue make formal pretesting impractical with adult audiences and at special events. In place of a pretest a survey may be sent to the members of the audience in advance of the presentation. This requires that the educator prepare in advance and be able to compile the survey results when received. The more formal written pretests should be used with presentations and programs in schools where the learning environment is more structured.

Preparation. In everyday speech, the term *preparation* describes the necessary "homework" that educators do prior to a class or presentation. In educational use and this chapter, the term *preparation* describes how the educator prepares the student to learn.

Preparation involves developing a desire in learners for the information being presented. The educator must establish the relevance of the information, that is, how the information applies to their everyday lives. The educator must also explain the benefit of the information to the learners, that is, how this information is going to help them in their everyday lives. Both the relevance and benefit to the learner are closely tied to the learner's development and personal experiences. Regardless of the age or experiences of the learner, the preparation step must be accomplished successfully for every audience.

Presentation. Presentation is the actual delivery of instructional materials and ideas. This activity involves explaining information, using supplemental training aids, and demonstrating methods and techniques.

Application. During the application step, students use or apply what the instructor has taught. Through application, students practice new techniques and skills. Whenever possible, each student should apply new knowledge by performing the task or solving problems. For example, students could demonstrate how to report a fire, perform the "Stop, Drop, and Roll" technique, or test a smoke detector. The fire and life safety educator should supervise the application step closely, checking key points and correcting errors.

Evaluation. During evaluation or testing, the fire and life safety educator finds out whether the educational objectives have been met. Seen another way, evaluation shows whether students can perform a task independently.

Selecting Instructional Methods

Instructional methods and educational materials are the vehicles that carry the fire and life safety education message to the audience.

Fire and life safety educators have many types of instructional methods available to them. The challenge is to select the most appropriate instructional method for the educational objective.

Types of Instructional Methods. Types of instructional methods include lecture, illustration, demonstration, and discussion.

Lecture. In a lecture, the fire and life safety educator tells, talks, and explains. Today's audiences are accustomed to the fast pace, as well as the visual and audio stimulation, of television, computers, and video games. Lectures can bore the audience. For this reason, fire and life safety educators should use the lecture format sparingly—and only for short periods.

Illustration. Through the illustration method of instruction, the fire and life safety educator shows the audience something, for example, how an overloaded electrical outlet looks. Unlike a *demonstration,* illustration does not show the audience how to perform a task. The illustration method relies heavily on educational materials (such as drawings, posters, photos, slides, overhead transparencies, videotapes or films, models, and diagrams) and props. Illustration is especially helpful in combination with the lecture format.

Demonstration. The demonstration method teaches new skills. The educator actually does the task, usually explaining the task step by step. The audience may then practice the skill through drills. *Safety is always a concern with demonstrations and drills,* especially so when live fire is involved. Whenever the safety of a live demonstration is in question, use another method or material.

Discussion. Group discussion can be valuable, especially when the audience already has basic knowledge. Types of discussion are *guided discussion* (an exchange of ideas directed toward a goal), the *conference method* of discussion (in which the group directs its thinking toward solving a common problem), the *case study* (the group reviews real or hypothetical events), *role playing* (in which the group acts out various scenarios), and *brainstorming* (in which the objective is to identify as many ideas or approaches as possible).

Matching Instructional Method to Educational Objective. Selecting the most appropriate instructional method to address a specific educational objective is a critical skill for fire and life safety educators; it is a matter of using the right tool for a particular task. Table 5.1.4 presents examples of matched instructional methods and educational objectives.

Choosing Educational Materials[24]

Educational materials are any material—printed matter, audiovisual materials, or props—that the educator uses to teach new fire and life safety skills to the audience. Through materials, the

audience will actually *see* the effects of fire and burns, as well as the specific steps to take to avoid them. The materials literally give shape and color to the information and skills that the educators are teaching. Effective materials are important tools in getting and keeping the attention of the audience.

As important as they are, materials alone do not make an education program. An education program has specific measurable objectives and evaluation instruments, uses instructional methods that match the objectives, and uses materials to reach the objectives and reinforce the methods.

Materials are also important from the standpoint of resources. Next to the educator's time, materials are the most expensive item in the budget.

For these reasons, fire and life safety educators must use special care in selecting or creating their materials. Recognizing that materials are tools (rather than a program) and matching the material to the educational objective and to the audience are especially key to selecting educational materials.

Kinds of Educational Materials. The three kinds of educational materials are (1) print matter, (2) audiovisual materials, and (3) props:

1. Print materials include brochures (also called flyers or folders), posters, fact sheets, coloring books, activity sheets, display or bulletin boards, educational card or board games, and pretests/posttests.

2. The variety of audiovisual materials is expanding and now includes films and filmstrips, videotapes and audiotapes, 35 mm slides and slide-tape combinations, overhead transparencies, CDs, and computers. Flip charts and blackboards are also examples of audiovisual materials.

3. Props are artifacts or samples that the audience can see, touch, smell, or hear. A burned object from a home fire, a piece of melted glass, a manual fire alarm pull station, or a smoke detector could each be an effective prop during a fire and life safety presentation. Props are effective teaching aids because they make the subject real. Since they often involve several of the senses, props are an excellent memory aid.

Evaluating Educational Materials. There are vast differences in the quality of fire and life safety educational materials. Whether purchased commercially, borrowed or adapted from another educator, or created in-house, all educational materials should be evaluated.

At a minimum, educational materials should be evaluated before their first use and should be re-evaluated every year or so. The purpose of the follow-up evaluation is to make sure that what was acceptable initially still is.

The techniques for evaluating materials range from asking a few simple questions to sophisticated testing. The amount of evaluation needed depends on (1) how much money the fire and life safety educator is investing, (2) how many people the material is expected to reach, and (3) how long the material will be used.

The kinds of evaluation techniques for educational materials can also vary greatly. For example, qualitative approaches are fairly subjective and rely on the fire and life safety educator's experience, judgment, and interpretation. Quantitative approaches are likely to be more sophisticated and to involve formal testing. In evaluating educational materials, the key point is to evaluate all materials being considered in the same way.

Qualitative Approaches. Evaluating educational materials can be as simple as reviewing the material against a standard checklist. Questions to ask during a review include the following:

1. How well does the material match the specific educational objectives of the fire and life safety program?

2. Is the material technically accurate? Is the material produced by a reputable organization?

3. Is the information clearly understood by members of the potential audience? Answering this question can range from asking several members of the audience to describe or demonstrate skills that the material is trying to teach, to more elaborate testing.

4. Is the material age appropriate? With 3- to 4-year-old children, for example, are stories or activities limited to the 5-minute typical attention span for that age group? For guidance

TABLE 5.1.4 Matching Instructional Methods and Educational Objectives

Educational Domain	*Sample Educational Objective*	*Effective Instructional Method*
Affective (values, feelings, or opinions)	At the conclusion of the 30 min presentation on residential fire safety, the adult participant will be able to state two factors that illustrate the importance of testing and maintaining smoke detectors.	Group discussion, role play, and case study
Cognitive (knowledge or understanding)	At the conclusion of the 30 min presentation on residential fire safety, the adult participant will be able to describe three key steps in testing and maintaining smoke detectors.	Lecture, illustration, guided discussion, conference discussion, and case study
Psychomotor (skills)	At the conclusion of the 30 min presentation on residential fire safety and given a smoke detector for demonstration purposes, the adult participant will be able to change the smoke detector's battery so that the detector alarms when tested.	Illustration, demonstration and drills, and role play

in determining how age appropriate the material is, see *Developmentally Appropriate Practice in Early Childhood Programs: Serving Children from Birth Through Age Eight.*[25]

5. Is the material free of bias? Does the material reflect how people in the audience really live and work? The only way to make sure that material is bias free is to invite (and *accept*) comments from representative members of the potential audience.

These questions essentially call for "yes" or "no" responses. The Pan-Educational Institute has developed a more sophisticated approach to evaluating materials as part of its *Practical Criteria and Instruments for Selecting and Implementing Sound Fire and Burn Education Programs in School and Community.*[26] The package includes work sheets for assessing posters and stand-alone print visuals, written informational materials (brochures, stand-alone handbooks, storybooks, coloring books, and workbooks/work sheets), and audiovisual materials (media campaigns, public service announcements, and audiovisual presentations). When the scoring is done, a material is found to fit one of five categories: (1) limited quality, (2) below average quality, (3) medium quality, (4) high quality, or (5) comprehensive high quality.

Quantitative Approaches. Reading ease is a major consideration in selecting written fire and life safety education materials. A seventh- to eighth-grade reading level is typical for adults in the United States. Daily newspapers are often written at about that reading level.

Several readability indexes measure how easy a passage is to read. Commonly used indexes are a passive sentence index (a simple percentage of passive sentences within a passage), Flesch Reading Ease/Flesch Grade-Level Index, and the Gunning Fog Index.

The Flesch Index is based on a 100-word passage of the written material and counts the average number of words per sentence and the average number of syllables. With the Flesch Index, 17 words per sentence and 147 syllables per 100 words is "standard" reading ease. The Gunning Fog Index, on the other hand, combines the average sentence length and the number of difficult words (three or more syllables). Curriculum specialists with local school departments, or the education and journalism departments of universities, can help fire and life safety educators use these or other readability indexes.

These indexes can be used manually and are included in some word-processing programs. Whether the indexes are used manually or through the word processor, *the important point is to check whether sample materials are harder or easier to read than some standard that reflects the audience.* A highly precise test is not necessary, so long as the fire and life safety educator knows whether written materials are "in the ballpark" for readability.

Testing Materials. In some cases, fire and life safety educators may need to test materials before going into full production. Questions to ask when deciding to test materials include the following:

1. Could someone get hurt if the educational message is misunderstood?
2. How widely will the material be distributed?
3. How difficult or expensive will it be to change the material once it is produced?

After considering questions such as these, the NFPA *Learn Not to Burn* Foundation, now the Center for High Risk Outreach at NFPA, decided to test a planned television public service announcement (PSA). The results are published in *Pre-Production Evaluation of the "Tell a Grown-Up to Put It Away" Public Service Announcement for 3–6 Year Olds.*[27] In that test, 50 children ages 3 to 6 saw the preproduction version of a 30-second PSA twice. The children were then interviewed, one at a time, after each viewing to determine understanding. The PSA was found to be ineffective with the target audience. The test results influenced the *Learn Not to Burn* Foundation's decision not to produce the PSA.

The *Learn Not to Burn* Foundation experience offers some lessons for all fire and life safety educators. The preproduction test had a *set* interview procedure and questions—so the results compared "apples and apples." The test evaluated how well the *target* audience responded; for example, if only middle-income children had been in the study, the results would have been different. Perhaps most important, the material was tested when *changes were still possible.*

Creating or Purchasing Educational Materials. Many fire and life safety educators like to prepare their own educational materials rather than buy them (from a business or nonprofit organization) or adopt what other educators have already created. The interest in developing materials often is related to saving money ("Those other materials are too expensive for me") or the desire to give materials a "local flavor."

Before deciding to create their own materials, fire and life safety educators can use the following as a checklist:

1. How much will it really cost to develop materials (including the cost of time spent)?
2. How important is "local flavor"? How can it be added at the lowest possible cost?
3. What is the motivation to create the materials? Are locally created materials really needed and cost-effective? Or does the educator just prefer to create materials?
4. Does the fire and life safety educator have the technical knowledge, experience, and equipment to create materials?

Selecting Audiovisual Materials. Audiovisual materials range from the simple—flip charts, 35 mm slides, and overhead transparencies—to the sophisticated—films and filmstrips, videotapes and audiotapes, slide-tape combinations, and computer simulators.

Flip charts, 35 mm slides, overhead transparencies, and digital slide shows can be very effective audiovisual educational materials and can be created in-house. The key points are (1) limit the text, (2) have effective visuals in audiovisual materials, and (3) keep the visual image as simple as possible. Large-size or projected words are simply words.

Flip Charts. Flip charts are often used to record ideas from meetings and can also be used as audiovisual educational materials. Flip charts are inexpensive, easy to change, and effective with small groups. Although the paper is always white, marking pens come in a wide variety of colors. Flip charts can be reused a few times but will need to be replaced when they get torn, rumpled, or soiled.

35 mm Slides. Occasionally 35 mm slides are still used for do-it-yourself audiovisuals. They are far superior to flip charts in illustrating concepts (e.g., the extensive damage caused by a home fire), emotions (e.g., the face of a fire fighter after a rescue), and objects (e.g., the parts of a smoke detector). Slides are also easy to rearrange into different presentations, are effective with large groups, and are more durable than flip charts or overhead transparencies.

There are, though, several disadvantages with slides. The lights must be down or off, making eye contact with the audience difficult or impossible. Once the presentation has started, the flexibility to change is gone. The fan on the slide projector may be noisy.

Overhead Transparencies. "Overheads" are among the most popular teaching aids of all time—for good reason. They are inexpensive and easy to make, are durable, and can be used in rooms ranging in size from a classroom to an auditorium. They show text and line art to good advantage. The user can mark on them to underscore a point during a presentation. The lights can be on full or almost full. Overheads can be rearranged for use in several presentations.

Like flip charts and 35 mm slides, overhead transparencies do have some disadvantages. Photographs do not reproduce particularly well on transparencies. Like the slide projector, the overhead transparency projector fan may be noisy.

Digital Slide Shows. Digital slide shows have become the most common projected media used in fire safety education presentations. Digital shows are created on a computer using presentation software. The show can be saved to disk and taken to a remote site for a presentation. A presentation does require a digital projector and a computer, which may limit its use. However, small projectors are now available that allow the presentation to be loaded directly, thus eliminating the need for a separate computer.

Developing Testing Tools

Testing tools can be pencil-and-paper tests or nonwritten tests, such as practical skills tests. Some fire and life safety materials include testing instruments. Local schools may develop testing tools or help fire and life safety educators develop them. Section 5, Chapter 8, "Evaluation Techniques for Fire and Life Safety Education," covers the analysis of test results.

Allocating Time

A key part of developing a lesson plan is deciding how much time to spend on various subjects. A basic rule of thumb is to spend time on topics and drills that support the educational objective. Topics and drills that do not support the educational objective should receive little (if any) time in the lesson plan.

TARGET AUDIENCE CULTURAL CONSIDERATIONS[28]

The ethnic diversity of the communities in the United States and Canada has significantly increased. In some metropolitan areas it is not unusual to have 30 to 40 different ethnic groups represented in local schools.

Each of these ethnic groups has cultural differences that may include differences in language, lifestyle, religious beliefs, and cultural norms and values. In some cases, these differences are subtle. For example, many Hispanic immigrants are devout Catholics and their religious practices are virtually the same as those already living in the United States and Canada. In other cases, the differences can be noticeable. For example, some of the groups from Southeast Asia have very close-knit families where several generations may live in the same apartment together. This is a contrast to the typical one-family–one-dwelling American lifestyle.

In all cases, these ethnic groups are still at risk from fire and preventable injuries. In fact, some of the groups have a higher incidence of fire than the average population. Regardless of where the group comes from, or where the individuals are living, they need fire and life safety information in a manner they can understand and act on. This is the responsibility of the fire safety educator.

Learning About a Target Audience's Culture

Once an educator has determined that there is an immigrant community that has developed in the department's jurisdiction, even if it is a small group, it is time to learn more about the culture of the community. There are several methods for developing such an understanding. The most effective method is to develop a working relationship with someone from within the culture. This person does not have to be leader in the group, but he or she must be able to make a connection between both worlds. In many cases high school age young adults are the best in this area. They have been immersed in the American culture long enough to understand it, and they still have deep roots in their ethnic culture.

Another source of information is the Internet. There is probably not a single ethnic group that may locate in your community that is not already established in some other community. In other words, some other government or nonprofit agency has already crossed the bridge you are trying to cross. When you do your search, don't limit it to just fire department programs. Search public health departments, schools, social services, crime prevention, and community development agencies and programs.

A third source of information is the staff at larger universities. The campus of a large university is a home of cultural diversity and ethnic membership. Faculty and professional staff can usually put you in contact with a student from that culture.

Some student life offices may even have programs and information files that can provide you with the information you need.

Information Needed

What information is needed in order to develop and deliver education presentations that will be effective in reducing risk from fire and preventable injuries? You should ask the following six questions when gathering information on the culture:

- What are the lifestyle habits and practices of the group?
- What the social practices of the group?
- What is the community and family hierarchy?
- How does the group communicate with each other and with the rest of the community?
- What is the group's experience with emergency services and government?
- In terms of interaction and support from the rest of the community, is the group independent or interdependent?

Lifestyle Habits and Practices. Any experienced fire safety educator knows that a large portion of residential fire risk has to do with the lifestyle habits of the individual and family. When asking this question you must pay attention to any habits that may increase the risk of fire or injury. For example, if it is a cultural norm to cook food in deep skillets filled with grease, the risk of kitchen fires and burns increases. The multigenerational living habits of Southeast Asians mentioned earlier is another example of a lifestyle habit.

It is important to also look a little deeper at these habits. In some cases the habit may reflect a situation that does not represent the culture of the group but rather a situation imposed on them as new immigrants living in this country. For example, in an area that utilizes a large number of Hispanic immigrants it is common to find several families living in the same house or apartment. This situation may be from economic necessity or from a lack of available housing rather than it being part of the cultural lifestyle. Is the risk of injury by not being able to escape during a fire still increased? Yes it is—and fire safety education is still needed.

Social Practices. How do the members of the community gather to socialize? What type of recreation do they participate in? Do they tend to live in close proximity to each other, or are the members of the group scattered throughout the community? These answers will identify potential methods for meeting with the group members.

Community and Family Hierarchy. In many ethnic groups there is a specific person or group of people that makes the decisions for the entire group. Many times this person is an elder. Sometimes this elder is the oldest male living in the area. In other cultures it is the oldest woman in the family. If it is necessary to gain the trust of the group in order to have the members take some type of safety action, you must understand this hierarchy. To violate this hierarchy can be an insult not only to the leader but also to the members of the group as a whole.

Group Communication. One of the most difficult challenges with fire safety initiatives involving immigrants is reaching the group with fire safety information that *every member of the group can easily understand*. The first element of this challenge involves actually getting the information to the group. Most immigrant groups will not speak or read English at a functional level, especially the older members. In fact, some may not even read their native language. Putting a story in the local English-language newspaper probably won't have much of an impact.

But because the members of the group may not be reading the local newspaper or may not watch local television does not mean that a communication network does not exist. There is probably a very effective communication network within the group. In some communities immigrants have a native-language newspaper that is widely read. These newspapers provide information from home, pertinent local news, advertisements, and so on. These newspapers are an excellent communication medium about fire safety information. Similarly, there may be a local radio station in the native language, which is also an excellent medium to communicate information.

Having the luxury of a native-language newspaper or radio station may make your job a little easier. Unfortunately, many immigrant groups will not have any formal communication mediums such as newspapers and radio. Rather, communication is through an informal network between members of the group and generally involves person-to-person communication during social activities such as religious meetings, dances, family events, and so on. Although this medium is not as easily accessed as newspapers, it can be just as effective and in some cases more effective. It will require work on your part to identify how to access the medium and the best way to format the messages so they can be understood and acted on.

You must remember that a fire safety concept that has meaning to you, or to someone who was raised in the United States, may not make any sense whatsoever to someone who has just moved here from another country. In most Third World countries, smoke alarms are not used. A message that encourages a family to mount a smoke alarm may not make any sense and consequently will be ignored.

Creating a successful message means putting the behavior in terms that a member of the group can understand *and* can act on. For some behaviors and risk issues, this objective may require reaching the younger children who can communicate the information to the adults and seniors in the group. In other cases, the most effective strategy may be to get the endorsement of the elder or leaders in the group. You may have to use pictures or symbols if the members of the group do not read their native language. Success in this area depends heavily on how well you gather information with the questions previously mentioned. However, the communication barrier can be overcome.

Group Experience with Emergency Services and Government. The fire service has long been part of the American culture. However, in many countries no organized fire protection exists. The concept of a fire fighter or of fire prevention simply does not exist. There are some countries that do have fire protection but those fire fighters do not have any interaction with the public. In still other cases, the fire department represents the

government—an institution that is viewed with suspicion and with which any interaction is avoided.

If any of these scenarios apply to the immigrant group with which you are working, it is critical that time is invested at the beginning of the initiative to gain the trust of the influential members of the group and from that gain credibility as a person and program concerned about their welfare and there to help them. In a real sense you may have to create their first positive experience with a government agency.

You must also understand the reality of the situation with some immigrant groups. Currently there is a clash between the need for low-cost labor that can be provided by immigrants and the illegal entry of those immigrants into the country. The very group you may be trying to reach is working hard to *not* be reached by a government agency. Initially you will probably be viewed as an agency with the authority to cause problems and even return them to their native country. Overcoming this stigma will require work by not only the fire safety educator but also by every member of the organization who interacts with the group. Word will quickly spread if the fire department and the fire safety educator are trying to ensure the fire safety of the members of the immigrant community. Likewise, word will spread just as quickly if the fire department ignores or worsens the living situation and safety of the group.

Independence or Interdependence of the Group. In terms of interaction and support from the rest of the community, is the group independent or interdependent? By the time you have answered the other questions you should understand how the group interacts with the community. If the immigrant group is well established in the community most likely there will be a large degree of interdependence, which means that members of the group are employed throughout the community, utilize the medical facilities on a regular basis, own businesses, participate in school activities, are active in civic groups, and so on. When interdependence exists it is much easier to reach the members of the immigrant or ethnic community. Keep in mind that in a well-established immigrant community there may be one or two generations of the ethnic group that were born and raised in this country.

OTHER EDUCATIONAL TECHNIQUES

Questioning Techniques[29]

During a presentation, questioning is an extremely effective educational technique. Questions encourage thinking, the exchange of ideas, and the molding of opinions, attitudes, and values. As a result, what the fire and life safety educator *asks* the audience may be as important as what the educator *tells* the audience.

Effective questions have the following traits:

- Are "open-ended" or require more than a "yes" or "no" answer
- Do not suggest the answer
- Seek information but do not make the audience feel uninformed

There are four kinds of questions:

1. *Direct questions* are aimed at one person in the audience. Because direct questions can intimidate the audience, they are not often used with adults.

2. *Overhead questions* are aimed at the whole group, and anyone is free to respond. Because these questions are particularly helpful in starting thinking or in bringing out ideas and opinions, they are frequently part of a case study or brainstorming discussion.

3. *Rhetorical questions* are directed at the entire group, but an answer is not expected. A rhetorical question can be an effective "attention getter." For example, a fire and life safety educator might open a presentation by saying, "What are the most important things that you and your family can do to protect yourselves from a home fire? By the end of this presentation, you will know how to answer that question."

4. *Relay questions* are those that the audience asks and the educator sends back to the audience. Relay questions are a good technique for opening up discussion. Relay questions should not be used to avoid a question that the educator cannot answer or to force the audience to guess about facts or techniques.

It is important to note that the use of questions may be limited with younger children. Preschool children may not understand the meaning of a "question" and may answer the question with a story. Also, the effective use of questions requires the learner to have some experiences from which to answer the question. This technique requires the educator to thoughtfully plan his or her questions based on the topic, the developmental stage of the audience, and the experiences of that audience.

Managing the Learning Environment

The term *learning environment* refers to the physical facilities where the learning will take place. The learning environment supports everything that the educator does in the classroom. For this reason, managing the physical learning environment is as important as selecting the best instructional method or educational material.

Individual factors that make up the learning environment include the *room size, temperature,* the level of *light, ventilation,* background *noise, acoustics,* the *comfort* of chairs and tables, and the *physical arrangement* of the room.

Experienced educators inspect the room before arriving for a presentation. It may be possible to move the program to another room or to correct what is wrong with the room. For example, removing extra chairs and rearranging chairs into a circle can make a huge room feel smaller. Videos or films *can* be shown in rooms with uncurtained windows—if the screen or monitor is placed so that the windows are behind the audience.

Rooms can be arranged in several ways, depending on the size of the group and whether or not tables are used. The choice of a room arrangement lies in satisfying three criteria:

1. Can everyone in the audience see and hear the educator and audiovisual materials?
2. Can everyone in the audience see and hear each other?
3. Does the arrangement place as many people as possible as close to the educator as possible?

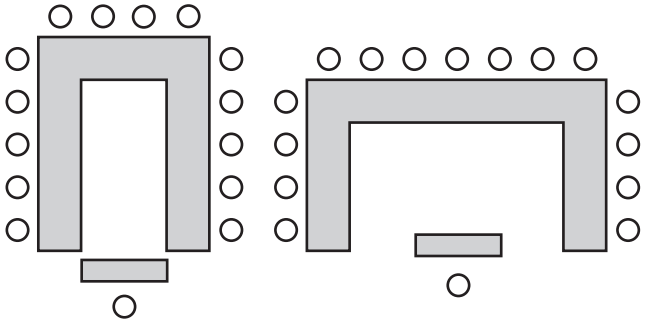

FIGURE 5.1.2 Examples of U-Shaped Arrangements

When tables are used for small groups, three common arrangements are (1) a U-shaped setup, (2) a hollow square, and (3) a conference table. The U-shaped arrangement offers eye contact between the educator and audience, as well as among members of the audience. The fire and life safety educator is able to move around the open U. All participants are able to see a screen or video monitor placed behind the educator's table. The U-shape can either be flat or long. The flat U-shape lets more members of the audience be closer to the educator and audiovisual material (Figure 5.1.2).

The hollow square is very similar to the U-shaped room setup. Participants may feel farther away from each other, even though the distance is the same as the U-shaped arrangement. A conference table setup is essentially a solid U-shaped arrangement. This arrangement is more commonly used for meetings but may be used for a class (Figure 5.1.3).

For larger groups that need tables, several classroom styles are available. The traditional classroom style setup is the most restrictive and provides little eye contact among participants. The chevron (sometimes called herringbone) and fan-style classroom setups place more members of the audience closer to the educator—and let participants see each other (Figure 5.1.4).

The most common way to arrange chairs without tables is the amphitheater or auditorium style. Rearranging the chairs into a slight semicircle provides for better eye contact between the educator and the audience (and among members of the audience). The semicircle also improves the audience's line of sight to a screen or video monitor (Figure 5.1.5).

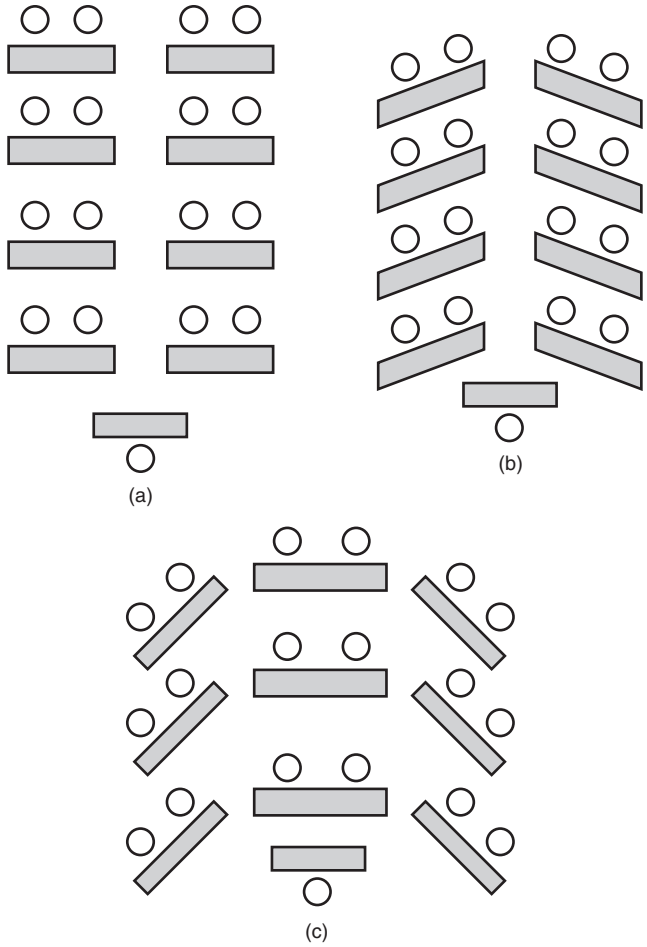

FIGURE 5.1.4 (a) Traditional Classroom Setup; (b) Chevron Arrangement; (c) Fan-Style Classroom. Note that these same seating arrangements can be used without tables.

Education, Message, and Communication Defined
The Communication Process
Appropriate and Effective Messages
Five-Step Planning Process as a Tool for Message Development
Ongoing NFPA Activities

Key Terms

communication, communications cycle, communications medium, community assessment survey, education, education message, five-step planning process, injury prevention, message

One of the most important tools used by the fire and life safety educator is the educational message. These messages are intended to change the receivers' understanding of fire safety and/or inspire them to take some type of safety action. These effective messages use appropriate language, put the information in the correct social and cultural context, consider the physical abilities of the receiver, and are communicated in a manner so the message is easy to understand.

Many commercially developed messages are available for use by the fire safety educator. Unfortunately, not all of them are effective. In fact, some may even communicate information or behaviors that are contrary to accepted fire and life safety practice. It is the responsibility of the fire safety educator to be able to recognize messages that are not appropriate and then make the needed changes so that the information will be understood by the receiver.

The purpose of this chapter is to introduce the educator to the concept of an appropriate fire or life safety message and how the communication process fits into the effective use or application of a message. Sample fire safety messages developed through a NFPA demonstration project will also be introduced to illustrate one process of message development.

See also Section 3, Chapter 4, "Use of Fire Incident Data and Statistics"; Section 4, Chapter 1, "Human Behavior and Fire"; Section 5, Chapter 5, "Reaching High-Risk Groups"; Section 5, Chapter 7, "Using Data for Public Education Planning and Decision Making"; Section 5, Chapter 8, "Evaluation Techniques for Fire and Life Safety Education"; and Section 12, Chapter 19, "Community Risk Reduction."

EDUCATION, MESSAGE, AND COMMUNICATION DEFINED

In lay use, the terms education, message, and communications are sometimes used almost interchangeably. The terms are certainly closely related to each other. In fire and life safety education practice and in this chapter, however, the terms have distinct meanings as described below.

Education Defined

Webster's Collegiate Dictionary, 10th edition, has at least two potentially relevant definitions of "educate." The first is "to provide with information." The second definition is "to persuade or condition to feel, believe, or act in a desired way."[1] NFPA 1035, *Standard for Professional Qualifications for Public Fire and Life Safety Educator,* defines public fire and life safety education as "comprehensive community fire and injury prevention programs designed to eliminate or mitigate situations that endanger lives, health, and property."[2]

Ernest Grant, RN, MSN, is the nursing education clinician for burn outreach with the N.C. Jaycee Burn Center at UNC Hospitals in Chapel Hill, North Carolina. He specializes in providing education and developing training materials focusing on the promotion of fire safety and the prevention of burn injury, both in the United States and overseas.

Rodney Eksteen is the chief of the public information, education, and relations division of the emergency management services department in Johannesburg, South Africa. He established the division in 2000 after providing emergency medical care in high-risk communities.

Education Message Defined

A fire or life safety education message is a spoken or written transmission of information that is satisfactorily received and understood, as demonstrated by a change in belief or behavior to produce greater fire and life safety.

Communication Defined

Although communication today involves many more methods than in years past, the goal and basic process of communication remains the same. The goal of communication is to "transmit information, thought or feeling so that it is satisfactorily received or understood."[3] In the case of fire and life safety messages, the goal of communication becomes the transmission of fire safety information and behaviors so that each is satisfactorily understood by the intended target audience or individual.

THE COMMUNICATION PROCESS

In the case of fire and life safety messages, the goal of communication becomes the transmission of fire safety information and behaviors so that each is satisfactorily understood by the intended target audience or individual. There are six elements in this communication process: the sender, the receiver, the fire or life safety message, the medium of communication, barriers to communication, and feedback between the receiver and the sender. The relationship of these six elements is sometimes described as the *communications cycle* or *communications loop*.

The Sender

The sender is the person who wishes to communicate some piece of information to another person or group. In the case of public fire and life safety education, the sender is typically the fire or life safety educator.

The Receiver

The receiver is the person or target audience for whom the message is meant. In some cases, the receiver will be a specific target audience. For example, the fire safety message "Tell an adult if you find matches or lighters" is intended for young children. In other cases, the receiver is the general public. For example, the fire safety message "Test your alarm" is meant for the general population, including older children.

For guidance on targeting messages for receivers at particularly high fire risk, see Section 5, Chapter 5, "Reaching High-Risk Groups."

The Message

The message is the information the sender wishes to convey to the receiver. Messages can be either informational or behavioral. Note that both informational and behavioral fire safety messages are intended to fulfill the objectives of education—that is, to provide with information, to persuade or condition to feel, believe, or act in a desired way.

Informational Messages. Some messages are informational in nature and designed to increase the awareness of the receiver about a certain fire or life safety issue. Informational messages are designed to persuade the receiver to feel or believe about fire safety in a specific manner. For example, the fire safety message "Smoke alarms save lives" is intended to educate the receiver about the importance of having smoke alarms.

Behavioral Messages. Behavioral messages are designed to persuade the receiver to act in a desired way, to inspire or convince the receiver to take some kind of action—to behave in a certain way. "Change your clock, change your battery" is intended to inspire the receiver to take a specific action: changing the battery in their smoke alarm.

It is not necessary for the sender and receiver to perceive the message in the same way, at least in all aspects. Any message unavoidably carries with it some information other than what was intended to be sent, including implied or inferred attitude of the sender toward the receiver. The purpose of the rest of this section is to provide a specific example of how a seemingly appropriate message can fail. In the example "Change your clock, change your battery," the intended message from the sender is that the receiver understands that this action is necessary to ensure that the smoke alarm will continue to work properly and provide an early warning in the event of a fire. In other words, the sender is inferring that the receiver understands this rationale, so there is no need to provide an explanation. The receiver, on the other hand, may not understand why there is a need to change the battery in the smoke alarm, other than the fact that he or she may be familiar with the campaign, or because someone the receiver views as having a position of authority has instructed him or her to do so. Because the receiver may not fully understand the rationale behind the need to change the smoke alarm battery, he or she may elect not to do so.

A message can fail to produce an intended change in belief and behavior in many ways. The receiver may not find the information contained in the message to be sufficiently compelling, intellectually or emotionally, to justify a change in belief. Most often, when a message fails to produce the desired result, the reason is at least in part a difference in understanding between the sender and the receiver. No message is entirely self-contained. Every message requires the receiver to provide some information, from the simple (what do these words mean?) to the complex (what am I supposed to do about this?). When the sender and receiver fill in different information—when they perceive the message in different ways—the result can be a failed communication.

Communication Medium

The medium or channel is the method used to deliver the message from the sender to the receiver. The medium may be direct delivery, such as during a fire safety presentation to young children. It may involve mass media such as television or radio delivery of fire and life safety education messages. The medium can also be a flyer, brochure, or other material such as a billboard along a major highway. A single medium or material can contain multiple messages. The medium is selected based on the

characteristics of the target audience. In other words, the mediums that are most likely to deliver the message to the receiver are those that should be used.

Barriers

There are barriers that can diminish the effectiveness of the communication process. The barriers may involve the receiver, the sender, the message itself, or the medium of communication. Some examples of barriers involved in the sender or receiver include language skills, beliefs and prejudices, cultural influences, or lack of experience with fire safety. Examples of barriers involving the message include improper use of language, the social or cultural context of the message, and the receiver's perceived relevance of the message. Examples of barriers involving the medium include selecting a medium that does not reach the receiver frequently enough for education to occur.

Feedback

Feedback is communication from the receiver back to the sender after the message has been received. Feedback allows the sender to evaluate the effectiveness of communication. In other words, has the receiver understood the message as intended by the sender? During presentations, feedback may be immediate through questions asked by the audience, the behavior being performed by children in class, and so on.

However, feedback from other mediums such as mass media or flyers is more difficult to observe or document. Surveys may be used to determine the effectiveness of the communication process and the changes that occurred as a result of the message. Reliable feedback may come in the form of fire and injury statistics. A change in occurrences of fire following a fire safety campaign may indicate that the messages were effective. It is important to note that other factors may be impacting the reduction in fires; it is the responsibility of the fire safety educator to evaluate all potential factors so the reasons for the reduction are accurately identified and understood.

Once feedback is received by the sender, the communication loop is closed. The sender may then choose to send additional messages to the receiver. This circular flow of information and feedback is illustrated in Figure 5.2.1.

APPROPRIATE AND EFFECTIVE MESSAGES

As mentioned earlier, appropriate and effective messages are those that reach the desired receiver and result in a change in understanding or behavior regarding fire or life safety. When developing a fire safety message, there are three factors to consider: the language used in the message, the social and cultural context of the message, and the relevance of the message to the receiver.

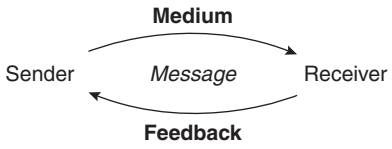

FIGURE 5.2.1 The Communications Loop

Language

A message must use language that can be easily understood by the receiver. Most of the time, this will involve the level of complexity of the text. Too much information, long words used in complex sentences, and technical language are confusing.[4] The message becomes even more confusing when dealing with someone who has limited literacy skills. The use of written materials becomes essential to assist with getting the message across. Such materials should be prepared at the lowest possible level of reading difficulty—generally fifth grade level or lower.[5]

For example, a message intended for adults should use words and grammar that are easily understood. Likewise, a message for second graders must use simple words and sentences. Keep in mind that the target audience may not be able to read the written word. In these instances, the message will have to be communicated verbally instead of in writing. Other forms of communication may include pictorial diagrams or demonstrations.

Another consideration of language is the native language spoken or read. If the target audience is immigrants who do not speak or read English, the group's native language must be used. Again, do not assume that everyone in the group will be able to read their native language.

Social and Cultural Context

The second factor of the message is its social and cultural context. Social context includes all aspects of the social environment that affect the audience day to day. A message may encourage the audience to take some type of action. The audience must, however, have the social resources available to take the action. For example, a message may stress the importance of always placing a child in a car seat. If affordable car seats are not available to the audience, the action—that is, using a car seat—is not possible. In this example the social condition of a lack of available car seats was not considered.

Similarly, cultural context comprises the values, beliefs, language, history, and habits of the culture to which the audience belongs. This may include specific behaviors, such as the use of candles to celebrate holidays. It may include general values, such as a strong sense of family. Failure to consider this context may create an immediate and significant barrier to communication.

The ability to make certain your message can be delivered across many cultures requires the sender to understand the attitudes and behaviors of a culture. Specific aspects of how the message may be used in the culture must be considered. In her book, *Cultural Issues in Business Communication,* Elaine Winters discusses the importance of communicating across cultures. She points out that one hidden aspect that differentiates cultures is the amount of context a culture's members expect in social interactions. People who study such things divide cultures into those that are high context and those that are low context. In general, high context cultures place great importance on ambience, decorum, the relative status of the participants in a communication,

and the manner of a message's delivery. People in low context cultures tend to ignore such things and emphasize the content of a communication, an attitude that might be expressed in the phrase "cut to the chase."[6] A primary consideration would be the possibility that the message changes going from one culture to another. Are there words in the culture to portray the same intended meaning as the sender had intended?

For example, consider the fire safety message that states "Candles kill—do not use candles at home." This message could be offensive to a culture that uses candles in the home to celebrate religious holidays and other important events. A better message, one which considers that culture, would be "Keep your home safe—use candles wisely." Please note that even the sample culturally appropriate message still fails to identify appropriate actions. NFPA's Educational Messages Advisory Committee (discussed later in the chapter) has developed the following official educational messages related to candles:

- Keep candles at least 12 inches from anything that can burn.
- Use sturdy, safe candleholders.
- Never leave a burning candle unattended. Blow out candles when you leave a room.
- Avoid the use of candles in bedrooms and sleeping areas.
- Use a flashlight, not a candle, for emergency lighting.
- Be careful not to splatter wax when extinguishing a candle.[7]

Another social/cultural context to consider is the specific or desired receiver of the message. Is it the father? The mother? The grandparent? In some cultures, the male head of the household may be the best receiver as he makes decisions about such things as installing smoke alarms. In other cases, the mother may be the best receiver because she is responsible for the care of the young children.

Finally, the last factor is the perceived relevance of the message to the receiver. This element is directly impacted by ensuring the social and cultural context of the message is appropriate. The receiver must perceive that the message applies to him or her. The greater the perceived relevance, the more likely the receiver is to act on the information—that is, the more likely education will occur. If the receiver's perception is that the message does not apply to them, for whatever reason, the message will be disregarded.

For example, a message on wildland fire safety will not have any relevance to a person living in the center of a large metropolitan city. There are no forests and there is no chance a wildland fire will destroy the receiver's home.

Characteristics of Appropriate and Effective Messages

Appropriate messages share certain characteristics. Those characteristics are self-containment, conciseness, comprehensibility to the receiver, logic, accuracy and technical soundness, and action orientation.

Self-Containment. When receivers of information say a message is not clear, they may mean that they have been provided too little or may require additional information to understand the message, some of which may not be known to them or may involve choices they are not sure how to make. (For example, I don't know what the action "feel" means in "feel the door" and I don't know how to choose which part of the door to feel.)

Conciseness. A message is more concise if it includes less (or no) information that is not essential to its intended content and the receiver's understanding. Concise does not mean that shorter is always better, because a brief message can sacrifice clarity by omitting essential information. For example, "feel the door" by itself is too concise; it leaves too many essential questions unanswered.

Comprehensibility to the Receiver. A message is more comprehensible if it fits well with the context of communication applicable to the receiver. For example, the message should use words and concepts as they are used in the receiver's culture, and it should use the receiver's language, including no language (i.e., pictures only) if the receiver has limited literacy.

Logic. A message is more logical if the sequence of concepts and ideas it communicates are arranged in a logical order, for example, in terms of the sequence in which they become relevant to the subject behavior. A message that is less logical will be difficult to follow. For example, "Stop, drop, and roll" is a perfect example of a message with parts arranged in a logical order.

Accuracy and Technical Soundness. A message is more accurate and technically sound if its stated or assumed facts can all be substantiated by reference to best evidence, scientific or otherwise. A message often has a long list of assumed facts that may not be recognized as such by the sender. These assumed facts can be identified by extensive review of the message by people with diverse relevant experience. (For example, what is the evidence to support feeling this part of the door versus that part of the door, using this part versus that part of your exposed flesh?

Action Orientation. A message is more action oriented if it makes clear what behavior the receiver should perform or what belief the receiver should change. Major campaigns have been built around phrases such as "Only you can prevent forest fires" or "Was somebody careless?" These phrases may serve to heighten attention to fire and life safety issues, giving them more urgency or higher priority, but they provide no information on recommended actions or behaviors.

FIVE-STEP PLANNING PROCESS AS A TOOL FOR MESSAGE DEVELOPMENT

A variation of the Five-Step Planning Process[8] can be used to develop appropriate fire and life safety messages or to revise existing fire and life safety messages to enhance the effectiveness of the message. The five steps are as follows:

1. Conduct a community assessment survey.
2. Define the injury problem.
3. Set goals and objectives.

4. Plan and test interventions.
5. Implement and evaluate interventions.

Table 5.2.1 summarizes the implications of each step in message development.

Community Assessment Survey

A comprehensive community assessment is done to identify potential injury-related problems. This assessment should provide demographic characteristics of the community, including individual neighborhoods and especially the population at highest risk. The survey should include information on culture, ethnicity, income, social services and resources available, and so on. It essential that this step be comprehensive as it provides invaluable background information about the target audience that is necessary for the development of effective messages.

The assessment should also determine if there are existing campaigns already being conducted by other groups or organizations. The duplication of such programs is rarely a good use of the educator's time or resources. Keep in mind that access to all data may not be possible; however, you should be able to gather enough to give a picture of the situation within the identified survey area.

Injury Problem Definition

Based on the community assessment data, the information received should allow the specific problem to be expressed in more quantitative terms. The answers to who, what, when, where, and how should be defined in more precise terms. This includes the specific behaviors involved, contributing factors, and so on. For example, it might be suspected that burns are a major concern within the state. After gathering the community assessment data, it was determined that burns were indeed a problem, but more precisely to young children (under a specific age) of a certain nationality, who reside in a certain geographical region, and so on. Having chosen the problem that may exist within the community, the next action is to decide how to actually accomplish reduction of the injury, usually through a change in behavior.

TABLE 5.2.1 Planning Implications for Message Development

Planning Step	*Implications*
Conduct a community assessment survey.	The survey provides valuable information on the demographics of the community.
Define the injury problem.	This will clearly identify *and* describe the fire or injury problem(s) involving the target audience.
Set goals and objectives.	The goals and objectives establish what is to be accomplished.
Plan and test interventions.	The messages are developed and incorporated into the interventions. The messages should be reviewed by members of the target audience.
Implement and evaluate the interventions.	The interventions are implemented and the messages are evaluated as to their effectiveness. Revisions are made as needed.

Goals and Objectives

The differences between goals and objectives are important considerations. A *goal* is a broad, general statement about the long-term outcome of the initiative. For example, a goal for a safety message may be that everyone feels the door in the correct manner.

An *objective* makes a time-limited and quantifiable statement about an initiative. The objectives will determine which issues will be addressed, what messages are needed, target audiences, and so on. There are two types of objectives. A *process objective* states how the program will be implemented, for example, a certain number of classes conducted within a certain amount of time. An *outcome objective* states what the program or message will change, including behaviors and attitudes. Keep in mind that baseline data are required to determine outcome.

Intervention Planning and Testing

Intervention may be defined as the actions taken to accomplish the identified goals and objectives. Examples of interventions include presentations, written materials, and public service announcements. There are generally five injury prevention categories: education/behavior change, environmental improvements, engineering modifications, enforcement of legislation/regulations, and economic incentives that are effective at reducing the incidence and severity of unintentional injury and death. These categories are sometimes referred to as the "5 Es of injury prevention." When considering any of the methods, it is imperative that the target population be evaluated to ensure that the interventions are culturally appropriate, understandable, and acceptable. It is also imperative that the educator clearly understands the social and cultural characteristics of the target audience so that all the interventions selected are culturally appropriate and understandable to the target audience.

Intervention Implementation and Evaluation

The final step of implementation and evaluation is actually a combination of smaller, recurring steps. For example, when you launch your initiatives, you will at the same time be evaluating the process and making improvements. Remember, implementation is not a one-time effort—prevention programs may take place over a number of months and require constant monitoring and improvement.

CASE STUDY: Creating Fire Safety Messages in South Africa. In 2000, the National Fire Protection Association provided assistance to the fire service of South Africa in the development of department-based fire safety education programs. The initiative was facilitated by NFPA's Center for High Risk Outreach. One of the primary goals of the initiative was the implementation of the *Learn Not to Burn Curriculum*® into South African schools, especially in high-risk areas.

While the *Curriculum* proved to be successful in South Africa in reducing fires and burn injuries, many of the messages were not appropriate due to differences in language, culture, and living environment. A decision was made to develop specific messages for South Africa that would be relevant to the target audiences and would be compatible with the nature of the fire problem and the social and cultural context of the country.

In 2005 a team from NFPA traveled to South Africa to work with leading fire safety and burn prevention educators, community leaders, and medical care providers to develop the unique South African fire safety messages. The target audience selected for the messages was 3- to-5-year-old children living in townships and informal settlements, as well as the care providers of these children. Figure 5.2.2 illustrates typical cooking facilities in the township environment.

Factors Leading to Burn Injury and Death

Using a group discussion process, the situations that most commonly led to burn injuries to the target group were identified and included the following:

- Child left unattended and fire begins (unsupervised)
- Shack fire starts; child does not or cannot escape
- Hot liquids spill from pot on stove
- Hot liquids spill from table
- Paraffin (kerosene) stove or candle tips, falls over, and starts fire
- Open flames of stoves cause clothing fire
- Stove not in proper working order
- Caregiver under the influence of alcohol
- Criminal action starts fire (intentional)

Although these identified events were not an exhaustive list, they painted an accurate picture of the common risks and main causes of burns in the shantytown environment.

The next step in the process was to prioritize the causes. The highest priority was given to those causes that occurred most frequently. Participants then developed a chain of events for each cause. From this chain of events, reasonable interventions were identified—that is, interventions that were possible for the children and caregivers. The following is a chain of events identified for a fire resulting in a burn to a child:

- A poor family builds a shack near urban areas for work opportunities.
- The family purchases a cheap paraffin stove to cook food.
- The interior of the shack is covered with cardboard and newspaper to insulate from cold.
- Combustibles contact the open flame of the stove.
- A fire spreads rapidly to other combustibles.
- Children have been left unsupervised and do not escape the burning shack.
- A child's clothes catch fire and the child is severely injured.
- An adult treats the burn wound with a traditional remedy (e.g., toothpaste, soap, metal cleaner).
- Transport of the child to the hospital is delayed.
- The child dies from burn injuries.
- The family rebuilds the shack as it was before.

FIGURE 5.2.2 Typical Cooking Facilities in a South African Township

Resulting Messages

The educational interventions were selected for development into messages. When developing the specific text of each message, the following elements were considered for a child 3 to 5 years of age:

- Linguistic readiness (will they understand the message)
- Emotional readiness (as stress levels increase, decision-making abilities decrease)
- Cognitive readiness (can they reason)
- Physical readiness (in terms of age/ability)
- Culturally appropriate (within value set they have been raised with)
- Language appropriate (remember idiomatic language/dialect)
- Child's locus of control (what they can/cannot influence)

As a result of this process, eight fire safety messages were developed for a new educational program, *Learn Not to Burn—Preschool, South Africa.* The eight messages are as follows:

1. Stay away from hot things; they can burn you.
2. Stay away from flames; they can burn you.
3. Stay away from paraffin; it can hurt you.
4. Matches and lighters are not toys; leave them alone.
5. If your home is on fire, go outside and stay outside.
6. If your clothes are on fire, stop, drop, and roll.
7. Cool a burn with water.
8. The fire fighter is a helper.

ONGOING NFPA ACTIVITIES

We as a society are in the midst of a major social transformation—a transition to a new way of living and acting. Our reliance on websites, podcasts, webonnaires, instant messaging, and texting

for news and information—as opposed to traditional sources of TV, radio, or print media—is an example of how our lives have changed over the past few years. Recognizing that, the National Fire Protection Association (NFPA) convened a meeting of fire and life safety experts from across the United States and Canada in 2003. The purpose of this meeting was the establishment of the Educational Messages Advisory Committee. The committee, meeting on an annual basis, is responsible for providing expert advice to NFPA public education staff on safety education messages.

The goals of the advisory committee are as follows:

1. Review current educational safety messages and determine if research is needed to validate the message
2. Create two versions of each educational message (one in an easy-use format for children and those who may not be able to comprehend more detailed information and a second version in an expanded format)
3. Develop a rationale for each educational message (using evidence-based outcome where possible)
4. Produce an educational message document to be made available on the NFPA website

The committee easily reached consensus on the elements of a good message: the message should be informative, short, concise, direct, and comprehensive. The next step was to consider the role the fire and life safety educator has in promoting and addressing change as it relates to safety messages in today's society. Educators must make a commitment to adapt to changing forces. In other words, rather than simply suggesting that everyone and everything must change, the educator must lead by example. The educator not only serves as a witness to change but must also show others how to adapt changes in their own lives.

For example, when advising the public about the use of security bars, the homeowner's main concern is safety from intruders. The educator's main concern may be a blocked means of egress in the event of a fire. In an attempt to compromise or adapt to change, the educator would advise the homeowner to install security bars with a quick release device (if a key is used, it should be kept nearby so everyone can find it). The homeowner is more likely to adapt to the suggested change (recognizing that his concern of security is met) and the educator will have succeeded in getting the homeowner to move fire safety higher up on the list of priorities.

Next, the committee addressed other forces of change such as updated life safety education for persons with disabilities or people who reside in multistoried buildings, new technology (i.e., ten-year lithium battery smoke alarms), and residential sprinklers. Educational messages on these topics have been around for quite some time; however, because technology has made some products simpler and less expensive, new messages must be designed to accommodate these changes.

The Educational Messages Advisory Committee has developed official educational messages on smoke alarms, escape, burns, smoking, candles, the "stop, drop, and roll" technique, and fire extinguishers. These messages can be viewed on the NFPA website: http://www.nfpa.org.

SUMMARY

Developing and revising fire and life safety messages is a critical skill for fire and life safety educators. Appropriate messages must consider the language used in the message, the social and cultural context of the message, and the perceived value by the receiver. Messages must also be comprehensible to the receiver, logical, accurate, technically sound, and action oriented. Messages that address these characteristics are more likely to successfully communicate the desired information to the target audience.

Key Terms

disaster, disaster preparedness, emergency operations center (EOC), hurricane, landslide, national incident management system (NIMS), public fire and life safety educator, public information officer, tornado, winter storm

Today's fire and life safety educator has an ever-expanding role in the community with regard to disaster preparedness education. The chapter starts with the definition of *disaster preparedness,* provides examples of different types of disasters (both natural and those caused by humans), and discusses organizations that are currently dealing with disasters, as well as the formation of collaborative interagency partnerships. Consideration is also given to the processes for identifying and analyzing community risks. A large part of this chapter deals with the educational programs currently addressing disaster preparedness, and the disaster-specific messages they provide for actions to take before, during, and after the disaster. Recommendations are made for "retooling" a fire and life safety education program to include disaster preparedness education. Finally, a list of resources and references for further information on this topic is made available. This resource list is by no means a complete and exhaustive one because disaster preparedness education is a fast-growing area with constant new information and many governmental agencies being designed or realigned. It does, however, provide a beginning pathway for the fire and life safety educator who is adding disaster preparedness education to his or her role in the community.

For related topics, see the following chapters in Section 5: Chapter 1, "Principles and Techniques of Fire and Life Safety Education"; Chapter 2, "Fire and Life Safety Education Messages"; Chapter 4, "Media's Role in Fire and Life Safety Education"; and Chapter 8, "Evaluation Techniques for Fire and Life Safety Education." See also Section 12, Chapter 12, "Disaster Planning and Response Services."

TYPES OF DISASTERS

According to *Merriam-Webster's Collegiate Dictionary,* a *disaster* is defined as "a sudden, calamitous event bringing great damage, loss, or destruction." Disasters can be natural or weather-related incidents, such as tornadoes, hurricanes, snow blizzards, landslides, earthquakes, flooding, and volcanic eruptions; or they can be caused by humans either unintentionally, such as a tanker rollover in icy conditions, or intentionally, such as acts of terrorism.

Natural or Weather-Related Disasters

Natural or weather-related disasters have increased in number and intensity over the past several years, due to changes in weather phenomena, including El Niño and global warming. Loss of life and destruction of property as a result of the Asian tsunami of December 2004 were astronomical. It left nearly 170,000 people dead or missing in the Indonesian province of Aceh alone. In addition, at least 5400 people died in Thailand and many remain missing.[1]

Similarly, the 2004 and 2005 Atlantic hurricane seasons were unprecedented. In 2004, Florida was hit by four major hurricanes in a six-week period. And the year 2005, which saw 28 named

Gerri Penney, M.Ed., is the community education coordinator for Palm Beach County Fire Rescue. She has served on the NFPA 1035 technical committee since 1997 and chairs the Juvenile Firesetter Intervention Specialist Task Group. A graduate of NFA's Executive Fire Officer Program, Ms. Penney also chairs the National Fire Prevention Professional Development Committee. She is pursuing her Ph.D. in educational leadership from Florida Atlantic University.

storms, was the first time in history that hurricanes had to be named based on the Greek alphabet because all of the names associated with the letters of the English alphabet had been used. As of the writing of this chapter, the largest natural disaster in the history of the United States was Hurricane Katrina, which occurred on August 29, 2005, along the Gulf Coast (Figure 5.3.1). Six months later, on February 23, 2006, the White House released its report, entitled *The Federal Response to Hurricane Katrina: Lessons Learned.* The following excerpt is taken from the report's Chapter 1, "Katrina in Perspective."

> The flooding destroyed New Orleans, the Nation's thirty-fifth largest city. Approximately 80 percent of the city was flooded. . . . Hurricane Katrina impacted nearly 93,000 square miles across 138 parishes and counties . . . an estimated 1,330 people died as a result of the storm. The vast majority of the fatalities—an estimated 80 percent—came from the New Orleans metropolitan area; Mississippi suffered greatly as well, with 231 fatalities. Many of the dead were elderly or infirm . . . As of February 17, 2006, there were still 2,096 people from the Gulf Coast area reported missing. Around 770,000 people were displaced. . . . The total cost to date is 96 billion dollars.[2]

CASE STUDY: Hurricane Katrina. Several national urban search and rescue (USAR) teams based in Florida, anticipating landfall of Hurricane Katrina in the Florida panhandle, had been deployed to the northern area of the state. When it was evident the hurricane would hit the Gulf Coast, these teams were sent on to that area. The fire marshal and a battalion chief from Palm Beach County Fire Rescue were sent in to assist in the establishment of the incident command post (ICP) in Biloxi, Mississippi, and were assigned the position of "liaison."

FIGURE 5.3.1 Hurricane Katrina Devastation (Source: National Oceanic and Atmospheric Administration)

The ICP was set up in the Gulf Coast Coliseum, which had taken on floodwaters up to the first balcony. When the water had receded and the ICP was established, the job of the USAR teams was to search three counties along the Gulf Coast and three counties to the North (Figure 5.3.2). The devastation that they saw was unbelievable. One of the lessons shared by the fire marshal upon his return was the necessity of staying focused on the job. The need was so great everywhere that, if the team members were not focused, they would be pulled in too many directions and would not complete the task at hand. James Lee Witt in his book, *Stronger in the Broken Places,* wrote: "The first mistake people often make in responding to a crisis is in trying to fix everything, respond to everything, all at once . . . they call it triage in medicine, the act of making split-second decisions about the priority of treating one medical case over another one."[3]

In an interview with the *Washington Times,* R. David Paulison, acting director of FEMA after the resignation of Michael Brown, said about Katrina, "It overwhelmed everyone; the system was not set up to deal with a catastrophe of that size. . . . Normally, we house [3,000 to 5,000] disaster victims a year. We went way beyond that, and we had to make up the rules as we went along." While preparing for the 2006 hurricane season, FEMA was still aiding 800,000 families affected by the previous year's storms, which had damaged 90,000 square miles.[4]

In addition to hurricanes, other types of natural disasters include earthquakes, floods, landslides, snow blizzards, tornadoes, volcanic eruptions, and wildfires. Fire and life safety educators, in whatever area of the country they may reside, will no doubt be affected by some type of natural disaster. In the past fire and life safety educators have left disaster response to line officers who have experience in special operations or to the emergency management divisions of their municipalities. Today, however, they consider it part of their jobs to help the people of their community know what to do by encouraging disaster preparedness before a catastrophe takes place.

Human-Caused Disasters

Although we commonly think of natural disasters as those caused by weather-related incidents, disasters can also be caused by humans, whether unintentional (such as a tractor-trailer hauling gasoline rolling over on the highway), or intentional (as in acts of terrorism). The hazards associated with human-caused disasters also need to be dealt with by fire and emergency services personnel. Many fire rescue departments have special operations teams that have been dealing with hazardous materials for many years. Hazards can be chemical, biological, radiological, nuclear, or explosive (CBRNE). The following case study highlights a bioterrorist event that happened within one month of the attack on the World Trade Center and the Pentagon.

CASE STUDY: Anthrax Mailing. An example of bioterrorism occurred when a 63-year-old male photo editor in Boca Raton, Florida, was diagnosed with inhalation anthrax on October 2,

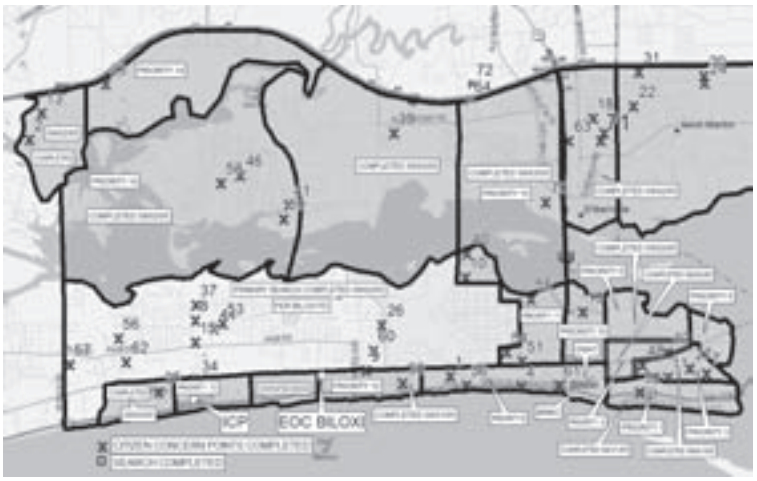

FIGURE 5.3.2 USAR Search Map After Hurricane Katrina (Courtesy of Fire Marshal, Deputy Chief Steve Jerauld)

2001. He died three days later. An environmental assessment of his workplace, American Media, a publisher of a national tabloid magazine, uncovered anthrax in the mailing and packaging facility. This story received a good deal of press coverage. The Centers for Disease Control assisted the local and state health departments in the investigation.[5] When the Palm Beach County Fire Rescue received many emergency calls from panicked residents because of the "white powder" scare, all personnel, including staff in the community education section, were involved in educating the public about safety precautions and steps to take if they suspected letters or packages of containing white powder.

Further press coverage continued when letters addressed to prominent news and political figures started to show up. The nation was on high alert as anthrax-laced letters surfaced in several places. NBC anchorman Tom Brokaw, two U.S. senators, and the offices of the *New York Post* were among the targets. The anthrax attacks killed five people and made 17 people ill.[6]

Many fanatical groups and terrorist cells have used explosive devices to make their statements. Bombs can be planted in vehicles or strapped to humans, who then become martyrs for their cause. However not all explosions in buildings have the same results. The National Science Foundation, in a report entitled *Preparing for the Worst—Making Buildings Stronger,*[7] discusses strengthening buildings as a good way to minimize fatalities.

CASE STUDY: El Nogal Social Club, Bogotá, Colombia. On February 7, 2003, a bomb demonstrated the critical benefits of solid construction when El Nogal social club in Bogotá, Colombia, withstood a devastating blast. Terrorists had used approximately 600 pounds of ammonium nitrate and chlorate mixed with fuel oil to create an enormous explosive device, which was placed in an automobile parked on the fourth floor of a 12 story building. At the time of the blast, 750 people were in the building; 38 were killed and 170 were injured. However, because the building remained standing, fatalities were minimized. El Nogal, composed of a 12 story structure and an adjacent four story structure, was designed to withstand seismic shaking (Figure 5.3.3).[7]

In comparison, the Oklahoma City bombing at the Alfred P. Murrah Federal Building (a structure not designed to withstand seismic shaking) resulted in a total of 168 people killed, including 19 children, and more than 500 injured. The building was later razed and a park was built on the site.[8]

Regardless of whether a disaster is caused by a natural event such as severe weather or is the result of a planned, intentional act of terrorism, the results are the same. People are killed or

FIGURE 5.3.3 Terrorist Attack on El Nogal Social Club, Bogotá, Colombia (Source: National Science Foundation)

injured, property is annihilated or damaged, and recovery takes time and money. People who survive a disaster need help to pick up the pieces and try to put their lives back together again.

FIRE AND LIFE SAFETY EDUCATOR

Fire and Life Safety Educator's Role

The role of today's fire and life safety educator has changed significantly over the past 20 years. Originally, someone in this position was involved in teaching only fire safety; however, as fire departments evolved and took on a more active role in rescue and emergency services, fire and life safety educators expanded their role to include teaching injury prevention.

After September 11, 2001, the world changed and, with it, the role of the fire and life safety educator. Terrorist incidents had actually taken place in the United States prior to that event; for instance, the Oklahoma City bombing on April 19, 1995, was "the first presidential declared disaster that was also a crime scene."[9] The difference, however, was that up until the time of the assault on the World Trade Center and the Pentagon, no large-scale, planned, direct attack on the nation had been executed by a hostile entity and had resulted in such a large loss of life. Since 9/11, the country has become more aware of hazards caused by humans, as well as the natural disasters that are happening more frequently and on a larger scale. The increasing strength and number of natural disasters—such as Hurricane Katrina; the Asian tsunami; and California, Texas, and Florida wildfires, which have caused such large life loss and massive property damage—have given rise to a focus on all hazards. As a result, the role of the fire and life safety educator has expanded to encompass disaster preparedness education.

Disaster Organizations and Programs

Organizations. Fire and life safety educators are great networkers. They often belong to and work with many coalitions, committees, and associations to expand the safety message in the community. They may undoubtedly have worked with organizations that deal with disasters on other projects. For instance, they may already be working with the American Red Cross on first aid, CPR, or the vial of life program. (In the latter, medical information is completed for the homeowner and placed on the refrigerator door. In an emergency, paramedics can take this information with them to the hospital.) They may have worked with the American Red Cross on the After the Fire program or on drowning prevention and water safety. The links are already there in the community even if the fire and life safety educator may not have been involved in disaster preparedness education.

Training Programs. One of the first places for fire and life safety educators to start is right inside their own department. Whether the department is career, volunteer, or a combination, it is still involved with training. The Department of Homeland Security has put a high priority on having every organization trained in the national incident management system (NIMS). Fire departments have been using the incident command system (ICS) for many years and it fits well within NIMS. If fire and life safety educators are not already trained in these programs, they would benefit from becoming familiar with such programs. A variety of courses are also available through the independent study program on the FEMA website.[10]

Emergency Operating Center. A municipality's emergency operating center is another great source of information on disaster preparedness education. Although the center may or may not have a person designated as an emergency management educator, the center's coordinator will have made contacts with all essential organizations in the community who would staff the EOC during a disaster. The state will also have an emergency management organization that can assist fire and life and safety educators. A list of national organizations that deal with disaster preparedness can be found at the end of this chapter. Many of these national organizations have an affiliation at the state or local level.

PRE-DISASTER ORGANIZATIONS, PROGRAMS, AND ACTIVITIES

Forming Collaborative Interagency Partnerships

Preparation *before* disasters strike is essential. Forming local coalitions that meet on a regular basis throughout the year will make all stages of dealing with a disaster run more smoothly.

Message Content. Statewide coalitions can be of great help to ensure consistent message content is provided for the public. When a collaborative interagency partnership is formed, all groups can reach a consensus on what messages to publish so that the same information is passed on regarding preparedness, disaster box contents, evacuation routes, and the like. These messages should be published on as many different websites and in as many different media outlets as possible. With consistent messages, the public will be more informed and less confused during all phases of the emergency. It is very important for agencies to form coalitions and share information to avoid giving mixed messages to the public. Remember to include media persons in this coalition group.

Resource Availability. Equally as important as a community analysis of risks and hazards is an analysis of the resources on hand and what resources could be obtained in the event of a disaster. Fire and life safety educators and public information officers have often built up networks and are familiar with what is available in their communities. This collaborative interagency partnership will allow everyone involved to know exactly what resources are available in the community.

Identifying and Analyzing Community Risks

Most fire departments have probably already done some type of community risk assessment to determine exactly what kind of hazards are present and where the hazardous occupancies in their jurisdiction are located. This risk assessment may have

been done with the aid of a software program or through a community risk assessment, prefire plans on the part of operations, and an examination and summary of inspections of properties, run reports, call volume, and the like. Such an assessment can be used to justify staffing, to apply for grant funds, to determine the location of future stations, to prepare for the accreditation process, and so on. With regard to emergency management and disaster preparedness, an assessment can help determine, for example, which areas may need to be evacuated, which populations may need special care during a disaster, which occupancies could be specific targets for terrorist activities, or which services could be affected during a major flood. Being familiar with the risks and hazards in the community will allow for preemergency planning. Having a plan in place to deal with a particular hazard beforehand makes disaster response easier.

Educational Programs Addressing Disaster Preparedness

Organizations put out many educational messages to address different types of disasters. These messages can be directed to adults and/or to children.

Programs for Children. Some websites tailor their messages and their graphics specifically to children—for instance, "FEMA for Kids" at http://www.fema.gov/kids/qzbwl01.htm and "Ready Kids" at http://www.ready.gov/kids/home.html.

From a comprehensive standpoint, an excellent program that addresses students from kindergarten through eighth grade is the NFPA curriculum, *Risk Watch: Natural Disasters.* Similar to the *Risk Watch: Unintentional Injuries* curriculum, *Risk Watch: Natural Disasters* was also put together by a technical advisory group of experts in the field of disaster preparedness. Funding in support of the program came from the Home Safety Council and FEMA. The curriculum is divided into five teaching modules (pre-K/kindergarten, grades 1–2, grades 3–4, grades 5–6, and grades 7–8), each of which addresses the following topics: general preparedness, earthquakes, floods, hurricanes, tornadoes, wildfires, and severe winter storms. Teachers and students can get additional support online from the website http://www.nfpa.org/riskwatch/RWND/faqs.html.

Another comprehensive educational program for children regarding disaster preparedness is the *Masters of Disaster* curriculum created by the American Red Cross. It consists of three teaching modules that cover grades K–2, 3–5, and 6–8. Disaster areas covered in each of the modules include general preparedness, hurricanes, floods, tornadoes, lightning, and earthquakes. Website support includes background for the teacher, general information on the disaster, and lesson plan adaptations. Teachers and students can get additional support on the program from the website http://www.redcross.org/disaster/masters/kit1.html.

Programs for Adults. Educational programs on disaster preparedness for adults are plentiful. Many training courses are available through the FEMA virtual campus. In addition, the http://www.ready.gov website has specific areas for businesses as well as for adults and children. (See the Disaster Preparedness Resources section at the end of this chapter.)

ROLES/ACTIVITIES BEFORE, DURING, AND AFTER A DISASTER

It is important that all local agencies meet and know what each agency's role will be. Establishing these roles well before disaster strikes will make everything run as smoothly as possible. Because several agencies may have positions for public information officers (PIO) and public educators, establishing well-defined roles will make better use of staffing and avoid duplication.

Pre-Disaster Roles/Activities

Before disasters, most public educators and PIOs are busy trying to help educate the public on how to be prepared. Agencies need to form coalitions and share information to avoid giving mixed messages to the public. Media people should be included in this coalition group. Each agency and media outlet needs to have the *same* messages regarding the following:

- Location of shelters
- Contents of disaster preparedness kit or box for the anticipated event
- When evacuation will be necessary
- Which areas should expect evacuation and suggestions on where to go
- How citizens need to prepare

Roles/Activities During Disasters

In past disasters, PIOs and public educators who were given specific jobs seemed to feel they were the most effective in such roles. Some were placed at emergency operation centers (EOC) where they were able to communicate with other agencies, making the best use of materials and staffing during disasters. They were also able to relay information back to their respective agencies. Also, at the EOC, they were available if other agencies needed anything from them. Some were placed in shelters and assigned the job of helping to keep the occupants as calm and informed as possible. Their calming presence was of great help to the volunteers working in the shelters.

Roles/Activities After Disasters

Public educators and PIOs assumed a wide variety of duties after local disasters. Some gathered information and wrote reports to FEMA and/or other governmental agencies. Some remained in their local emergency management facilities, keeping communication up and running efficiently between agencies. Others helped to ride streets and radio in as to where hazards prevented rescue equipment from safely passing, what equipment was needed to clear main streets, and what the priority was regarding needed emergency equipment. Because they are usually very familiar with the geographic area and which citizens might need assistance, public educators and PIOs are valuable personnel during disaster events.

Areas Needing Improvement

Almost everyone can agree that improvement could always be made in communication, especially from state or federal

agencies to local ones. Establishing good lines of communication by telling each entity what is expected of them and what they can expect from each other will avoid a lot of confusion.

NATURAL DISASTER MESSAGES

Pre-Storm Messages

Pre-storm messages include messages on the following topics:

Generators

- Provide information on proper exterior placement of generators.
- Provide information on carbon monoxide poisoning.
- Provide information on fire safety when using a generator.
- Provide information on amount of fuel that can be stored on the property.
- Refer citizens to the USFA website for general information on generators.

Pets

- Ensure that all pets have information tags.
- Ensure pets' vaccinations are up-to-date.
- Prepare a pet disaster kit.
- Investigate options for shelters that take animals.
- Consider making reservations for pets at pet shelters.

Power

- If you evacuate, be sure to shut off the main electric breaker in your home in case of a power outage.
- Turn gas main off, then have gas company turn it back on.

Tree Trimming

- Make sure that trees are trimmed before the storm season.
- Contact the local electric company if tree limbs interfere with wires.
- Do not put tree trimmings out for trash pickup before a storm.

Public Safety Response

- Warn citizens about the possible delayed response of emergency vehicles.

Messages During a Storm

Messages during a storm include the following:

- Provide information on candle safety.
- Suggest the use of flashlights, not candles, in a power outage.
- Provide information on using grills and generators outside the house or garage.
- Suggest not cooking or cooking safely on an outdoor grill.
- In a power outage, shut off the main electric breaker, so there will be no surge when electricity resumes. This also prevents fires if the stove was turned on before the power outage.

Post-Storm Messages

Post-storm messages include the following:

- Beware of foodborne illness; dispose of foods that have thawed or been without refrigeration.
- Stay off roads until told that they are safe for travel.
- Stay away from downed power lines.
- Stay away from flooded areas.
- Practice safety around generators.
- Practice safety when using candles.
- Repair downed/damaged pool enclosures and fences.
- Practice safety around loose pets and other animals.
- Practice safety around electricity.
- If it is safe, consider making welfare checks on elderly persons who did not evacuate.
- Provide adult supervision of children.
- Practice safety around water hazards such as drainage; sewage; storm drains; ponds, creeks, and canals.
- Pay attention to your municipality's information on drinking water.
- After the storm, remove shutters or plywood from windows and exits.
- Be aware that some family members may need help dealing with stress after the storm.
- After the storm, do a damage assessment and contact your insurance provider.

TORNADO-SPECIFIC MESSAGES

Tornado Defined

According to the *Glossary of Meteorology,* a tornado is "a violently rotating column of air, pendant from a cumuliform cloud or underneath a cumuliform cloud, and often (but not always) visible as a funnel cloud."[11] In order for a vortex to be classified as a tornado, it must be in contact with both the ground *and* the cloud base (Figure 5.3.4).

Weather scientists have not found it so simple to classify and define tornadoes. There is also disagreement as to whether

FIGURE 5.3.4 Sand Point, Alaska, Tornado (Source: National Oceanic and Atmospheric Administration)

separate touchdowns of the same funnel constitute separate tornadoes. The difference is unclear between a strong mesocyclone (parent thunderstorm circulation) on the ground and a large, weak tornado. It is well known that a tornado may not have a visible funnel. Tornadoes can last from several seconds to more than an hour; most last less than ten minutes.

A waterspout, which is a tornado over water, is common along the southeast U.S. coast, especially off southern Florida and the Keys. Waterspouts can happen over seas, bays, and lakes worldwide.

Tornado Safety

There is no such thing as guaranteed safety inside a tornado. Freak accidents happen; the most violent tornadoes can level and blow away almost any house and its occupants. Extremely violent tornadoes are very rare, though. Most are much weaker and can be survived using the safety suggestions provided in the following sections.

Pre-Tornado Planning. At home, have a family plan in place, based on the kind of dwelling you live in and the safety tips provided below. Know where you can take shelter in a matter of seconds, and practice a family tornado drill at least once a year. Have a predetermined place to meet after a disaster. Flying debris is the greatest danger in tornadoes, so store protective coverings (e.g., mattress, sleeping bags, thick blankets, etc.) in or next to your shelter space, ready to use on a few seconds' notice.

When a tornado watch is issued, think about the drill and check to make sure all your safety supplies are handy. Turn on local TV, radio, or NOAA Weather Radio and stay alert for warnings. Forget about the old notion of opening windows to equalize pressure; the tornado will blast open the windows for you. If you shop frequently at certain stores, learn where the bathrooms, storage rooms, or other interior shelter areas in these stores are that are away from windows and make note of the shortest ways to get to these areas. If you are planning to build a house, especially east of the Rockies, consider an underground tornado shelter or an interior "safe room."

Tornado Signs and Sounds. Besides an obviously visible tornado, the following are some signs to look and listen for:

- Strong, persistent rotation in the cloud base
- Whirling dust or debris on the ground under a cloud base; note that tornadoes sometimes have no funnel
- Hail or heavy rain followed by either dead calm or a fast, intense wind shift; many tornadoes are wrapped in heavy precipitation and cannot be seen
- Day or night: a loud, continuous roar or rumble that doesn't fade in a few seconds like thunder does
- Night: small, bright blue-green to white flashes at ground level near a thunderstorm (as opposed to silvery lightning up in the clouds); these flashes indicate power lines are being snapped by very strong wind
- Night: *persistent* lowering from the cloud base, illuminated or silhouetted by lightning, especially if it is on the ground or there is a blue-green-white power flash underneath

Tornado Safety Tips

The following are safety tips for actions to take depending on where you are when the tornado strikes.

House with a Basement

- Avoid windows.
- Get in the basement and under some kind of sturdy protection (heavy table or work bench), or cover yourself with a mattress or sleeping bag.
- Know where very heavy objects (pianos, refrigerators, waterbeds, etc.) rest on the floor above and do not go under them.

House with No Basement, Dorm, or Apartment

- Avoid windows.
- Go to the lowest floor, to a small center room (like a bathroom or closet), under a stairwell, or in an interior hallway with no windows.
- Crouch as low as possible to the floor, facedown, and cover your head with your hands. A bathtub may offer a shell of partial protection.
- Cover yourself with thick padding such as a mattress or blankets to protect against falling debris.

Office Building, Hospital, Nursing Home, or Skyscraper

- Go directly to an enclosed, windowless area in the center of the building, away from glass. Interior stairwells are usually good places to take shelter, and if not crowded, allow you to get to a lower level quickly.
- Crouch down and cover your head.
- Stay out of elevators.

Mobile Home

- Get out! Even if your home is tied down, you are probably safer outside, even if the only alternative is to seek shelter out in the open.
- If there is a sturdy permanent building within easy running distance, seek shelter there.
- Otherwise, lie flat, facedown on low ground away from your home, protecting the back of your head with your arms.
- Use open ground away from trees and cars.

School

- Follow the drill!
- Go to the interior hall or room in an orderly way as you are told.
- Crouch low, head down, and protect the back of your head with your arms.
- Stay away from windows and large open rooms like gyms and auditoriums.

Car or Truck

- Vehicles are extremely dangerous in a tornado. If the tornado is visible, far away, and traffic is light, you may be able to drive out of its path by moving at right angles to the tornado.
- Otherwise, park the car as quickly and safely as possible, out of traffic lanes.

- Get out and seek shelter in a sturdy building.
- If in open country, run to low ground away from any cars (which may roll over on you).
- Lie flat and facedown, protecting the back of your head with your arms.
- Avoid seeking shelter under bridges, which can create deadly traffic hazards while offering little protection against flying debris.

Open Outdoors

- Seek shelter in a sturdy building.
- If no building is available, lie flat, facedown on low ground, protecting the back of your head with your arms.
- Get as far away from trees and cars as you can.

Church or Theater

- Do not panic.
- Move quickly but in an orderly fashion to an interior bathroom or hallway, away from windows.
- Crouch facedown and protect your head with your arms.
- If there is no time to do that, get under the seats or pews, protecting your head with your arms or hands.

Post-Tornado Activities. After the tornado has left your vicinity, take the following actions:

- Keep your family together and wait for emergency personnel to arrive. Carefully render aid to those who are injured.
- Stay away from power lines and puddles with wires in them; they may be carrying electricity.
- Watch your step to avoid broken glass, nails, and other sharp objects.
- Stay out of any heavily damaged houses or buildings; they could collapse.
- Do not use matches or lighters, in case of leaks in natural gas pipes or fuel tanks nearby.
- Remain calm and alert, and listen for information and instructions from emergency crews or local officials.

HURRICANE-SPECIFIC MESSAGES

Hurricane Defined

The *Encarta* dictionary defines a *hurricane* as a severe tropical storm with torrential rain and extremely strong winds above 74 miles (119 km) an hour. Hurricanes originate in areas of low pressure in equatorial regions of the Atlantic or Caribbean, and then strengthen, traveling northwest, north, or northeast. Hurricanes can be dangerous killers. Learning the hurricane warning messages and planning ahead can reduce the chances of injury or major property damage (Figure 5.3.5).

Pre-Hurricane Activities

Planning an Evacuation Route. Plan an evacuation route. Contact the local Emergency Management office or American Red Cross chapter and ask for the community hurricane preparedness plan. This plan should include information on the safest evacuation routes and nearby shelters. Learn safe routes inland. Be ready to drive 20 to 50 miles inland to locate a safe place.

FIGURE 5.3.5 Airplane Destroyed by Hurricane Charley in Florida in 2004 (Photo by Andrea Booher, FEMA)

Assembling Hurricane Supplies. Assemble hurricane supplies before hurricane season. The following supplies will be essential if you plan to shelter in place and are not in an evacuation area:

- Cash
- Flashlight and extra batteries
- Portable battery-operated radio and extra batteries
- Lantern
- First aid kit and manual
- Emergency food and water (food should be nonperishable—e.g., canned meat and fish, canned fruits and vegetables, canned soups and puddings, canned fruit juices, dried fruits, baby formula and baby food, bread, cookies, crackers, peanut butter and jelly, coffee and tea—and 2 gallons [75 L] of water per person for 7 days is a good rule of thumb)
- Nonelectric can opener
- Essential medicines
- Pet food
- Disposable plates
- Infant care items such as diapers and wipes
- Sturdy shoes
- Emergency cooking facilities
- Matches
- Masking or duct tape
- Canned heat (Sterno®)
- Outdoor camping stove or grill with adequate fuel supply
- Plastic trash bags
- Plastic sheeting or drop cloth
- Bleach
- Fire extinguisher
- Telephone that plugs directly into the phone line and does not require electricity. Note: These are usually the old style and not the cordless variety.

Other useful hurricane supplies to assemble include the following:

- Hammer

- Screwdriver
- Pliers and wrenches
- Handsaw
- Razor knife
- Ax or chainsaw with adequate fuel
- Rope and wire
- Caulking
- Nails and screws
- Bucket, mop, broom, scrub brush, rags
- All-purpose cleaner
- Ladder
- Shovel, rake, wheelbarrow
- Tree pruner

Hurricane Evacuation Kit. Assemble a hurricane evacuation kit. In the event that you chose to (or are ordered to) evacuate, the following items are essential:

- Cash
- Foods that do not need cooking
- Drinking water (2 gallons per person per day)
- Special dietary food, if required
- Identification, valuable papers, insurance policies, and photos in a waterproof container
- Personal hygiene items (soap, deodorant, shampoo, toothbrush, toothpaste, aspirin, antacid, diapers, washcloth, towel)
- Utensils (manual can opener, disposable plates, cups, forks, knives, spoons, napkins)
- Personal aids (eyeglasses, hearing aids, prosthetic devices)
- Prescription medications
- Specific medical information
- Books, magazines, cards, toys, games
- Infant care items (baby formula, baby food, wipes, disposable diapers)
- Battery-operated radio
- Flashlight or lantern
- First aid kit, including betadine, gauze bandages, adhesive tape, sterile pads, bandages, triangular bandages, safety scissors, and nonprescription medication
- Extra batteries for radio and flashlights
- Sleeping bag or blanket, sheet, pillow
- Change of clothing
- Rainwear

Other Pre-Hurricane Activities. Other pre-hurricane activities range from what to do about pets to developing an emergency communication plan, as follows:

- Remember that alcoholic beverages and weapons are not allowed inside emergency public shelters.
- Make arrangements for pets because they may not be allowed into emergency shelters for health and space reasons. Contact your local humane society for information on local animal shelters.
- Make sure that all family members know how to respond after a hurricane. Teach family members how and when to turn off gas, electricity, and water. Teach children how and when to call 9-1-1, police, or fire department and which radio station to tune to for emergency information.
- Protect your windows. Permanent shutters are the best protection. A lower-cost approach is to put up plywood panels. Use ½ inch (1.25 cm) plywood cut to fit each window. Marine plywood is best. Remember to mark which board fits which window. Pre-drill holes every 18 inches (45.72 cm) for screws. Do this long before the storm.
- Trim back dead or weak branches from trees. Do this well before storm season. Leaving yard waste by the road the day before the storm arrives is dangerous.
- Check into flood insurance. You can find out about the National Flood Insurance Program through your local insurance agent or emergency management office. There is normally a 30 day waiting period before a new policy becomes effective. Note that homeowners polices do not cover damage from the flooding that accompanies a hurricane.
- Develop an emergency communication plan. In case family members are separated from one another during a disaster (a real possibility during the day when adults are at work and children are at school), have a plan for getting back together. Ask an out-of-state relative or friend to serve as the "family contact." After a disaster, it's often easier to call long distance. Make sure everyone in the family knows the name, address, and phone number of the contact person.

Hurricane Watch and Hurricane Warning Activities

Hurricane Watch. A hurricane watch is issued when there is a threat of hurricane conditions within 24 to 36 hours. The following are actions to take during a hurricane watch:

- Listen to a battery-operated radio or television for hurricane progress reports.
- Check emergency supplies.
- Fill the car's fuel tank.
- Bring in outdoor objects such as lawn furniture, toys, and garden tools; anchor objects that cannot be brought inside.
- Secure buildings by closing and boarding up windows. Remove outside antennas.
- Turn the refrigerator and freezer to their coldest settings. Open them only when absolutely necessary and close quickly.
- Store drinking water in clean bathtubs, jugs, bottles, and cooking utensils.
- Review the evacuation plan.
- Moor boats securely or move them to a designated safe place. Use ropes or chains to secure boats to trailers. Use tiedowns to anchor trailers to the ground or house.

Hurricane Warning. A hurricane warning is issued when hurricane conditions (winds of 74 miles per hour or greater or dangerously high water and rough seas) are expected in 24 hours or less. The following are actions to take during a hurricane warning:

- Listen constantly to a battery-operated radio or television for official instructions.

- If in a mobile home, check tiedowns and evacuate immediately.
- Store valuables and personal papers in a waterproof container on the highest level of your home.
- Avoid elevators.

Activities During a Hurricane

The following are actions to take during a hurricane:

- Stay inside, away from windows, skylights, and glass doors.
- Keep a supply of flashlights and extra batteries handy. Avoid open flames, such as candles and kerosene lamps, as a source of light.
- If power is lost, turn off major appliances to reduce power "surge" when electricity is restored.
- Use flashlights instead of candles or kerosene lamps.
- Continue to conserve refrigeration. Open the refrigerator as infrequently as possible.
- If the calm eye of the hurricane passes through your area, continue to stay indoors. Beware: The wind will pick up again from the opposite direction, possibly with greater force than before.
- Remain indoors until the official "all clear" is given.

If officials indicate evacuation is necessary, take the following actions:

- Leave as soon as possible. Avoid flooded roads and watch for washed-out bridges.
- Secure your home by unplugging appliances and turning off electricity and the main water valve.
- Tell someone outside of the storm area where you are going.
- If time permits, and you live in an identified surge zone, elevate furniture to protect it from flooding or better yet, move it to a higher floor.
- Bring preassembled emergency supplies and warm protective clothing.
- Take blankets and sleeping bags to shelter.
- Lock up home and leave.

Post-Hurricane Activities

The following are actions to take after a hurricane:

- Stay tuned to local radio for information.
- Return home only after authorities advise that it is safe to do so.
- Help injured or trapped persons.
- Give first aid where appropriate.
- Do not move seriously injured persons unless they are in immediate danger of further injury. Call for help.
- Avoid loose or dangling power lines and report them immediately to the power company, police, or fire department.
- Enter your home with caution.
- Beware of snakes, insects, and animals driven to higher ground by floodwater.
- Open windows and doors to ventilate and dry your home.
- Check refrigerated foods for spoilage.
- Take pictures of the damage, both to the house and its contents, for insurance claims.
- Drive only if absolutely necessary and avoid flooded roads and washed-out bridges.
- Use the telephone only for emergency calls.
- Inspect utilities in a damaged home:
  - Check for gas leaks. If you smell gas or hear a blowing or hissing noise, open a window and quickly leave the building. Turn off the gas at the outside main valve if you can and call the gas company from a neighbor's home. If you turn off the gas for any reason, a professional must turn it back on.
  - Look for electrical system damage. If you see sparks or broken or frayed wires, or if you smell hot insulation, turn off the electricity at the main fuse box or circuit breaker. If you have to step in water to get to the fuse box or circuit breaker, call an electrician first for advice.
  - Check for damage to sewer and water lines. If you suspect sewer lines are damaged, avoid using the toilets and call a plumber. If water pipes are damaged, contact the water company and avoid the water from the tap. You can obtain safe water by melting ice cubes.

WINTER STORM–SPECIFIC MESSAGES

Heavy snowfall and extreme cold can immobilize an entire region. Even areas that normally experience mild winters can be hit with a major snowstorm or extreme cold (Figure 5.3.6). Winter storms can result in flooding, storm surge, closed highways, blocked roads, downed power lines, and hypothermia. Figure 5.3.7 shows winter storm occurrences by state.

Winter Storm Terms

Familiarize yourself with the following terms to help identify a winter storm hazard:

FIGURE 5.3.6 Snow Drifts After a Major Snowstorm (Source: NASA)

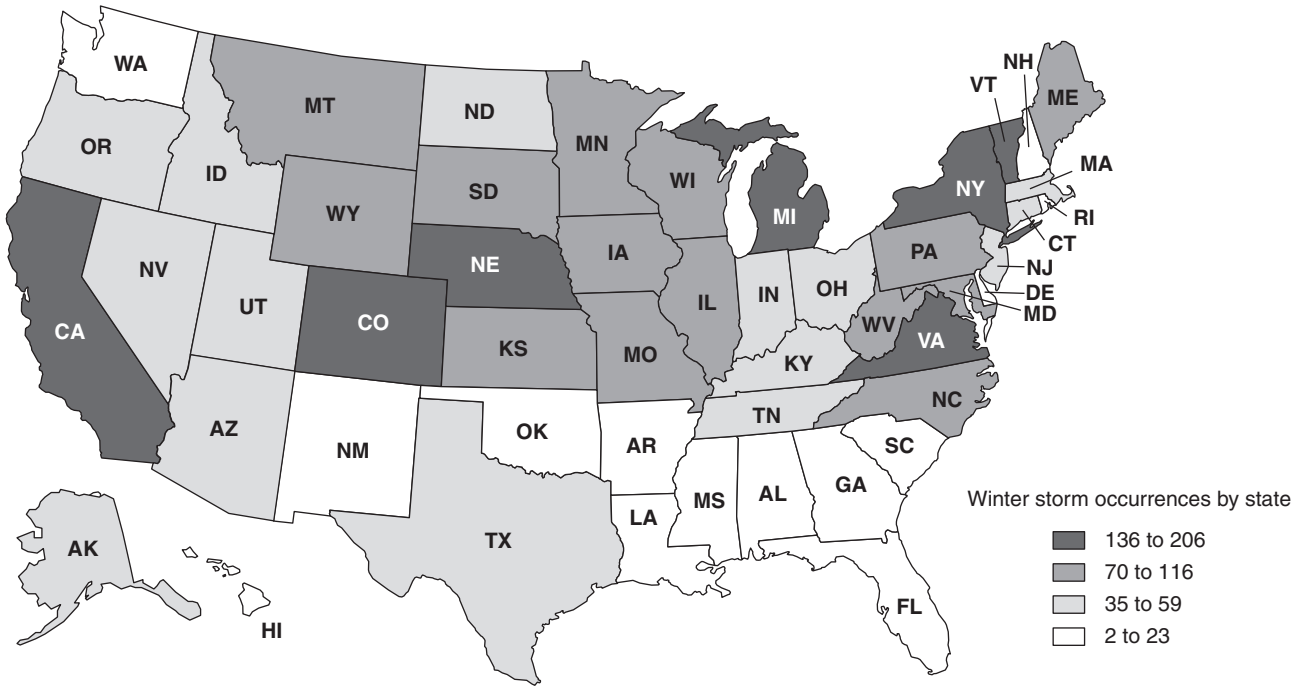

FIGURE 5.3.7 Winter Storm Occurrences by State (Source: ITS Mapping and Analysis Center, National Oceanic and Atmospheric Administration, Washington, DC, 2003)

Freezing Rain. Freezing rain is rain that freezes when it hits the ground, creating a coating of ice on roads, walkways, trees, and power lines.

Sleet. Sleet is rain that turns to ice pellets before reaching the ground. Sleet also causes moisture on roads to freeze and become slippery.

Winter Storm Watch. A winter storm watch is an advisory that a winter storm is possible in your area. Tune in to NOAA Weather Radio, commercial radio, or television for more information.

Winter Storm Warning. A winter storm warning is an advisory that a winter storm is occurring or will soon occur in your area.

Blizzard Warning. A blizzard warning indicates a condition of sustained winds or frequent gusts to 35 miles per hour or greater and considerable amounts of falling or blowing snow (reducing visibility to less than a quarter mile) are expected to prevail for a period of three hours or longer.

Frost/Freeze Warning. A frost/freeze warning is an advisory that below freezing temperatures are expected.

Pre–Winter Storm Activities

Disaster Supplies Kit. Before the arrival of winter storms and extreme cold, prepare a disaster supplies kit, including the following:

- Rock salt to melt ice on walkways
- Sand to improve traction
- Snow shovels and other snow removal equipment

Home Heating. Take the following actions to ensure keeping your home and yourself warm:

- Consider buying emergency heating equipment, such as a wood- or coal-burning stove or a kerosene heater as a backup.
- Prepare for possible isolation in your home by having sufficient heating fuel. (Regular fuel sources may be cut off.) For example, store a good supply of dry seasoned wood for your fireplace or wood-burning stove.
- Have fireplace and woodstove chimneys inspected annually to ensure the residue left by burning wood has not accumulated.
- Winterize your home to extend the life of your fuel supply by properly insulating walls and attics. Caulk and weatherstrip doors and windows. Install storm windows or cover windows with plastic from the inside. Protect pipes by wrapping them in insulation and let faucets drip to prevent freezing.

Road Safety. Take the following actions to prepare for safe winter driving:

- Ensure that the battery and ignition system are in top condition and battery terminals are clean.
- Ensure antifreeze levels are sufficient to avoid freezing.
- Ensure the heater and defroster work properly.

- Check and repair windshield wiper equipment; ensure proper washer fluid level.
- Ensure the thermostat works properly.
- Check lights and flashing hazard lights for serviceability.
- Check for leaks and crimped pipes in the exhaust system; repair or replace as necessary. Note that carbon monoxide is deadly and usually gives no warning.
- Check brakes for wear and fluid levels.
- Keep cars and other vehicles fueled and in good repair.
- Check oil for level and weight. (Heavier oils congeal more at low temperatures and do not lubricate as well.)
- Consider snow tires, snow tires with studs, or chains.
- Replace fuel and air filters. Keep water out of the system by using additives and maintaining a full tank of gas.

Activities During a Winter Storm

During winter storms and extreme cold, take the following actions:

- Listen to your radio, television, or NOAA Weather Radio for weather reports and emergency information.
- Eat regularly and drink plenty of fluids, but avoid caffeine and alcohol.
- Avoid overexertion when shoveling snow. (Overexertion can bring on a heart attack—a major cause of death in the winter.) If you must shovel snow, stretch before going outside.
- Wear several layers of loose-fitting, lightweight, warm clothing rather than one layer of heavy clothing. Other garments should be tightly woven and water-repellent.
- Wear mittens, which are warmer than gloves.
- Wear a hat.
- Cover your mouth with a scarf to protect your lungs.
- Watch for signs of frostbite, including loss of feeling and white or pale appearance in extremities such as fingers, toes, ear lobes, and the tip of the nose. If symptoms are detected, get medical help immediately.
- Watch for signs of hypothermia, including uncontrollable shivering, memory loss, disorientation, incoherence, slurred speech, drowsiness, and apparent exhaustion. If symptoms of hypothermia are detected, get the victim to a warm location, remove wet clothing, warm the center of the body first, and give warm, nonalcoholic beverages if the victim is conscious. Get medical help as soon as possible.
- Conserve fuel, if necessary, by keeping your residence cooler than normal. Temporarily close off heat to some rooms.
- Maintain ventilation when using kerosene heaters to avoid buildup of toxic fumes. Refuel kerosene heaters outside and keep them at least three feet from flammable objects.
- Drive only if it is absolutely necessary. If you must drive, take the following precautions:
  - Drive only at speeds dictated by conditions and increase distances between vehicles.
  - Share travel schedules and routes and stay on main roads. Carry a cell phone.
  - Travel in daylight and do not travel alone.
  - Many states have free road condition hotlines. Be familiar with your state's services.

LANDSLIDE-SPECIFIC MESSAGES

Landslide Hazards

Landslide hazards occur in many places around the world and include fast-moving debris flows, slow-moving landslides, and a variety of flows and slides initiating from volcanoes. Each year, these hazards cost billions of dollars and cause numerous fatalities and injuries.

Mudslides. Landslides are caused by disturbances in the natural stability of a slope. They can accompany heavy rains or follow droughts, earthquakes, or volcanic eruptions. Mudslides develop when water rapidly accumulates in the ground and results in a surge of water-saturated rock, earth, and debris (Figure 5.3.8). Mudslides usually start on steep slopes and can be activated by natural disasters. Areas where wildfires or human modification of the land have destroyed vegetation on slopes are particularly vulnerable to landslides during and after heavy rains.

Volcano Landslides. Volcano landslides range in size from small movements of loose debris on the surface to massive collapse of the entire summit or sides of a volcano. Steep volcanoes are susceptible to landslides because they are built partly of layers of loose volcanic rock fragments. Landslides on volcano slopes are triggered when eruptions, heavy rainfall, or large earthquakes cause these materials to break free and move downhill.

Health Threats. In the United States, landslides and debris flows result in 25 to 50 deaths each year. The health hazards associated with landslides and mudflows include the following:

- Rapidly moving water and debris that can lead to trauma
- Broken electrical, water, gas, and sewer lines that can result in injury or illness
- Disrupted roadways and railways that can endanger motorists and disrupt transport and access to health care

At-Risk Areas. Some areas are more likely to experience landslides or mudflows, including the following:

- Areas where wildfires or human modification of the land have destroyed vegetation
- Areas where landslides have occurred before
- Steep slopes and areas at the bottom of slopes or canyons
- Slopes that have been altered for construction of buildings and roads
- Channels along a stream or river
- Areas where surface runoff is directed

Pre–Intense Storm and Rainfall Activities

Before intense storms and rainfall, take the following actions:

FIGURE 5.3.8 Mudslide Caused by Heavy Rain (Source: National Oceanic and Atmospheric Administration)

- Assume that steep slopes and areas burned by wildfires are vulnerable to landslides and debris flows.
- Become familiar with the land around you. Learn whether debris flows have occurred in your area.
- Watch the patterns of storm-water drainage on slopes near your home, noting especially the places where run-off water converges, increasing flow over soil-covered slopes.
- Watch the hillsides around your home for any signs of land movement, such as small landslides or progressively tilting trees.
- Learn whether landslides or debris flows have occurred previously in your area by contacting local authorities, a county geologist or the county planning department, state geological surveys or departments of natural resources, or university departments of geology.
- Contact local authorities about emergency and evacuation plans in your area.
- Develop emergency and evacuation plans for your family and business.
- Develop an emergency communication plan in case family members are separated.
- If you live in an area vulnerable to landslides, consider evacuation.

Pre-Landslide Signs

The following signs and features may be noticed prior to major landslides:

- Springs, seeps, or saturated ground in areas that have not typically been wet
- New cracks or unusual bulges in the ground, street pavement, or sidewalk
- Soil moving away from foundations
- Ancillary structures such as decks and patios tilting and/or moving
- Tilting or cracking of concrete floors and foundations
- Broken water lines and other underground utilities
- Leaning telephone poles, trees, retaining walls, or fences
- Offset fence lines
- Sunken or down-dropped roadbeds
- Rapid increase in creek water levels, possibly accompanied by increased turbidity (soil content)
- Sudden decrease in creek water levels, although rain is still falling or just recently stopped
- Sticking doors and windows and visible open spaces indicating jambs and frames out of plumb

Pre-Landslide Activities

If you suspect imminent landslide danger, take the following actions:

- If possible, evacuate.
- Contact your local fire, police, or public works department.
- Inform your family and neighbors of your destination.

Activities During Intense Storms and Rainfall

During intense storms and rainfall, take the following actions:

- Listen to the radio or watch TV for warnings about intense rainfall or for information and instructions from local officials.
- Be aware of any sudden increase or decrease in water level in a stream or creek that might indicate debris flow upstream. A trickle of flowing mud may precede a larger flow.
- Look for tilted trees, telephone poles, fences, or walls, and for new holes or bare spots on hillsides.
- Listen for rumbling sounds that might indicate an approaching landslide or mudflow.
- Be particularly alert when driving. Roads may become blocked or closed due to collapsed pavement or debris.
- If landslide or debris flow danger is imminent, quickly move away from the path of the slide. Getting out of the

path of a debris flow is your best protection. Move to the nearest high ground in a direction away from the path.
- If rocks and debris are approaching, run for the nearest shelter and take cover (if possible, under a desk, table, or other piece of sturdy furniture).

Post-Landslide Activities

After a landslide or mudflow, take the following actions:

- Stay away from the site. (Flooding or additional slides may occur after a landslide or mudflow.)
- Check for injured or trapped people near the affected area, if it is possible to do so without entering the path of the landslide or mudflow.
- Listen to the radio or TV for emergency information.
- Report broken utility lines to the appropriate authorities.
- Consult a geotechnical expert (a registered professional engineer with soils engineering expertise) for advice on reducing additional landslide problems and risks. Local authorities should be able to tell you how to contact a geotechnical expert.

RETOOLING TO INCLUDE DISASTER PREPAREDNESS EDUCATION

Many fire and life safety educators believe that if a fire department responds to a call, then they should also be involved in creating an educational program that addresses that risk area. Although traditionally fire and life safety educators have not been heavily involved with disaster preparedness education, today's emphasis on *all hazards* has brought disaster education to the forefront as a very important and relevant topic. Because fire and life safety educators and public information officers already have networks and coalitions formed for other topics such as injury prevention, it would take minimal effort to include disaster preparedness education. Creating a liaison with emergency management and working with the organizations with which they already have partnerships would seem to be a natural fit. This seems to be the most direct way to retool the program in order to include disaster preparedness education.

SUMMARY

After defining disaster preparedness and providing case studies and specific examples that focused on both natural disasters and those caused by humans, the chapter discussed the role of today's fire and life safety educator, specifically as it relates to disaster preparedness education. Because life and safety educators work with coalitions and organizations already formed in the community, expanding their role into disaster preparedness education seems like a natural fit. Educational programs and detailed messages specific to the different types of disasters, such as tornadoes, hurricanes, extreme winter storms, and landslide hazards, were expanded on. In addition, steps for "retooling" the fire and life safety education program to include disaster preparedness education were suggested. The chapter concludes with a list of disaster preparedness resource websites for further information on the topic.

Chapter 4

Media's Role in Fire and Life Safety Education

Revised by
Robin J. Adair

Chapter Contents

Defining Terms
Communication Goals
Community Media Services
Matching the Medium with the Message
Publicity Campaigns
Emergency Scene Public Information
Exploring Legal Issues
Future Communication Technologies and Public Education
Evaluating Efforts

Key Terms

broadcast media, copyright, fire and life safety educator, Freedom of Information Act, Health Information Portability and Accountability Act (HIPPA), practical publicity, print media, public information officer, public service announcements

Since the goal of fire and life safety educators is to improve safety knowledge and skills in their communities, they must find effective ways to communicate with the public. This requires the educator to develop a working relationship with members of the media. Whether it is in a large city where the fire department employs full-time media relations staff, in a small town where all the fire fighters know the only local reporter, or anywhere in between—the media are a means to reach the community as a whole or in specific target audiences. The mass media can be an effective, cost-efficient, and appropriate way to reach some education goals.

The goals of fire and life safety educators, however, are not always the goals of the media. Reporters sometimes need facts before educators know what the facts are. The media may ask for details that educators may consider an infringement on privacy. Newspeople want to get accurate information disseminated as quickly as possible and to deliver it in a compelling manner that will interest the audience. Those priorities are not always in harmony with fire service concerns.

These differences do not need to be interpreted as conflicts, however. Fire service information officer Leo M. Brown writes, "The 'us against them' philosophy, which has dominated our relationship with the media for years, is inaccurate and counterproductive."[1] The media are necessary to the success of educators, and the fire department can meet the needs of the media and the public we both serve. Fire and life safety educators need to understand the media—and the educators' own options for dealing with the media—to best pursue the educators' goals. That is the focus of this chapter.

Entire books are written every year on communications, media, and education. This chapter outlines just the basics and aims to provide practical information to aid fire personnel who communicate with the media. Specifically, this chapter will discuss the following topics:

- *Fire department communication goals.* Internal and external audiences
- *Media community services.* Who is out there, and what do they do?
- *Matching the medium to the message.* Similarities and differences in media
- *Publicity campaigns.* Media as part of structured public appeal
- *Emergency scenes.* When the educator is the public information officer
- *Legal issues.* Privacy, free speech, and asking permission
- *Evaluation.* Measuring the effectiveness of communications efforts
- *Future communication technologies and public education.* What's next?

See also Section 5, Chapter 2, "Fire and Life Safety Education Messages"; and Section 5, Chapter 8, "Evaluation Techniques for Fire and Life Safety Education."

DEFINING TERMS

Public Relations, Public Education, and Public Information

The distinctions among public relations, public education, and public information are fine but critical. There are many similarities among these concepts. All require a carefully thought-out planning

Robin J. Adair served with South Metro Fire Rescue near Denver, Colorado, for more than 11 years, as both public educator and public affairs officer. Prior to joining the fire service, she was a television news broadcaster for more than a decade and has also worked in various radio, newspaper, and public relations positions.

process, including a solid implementation strategy. All can and should be evaluated for their effectiveness. The goals of communication for each, however, are different.

The goal of a public relations strategy is to improve or sustain the positive working relationship between the fire service and the community that supports it.[2] The goal of a public education program is to enlighten people, giving them the knowledge and skill to improve their existence.[2] The goal of a public information officer is to service requests for information within the unique scope of the department so that listeners see and understand issues the way the department does.

Both public education and public information delivery can contribute to good public relations, although that is not their primary goal. Both rely on good public relations for their effectiveness.

A public relations professional might describe *public relations (PR)* as "communicating specific messages at targeted publics as a means of helping to achieve an organization's goals and objectives."[3] Tim Birr aptly describes PR as "the art of doing something well and getting caught at it."[3]

Some departments believe the public information officer (PIO), who is responsible for disseminating information to the media at disasters and emergency incidents, serves solely as the department's spokesperson. The International Fire Service Training Association's *Public Information Officer* manual,[4] however, broadens the definition to include one who may also provide education to the public, promote public safety, and talk about the services the department provides. As a PIO, the ultimate goal is to enhance the public perception of the department.

Communications

Communications is the process by which people interact and, thereby, influence each other.[5] To communicate is to impart information. However, information is not necessarily knowledge. Information converts most effectively into knowledge when it is needed, useful, and sought. The PIO should keep two points in mind:

- The audience is *always* in the driver's seat in any communications situation. Audience members ultimately decide whether to listen to, accept, reject, or act on any new information.
- No one—including our audience—has much interest in operating totally within the confines of someone else's agenda.[6]

Active listening and using focus groups and community surveys can help with this process of understanding.

Media

A *medium* is defined as the physical environment through which information can be transmitted by controlled variations in that environment. Variations may be ink patterns on paper, electronic patterns in wires or in air, or sound variations in air. Media include radio, television, newspapers, magazines, motion pictures, direct mail, cable television, books, records, tapes,[7] e-mail, and websites. Different media outlets within the community have different advantages and disadvantages in terms of the messages they send (e.g., short versus long, emotionally stripped versus emotionally laden) and the audiences they reach within the community.

Media Relations Terms

The PIO should be familiar with media relations terms. The following definitions clarify several terms commonly used in media relations.

Advance. A news story written before an event and held for later release. Also called an "advancer"[5] or "advisory."

Fact Sheet. An information handout of one or more pages about a person or event provided to assist the media.[4] The name and telephone number of a contact person should be provided at the top of the front page. Each page ends with a completed paragraph and "(more)" typed across the bottom of the page if necessary. The last page ends with "-30-" or number signs (###) typed at the bottom.

News Release. A short, factual description of an event prepared for the media. Although some use the terms *press release* and *news release* interchangeably, be aware that "press" indicates print media, and broadcast or electronic media members are often sensitive about this issue. The first sentence (the "lead") in a news release summarizes what needs to be conveyed, particularly these details: who, what, where, when, why, and how. The release should be written as if you expect it to be printed verbatim or read word for word to the public. The PIO should always provide the source of the information, the headline, the date or dates of the event, and whom to contact for additional information.

The PIO should use the "inverted pyramid" writing style, with the most important facts presented in the beginning paragraphs, followed by facts of lesser significance. An editor can then decide the article's value with only a glance. The news release should meet the following requirements:

- Be doubled-spaced, with 2-inch margins
- Be printed on only one side of the paper on agency letterhead
- Carry the date at the top
- Have "FOR IMMEDIATE RELEASE" inserted when prompt publishing is desired
- Have "FOR RELEASE ON (DATE)" on releases that need to be held until a certain date
- Be limited to one page whenever possible
- Have pages numbered, if more than one page, with "(more)" placed at the bottom of continued pages and "end" or "-30-" or "###" inserted at the bottom of the final page

News agencies usually have a preference for whether they receive news releases online, via fax, or by mail. The PIO should ask if the news organization wants the material sent electronically. For online releases, the PIO should try to limit the length to two screens and should include any related websites.[8]

Several reference books specified at the end of this chapter offer more in-depth advice on how to compose effective news releases for different types of media.

Press Conference. A meeting between members of the press and a newsworthy figure in which statements are made and/or questions are asked.[5]

Media Kit. A portfolio of news releases, pictures, background information, and so on distributed to the press for publicity purposes.[7] Historically, the media kit was called a "press kit" and focused on providing print-ready graphics, logos, and photos for the newspapers or magazines. Today, media kits might include video clips, audio recordings, or digital files as well (Figure 5.4.1).

Public Service Announcements (PSAs). Any announcement for which no charge is made and which promotes programs, activities, or services of federal, state, or local governments or programs, activities, or services of nonprofit organizations and other announcements regarded as serving community interests[9] (Figure 5.4.2). PSAs may be provided to the media as simple written scripts or as fully produced, ready-to-air broadcast pieces.

COMMUNICATION GOALS

Communications Within the Fire Department

Fire department administration should have goals for communication within the fire department, but the public educators, public relations officer, and PIO also have goals defined by external audiences. These goals usually require assistance and participation by people in the fire department beyond the staff dedicated to communications. The goals themselves may be shaped by concerns or information held by others in the department. Therefore, internal fire department communication must be effective in the following areas:

- Employee/employee communication
- Staff/suppression communication
- Fire fighter/fire chief communication

Fire and life safety educators and PIOs need the backing and support of the fire department before proceeding into the community and introducing themselves to the media. They must know which areas the department wishes to highlight, which departmental goals need an explanation, and how the department wishes to address potentially difficult situations. They must also know whether other members are willing to be available for interviews and whether media representatives are welcome to stop by the department.

After devising a plan to work with the media, department members must help prepare campaigns and programs. Fire department administrators need to review news releases prior to dissemination to prepare for reporters' calls.

A good relationship between the educator/PIO and operations personnel is essential. Members of the agency are a tremendous source of story ideas for the media and educational suggestions for the community. Every fire fighter, inspector, and EMS provider has daily opportunities to promote good media relations and further educational efforts to the public. By maintaining a positive working relationship and regular communications, the educator/PIO can include operations personnel in the cooperative effort to inform the community.

FIGURE 5.4.1 NFPA Fire Prevention Week Media Kit

Communications Outside the Fire Department

A second, more obvious, mission includes communicating information to the public, both before an emergency occurs and at the scene of the emergency. Fire service members possess extensive information. Media representatives are interested in the information educators can provide.

One key to successful media relations is identifying the audience. Identifying a very general audience may ease the communications planning but will complicate all other parts of the process. It results in diluted messages and weak delivery and compromises the timing of messages. It also wastes time and materials, forcing fire chiefs, fire and life safety educators, and PIOs to send messages to persons who have neither need for nor interest in them.[7] For example, a smoke alarm installation campaign would be well suited to older neighborhoods where alarms are scarce but not for areas of new growth where smoke alarms are required by code. Therefore, the target audience could be reached by street address or zip code, through homeowner's groups, or during neighborhood events more efficiently than through "mass" media such as regional television or daily newspaper.

The audience should be specifically identified; this greatly increases any program's potential effectiveness. Fire and life safety educators or public information officers who define their audience as "everyone" or "the general public" lack a sufficiently clear understanding of whom they are trying to reach and should not proceed any further until they clarify who their audience is.[6]

Organization Name on Letterhead

[Double-space body copy.]

DATELINE—*[Insert location for the origin of the release (in capital letters) plus a dash, followed by the first line of the lead.]*

Lead: *[Start with a hard-news lead, particularly on releases for news events or announcements.]*

Body: *[Write tightly. Limit copy to one page if possible, no more than two. If you have two pages, write "more" at the end of the first page and number the pages.]*

Ending: *[As part of the ending, tell where more information is available such as graphics and websites.]*

—30—, —End—, or ###

FIGURE 5.4.2 Format for a Public Service Announcement (Source: *Writing and Reporting News*[8])

Each news station, newspaper, and news outlet claims a particular audience and a particular area as its own. Media outlets within the fire department's service delivery area can provide information on their particular target audiences.

A second key to media success is choosing the right PIO. NFPA 1035, *Standard for Professional Qualifications for Public Fire and Life Safety Educator* (2005 edition), includes job performance requirements for the PIO (Figure 5.4.3).

8.1 General Requirements. The Public Information Officer shall meet the job performance requirements defined in Sections 8.1 and 8.2.

8.1.1 General Requisite Knowledge. Report writing, professional appearance based on situation, media characteristics, news process, organizational policies, methods for informal dissemination, and laws and procedures pertaining to release of information.

8.1.2 General Requisite Skills. Communicate orally and in writing, exhibit professional demeanor, manage interaction with the media, utilize various means of information technology.

8.2 Administration.

8.2.1 Conduct media interviews, given incident information, Public Information Officer (PIO) worksheets, and departmental policies, so that all information compiled on worksheets is disseminated to the media in a timely, accurate, and understandable manner.
- **(A) Requisite Knowledge.** Interview methodology.
- **(B) Requisite Skills.** Demonstrate interviewing skills, collect incident information, complete PIO worksheets.

8.2.2 Establish a media area at an emergency incident, given incident information, departmental policies, and types of media present at incident, so that the area provides for the safety of all media, enables communication with incident commander, and is accessible and clearly visible.
- **(A) Requisite Knowledge.** Incident management system, incident safety considerations, other responding agencies.
- **(B) Requisite Skills.** Manage media area participants, coordinate communication between command and media.

8.2.3 Coordinate dissemination of information to specific nonmedia groups, given departmental policies and methods available for contacting other groups and organizations available to assist, so that the information is communicated to the groups accurately and within the desired time frame.
- **(A) Requisite Knowledge.** Awareness of nonmedia groups.
- **(B) Requisite Skill.** Maintain liaison with community groups.

8.2.4* Write news releases, given incident information, departmental policies, and news release format, so that the news releases are accurate, pertinent, and concise.
- **(A) Requisite Knowledge.** Media requirements for news releases.
- **(B) Requisite Skill.** Compose information in accordance with media source specifications.

8.2.5* Write a media advisory, given information to be disseminated, media advisory format, and departmental policy, so that the media advisories are accurate, pertinent, and concise.
- **(A) Requisite Knowledge.** Media requirements for media advisories.
- **(B) Requisite Skill.** Compose information in accordance with media source specifications.

8.2.6 Disseminate information to the media, given news release or media advisory, characteristics of local media including deadlines, departmental policies, and methods available to reach media, so that, prior to the deadline, the information reaches the media in a form usable to each specific local medium.
- **(A) Requisite Knowledge.** Specific methods for disseminating information to the media.
- **(B) Requisite Skill.** Maintain liaison with media group.

8.2.7 Disseminate information to organizational personnel, given incident or event information, departmental policies, methods available to reach personnel, and time frame for releasing information, so that the information reaches all desired personnel within the time frame and is accurate and concise.
- **(A) Requisite Knowledge.** Specific methods for disseminating information within the organization.
- **(B) Requisite Skills.** Maintain liaison with organizational personnel, operate office information systems.

8.2.8 Coordinate a press conference for local media, given an event or issue, local media characteristics, methods available for reaching media, and departmental policies on press conferences, so that a site is obtained, desired media are notified, a press conference agenda is established, a media information package is produced, and participants in the press conference are notified.
- **(A) Requisite Knowledge.** Event planning requirements.
- **(B) Requisite Skills.** Establish liaison with media, disseminate information, coordinate site selection and use, review media materials.

FIGURE 5.4.3 Job Performance Requirements for Public Information Officer (Source: NFPA 1035, 2005 edition)

Certain traits and skills make some individuals more suited than others to the position of public information officer. First and foremost, an agency should choose a PIO who does *not* view the media as adversaries and is able to function as part of a team with a diverse membership. Furthermore, just as it would be difficult to manage a fire incident without knowledge of fire behavior, a PIO will benefit from knowledge about media behavior. A background in communications, journalism experience, or personal interest in media operations is a valuable characteristic. Knowledge of "new" media and computer skills is essential. Since PIOs are often agency spokespersons in both verbal and written forms, they should have the ability to speak effectively in front of cameras and the public. They should also be able to write in a clear, concise, conversational manner. The U.S. Department of Labor includes those traits in its PIO job description and suggests that a good public relations person should also be one who exhibits creativity, initiative, and good judgment on a regular basis. The best PIO will have strong skills for decision making, problem solving, and research. In terms of personality, the Department of Labor recommends a person who is outgoing, self-confident, understands human psychology, and is enthusiastic about motivating people.

COMMUNITY MEDIA SERVICES

Another key to successful media relations includes understanding the media's various roles. To do so, educators need to identify

local media, establish credibility, and identify key players at each outlet. In an age of global communications—immediate, on-the-spot news coverage and fast-paced marketing—fire service information must be provided faster than ever to be considered timely, but it must still be accurate and delivered calmly and courteously despite the heightened time pressure. To provide information effectively, fire service personnel must understand the workings, the goals, and the changing world of the media: how the media function, how reporters and editors view their jobs, and how the fire service may best utilize ever-changing communication resources.

Identifying Local Media

To create a positive relationship with the media, fire service personnel must take time to understand each media outlet's responsibilities and target audience. The essential issues are (1) What sort of relationship can full-time fire and life safety educators and PIOs develop with local media representatives? and (2) How can they work cooperatively with writers, editors, and broadcasters?[6]

Media relations means more than just contacting the media. It is establishing a rapport and mutual respect and understanding of each other's professions.[10]

It is critical that relationships be established *prior* to emergency incidents or the launch of a new public education campaign. Reporters often emphasize that PIOs need to be available when the media need them—not just when the fire department needs the media. Be sure every reporter or editor on your calling list has your number, too—to contact a spokesperson for the fire department, night or day. Reporters, who live under constant deadline pressure, greatly appreciate a PIO who gets back to them right away. Tim Padmore of the *Vancouver Sun* says, "Return phone calls from reporters immediately. It will make them love you. Do this even if you have nothing to report."[11] A Denver radio reporter explained, "The department is fulfilling the reporter's need to relay information and the public's need for news while building a relationship of trust with both the reporter and the public." When the media call on you, always deliver the "Five F's": be frank, factual, friendly, fast, and fair.[12]

Fire department representatives must meet reporters, editors, photographers, and station managers and get to know them and become familiar with their specific job responsibilities. That may be accomplished simply by scheduling appointments with the various media personnel in the area. Some regions have public information officer organizations that arrange opportunities to network with media members. Efforts may include educating future journalists by setting up a time for the local college journalism classes to visit the station, learn about the fire service, and interview the chief.

Some departments hold half-day media academies to allow journalists an opportunity to interact, learn, and build relationships with fire service personnel. Others such as the City of Phoenix Fire Department provide extensive weeklong training sessions (Figure 5.4.4).

Job turnover occurs regularly in the media business. Reporters and editors move frequently, so getting to know new personnel is a never-ending task. PIOs should keep a contact list and update it regularly. Media sources can be identified in several ways: (1) by checking media directories, (2) by scanning the Yellow Pages of the phone directory, (3) by talking with other public relations personnel in the community, and perhaps most effectively (4) by contacting media outlets directly to obtain contact information.

Certified Fire Journalists

The City of Phoenix Fire Department invited media to train as certified fire journalists. The fire department held an intensive training academy for members of the media, requiring them to commit to a full 40-hour, 5-day week. The class size was limited to a maximum of 12. The benefit to the media was the loan of protective gear and certification, allowing the graduates inside fire lines to photograph and report closer to the action on both fire and medical emergencies.

The training program included fireground operations; fire behavior; fire suppression; search and rescue; hazardous materials; helicopter, trench, and mountain rescue; emergency vehicle driving (a favorite); emergency medical services; flash over/back draft chamber; and stress management. All students took advantage of an optional hour of physical training. The academy ended with the traditional "Barrel Squirt" competition.

FIGURE 5.4.4 Certified Fire Journalists

PIOs should enhance published media lists by including neighborhood ethnic, specialty, trade, and suburban publications. Thorough PIOs or educators should not overlook printed and e-mailed newsletters for homeowner associations, community service groups, and special interest groups they may wish to target. They should collect and learn the names, titles, phone numbers, and fax numbers or e-mail addresses of those in charge.

Figure 5.4.5 shows an example of a media quick-call list that can be used during an emergency. Pertinent names and telephone numbers are readily accessible to the PIO, whose role is the one most likely to be prominent in an emergency. In the event of a crisis, the PIO will benefit greatly from having preprogrammed call lists, e-mail groups, and broadcast fax numbers into whatever devices are available to deliver messages. The PIO should keep copies of the lists at home, in the office, and in the vehicle generally used in emergencies.

Establishing Credibility and Identifying Key Players

Building the fire department's reputation with the media is critical. Reporters, editors, station managers, and producers can quickly form opinions about a person's operating style and credibility. To establish credibility, the PIO must (1) understand what makes news, (2) know what the media need to know, and (3) use imagination and creativity to find new ways to keep the media updated on the fire organization.[13] Reporters need to know the latest trends and opportunities, activities, and resources. The PIO should assure them that accurate and timely facts will be

provided, promises will be kept, and deadlines will be met. Then the PIO should *follow through.* Deadlines are critical in broadcasting and journalism; being late is inexcusable.

Creating an archive system is an efficient way to keep track of much departmental information and to be prepared for grant requests, media inquiries, and city manager details (Figure 5.4.6). Having information at one's fingertips may make the difference between being or not being in the nightly newscast. Educators must identify key players at local television and radio stations and newspapers and must understand what reporters, station managers, and editors do. In turn, local television and radio station personnel will most likely better understand the fire and life safety educator's role in the fire service.

MATCHING THE MEDIUM WITH THE MESSAGE

All communications channels have distinguishing features. Each situation is different, and each requires a fresh look.[5] The nature of the message should be considered when choosing an appropriate medium for delivery.

Broadcast Media

Radio. Radio has been called the medium of the mind;[13] the absence of pictures allows more room for the listeners' imagination to be engaged. Radio is also cost-effective, and most of it is local. Radio appeals to audiences for many reasons. An intimate medium, far less intrusive than television, it demands less concentration than do newspapers. Portable, it can be listened to while doing most anything.

Given the way people listen to radio, programs are built in short segments. The medium, therefore, works best when used to notify, remind, or tell easily remembered, uncomplicated stories. Radio messages must be simple and concise. Radio reporters rely on lively interviews to add color to their stories. Broadcasters suggest stories 20, 30, and 60 seconds in length.

The station manager (general manager) oversees all operations. The program director oversees news and sports. Fire

How to Create an Information Archive System

Here are some general suggestions for setting up an Information Archive System for publicity and proposal purposes. Although publicity and proposal needs may be similar, bear in mind that the information you send should "speak" to the audience in their language and fit the purpose. For instance, there are some items of information that may be required for a grant proposal that would not be appropriate if given to the media.

What to Include

- Articles and editorials that mention your program specifically
- Articles and editorials that relate to or support the work of your program
- Photographs that were taken for articles or brochures
- Video tapes of broadcasts of interviews or those that relate to your program
- Support letters and "nice notes" from various resources
- Copies of website printouts that relate to your program
- Printed listing of websites of importance to program
- Current organizational charts, staff and board lists, operational flow chart
- Documentation of significant fires and statistics for both your site and others of importance
- Resource needs list of items with value, current operating budget, mission statement
- Brochures, flyers, and other program-specific information

How to Store the Information

- You will use an assortment of binders, files, and computer storage for the information.
- Newspaper clippings, support, and photos are best saved in sheet protectors placed in binders. Put original clipping in its own protector and mark on it "original do not remove." Make copies for distribution. BE SURE to record publication name and date of clipping on the original and copies. BE SURE to have name of professional photographer on photo for photo credit.
- Clippings, photos, and other information can be scanned for even more convenient storage.
- Computer storage of files, charts, clippings, and photos should be maintained in a well-organized directory. BE SURE to back up this directory regularly.
- Videotapes and dupes should be well labeled. Master copies should be kept locked from dupes so that they are not given away accidentally.
- Keep copies of brochures in file folders or in a binder separate from regular inventory. This ensures that you always have enough for publicity and proposal needs.

Where to Store the Information

- Keep the information in a central location that is easily accessible to those who need to distribute the information.
- Keep files for grant proposals in a special drawer in a file cabinet for easy access.
- You may want to consider keeping your Information Archive locked if it is housed in an area where you share space.

Maintaining the Information

- Establish procedures and train staff so that everyone is on the same wavelength when it comes to saving and distributing the information.
- Keep information current! You could be disqualified for funding or ruin a media opportunity if information is obviously outdated.
- Have program kids assist you in clipping articles and maintaining photo and clipping files.
- Keep a master inventory of the types and quantity of information you have on hand so that you always have enough copies.
- Keep an inventory sheet in the file to record when an item is removed, who removed it, and what purpose the item was used for.
- Pick a regular time once a month or quarter (minimum) to review the files to ensure that they are in order, stocked, and up-to-date.

FIGURE 5.4.6 Creating an Information Archive System (Source: © Mary Beth Miller, The Right Steps Resource)

service personnel work frequently with the radio news director or, at larger stations, with individual reporters. Note, however, that at smaller stations the station manager could be the owner, program director, and chief engineer. Figure 5.4.7 shows the general organization of a radio station. Individual stations vary considerably, depending on their size and programming. The fire department should identify persons in the offices shown, however, and maintain contact with the news director and individual reporters, as well as the promotion director and public affairs director.

Television. "When nightly television news began in 1948, newscasts were 15 minutes long. In 1963, the first 30 minute newscast was broadcast. Today, CNN, MSNBC and other national and local cable networks broadcast news around the clock. Since then, television has become America's predominant source of news."[14] Just as with radio, understanding the television system helps the fire department receive coverage and may increase its credibility.

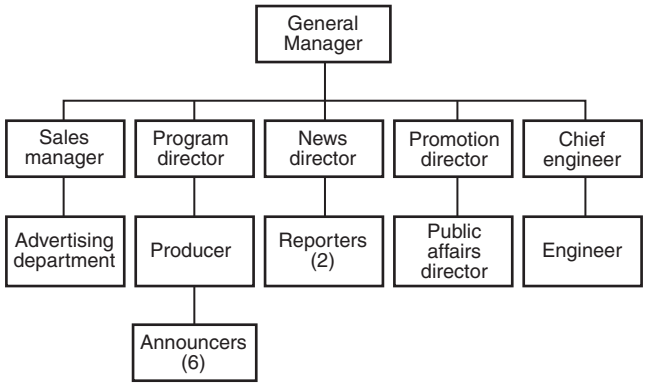

FIGURE 5.4.7 Generalized Organization of a Radio Station

Key contacts in the television news department include the news director, who oversees news and broadcast staff; the assignment editor, who assigns reporters to stories and ensures coverage of major stories and "beats"; the news producer, who determines which reports will air; and reporters who cover the stories. At an emergency scene, often the videographer is the primary contact for the PIO. For information on television public affairs, the PIO should approach the public affairs director or the public service director.

Figure 5.4.8 shows the general organization of a television station. Stations in larger population centers have large staffs, sometimes numbering into the hundreds. Key contacts include the vice president for news, the news director, the assignment editor, and individual reporters, as well as the vice president for public affairs and members of the public affairs staff, such as the public service director and the editorial writer. Before approaching a television news department with a story idea, the PIO should know the station's format and the individual to whom the idea should be pitched.

Television reporters believe the best stories have strong visual elements that grab and hold a viewer's interest. A television reporter is attracted to activities that make exciting or interesting footage and to interview subjects who talk in clear, concise language.[13]

Public Access Television. Public access television is another excellent and inexpensive way to provide community education programs. Approximately 2000 public educational or governmental access channels in the United States are either city supported, member based, or franchised from the cable company. The community cable company can explain how the system operates locally.

Local talk shows also provide an excellent forum for sharing information. Educators should take time to view a segment of a program before agreeing to appear.

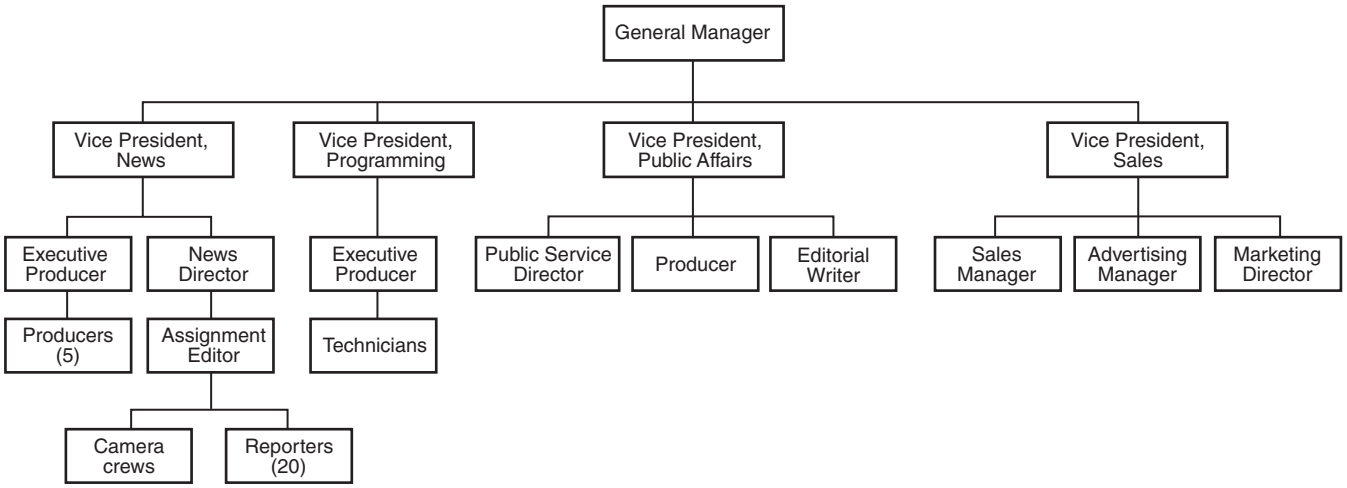

FIGURE 5.4.8 Generalized Organization of a Television Station

Television tends to be underutilized for educational purposes. In the emerging information age, when the trend is to move "from institutional help to self-help," television and videotapes can be the educator's forum to speak with millions of people in the places where they live, study, work, and play. The equipment is in place. The channels are open. The medium is available and waiting for the message.[13]

Print Media

Print journalism includes daily and weekly newspapers, magazines, and wire services. Print media have space for longer items—long enough to have an educational impact, not just awareness—and their readers are receptive to such longer pieces. Never underestimate the ability of publications with small circulation numbers. Although the number of newspapers has declined, the number of newspaper copies read and the average circulation of weekly publications have climbed—and smaller community newspapers are at a near all-time high for readership.[15]

As in broadcast media, understanding the print media hierarchy is helpful. Most newspapers are staffed similarly with the same general titles; however, the work done under those titles varies from paper to paper and city to city. To better understand this, look at the major divisions in a large daily newspaper. There are generally three: (1) the corporate board and executive committee, (2) the business division, and (3) the editorial division.[16]

The first two divisions have little to do with the fire department's publicity and media needs. The editorial and news staffs can provide more assistance. A large daily, for example, the *Washington Post,* contains many sections. For that reason, it is important for the PIO to identify the sections of the paper most likely to use safety information and the person on the staff best suited to help.

When dealing with a medium-sized newspaper, the PIO will likely have contact with the news editor, assistant news editor, features editor, and one or two reporters on the mailing list.

Figures 5.4.9 and 5.4.10 show the organization of weekly newspapers. The small weekly newspaper has an average circulation of 7600 readers. Editors and reporters of a paper this size can all be used as publicity contacts. Efforts should be made, however, to identify precisely the "beats" or areas for which each editor and reporter is responsible. A newspaper or magazine reporter will generally interview sources in person or on the telephone, looking for photographic possibilities or statistics for an eye-catching piece of graphic art.[13]

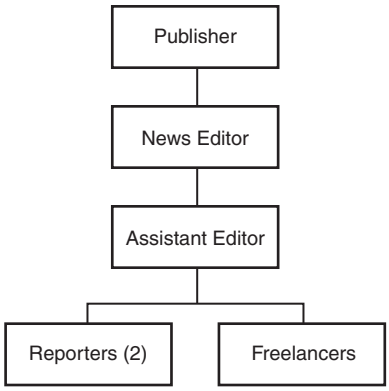

FIGURE 5.4.9 Generalized Editorial Structure of a Small Weekly

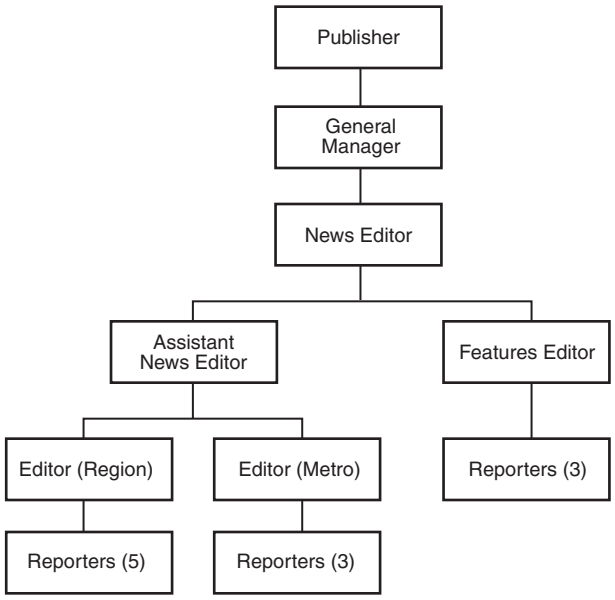

FIGURE 5.4.10 Generalized Editorial Structure of a Medium-Sized Weekly

News Trends, "New" Media

In disseminating information the Internet has taken shape as an established news medium alongside television, radio, and the press. The Internet is also now a full participant in the process of incorporating media into the event itself.[17] The team of Web editors and designers, working in the same building in Atlanta from which the television networks are also administered, clearly want their technology to be "television only better." In response, older electronic and print media are seeking to reaffirm their status within our culture as digital media challenge that status.[17] Immediacy is more important to the media than ever before.

Today's reporters often are multitaskers. The radio station may expect a reporter to place broadcast news stories and information on the station's website. The television station may post news clips from the 6 p.m. broadcast on its Internet site. This concept, called convergence, is the blending of print, audio, and video to create multimedia news products for television, newspapers, and the Internet.

The Internet and the explosion of cable and satellite TV channels are blurring the boundaries between news and information. This does not mean the end of newspapers or TV news programs. It surely means that they will lose influence and dispense less "traditional" news.[18]

Many large and even small communities have media bureaus to aid in the distribution of information and the design of brochures and ads. Others have no such resources. With the advent of personalized Web pages, however, any department may offer information by simply establishing a presence on the Internet. Fire and life safety educators need to understand how technology has transformed the mass communications landscape. PIOs should be prepared for and monitor changes that will affect how the fire department does business with the media.

Public Service Announcements (PSAs)

Public service announcements (PSAs) are prepared for radio and television stations. They are short announcements, generally running between 10 and 60 seconds. Broadcasters are no longer required by law to provide a minimum amount of public service airtime as they once were; however, many stations have a continuing commitment to the community and still use PSAs when possible.

In a small-to-midsized market, the educator may deliver PSAs and reasonably expect that they may be used. In major markets, placing PSAs becomes increasingly difficult. Because competition is strong, many stations stylize their newscasts to stand out on the crowded dial. They simply refuse to run anything their competition might have also received. In most large markets, it is best simply to become a news source. Provide information in a regular and timely fashion.[13]

Another place PSAs may be utilized is on local access cable television or other community access channels. They may also be delivered via the Internet through the fire agency's website.

Understanding What Makes News

News may be defined as any piece of information that will affect your head, heart, or pocketbook.[13] News reports something new—information that is a break from everyday events. Some news is information that people need in order to make sound decisions about their lives.[19] News editors decide if information they receive is indeed newsworthy by checking news values or news pegs. These news pegs are the basis for deciding what makes it to print and what does not.

Michigan State University conducted a survey of journalists, and from their viewpoint, five factors determine an event or an idea's newsworthiness:

- *Consequence.* Is it important? To how many?
- *Interest.* Is the event an unusual, rare, odd, or interesting situation?
- *Timeliness.* Are the events immediate or recent? Is there a new angle or a trend?
- *Prominence.* Does the event involve well-known personalities or institutions?
- *Proximity.* Does the event occur within the circulation or broadcast area?[18]

At least three-fourths of all news stories fall into the first two general categories of consequence and interest.[19]

News is relative. Each day, changing dynamics define "news." These dynamics include how much news occurred that day, the advertising load for the day, the type of audience, and the type of medium.

Hard News. Hard news is "perishable" and must be covered immediately or it becomes stale. Today's news is not necessarily tomorrow's news. Fire and emergency disasters are in the category of hard news. If the facts about an emergency emerge slowly, the story may develop longevity while remaining hard news.

The basic hard news story for the Web, for print, or for broadcast is written in what is called an inverted pyramid style. The most pertinent details appear at the top of the story; less important details are toward the bottom of the story, allowing the editor who is short on space or time to cut the bottom of the story while still preserving the most important information.

Soft News. Many news items do not fit the emergency (hard news) model yet are still newsworthy or educational. "Soft" news is less urgent, more complex, and often has more perspective than hard news. Soft news items that originate as such usually cannot be committed to a specific day; news editors decide how or when to place these items. By identifying an event, writing an appropriate headline, relating how it affects the community, and explaining how this information can help to avoid another incident, an educator can increase the chances of the media using the information.

Although local fire service stories lack the urgency of a hard news event, ample community interest exists to warrant sharing information. Many fire service activities are considered news, and announcements of them may be locally broadcast and printed. Local media and community members may want to know of meetings, rallies, seminars, and open houses. Workshops, National SAFE KIDS Campaign® activities, bicycle safety demonstrations, and checkpoints can raise citizens' safety consciousness.

Public statements on local affairs, awards given and received, fund drives, calls for membership, and the appointment and resignation of organization officials can generate considerable interest. Announcements of the availability of free speakers, films for loan, and the findings of reports and surveys conducted by the department have community news value. There is no limit to the activities that can generate publicity—especially for a well-organized, positively focused, energetic group. The PIO should let the media know—in their terms—how fire service information provides their audiences with useful, creative, positive information. Be cautioned, however: educators should never overstate or distort the significance of an event, inflate serious issues, or be theatrical in an attempt to solicit news coverage.

Interviews

Reporters are experts in reporting; otherwise they are usually generalists. Especially in radio and television, they report on a wide variety of topics from day to day. Most of them are bright and dedicated workers, but even the best of them may be relatively unknowledgeable about your particular subject or issue.[20] Be ready to provide some basic education about your topic and do not assume reporters will know what you are talking about.

Providing Firsthand Information. Be aware that although most reporters are happy to receive *information* from the PIO, they would greatly prefer to get the *interview* with someone on the front line. To bring their audience closer to the action and to provide the energy level needed to maintain viewer interest, stories should feature firsthand accounts as often as possible (Fig 5.4.11). This is one reason fire departments should consider training all fire fighters and prevention personnel in basic media relations—so they will be more confident and prepared when they are the ones being asked to step in front of the camera. This is also one reason all departments should have a media relations policy in place and familiarize personnel with proper procedures for on-duty media inquiries.

For the educator/PIO and for all whom the media may approach for comment, here are some guidelines.

Interview Tips. An interview is a formal exchange of information. The PIO should know as much as possible about the reporter(s), audience(s), and issue(s) before providing an interview. The PIO must be aware that the message goes to all readers, listeners, and viewers to whom the interviewing reporter provides information.

FIGURE 5.4.11 Fire Fighter Interview at Fire Scene

Communicating clearly and credibly and defining the "headlines" that the audience should see or hear are essential in an effective interview. When being interviewed keep the following points in mind:

- *Be prepared.* Review all pertinent information before the interview. Anticipate and prepare for questions the interviewer is likely to ask. Have reference notes. When possible, practice your answers out loud.
- *Be professional.* Dress appropriately. Avoid unnecessary movements and gesture calmly. Move more slowly than you normally would. Avoid chewing gum, smoking, or eating when providing reporters with information. Be confident. Look the reporter in the eye. During an interview, resist the temptation to look straight into the camera or at yourself on the TV monitor.
- *Be newsworthy, factual, and correct.* Double-check information before releasing it to the media.
- *Plan points to be made.* Present two or three main points as quotable single-sentence summaries. Begin the interview by stating the most important points or conclusions.
- *Be understood.* Use common language; avoid fire fighter jargon and technical terms. When technical terms must be used, explain them.
- *Assume that all is "on the record."* Anything said can and likely will be used. Assume that the camera is always on—including before and after the interview. And remember, modern lens microphones can collect audio and video from *very* far away.
- *Never say "no comment."* It invites speculation. Rather, say "I don't have enough information to properly answer that question."
- *Avoid "traps."* If the reporter's question contains objectionable words, don't repeat them in any answer, even to refute them. If a reporter poses a hostile or inaccurate remark, respond by saying, "First let me correct a misperception that was part of your question."
- *Maintain composure.* Some interviewers try to provoke angry responses to get additional information. Always remain calm and courteous.
- *Be prepared to restate your policy or position.* Do not attempt to answer hypothetical questions. Refocus the interview on the issue by saying, "Here's the situation we are focusing on."
- *Don't be afraid to say, "I don't know."* If the answer to a question is not known, say so. Follow with, "As soon as I get the information, I'll get right back to you." Make note of the question and get the answer.
- *Stay on track.* Don't digress from the subject. Lead a reporter who starts to wander back to the subject at hand.
- *Be accountable.* Never assign blame or criticize.
- *Be available.* Offer to answer any follow-up questions a reporter may have and help clarify problems that may arise as the story is being written or edited.
- *Be honest.* Never lie or "stretch the truth." Such tactics rarely work and, when discovered, can have severe consequences.
- *Be patient and willing to teach.* Reporters have different professional knowledge and backgrounds. They need education on some fire and life safety issues.

- *Stand up and be counted.* Keep records of media calls. See how and if department comments were used. If a serious misinterpretation becomes apparent, call the reporter or editor and ask for a correction. If reporters used comments in an appropriate and effective way, tell them so.

Another consideration for the PIO on an emergency scene is to keep the media out of harm's way and prevent them from interfering with operations, while still providing them their constitutional rights to public property access and freedom of speech. Therefore, the PIO should establish a plan with commanders in advance on how and where the media should be accommodated.

PUBLICITY CAMPAIGNS

Practical Publicity

Fire and life safety educators must carefully plan how to spend limited money and time. One approach is practical publicity. *Practical publicity* is used here to mean a program with a substantial public relations front end that is designed to set up a public education campaign with broad reach. First, educators get the public's attention. Second, they build interest and trust. Finally, they teach. Distributing Frisbees shaped like smoke alarms and imprinted with "Test Your Detector" helps provide departmental recognition. More complex examples might include an open house or a mass CPR training.

Three-Phase Publicity Framework

There is no single "best" way to run a publicity campaign. Communities have individual traits and characteristics. Groups within communities have specific needs and interests. However, a three-phase publicity framework from which to build exists; it can also be used as a benchmark for evaluation.[16]

Kick-Off Phase. This "name recognition" phase explains who the group is—that is, the education division of the fire department, its foundation and origin, and its plans for the future. Billboards, lawn signs, placards, news releases, flyers, and rallies support this phase.

Expansion/Issue-Oriented Phase. This phase comes after the public knows what the public education group in the fire department does and believes it to be credible. At this stage, the goal is to acquaint citizens with issues important to the fire department. The key is to emphasize issues, educate, and inform. Providing accurate information maintains credibility. Use seminars and workshops, radio and television editorials, newsletters, PSAs, and news releases. Meet the people face-to-face.[16] Note that this phase is still a public relations activity, but by moving from a broad department focus to an issues focus, it sets the stage for education.

Culmination Phase. After establishing an identity, informing citizens, and focusing on important issues, the fire department can educate.[16]

Use local as well as national statistics and data to add credence to a specific campaign, for example, statistics concerning increased use of sprinkler systems within new residential construction. Begin to work more closely with like-minded agencies such as the National SAFE KIDS campaign, local police department, park district, water conservation specialists, and cooperative extension agencies. The more groups there are sending a similar message, the more likely "airtime" will come for all involved.

Educators could investigate hiring (or soliciting a donation of effort from) a public relations firm if there is a specific issue that needs to be addressed. They could call on the already informed public if a popular issue, for example, passing fireworks reform legislation, arises. Phone "trees" (in which one group of people calls a second group, the second group calls a third group, etc.), newsletters, direct mailings, letters to the editor, letters to politicians, press releases, news releases, citizen editorials, and media coverage are effective after publicity efforts have made issues newsworthy. The effect is an amplification of the group's plea—a far greater noise than the group could ever make alone.[16]

Other options for the public relations phase include alternative outlets and campaign strategies, such as the following:

- Exhibits and displays
- Newsletters
- Poster contests
- Attention-grabbing methods (e.g., hot-air balloons)
- Instructional slide shows or videos
- Signs, billboards, and bumper stickers
- Safety trailers
- Flyers, brochures, grocery bags, and placemat announcements

EMERGENCY SCENE PUBLIC INFORMATION

Role of the PIO

Often the fire department media liaison or public information officer who conveys information to reporters in times of emergency is the fire and life safety educator. The PIO is responsible for gathering, preparing, and providing information to the media. The PIO helps convey the needed story safely, quickly, and efficiently and serves as the contact between the incident commander and the media. The PIO's goal is to help the media present an accurate, understandable, fact-filled account of the emergency and to ensure that reporters are safe and not interfering with those who are attempting to secure the scene.

The emergency scene is also a place where extremely effective public education can be accomplished. There is no more opportune moment to convince the community of a safety message than when that message is illustrated by an immediate, compelling example close to home. The PIO has the opportunity not only to provide accurate, timely information but also to impart knowledge in a learning environment like few classrooms—an environment where the audience is intensely interested.

Public information officers link the fire service and the community. The PIO, acting in a professional capacity, assembles as much timely and accurate information as possible and informs

reporters so they, in turn, can provide it to their viewers, listeners, and readers. The job of PIO is a "role rather than a rank."[21]

On an emergency scene or during any other activity that involves the Incident Command System, it is important to remember that the public information officer position is a component of the command staff, reporting directly to the incident commander. Every PIO should be trained in the National Incident Management System and follow the procedural and functional guidelines established for that position.

The professional PIO does not attempt to stand in the limelight or upstage a fire officer. After gathering information, the PIO streamlines the process of providing reporters with needed information as fire fighters continue their work. Some excellent resources that should be in the library of every PIO include the following:

- Birr, Tim, *Public and Media Relations for the Fire Service,* Fire Engineering Books and Videos, PennWell Publishing Company, Saddle Brook, NJ, 1999, 156 pp.
- Charlesworth, Michelle, *Public Information Officer,* International Fire Service Training Association, Fire Protection Publications, Oklahoma State University, 1999, 104 pp. and disc with forms.
- NFPA 1035, *Standard for Professional Qualifications for Public Fire and Life Safety Educator.*
- Brown, Leo M., *Media Relations for Public Safety Professionals,* Jones & Bartlett Publishers, Sudbury, MA, Feb. 2004, 180 pp.
- Schaper, Frank, and Greg Gerber, *Public Information Officer, Winning with the Media,* 1st ed., Thomson Delmar Learning, Florence, KY, 2007.

As in every other aspect of the fire and life safety educator's job, the PIO will be more efficient and effective if planning and thought have been put into practice ahead of time, before the inevitable emergency arises.

Creating and Following Standard Operating Procedures (SOPs)

Creating standard operating procedures (SOPs) expedites work with news media at an emergency scene or at any other time or place reporters might be contacted. SOPs establish (1) who in the department may speak with the media on behalf of the agency and (2) how the fire chief wants media matters handled. Figure 5.4.12 is an example of specifics that may be included in a media policy.

The PIO provides the bridge between the fire department and the community served. Often the community does not understand the fire department's day-to-day operations and activities. The community may not know how the modern fire service operates or the various tasks fire personnel perform despite impressive efforts in evidence. In most jurisdictions, the percentage of citizens who call the fire department for emergency assistance is low. Although the fire service conducts many public education and community service activities, a high percentage of the community learns of these activities only through the media. Providing clear, concise, and timely information to the media benefits everyone.[22]

PIO Tools

When facing reporters at an emergency scene, the PIO needs essential tools:

- A radio. Having a radio enables the PIO to communicate with fire command and other suppression personnel.
- Two pencils, a notepad, and a small tape recorder. Addresses, names of persons injured, telephone numbers, and so on can easily be forgotten in the rush of a large emergency. The PIO should write them down. If the PIO's style is to include every detail, the conversation should be taped. Taping conversations allows self-critiquing later. If inaccurate reporting becomes a problem, the tape recorder may show reporters that the PIO expects them to provide correct information.
- A cellular telephone for updating the news media and communicating with others involved in the situation. Wireless Internet access and the ability to upload news releases and/or photos from the scene are valuable if available.
- A media quick-call list. The quick-call list provides up-to-date phone numbers and is a short version of the media address and phone list. In an escalating emergency, the PIO must be prepared to notify media sources or update them as the situation changes. The list includes essential local broadcast and print media news reporters and personnel (as seen earlier in Figure 5.4.5).
- Basic question list. The list should contain a media work sheet, including basic interview tips, fire information, EMS information, hazmat information, and rescue information (Figure 5.4.13).

EXPLORING LEGAL ISSUES

The fire department must be aware of various legal terms and issues. Copyright laws, privacy acts, broadcast regulations, and the federal Freedom of Information Act (FOIA) should be understood and addressed. PIOs should develop a working relationship with the department's legal counsel.

Copyrights

Copyright questions arise frequently. Downloading a photo or document from the Internet without permission is a violation of copyright laws. U.S. copyright laws protect everything written the minute the information is offered in "fixed form," which includes online or print information.

Enacted in 1997, the No Electronic Theft Act provides penalties of up to $500,000 and five years in jail for copying software or online materials even if no profit is made. The Digital Millennium Copyright Act of 1998 provides further penalties of up to $1 million for copying online materials for profit.[8] The fire department user must receive permission from the author or publisher. Copyright laws dictate that copyright owners have the exclusive right to reproduce, distribute, and use original works of expression fixed in a tangible medium.

NFPA's Sparky® is an example of a registered trademark. The National Fire Protection Association's legal office must grant permission before a fire department may use Sparky for any promotion, activity, or brochure.

Public Information Officer Guidelines

The following are examples of details that may be included in operating procedures for PIO. Some are based on actual policies of agencies across the country. Guidelines for each agency may vary depending on policies and organizational structure.

DEFINITION: The Public Information Officer (PIO) is a member of the Command Staff, providing timely information to the media regarding emergency incidents and department activities. Any employee may be assigned to this position under the direction of an Incident Commander. The PIO will follow the responsibilities and procedures outlined by the National Incident Management System.

SCOPE: The PIO position will be established for any incident involving multiple alarms, a death or serious injury, Special Operations (Dive Team, hazmat, etc.), events of community interest, and any other activity for which Command determines a PIO is appropriate.

PURPOSE: To specify the procedure for release of fire department information to the news media and the public.

POLICY: It is our policy to maintain a positive and cooperative relationship with the public and the news media, and to provide in a timely manner all information deemed open for public access by law. Media inquiries will receive a response from a designated PIO at the earliest possible time. Every employee is expected to respond to the media and members of the public in a helpful, concerned, and respectful manner.

PROCEDURE: Command is responsible for the release of information to the media. The Incident Commander or Battalion Chief may designate an individual or group to perform this function. Other employees who receive media inquiries on an emergency scene or during day-to-day operations should refer those questions directly to Command Staff or to the on-call PIO. Employees may freely provide the on-call PIO pager number to the media.

On an emergency scene, the PIO will report to the Incident Commander. As soon as possible, the PIO will begin gathering information regarding the incident. The agency PIO work sheet may be used as a guide. The PIO will communicate with all media representatives on scene to establish safety and operational boundaries and to designate a time and location for information updates or briefings if needed. The PIO is responsible for advising the media of the need for protective equipment when necessary.

NO information is to be released regarding medical patient names or personal medical information, the identities of deceased or seriously injured victims (prior to notification of family), or any issue under investigation. NEVER broadcast this protected information over fireground radio channels.

The PIO will obtain video and still photography records of the incident, or will designate an incident photographer, and is responsible for storage and release of those images.

FIGURE 5.4.12 Sample Media Policy

Copyright statutes, revised in 1976, take into account developments in photocopiers, videotapes, motion pictures, broadcasting, cable television, and other technologies developed after the act's adoption in 1909.

To claim a copyright, follow this procedure:

- Place a copyright notice on the work. This information, written in the upper-right-hand corner of the work, claims the copyright.
- Complete a copyright form and pay the designated fee (optional, see below).
- Register the work with the copyright office in Washington, DC.

Registration is not necessary for a valid copyright, but if a suit is brought, the work must be registered. Generally, copyrights last the author's lifetime plus 50 years. For copyright information, contact the copyright office at this address:

Copyright Office
Information and Publications Section, LM-455
Library of Congress
Washington, DC 20559
http://www.copyright.gov

Further, when using copyrighted material, include the following information:

FIGURE 5.4.13 Phoenix Fire Department Public Affairs Media Guide (Source: Phoenix Fire Department, courtesy of Fire Chief Bob Khan)

- The word "copyright," the abbreviation "Copr.," or the symbol "©"
- The name of the owner of the copyright
- The year of publication

Publications available include the following:

- Catalogue of materials published
- Highlights of new copyright law (#R99)
- Copyright basics (#R1)
- Trademarks (#R13)

Freedom of Information Act

What rules pertain when a citizen asks for access to a private meeting? When must meeting transcripts be released? *Freedom of information* is defined as the "access to government documents that do not compromise national security or violate privacy rights of individuals."[7] "Sunshine" laws address media access to public meeting records. Varying from state to state, these laws generally cover these topics:

- The amount of notice required to hold a public meeting
- Whether or not a meeting is open to the public
- Requirements on meeting minutes or transcripts
- Executive session rules

The federal Freedom of Information Act, a 1966 statute, requires all federal executive and administrative agencies to furnish information to the public when it is requested, unless that information is in one of nine protected categories. The scope of the act was expanded in 1974.[5] A model for many state laws, it is designed to make government information available to the public. The government has 10 days to respond to a request and 20 days to respond to an appeal if records are denied.[19]

Libel and slander laws protect the reputation of a person or institution. Libel is written defamation. It is essentially a false or defamatory attack on a person's reputation or character in written form. Broadcast defamation is libel because there usually is a written script. Oral or spoken defamation is slander.[19] The fire department must be constantly watchful for photographs and statements that might defame or invade another's privacy.

HIPAA

The federal Health Information Portability and Accountability Act (HIPAA) restricts the release of personal medical information, including information that would identify the patient in certain emergency medical situations. Because the PIO is responsible for information release at the scene of an incident where patients are involved, familiarity with the specifics of these restrictions is crucial. Fire agencies may need to seek legal counsel for specific answers to their questions regarding HIPAA policies. Generally, HIPAA restricts releasing the name, address, phone number, specific injuries, or known medical history (such as heart attack or diabetes)[1] of a patient. Some nonidentifying information is releasable. Fire agencies that provide medical treatment and/or transport should have HIPAA procedures in place. For more specific details, visit the HIPAA website at http://www.hhs.gov/ocr/hipaa.

FUTURE COMMUNICATION TECHNOLOGIES AND PUBLIC EDUCATION

Today's PIOs and fire and life safety educators have the world at their fingertips: databases, e-mail, educator groups, and millions of websites. With an Internet connection and account and a computer, they may pick the brains of the best and the brightest fire and life safety educators across the globe. The Internet is filled with pages containing hundreds of valuable links.

Indeed, advances in computer technology have strengthened the relationship between communications and education. What once seemed impossible is today commonplace. Fire service personnel need to be trained and updated frequently on not only the advances in suppression technologies but also developments in computer technologies.

Self-education via online classes and CD-ROM is common today. Personalized educational programs may be found on many departmental websites. Pull-down menus allow people to create personal home escape plans, hunts for hazards, or search for specific injury or prevention information.

The success of the Internet and online magazines such as http://www.firehouse.com have made information gathering decidedly more friendly than in the past. Up-to-the-minute updates may be found with a click of the mouse. More information and data than a mind can comprehend may be located with that same mouse.

Computing, publishing, entertainment, communications, and consumer electronic devices all use and produce digital data. In this uncharted information environment users may copy, move, and interchange all types of data. This leads to one caution: Everything on the Internet may appear to be official. It is easy to assume it is fact. Often, however, information posted on the Web is incorrect. PIOs should always double-check facts with another source and develop their own tough standards for which sources are reliably accurate and credible.

Educating with computer-based media offers numerous possibilities, for example, one-to-one teaching, continuing education, and professional development for fire and life safety educators. Many North American universities use computer-based communication technologies. Among the technological possibilities are audioconferencing, satellite videoconferencing, and computer-based interactive exchanges. Portions of these educational resources are available, at minimal cost, to fire and life safety educators through cooperative extension offices that operate through partnerships with federal and state authorities and through community colleges and other communications facilities.

The challenges and opportunities for the PIO and fire and life safety educator are limited only to their creativity, energy, and the technologies available to them. Amidst the explosive expansion of these opportunities, however, the basic and fundamental steps of researching, face-to-face communications, and understanding how the "other side" thinks will never go out of style.

EVALUATING EFFORTS

In any process, the final stage is evaluation. To assess success, PIOs should compare the results of a program with its original objectives. Although it is not this chapter's purpose to discuss evaluation in depth, PIOs should understand the importance of evaluation and feedback. For example, if the percentage of the public that is aware of bike safety as an issue increases by half after the fire and life safety educator provides three public service announcements and appears on local community calendar talk shows, the value of the effort is evident. If the number of bike-related injuries decreases by half after the educator conducts a school program to teach bike safety, the value is evident. If most of the public is aware of a recent large fire, can describe its points accurately, and can report that they trust the information provided by the fire department, then PIO efforts have been successful by those measures.

Evaluations may be conducted either throughout the program or after completion of the program. If the objectives are met, pertinent information for future planning becomes available. If the objectives are only partially met, reasons for failure can be explored.

See also Section 5, Chapter 8, "Evaluation Techniques for Fire and Life Safety Education."

SUMMARY

Honest, forthright communications, data collection, and evaluation are at the heart of any outstanding public relations/public information campaign. Wise administrators recognize the value of training fire personnel in communication skills and marketing techniques. The positive dividends reaped through targeting

identified audiences allow citizens to be trained appropriately and money to be well spent. Emphasis and training on public information services enhance the positive relationship fire departments worldwide value and enjoy with the citizens they serve.

Key Terms

fire risk, *Learn Not to Burn® Curriculum,* occupant characteristics, public fire and life safety education, *Remembering When: A Fire and Fall Prevention Program for Older Adults™, Risk Watch®*

Certain groups are disproportionately affected by fires. Even though civilian fire deaths in the United States have dropped substantially over the past century and fairly steadily over the past several decades (e.g., from 7395 in 1977 to 3900 in 2004), and even though progress in fire safety has been made across the board, the same groups continue to incur disproportionate rates of fire deaths and deaths from other unintentional injuries.[1]

In particular, preschool children, older adults, and people who are disadvantaged (by income or education) are at highest risk of fire deaths in the United States. Children under age 5 are 74 percent more likely to die in a home fire than the average person. Adults 65 and older are roughly twice as likely to die in a fire and adults 75 and older have nearly three times the risk. The two high-risk groups—ages 5 and under and ages 65 and over—have been increasing their domination of home fire deaths. Together they accounted for 38.9 percent of home fire deaths in 1980 and for 53 percent in 2002.[2]

Statistics show that high fire death rates are often associated with key measures of socioeconomic disadvantage, starting with poverty and the lack of a high school education among adults.[3] For fire departments to be effective in continuing to reduce deaths, injuries, and fires in their communities, they will need to be sure that their programs at least include and at best focus on those at greatest risk.

See also Section 4, Chapter 5, "Strategies for Occupant Evacuation During Emergencies"; Section 5, Chapter 1, "Principles and Techniques of Fire and Life Safety Education"; and Section 5, Chapter 2, "Fire and Life Safety Education Messages."

PRESCHOOL CHILDREN

Children age 5 and younger have a fire death rate nearly twice the national average based on 1999–2002 yearly averages. Each year in the United States until 1995, 700 children age 5 and under had died in fires in the home each year. Beginning in 1995, that death toll has dropped sharply and was just under 270 in 2002. Representing 12 percent of the home fire deaths from 1999 to 2002, this age group still had a fire risk nearly twice the national average.[2] Preschool-age children are less able than older children to control their environments, are more dependent on adults, and are less likely to receive or understand information about fire safety.

Characteristics of This Group

The leading cause of fire deaths of preschool children is children playing with fire, usually matches or lighters. From 1994 to 1998, child-playing fires accounted for 36 percent of home fire deaths of children age 4 or younger, whereas by 1999 to 2002, child-playing fires, though still the leading cause, accounted for only 26 percent of home fire deaths in this age group. Part of this decline reflected a real decline linked to the child-resistant lighter standards that became effective in 1994. Part of the decline reflected changes in incident coding and may not reflect real changes in risk. NFPA's best estimate for 2002 was that 13,900 structure fires were started by children playing with fire. These fires resulted in 210 civilian deaths, 1250 civilian injuries, and $339 million

Sharon Gamache is executive director of the NFPA Center for High-Risk Outreach. She oversees the development and implementation of programs for people at high risk of fire, burns, and related injuries.

in direct property damage. Preschool children accounted for the majority (55%) of child-playing home fire deaths in 1999 to 2002, and the fatally injured children were often younger siblings or playmates of the firesetters rather than the firesetters themselves.[4]

How Preschool Children Learn. An instructive video, *From Theories to Play: Providing a "Creative" Developmentally Supportive Environment for Young Children,*[5] reviews characteristics of play in an environment for young children. This video can help fire safety instructors with developing or using appropriate safety activities with young children.

The following are some general principles discussed in the video:

1. Children need a variety of play environments. They need outdoor and indoor play and a variety of play materials that support sensory/motor, dramatic, and constructive play. Construction materials can range from fluid, such as sand and paints, to more complex materials, such as puzzles or interlocking building blocks. The *Learn Not to Burn® Preschool Program,*[6] created by NFPA's Learn Not to Burn Foundation (now the NFPA Center for High-Risk Outreach), adopted this general developmental insight into one of its basic approaches when teaching young children: "Don't scare children. Teach them what to do." Young children learn in several ways. Lessons to preschoolers should use a variety of activities to get behaviors across. Children learn best when they can use all the senses—through what they see, hear, smell, taste, and touch, as well as how they move.

2. Activities should provide opportunities for children to interact with adults and other children in a language-rich environment. Children should be provided experiences with music, puppets, stories, and dramatic play to enhance language development.

3. Children like to create or recreate dramatic activities in the miniature, using items, such as little characters, building blocks, puppets, and so on, or with activities, such as acting out family scenes with costumes and props.

4. Children at this age have difficulty waiting for turns. Games with rules are inappropriate at this time, as children of this age do not understand the concepts of winning and losing.

In a Federal Emergency Management Agency (FEMA) investigation on how children respond to disasters, Children's Television Workshop (CTW) found that young children ages 3 and 4 look to adults to help interpret their world, whereas children ages 5 through 7 begin to recognize cause and effect in relation to the disaster. This natural dependence on adults is also an opportunity to introduce new adults, such as fire fighters, into the child's environment, allowing those new adults to assist in interpretation of fire safety, their special area of expertise.[7]

As noted in Section 5, Chapter 1, "Principles and Techniques of Fire and Life Safety Education," frightening images do not motivate effective learning of fire safety behaviors in any age group. Such images typically inspire efforts to flee the images, either physically or otherwise, for example, by looking away. The *Learn Not to Burn Preschool Program* teaches fire safety awareness and skills in a nonthreatening way. Caregivers do not scare children by showing them burned toys or pictures of burned people.

Lessons need to be repeated for reinforcement. Participatory activities do not seem so repetitive even when they are. Embedding lessons in songs can also make repetition more acceptable and even enjoyable. The *Learn Not to Burn Preschool Program*'s English-language version makes extensive use of songs as aids to learning behaviors.

Legislation and Engineering

Since children playing with fire represents the single greatest source of their above-average fire risk, it is appropriate that legislative and engineering strategies focus on this hazard.

In 1994 the U.S. Consumer Product Safety Commission (CPSC) enacted legislation making it a requirement that all disposable and some novelty cigarette lighters be child resistant. This legislation specified that 85 percent of children age 2½ years to 4½ years tested must not be able to activate these lighters. Canada enacted its own legislation in 1995, making child-resistant lighters mandatory.

The U.S. standard has resulted in a reduction of fires and property loss and, more importantly, of deaths and injuries of children age 5 and younger playing with matches and lighters. CPSC estimated that 70 deaths occurred in residential structure fires caused by children younger than age 5 playing with cigarette lighters in 1998. In the absence of the standard, there would have been an estimated 200 deaths. CPSC reports that the difference of 130 deaths represents deaths prevented during 1998 because of the standard.[8]

An estimated 480 injuries occurred in residential structure fires caused by children younger than age 5 playing with cigarette lighters in 1998. In the absence of the standard, CPSC estimates that 1430 injuries would have occurred. Again, the difference of 950 represents injuries prevented during 1998 that CPSC attributes to the standard.[8]

However, a significant number of fires that kill young children are begun by matches.[4] It is, therefore, extremely important to get the message to adults and caretakers to keep all lighters and matches away from children.

Reaching Young Children Through Others

Because preschool children need and rely on adults to learn, a strategy of reaching these high-risk children through adults is essential. Adults are the ones who control the environment and are responsible for safety measures to be taken in the house, such as safely storing matches and lighters, safely using candles, and ensuring that there are adequate smoke alarms.

An adult component must be included in a comprehensive safety education program for preschoolers. The NFPA *Learn Not to Burn Preschool Program* has the following three letters for educators to send home to parents or caregivers at different times during the course that teach eight key behaviors to young children:

1. The introductory letter tells parents what behaviors the children are learning in school but reminds parents that, although

children are learning these fire safety behaviors, fire safety is still the parents' responsibility. It emphasizes four points for parents; for example, keep matches and lighters out of the reach of children, preferably in a locked cabinet.

2. A second letter is sent home when the match and lighter lesson is taught. This letter emphasizes that children must be taught to stay away from matches and lighters and to tell a grown-up when they see matches and lighters. It then repeats the information to parents to keep matches and lighters away from children.

3. The third letter describes how to design and practice a fire escape plan and emphasizes the importance of having smoke alarms in the home.

Drawings or art activities from preschool programs can also be sent home to parents or caregivers to reinforce understanding of what the children are learning in school. Some parents may not always read information sent home, but some of these are more likely to respond to a video shown at parent meetings or at home.

The NFPA Center for High-Risk Outreach produced *A Lighter Is Not a Toy*™ video[9] for the parents of young children. The 8 minute video depicts several scenes of preschool children interacting with their parents or grandparents. It suggests actions that can prevent serious burns and deaths from fires started by children who have access to matches and lighters.

Programs to reach preschool children through their parents or other caregivers can be targeted through child care centers; public housing developments; foster care training; Women, Infants, and Children's (WIC) programs; parenting skill programs; and babysitting classes. Reaching young children in child care settings directly is probably the easiest way to deliver a program. There are child care centers, preschools, and prekindergarten programs in public school systems.

Since day care providers are not necessarily linked under one organization, it is often necessary to contact several groups before identifying all day care providers in a community. Many states have programs. These organizations often provide training and are a good resource when working at the state level. In Canada, the Ministry of Social Services and various provincial child care associations help coordinate activities.

Teaching Young Children

Fire safety materials must be appropriate for preschoolers. This means that they cannot be simply adapted from materials used to teach children in elementary schools.

The developmental limitations of young children mean that fire safety must be taught in an environment providing interaction with adults. This is necessary because, in the absence of a strong adult role, lessons transmitted by television, for example, are likely to be misunderstood, perhaps dangerously so, or simply not understood at all. This conclusion has been reached repeatedly in the history of design of fire safety education for children.

In 1979 the U.S. Fire Administration (USFA) asked Children's Television Workshop (CTW) to explore ways of including burn prevention and fire safety messages in its *Sesame Street*® programming. Initial research recommended against this course of action.[10]

> Because of the one-way nature of viewing, television presents a difficult challenge especially with regard to such serious and important topics. For example, we need to be concerned that if a child viewed (the program) alone, questions could not be answered or clarified by an adult and a dangerous misunderstanding could occur.[10]

Resulting from this initial research was the USFA-funded *Sesame Street* fire safety curriculum, one of the first available fire safety programs for preschool children.

In 1990 the Learn Not to Burn Foundation concluded that public service advertising to young children with messages on matches and lighters would most likely be ineffective.[11] The foundation tested 50 children in day care settings with a video prototype and found that the youngest children (3 and 4 years old) did not understand the safety message well enough to risk putting the public service announcement on television; that is, mere exposure to the message and pictures of matches and lighters without comprehension could have the opposite effect on children, possibly causing them to have more of an interest in playing with or exploring matches and lighters.

Because they do not understand "if-then" situations, young children need to act out different scenarios. For example, if preschoolers only learn the behavior "stop, drop, and roll," they are likely to do that behavior for every fire situation (e.g., when there is fire and smoke in the room, if they burn themselves, etc.).

For many years fire safety programs for preschoolers have taught basically the same behaviors. In order to examine whether these behaviors are still appropriate and which behaviors are most effectively taught at ages 3, 4, or 5, Oklahoma State University worked on a project funded by a Fire Act grant.[12] The project was based on two assumptions: "(a) children can only be expected to understand and use fire safety messages when they have achieved the necessary physical, cognitive, and socioemotional milestones; and (b) the better educators understand the capabilities of children, the greater the likelihood a fire safety program has at succeeding."[12]

The project report provided an introduction to developmentally appropriate practice (DAP) and a checklist of developmentally appropriate expectations (CDAE) applied to the eight fire safety messages used by popular fire safety programs for preschoolers. The study used ages 3, 4, and 5 as milestones of development and described those milestones in three realms: physical (gross and fine motor) skills, cognitive skills, and socioemotional skills. The following are some points made in the analysis of "cool a burn" behavior. Under fine motor developmental education strategies, 3-year-olds can complete the "cool a burn" message physically by turning on the water but they cannot cognitively understand it. This is a difficult message for 3- and 4-year-olds because it is a three-part directive: go to a sink, turn on cold water, and put burn under cold water. Five-year-olds have the fine motor skills to turn on cold water. They have a basic grasp of right and left but they mix them up at times.

The authors hope that their analysis of this behavior and others will help early childhood and fire safety educators adapt and implement existing programs or develop new programs to reduce fire and burn injury in young children.[12]

Evaluation and Innovation

Preschool programs should be field-tested, pretested, and posttested in their development and implementation. However, one cannot use written tests to evaluate young children's knowledge gain. Using and documenting one-on-one interviews in which children demonstrate specific behaviors prior to and after the program is one way to assess children's knowledge gain.

In 2002, the Community Education and Child Advocacy Department of Riley Hospital for Children conducted pretest and posttest evaluations of the *Learn Not to Burn (LNTB) Preschool Program.* Riley Hospital had already worked with the Healthy Child Care America campaign managed through the American Academy of Pediatrics training 600 child care providers on the *LNTB Preschool Program* and 150 "supertrainers" to teach the program throughout the state between 1996 and 1999.

The goal of the study was to evaluate what gains in knowledge occurred in children ages 3 to 5 who had been taught the eight basic fire safety behaviors presented over 1 month's time compared to over a 3-month period. Children in a control group received fire and burn information on health and safety topics. A 2-hour training session was conducted at each of the 12 child care settings from the corp of "supertrainers." Pretests and posttests were administered on a one-on-one basis with each child participating in the study by the supertrainers working with the site. The pretest and posttest were the same instrument and consisted of 15 questions asking the children to demonstrate fire safety knowledge and behaviors. Results were compared with pretests and posttests of children receiving instruction over 1 month and over 3 months. Also pretests and posttests from children receiving the *LNTB Preschool Program* were compared with pretests and posttests of children at control sites. The percentages of improvement in test scores by intervention groups were the following: control group, 12.2%; 1 month group, 23.3%; and 3 month group, 33.5%. Children at ages 2 and 3 realized the greatest gains in knowledge.[13]

Although it is important to measure the knowledge gain accomplished by a fire safety education program, it is even more important to measure the effectiveness of the program in reducing fire deaths and injuries in the target population. The use of evaluation is well illustrated by the experience of the Portland (Oregon) Fire and Rescue Department, which implemented the use of the *Learn Not to Burn (LNTB) Preschool Program* and *Play Safe! Be Safe!*®.[14] (The Play Safe! Be Safe! program is a safety education program for children ages 3 to 5 created by the Bic Corporation. It uses video lessons, storyboards, and other games and activities to teach fire safety behaviors.[15]) In fiscal year 1992–1993, the *LNTB Preschool Program* was delivered to 29 Head Start classrooms in Portland. The primary means of evaluation was a focus on behavioral changes, which would be measured against the history of the juvenile fire problem in Portland. In 1994 and 1995, the Fire Bureau decided to expand the outreach to preschool-age children in group child care facilities, serving 12 or more children in nonresidential settings. The *Play Safe! Be Safe!* program was used for the children in these settings. In all, more than 200 copies of both programs were distributed into formal learning settings in the Portland area.

Some of the positive findings of the evaluation were the following:

- In the target age group of 3- to 5-year-olds, the success measure was the reduction in the percentage of children having to be referred to the juvenile firesetting intervention program for reasons of low knowledge and skills. The preprogram referral rate of 6.2 percent was reduced to a low of 1.8 percent by fiscal year 1996–1997.
- Prior to the implementation of this program, the city of Portland experienced an average of two deaths a year attributed to child-set fires. Since the implementation, the death rate due to child-caused fires has dropped to one death every 6 years, on average.
- The rate of child-set fires per thousand children in the targeted population, expressed as a fraction of the rate of child-set fires per thousand children in the entire community, has declined by roughly half.

Portland Fire and Rescue is convinced that this level of reduction in the different success measures points to education as the key to success.[14]

More evaluation such as the pretesting and posttesting and impact studies such as those done in Portland should be conducted. Too many programs are still in use based only on the reasonableness of their design assumptions and favorable, but unquantified, impressions of them by their lead adopters. The need for more evaluation will only grow as various preschool programs are adapted for international use.

Programs should continue to be developed and existing ones improved. It is also important to develop more lab research on how young children learn fire safety behaviors to get a better sense of whether young children understand the message and whether we are giving the right messages and teaching the right behaviors.

New programs for caregivers should also be developed and tested. Messages and programs for a variety of cultural groups should be studied and evaluated. New implementation methods should be used to reach children who are not in formal child care settings. Funding to conduct longitudinal, full program, sustained behavior change and impact evaluations should be obtained from groups such as the Centers for Disease Control and Prevention.

Even when a strategy emphasizes an engineering change, it needs an educational counterpart for maximum advantage. As an example, consider the standard on child-resistant lighters. Some children will be able to operate child-resistant lighters. Among the children younger than age 5 who ignited cigarette lighters in the CPSC study, about one-third were older than 4 years and 3 months, the oldest age of the children required to be tested by the CPSC standard-testing protocol.[8]

OLDER ADULTS

Older adults are the only one of the high-risk groups that is growing rapidly. In 2002, there were 36.6 million people age

65 or older representing 12.3 percent (or roughly one-eighth) of the population of the United States. The number of older adults has increased 10.2 percent since 1992. This compares to an increase of 13.5 percent in the population under age 65. Another significant increase, however, is that of Americans aged 45 to 65, who will all reach age 65 over the next 20 years. Their numbers increased by 38 percent in the same period. By 2030, adults age 65 or older will represent a projected 20 percent of the population.[16]

Internationally the population is also aging rapidly. One can see the increases in certain developed countries, such as Japan and Western Europe. However, even developing countries are seeing an increase. As pointed out by Dr. Alexandre Kalache, chief of aging and health for the World Health Organization, the developed world became rich before it got old, whereas the developing world is going to get old before it gets rich. This has important implications since poorer countries do not have the resources to deal with injuries that are available in the developed world.[17]

Although only 17.2 percent of persons age 65 and older in the United States are minorities, the rate of growth in numbers of minorities is increasing rapidly. By 2030 it is projected that minorities will represent 26.4 percent of the elderly population. Between 1999 and 2030, the white population age 65 and older is projected to increase by 77 percent compared with 223 percent for older minorities, including Hispanics (342%), African Americans (164%), American Indians, Eskimos, and Aleuts (207%), and Asians and Pacific Islanders (302%).[16]

In targeting programs to reach older adults, it should be noted that older adults vary in their physical and mental abilities and probably in their risk of death from fires and burns. As health care has improved and more is known about exercise and nutrition, people are more active and in good health and involved longer in the community. Also many older people are financially secure and living in good housing.

People age 85 and older or the "vulnerable elderly" have the greatest risk. Not only do they have the highest risk for both fire deaths and fire injuries but also their injury rate is 57 percent higher than the national average. From this statistic, one may infer that this is a different population from those people age 65 to 74 whose risk of home fire injury is actually lower than the all-ages average.[2]

Putting all this together, fire death risk continues to increase as people age, beginning at about age 50. People age 65 and older have about twice the risk of dying in a home fire as the general population. For people age 75 and older, the risk is almost three times as high, and it is almost four times as high for people age 85 and older.

Characteristics of This Group

For older adults, the principal causes of fatal fires are primarily the same ones as for other adults. They suffer less from child-playing fires.

Most fire safety messages for older adults are similar to those for other adults, but there are some variances in patterns that may affect relative emphasis on messages by an educator. Smoking-related fires are the leading cause of fire deaths. Heating equipment fires rank second, but they are a close second only for the oldest adults, accounting for nearly 21 percent of deaths among the 85 and older age group as compared to smoking materials (25%).[2]

Older adults are more likely than others to be intimately involved with the ignition source. For adults 65 and older, more than 14 percent are intimate with the ignition in structure fires. Males are a high-risk group compared to females for nearly all age groups. The death rate for males from 1999 to 2002 was 12.1 fire deaths per million population, which was 38 percent higher than the death rate for females at 8.8 fire deaths per million population. The largest difference was for age 85 and over, where the male death rate of 58.5 deaths per million was nearly twice the rate of 27.8 for females.[2] Men age 85 and over also had the highest risk of injury from fires of all ages.[2] Programs developed for older adults should be appealing to both men and women because men are at higher risk, but women make up a larger portion of the older population.

With so many important and distinct causes of injury, programs developed for older adults need to be multifaceted. For example, *Remembering When: A Fire and Fall Prevention Program for Older Adults*™[18] developed by the NFPA Center for High-Risk Outreach and the Centers for Disease Control and Prevention uses three strategies for reaching older adults: group presentations, home visits and smoke alarm installation, and fall intervention. (*Remembering When* is described in more detail later in this chapter.) Figure 5.5.1 is a sample fire message card from *Remembering When.*

How Older Adults Learn

In 2005, the U.S. Consumer Product Safety Commission staff examined consumer product safety issues associated with adults age 65 and older by conducting a literature review to identify changes or differences associated with aging that could affect an individual's ability to interact successfully with a product. The resulting study provided product- or environment-related interventions that could compensate for the age-related differences. The information learned could also be applied to those trying to teach fire and life safety education lessons to older adults. Sensory differences identified included such factors as glare sensitivity, reduction in peripheral vision, reduction in ability to hear higher frequencies, and difficulty understanding speech in noisy environments. In the study, the CPSC staff recommends interventions such as the following to compensate for differences:

- Increase levels of illumination, especially in situations where consumers must read information.
- Use nonreflective, matte, or semimatte finish to reduce the potential for glare on surfaces that include warnings or other information that consumers must read or focus on.
- Provide high contrast between text or graphics and the background.
- Use at least 12- or 14-point and preferably 18-point type for consumers 80 years of age and older.
- Increase the intensity of speech relative to background noise.[19]

The study also looked at cognitive differences that may affect product design. The processing resources most commonly cited that limit cognition in older adults were memory capacity

FIGURE 5.5.1 Sample Message Card on Kitchen Fire Safety from *Remembering When*

and, to a somewhat lesser extent, attention capacity. The authors suggest environmental supports that could be useful as external cues, such as pictures and lists or restructuring a task to allow individuals to rely on relevant prior knowledge.

Memory for previously acquired skills generally does not decline with increasing age. There is evidence, however, that it takes longer for older adults to acquire news skills than it takes for younger adults, especially for complex tasks or those where an individual must unlearn a previously acquired skill.

The authors concluded that opportunities for practice and training were very important for older adults. Training that focuses on procedural information is more important for older adult understanding than conceptual information. Training that gives "hands-on" practice tends to be better than training that simply presents facts and descriptions.[19]

In addition, older adults in focus groups conducted by the NFPA Center for High-Risk Outreach and the Centers for Disease Control and Prevention said that a program should focus on the key safety messages dealing with the major causes of fires and falls and how they can be prevented. To encourage program attendance, respondents said that program leaders should provide transportation for older adults who do not have transportation, provide food, and advertise that they will have food. The majority of those surveyed felt that the ideal time to hold an educational program is about 10 o'clock in the morning.[20]

Results indicated that older adults wanted both group presentations and home visits. Older adults thought visits to people in the home should be one-to-one and conducted by someone with whom older adults felt comfortable, such as a fire fighter or someone who already visits the home.[19]

Legislation and Engineering

Properties designed to provide special care to older adults are covered by the NFPA *101®*, *Life Safety Code®*, other model codes, and related governmental requirements. Many other engineering provisions—for example, to reduce the risk of fall injuries—are contained in guidelines such as those contained in NFPA's *Remembering When.*

Most older adults, however, live in their own homes, where there is less control and regulation for their safety. However, there are many engineering solutions that can be helpful for older adults. Advancements such as 10-year lithium battery smoke alarms, alarms that can be tested by a remote, or interconnected smoke alarms can provide more convenience and better protection for older adults.

Although the use of smoke alarms is associated with a reduction in fire fatalities in the general population, recent studies suggest that older adults may not fully benefit from conventional smoke alarm systems, particularly during sleeping hours. The tendency for older adults to experience high-frequency hearing loss has been attributed as a potential fire safety problem, since typical residential smoke alarms have a high-frequency signal between 3000–4000 hertz. The findings of a study by the NFPA Research Foundation[21] together with previous literature indicate that a mixed frequency T-3 signal has performed better than the current high-frequency (T-3) signal in its ability to awaken sleepers in every sample group tested so far. This includes children, young adults (sober and alcohol intoxicated), and older adults. Voice signals appear to be as effective as the mixed T-3 for the children and young adult groups but are less effective than the mixed T-3 for older adults.

In the meantime, the following are some recommendations that can increase the chance of sleeping individuals waking to a fire:

1. Encourage interconnected alarms. Interconnected alarms that include an alarm in the bedroom will mean that the volume at the pillow is likely to be above 85 dBA.

2. Consider the special hearing needs of older adults with "normal hearing." Given the hearing thresholds for high frequencies of older adults, it is inadequate to require their current high-frequency smoke alarm to be a minimum level of 70 dBA at the pillow. The current study shows that those older than 75 years of age were particularly poor at waking to the current high T-3 (median of 65 dBA for high T-3 compared with 40 dBA for the mixed T-3). One possibility would be to recommend that older adults should have interconnected alarms or at the very least stand-alone alarms (with the current signal) in their bedroom. An additional more satisfactory possibility is for smoke alarm manufacturers to market special alarms for this age group that emit a mixed T-3 signal and suggest placement, as a minimum, in the bedroom.[21]

Also, advocating for engineered product changes such as home fire sprinklers, flame-resistant sleepwear, and fire-safe cigarette legislation is another priority for those working to reduce deaths and injuries among older adults. Mandating fire-safe cigarettes can be beneficial to people of all ages but particularly older adults. The highest death rate from cigarette fires is suffered by people aged 65 or older, even though they are only half as likely to smoke as are younger adults.[22] By the end of 2006 firesafe cigarette legislation had been passed in six U.S. states, as seen in Table 5.5.1. The National Fire Protection Association also formed the Coalition for Fire-Safe Cigarettes made up of more than 50 national organizations to work toward state-by-state legislation.

Reaching Older Adults Through Others

Many older adults have people who provide them with care or support, but the typical independent older adult does not cede authority to any of these volunteer caregivers. The options available to caregivers of young children do not exist in the same form for caregivers of older adults.

TABLE 5.5.1 States with Legislation for Fire-Safe Cigarettes

State	*Percentage of U.S. Population*	*Law in Effect*
New York	6.5%	June 28, 2004
Vermont	0.2%	May 1, 2006
California	12.2%	January 1, 2007
Illinois	4.3%	January 1, 2008
New Hampshire	0.4%	October 1, 2007
Massachusetts	2.2%	January 1, 2008
Total	25.9%

Teaching Older Adults

The earlier lessons on how older adults learn can be translated into the following concise set of generic guidelines for constructing an effective safety education program for older adults:

- Find venues where older adults congregate and are receptive to an educational program. Older adults can be reached through a variety of organizations including senior housing, parks and recreation departments, places of worship, nutrition centers, or AARP chapters.
- Construct interactive presentations focused on specific safety behaviors, so that the interactive participation by the older adults can help to lock in the safety knowledge and serve as a start on practicing the safety behavior.
- Tailor the presentation to address potential physical limitations of the audience but unobtrusively and without overcompensation based on stereotypes.
- Use the presentations to set up home visits for follow-up. Extend the reach of the programs by arranging home visits with additional older adults who may not desire or be able to be involved with organizations that sponsor presentations.
- Involve older adults on every facet—from program design to program delivery—to assure that the high level of respect and credibility needed for success is achieved consistently.

Sample Programs for Older Adults

Older and Wiser. In response to the disproportionate number of fire deaths that occurred among older adults in the Canadian province of Ontario, the Ontario Fire Marshal's Public Fire Safety Council organized an older adults task force to reduce fires, injuries, and fire deaths among adults age 65 and older.

Research into the fires showed several different fire scenarios in which older adults were dying or being injured. To effectively address each scenario, a program had to be developed using a multipronged approach because those dying in fires were either very active in the community or lived on their own and were often isolated in urban and rural areas.

The Ontario Fire Marshal's Public Education Office developed a fire safety resource kit entitled *Older and Wiser*[21] based on the research and testing by the older adults task force. The kit includes a checklist for friends and families of older adults, a large-print pamphlet with fire safety tips, a high-rise pamphlet, a fire safety quiz, a booklet on working with the media, and an instructional booklet entitled "Getting the Community Involved." Program aids such as a booklet entitled "Planning for Success" and a presentation script help program leaders deliver a presentation to groups of older adults. The Ontario Fire Marshal's Office also provides a presentation to older adults in PowerPoint, overhead, or slide show formats to fire safety educators.[23]

Older and Wiser was distributed free of charge to every fire department in Ontario with funding by the City of North York. (North York experienced several fire deaths of older adults in 1997.) Surveys are sent out periodically to determine who is

using the program, how it is being used, and to see if there is need of additional resources or tools to educate this group.

Some of the most important community partners for *Older and Wiser* are the home support workers who visit the homes of older or physically and mentally challenged people to assist them with their daily chores. Many support workers test alarms in the homes of their clients. An *Older and Wiser* checklist was developed and field-tested by home care agencies in Ontario. In some communities fire service personnel train home support workers to conduct basic fire safety checks in the homes they visit. Smoke alarms are installed or replaced, and older adults are taught how to prevent fire and protect themselves if there is a fire.

Part of the success of the *Older and Wiser* program is attributed to the fact that in Ontario public fire safety education is mandatory. Under the Fire Protection Act, municipalities must deliver public education programs based on local needs and circumstances. Because many communities have many older people, a program that provides materials and resources to help reduce fires among this group is often welcomed.

Remembering When: A Fire and Fall Prevention Program for Older Adults.[18] In 1997 the NFPA Center for High-Risk Outreach had many programs to reach high-risk fire groups but had few materials to use to reach older adults. The center met with representatives from the Centers for Disease Control and Prevention Division of Unintentional Injury (CDC), which also had an interest in reducing fires among older adults. Both organizations agreed that a program designed for older adults regarding preventing fires could also include how to prevent unintentional injury from falls. (Fires and falls are the leading cause of unintentional injury in the home among older adults.) Many fire service personnel respond to emergency calls for older people falling as well as fires. Also, since many more older adults had experienced a fall than had been in a fire, the two organizations thought there would be more interest in a program that included both injury areas. Research was conducted at all stages of program development.

Because no single agency is responsible for reaching all older adults in a given community or jurisdiction, *Remembering When* is designed to be implemented by coalitions of local fire departments, public health departments, service clubs, social and religious organizations, area agencies on aging, and other organizations. As a team, coalition members can decide how to best approach the local older population.

Once the program was developed, 5000 free copies were made available to fire fighters, public health workers, other professionals serving older adults, hospital workers, and other organizations throughout North America. Some state organizations and corporations funded distribution of *Remembering When* for each fire department and other organizations in their states. Most people who received the program materials implemented the program without extra outside technical assistance. The NFPA Center for High-Risk Outreach has a corps of diverse trainers who provide training on the *Remembering When* program for state and local conferences of fire safety educators, organizations serving older adults, and public health officials.

The Centers for Disease Control and Prevention Division of Unintentional Injuries provided 3-year grants for the implementation of *Remembering When* in Arkansas, Maryland, Minnesota, North Carolina, and Virginia. Between 2000 and 2003 in the CDC project, 511 group presentations were made, 3566 home presentations, 4308 smoke alarms installed, 3221 bath mats given out, and 6251 night lights handed out; nearly 500,000 older adults were reached through the *Remembering When* program. The evaluation also included a written pretest and posttest for the implementation.[24] For other local groups that want to evaluate the program, the Center for High-Risk Outreach provides a local evaluation packet including questionnaires and a template for a final report to local officials.

The *Remembering When* program focuses on 16 fire and fall prevention messages. The program uses the following approaches to reach older adults:

- *Group presentations.* This section gives steps on reaching older adults through senior centers, high-rise housing, and other places people gather in groups. Three optional lesson plans feature interactive activities such as a trivia game to support the presentations.
- *Home visits.* This section focuses on reaching older people in their own homes through service providers who already visit the home. It includes several visitation formats, support checklists, and handouts.
- *Installation and intervention.* This section outlines how to organize a smoke alarm installation and fall intervention program, including the installation of smoke alarms and the distribution of night lights, nonskid bath mats, and other items.

Evaluation and Innovation

When the *Remembering When* program was in development, a formative evaluation was conducted. Hundreds of older adults in the five test sites participated in the group presentations and home visits.

In addition to the 3-year implementation and evaluation of five states by the Centers for Disease Control and Prevention mentioned in the preceding section, the CDC's Division of Unintentional Injury conducted an additional evaluation through Georgia State University. The state of Virginia was picked as the evaluation site because it had a particularly robust implementation program. Knowledge pretests and posttests of those attending presentations showed a significant pretest to follow-up change on 8 of the 19 knowledge items whereas the control site showed a significant pretest to follow-up change on 3 of the 19 knowledge items. The average increase for the fire items from pretest to follow-up was more than double in the treatment site versus the control (i.e., 11.3 percent versus 4.4 percent). The average increase for fall items from pretest to follow-up was 7.5 percent for the treatment site and 5.1 percent for the control site. In addition there was a home assessment evaluation of 23 items between the initial and follow-up home visits. In particular, the treatment site had significant home safety changes on three of the smoke alarm messages, including increased number of smoke alarms, working smoke alarms outside the bedroom, and at least one smoke alarm on every level of the home. Home

assessments showed no significant smoke alarm changes in the control site.[25]

Fire departments worldwide need to conduct a sustained effort on reaching older adults. This population will continue to grow rapidly. Training of fire service personnel should include not only the content of the program such as *Remembering When* but also model sensitivity to older adults and cultural relevancy to the period history of events that older persons have experienced. Also humor and fun activities should be part of all training and programs to overcome possible preconceived ideas many have regarding the target group. Fire and life safety educators who have worked over the years with older adults report enjoying their work with this group.

Programs should also be targeted to the adult children or nieces and nephews of older adults. This group could benefit by learning more about how they can assist their parents, aunts, and uncles in making their homes safer as well as learning how to design their own homes to be safer as they age and to increase their safety behavior.

LOW-INCOME AUDIENCES

Today's urban and rural environments offer challenges to anyone working to improve schools or provide health services, city services, crime prevention, or fire and life safety measures. Traditionally programs for fire safety tended to reach those who needed it least. And without concentrated effort to understand the urban or rural poor situations, it is unlikely that programs developed for more affluent communities will be effective.

A number of statistical studies, stretching back at least a quarter of a century, have demonstrated that the risk of fire or fire death is higher among low-income populations.[26] Many measures of what it means to be disadvantaged have shown this relationship to high risk, but the various conditions all tend to be correlated with each other, so it is probably impossible—and unnecessary—to determine which condition is most critical in creating higher fire risk. Lack of income (poverty) and lack of education are the two conditions that most consistently show a substantial relationship to high risk. Only 65 percent of poor household heads are high school graduates, compared with 81 percent of all household heads.[27]

The correlation with poverty and low education appears to explain why race and age of housing, by themselves, appear to be factors in high risk. When the effects of poverty and low education are removed, neither race nor age of housing appears to be a good predictor of high risk. Although blacks are overrepresented among the poor, whites make up 67 percent of America's poor compared with 83 percent of the overall population. Blacks, who represent 13 percent of the population, make up 29 percent of the poor. The black ratio has barely budged since the mid-1960s.[27]

Similarly, fire risk is high both in large cities and in small, rural communities, the two sizes of communities with the highest shares of this population living in poverty. And among regions of the United States, the higher incidence of rural poverty, in particular, provides an explanation for the consistently higher fire death rates in the South.

A more recent study of deaths and injuries from house fires in the city of Dallas, conducted from 1991 through 1997 and reported in the *New England Journal of Medicine,* confirmed the previous findings. It found that the rate of injuries was highest among older adults, low-income populations, minorities, and in houses without functioning smoke alarms.[28] Homes with low incomes are less likely to have smoke alarms.[29] The study also showed that census tracts with the lowest median incomes had rates of injury 20 times as high as the rates in tracts with high median incomes[28] (Table 5.5.2).

As noted earlier, older adults account for one-fourth and young children account for one-sixth of the population. People with low incomes are the smallest part of these high-risk populations, depending on how the condition is measured.

More than one in seven Americans live in poverty, including more than one of every five children. This means that people do not earn enough to feed, clothe, and house their families at a level that the federal government considers adequate. The minimum incomes needed to do this are $7363 for singles to $14,763 for a family of four to $29,529 for a family of nine or more.[27]

Older adults are less likely to be poor than other age groups, thanks in large part to Social Security, Medicare, and Medicaid. In 2002 about 3.6 million persons age 65 and older (10.4%) were below the poverty level. The historic level of 9.7 percent was reached in 1999. Another 6.4 percent of the elderly were classified as "near poor" (income between the poverty level and 125% of this level). Older women had a higher poverty rate (12.4%) than older men (7.7%) in 2002. Older persons living alone or with nonrelatives were much more likely to be poor (19.2%) than were older persons living with families (6.0%). The highest poverty rate (47.1%) was experienced by older Hispanic women who lived alone.[16]

Of the elderly white population, 8.3 percent were poor in 2002, compared to 23.8 percent of elderly African Americans and 21.4 percent of elderly Hispanics. Higher than average poverty rates for older persons correlated with living in central cities (12.2%), in rural areas (11.9%), and in the South (12.7%).[16]

Poor families are not unusually large families. The average poor family receiving Aid to Families with Dependent Children (AFDC) consists of 2.9 people. The typical American family is 3.2 people.

Although everyone grows out of the high-risk group of young children and often into the high-risk group of older adults, being disadvantaged is often regarded as a lifelong affliction. This stereotype misses a sizable share of the disadvantaged who do leave the group. Studies show that although about a third of the poor are elderly or disabled and, thus, unlikely to climb out of poverty, one of every five poor people in a given year isn't poor in the following year. Isabel V. Sawhill, a senior fellow at the Urban Institute think tank, estimates that roughly a third of the nation's poor remains impoverished only temporarily because of job loss, illness, or divorce.[27]

Characteristics of This Group

Only 9 percent of poor working-age adults work full-time year around compared with 42 percent of all working-age adults; 40 percent of the poor do work part-time or part of the year, compared with 69 percent of all adults.[27]

TABLE 5.5.2 Rates of House Fires and Injuries Related to House Fires, According to the Median Income of the Census Tract, in Dallas from 1991–1997[a]

Median Income per Year	*No. of House Fires*	*No. of Houses*	*No. of Injuries*	*Population*[b]	*Injuries per 100,000 Population per Year*	*Relative Risk (95% CI)*[c]	*House Fires per 1000 Houses per Year*	*Relative Risk (95% CI)*[c]	*Injuries per 100 House Fires*	*Relative Risk (95% CI)*[c]
<$20,000	1681	33,411	75	107,944	9.93	8.1 (2.5–32.0)	7.19	2.4 (2.1–2.8)	4.46	4.1 (1.2–16.2)
$20,000–$39,999	4085	97,205	121	286,892	6.03	4.9 (1.5–15.4)	6.00	2.0 (1.8–2.3)	2.96	2.7 (0.8–10.7)
$40,000–$59,999	800	40,454	17	103,242	2.35	1.9 (0.5–8.2)	2.83	1.0 (0.8–1.1)	2.13	1.9 (0.5–8.4)

It is not true that most of the poor live in inner-city ghettos. Only about one in eight poor Americans lives in census tracts with poverty rates of 40 percent.[27] Part of the reason for this fact is that poor people can be found in most communities that are not poor. A more important reason for this is the large share of poor people located in rural communities where census designations are not defined at the tract level. If relative fire rates and fire death rates are any indication, then rural poverty is a greater risk factor than urban poverty.

Special Fire Risk Characteristics. One reason that rural poverty is a greater risk factor than urban poverty is the larger number of rural poor who are located in the South. Here winters tend to be milder, and it is possible to at least attempt to heat whole housing units with portable or fixed-space heaters designed for safe use only in smaller spaces. Fire deaths due to heating equipment fires account for a larger share of all fire deaths in the rural South than elsewhere.[30]

The other fire causes for which the poor have distinctly higher risk than others, at least in large cities, are child-playing fires and incendiary or suspicious fires, which are known to be dominated by juvenile firesetting. A possible explanation for this pattern follows this chain: Most of the poor live in single-parent households headed by women. Just over half of the poor families (52%) in America are headed by single females compared with only 18 percent of all U.S. families.[23] Single-parent families have less total person-time available for close supervision of children, which creates more opportunities for children to start fires, as well as reduces the ability of the family to respond quickly and effectively to help children escape any type of fire that may occur.

Other factors related to poverty that also contribute to high fire deaths are unattended or unsupervised children; a lack of utilities; the use of safety devices, such as window bars, to prevent crime; a lack of smoke alarms; and older electrical wiring.[30]

A study investigating the social and demographic relationship of nonfatal structural fire injury rates for the civilian population of Philadelphia census tracts during the 1993–2001 period was conducted by the Department of Sociology of Villanova University. Findings showed that those tracts with older housing, low income, the prevalence of vacant houses, and the lack of ability to speak English have significant independent effects on fire injury rates in Philadelphia. The problem of the housing is not its age alone but the combination of housing and low income. The proportion of vacant houses was highly significant not just that injuries occurred in vacant housing but also that the presence of vacant housing was a significant indicator of decline in the areas and had an even more important indirect effect on fire injures in a census tract.[31]

How the Group Becomes Safer. Any effective fire and life safety program targeting the disadvantaged must reflect the limitations that low income and less education impose. Even one single-station smoke alarm with a battery may be beyond the poor family's budget, let alone annual battery replacement. Reading levels need to be kept low if educational materials are to be readily grasped by a target disadvantaged population.

For a number of low-income communities, there may also be language barriers. In most urban and some suburban and rural communities, the fire safety educator must be prepared to provide instruction and information in languages other than English. According to the U.S. Census Bureau, there were 28.4

million foreign-born residents (10.4% of the total U.S. population) in 2000. Among the foreign born, 51 percent were born in Latin America, 25.5 percent were born in Asia, 15.3 percent were born in Europe, and the remaining 8.1 percent were born in other regions of the world.[32]

Almost half of the foreign born lived in the central city of a metropolitan area (43.1%), compared with slightly more than one-quarter of the native population (people born in the United States, 27.5%). The percentage living outside these large central cities but within a metropolitan area was slightly less for the foreign born than for the native population (48.8% and 51.0%, respectively). The percentage of the foreign born living in nonmetropolitan areas (5.1%) was much smaller than the percentage of natives (20.7%).[32]

Although a large proportion of immigrants moves to the large metropolitan areas, many smaller communities also experience changes in their ethnic makeup. For example, Sioux Falls, a city of about 140,000 in the mostly rural state of South Dakota, estimates that 17 percent of its population was not born in the United States. The Sioux Falls school district has documented 47 different languages spoken by students in grades K–12. In addition the Sioux Falls Multicultural Center states that there are over 80 languages and dialects spoken in the community.

Challenges to the fire department there include not only reaching families, especially adults who speak a different language, but also reaching people with cultural and socialization issues related to fire, such as teaching people to use stoves with several burners and ovens when they may have cooked on an open fire in their native country and teaching people not to use hibachis or barbecue grills inside their homes. In the last 10 years there have been 12 fire deaths in the community. Seven of these deaths were to immigrants. In order to address this community risk Sioux Falls Fire Rescue along with the Sioux Empire Safety Village (a local nonprofit organization) translated a locally written, 11-page home fire safety guide into 15 languages and produced a video series covering the same information in 13 of the same languages.[33]

The multilingual nature of Canada is growing as a result of increased immigration. In 2001, there were 5.3 million people who reported a mother tongue other than English or French, which was a 12.5 percent increase from 1991. This increase was three times greater than the overall growth rate of the Canadian population (4.0%). The number of people reporting English as their mother tongue increased by only 2.6 percent from 1996 and those reporting French increased by only 1.1 percent. Chinese is the third most common mother tongue. People reporting Chinese as their mother tongue accounted for 2.9 percent of the total Canadian population.[34]

The trend of multilingualism is likely to increase in Canada and the United States. Europe, Australia, and other nations are also experiencing growth in immigrants who speak other native languages. This presents a challenge to public educators as they try to reach people in their communities with safety messages and culturally appropriate programs.

Legislation, Engineering, and Government

The principal concern with safety programs for low income populations is that normal program funding dynamics will tend to target *away* from the disadvantaged rather than *toward* them. Resources that can be tapped for safety programs anywhere else are likely to be missing in a poor neighborhood or community.

One Chicago neighborhood, North Lawndale, according to the *Chicago Tribune,* has one bank, one supermarket, 48 state lottery agents, and 99 licensed bars and liquor stores. "With only one bank, there are few loans available for home repair; private housing has therefore deteriorated rapidly."[35]

In his book *Other People's Children: Savage Inequalities, Children in America's Schools,* Jonathan Kozol reports further that in the school system the city often relies on low-paid substitute teachers who represent one-fourth of Chicago's teaching force. Even substitute teachers are in short supply. On an average morning in Chicago, 5700 children in 190 classrooms come to school to find no teacher.[35] In his 2005 book, *The Shame of the Nation: The Restoration of Apartheid Schooling in America*, Kozol goes on to demonstrate the isolation of poor and minority children in major cities in the United States. In Chicago by year 2000–2001, 87 percent of Chicago public school enrollment was black or Hispanic and less than 10 percent of children in schools were white. School funding for schools in the city of Chicago is considerably less than more affluent suburbs as well. For example, in the 2002–2003 school year the spending per student (grades K–8) for Glencoe with 1 percent low-income families was $10,935 and for Chicago with 85 percent low-income families was $8,482 per student (grades K–8).[36]

Lack of adequate smoke alarms in homes in poor communities can especially put people at risk. Any education program targeting low-income communities should provide a mechanism in which residents can get alarms installed in their homes. Homes with smoke alarms have a death rate that is about 40 to 50 percent less than the rate for homes without alarms. Based on a telephone survey as of 2004, 96 percent of U.S. homes had at least one smoke alarm. However, four of every ten home fires reported to U.S. fire departments still occurred in the small share of homes without alarms.[29] Although telephone surveys conducted for NFPA showed 96 percent of homes had alarms, results from surveys filled out by installers in a 2005 NFPA smoke alarm program reaching more than 8000 residences in high-risk communities in Mississippi, Alabama, and the Navajo Nation showed a much lower presence of alarms in homes before the new alarms were installed. In targeted communities in these three locations presence of alarms were 33 percent in the Navajo Nation, 43 percent in Mississippi, and 63 percent in Alabama. In the years 2003–2004 NFPA/USFA conducted an installation program reaching nearly 4000 residences in Holmes County, Mississippi, one of the poorest counties in the United States. Surveys of installers working in Holmes County reported that 53 percent of the homes had at least one smoke alarm before the installers put in new alarms.[37]

Reaching the Group Directly and Through Others

Community-Based Fire Safety Education Model. A community-based fire safety education model[32] has been designed to address the challenges of the poor urban areas, for example, working with tight budgets, large numbers of unsupervised children, non-English-speaking residents, and other issues

related to social and economic changes. An important concept of the community-based approach is that no two communities are exactly alike. Fire departments must adjust approaches to fire safety education to fit the audience they are trying to reach.

The fundamental principles of the community-based approach are geographic targeting, market research, and grassroots community involvement, which are explained as follows:

- *Geographic targeting.* Identify specific neighborhoods or areas where the fire problem is most severe and concentrate efforts on reaching residents of these high-risk areas.
- *Market research.* Use methods developed by the advertising industry to learn more about the target audience to understand how they get information and what will motivate them to listen and respond to fire safety messages.
- *Grassroots community involvement.* Invite the active participation of as many of the targeted audience members as possible in each aspect of the program.[38]

Community involvement is not just a means for disseminating information but also should be a goal in itself. When people actively participate in a program, they develop a personal stake in fire safety that they bring back to family, friends, and neighbors.[39]

The following basic steps are the foundation of a successful community-based fire safety education program:

- Educators analyze fire data to identify the geographic target areas with the most fires and deaths and to determine the main causes.
- A market researcher or other qualified individual conducts focus groups among people in the target area to identify the leaders in the community and determine the best strategies for communicating fire safety messages to residents.
- Meetings are held with the leaders of community groups identified during the market research.
- Educators implement the program with the cooperation of the community groups. Some programs give free smoke alarms and educational materials as part of each pilot program. Most of the programs include a door-to-door canvass of households in the target area. Fire fighters or trained volunteers install the detectors.
- The success of each program is evaluated by documenting citizens' response and analyzing fire data by comparing the number of fires or fire deaths and injuries before and after the program's implementation.[39]

The qualities necessary to be an effective fire and life safety educator in low-income and other communities are very similar to those necessary to be a community organizer trying to improve overall conditions in neighborhoods. The following list identifies qualities needed by fire and life safety educators:

- Being able to find leaders in the community
- Being able to find the networks and organizations in the community that really work for people
- Understanding the enlightened self-interest of the person or persons to be motivated
- Recognizing differences without stereotyping people
- Having imagination or empathy
- Being ready to give volunteers and leaders in the community recognition and empowering others to act and lead on their own
- Having a sense of humor

School-Based Programs. School-based programs have been very popular in reaching children and their parents. Example programs are (1) ones in which the fire department does all the teaching directly to students in their classrooms or in auditoriums, (2) fire safety houses and trainers, and (3) ones that concentrate on training the teacher to teach fire and life safety as part of the ongoing curriculum.

The public educator needs to take into account what teachers and administrators are dealing with in schools in urban or rural communities. There are many groups eager to provide their messages to children in these schools; therefore, in order to get fire and life safety on the priority list, the fire and life safety educator must be able to communicate the urgency of the safety issue and provide new resources to the school system.

An example of a fire department reaching children in urban schools is the Philadelphia Fire Department. The department implements NFPA's *Risk Watch*®[40] curriculum in 40 schools in high-risk communities. (*Risk Watch* teaches eight safety subjects of motor vehicle safety; fire and burn prevention; choking, suffocation, and strangulation prevention; poison prevention; falls prevention; firearms injury prevention; bicycle and pedestrian safety; and water safety for preschool to grade 8.) The communities were targeted by observing census tract information showing low incomes combined with information on areas where there was a greater rate of fire deaths and injuries.

Joseph Flores, former captain in the Philadelphia Fire Department and community outreach liaison for the University of Pennsylvania to the Philadelphia Fire Department, supplemented the *Risk Watch* materials in order to address the needs of urban children. Some of the subjects for which he wrote supplemental materials were children playing on playgrounds with glass, needles, or crack vials; children playing in abandoned cars or houses; and children opening fire hydrants during the summer to cool off. The department also added information on lead paint and dog bites—other problems in the city.

In addition to the *Risk Watch* curriculum implementation, a Philadelphia-wide smoke alarm program provides for the installation of free smoke alarms in the homes of any child who does not have a home smoke alarm. The department also installs 10-year battery smoke alarms in homes in high-risk areas.[41]

Another innovative use of *Risk Watch* was organized by the Rochester, New York, Fire Department for mothers and children living in homeless shelters. "Shelters and Safety" was funded by the Rolf H. Jensen Memorial Public Education Grant awarded by the NFPA. The seventh- and eighth-grade module of *Risk Watch* is the primary resource for the program. The women in the program create a personal journal, called *My Safety Book,* that they are encouraged to read to their children. Each adult attendee must participate in the exercises of the program and demonstrate proficiency in the prevention of each of the eight *Risk Watch* risk prevention areas. Pretests and posttests are administered to measure the success of the program. Each woman who successfully completes the program receives a graduation

certificate. When the graduate moves into her own apartment, she receives a housewarming gift of safety-related materials, including smoke and carbon monoxide alarms, pot holders, bath mats, bicycle helmets, car seats, and cupboard locks and latches.[42]

Spanish-Language Materials from NFPA. In response to the dramatic growth of Latinos in the United States (Latinos now make up 12% of the U.S. population)[43] and the demand for bilingual materials in schools, the NFPA Center for High-Risk Outreach developed its *Learn Not to Burn Preschool Program* in Spanish. It is entitled *Mis primeros pasos en prevención contra incendios*®[44] or *My First Steps to Prevent Fires.* Project staff not only translated the teacher's guide into Spanish but also produced eight original Latin songs on a cassette tape to accompany the guide. Each song was written in a different Latin style characteristic of the music in a variety of Latin American countries (e.g., the Cuban cha-cha-cha, the Puerto Rican plena, the Mexican polka norteña, and the Dominican Republic merengue). The words for the new songs were reviewed by a team of Latino fire safety educators to determine that all words were appropriate for Latinos having varied countries of origin (Figure 5.5.2).

Individual songs were given to child care providers for Spanish-speaking children. The teachers would try them out over several weeks to determine if the children understood the messages of the songs, whether there were words that children did not recognize, and if the children could sing the songs easily. Changes in the song were made after feedback was given to the project team.

Artists were hired from Mexico to provide new illustrations in a style attractive to the Latino audience. To implement *Mis primeros pasos* in the United States, the center trained a network of Latino fire fighters from various communities in the United States with a large number of Latinos.

A partnership between NFPA and the National Association of Hispanic Firefighters (NAHF) introduced the program to the National Association of Bilingual Educators. "One of the goals of NAHF was to make sure that the Latino community had a culturally relevant education program in their school and community. For many of the children who are immigrants, this is the first time that they have ever received any fire safety education because in the past, public fire safety education was not provided in their mother countries. We want to improve the well-being of the Hispanic community in the communities where Hispanic fire fighters serve," according to Sal Morales, past president of the National Association of Hispanic Firefighters.[45]

Fire fighters from other countries began hearing about *Mis primeros pasos* after its introduction outside the United States at the Mexican Association of Fire Chiefs Conference in Leon, Mexico, in 1997. The center's four bilingual trainer/consultants have trained users in Argentina, Mexico, Costa Rica, and Puerto Rico, and comprehensive programs are being conducted in Argentina, Costa Rica, and Puerto Rico. Figure 5.5.3 illustrates one such session.

NFPA's *Remembering When* program has been translated into Spanish. It is entitled *Los buenos recuerdos* (*The Good Memories*), and it too will be implemented in the United States and Latin America. Using the program in other countries requires working through the appropriate networks in those countries to keep the program going. Some of the challenges include difficulties in getting materials, lack of money for materials in poor communities, and lack of availability of safety devices such as smoke alarms or child-resistant lighters.

In 2002 in order to provide local fire fighters and teachers with public education skills and leadership abilities to implement *Mis primeros pasos* and *Los buenos recuerdos* in Mexico, the Center for High-Risk Outreach created the Mexican Champion (*Campeone*) program. Candidates send in their application with support letters from their fire chief and local schools. The Center for High-Risk Outreach provides training and free materials for the *campeones* to use in the schools in various Mexican states. Results from teacher surveys and parent questionnaires show an increase in the understanding of fire safety behaviors

FIGURE 5.5.2 Elementary School Children in East Los Angeles Demonstrating Things That Can Get Hot and Singing "Cuidado, Puede Estar Caliente" ("Careful, It May Be Hot") from NFPA's Spanish-Language *LNTB Preschool Program*

FIGURE 5.5.3 A Teacher Training Session Conducted in the State of Aguacaliente in Mexico

and positive reaction from Mexican families. They also bring to the program leaders' attention related problems, such as not being able to locate residential smoke alarms in stores and families often not practicing the escape plan when there are no alarms in the home.

Other Resources to Support Foreign-Language Materials. It is essential to use professional translators to create foreign-language versions of fire safety materials. Professional associations such as the American Translator Association[46] can help locate translators. Educators should use an advisory group of people who are native speakers of the language to review the copy.

Educators should be sensitive to the audience. Foreign-language populations may include some who are not literate in their own spoken language; therefore, the educator may have to rely on illustrations to describe the message.

Furthermore, translated materials may be best given to the consumer with one side in English and one side in the foreign language because household members may be at different levels in their reading skills in English, with some primarily reading English and others primarily reading their mother tongue.

FIRST NATIONS POPULATIONS

In the United States native populations may be called the First Nations, American Indians, Native Americans, or by the name of a specific nation. In Canada, they may be called the First Nations, aboriginals, First Peoples, or by the name of a specific nation. Regardless of nomenclature, many of them qualify as disadvantaged populations.

During the 1997–1998 period, fire death rates were 2.1 times greater for Native Americans/Alaska Natives than for whites, with the highest death rates occurring among children 0–4 years old.[47]

The 2003 fire death rate in First Nations communities, expressed as the number of deaths per 100,000 population, was 3.0. The rate has generally been declining, except for sharp increases in 1988 and 1993. The 2003 rate shows a slight decline but is still higher than the 1998 figure of 1.7. The rate is 2.4 times higher than the 1999 Canadian national average of 1.27 (the latest available figure), which is considered high among first world countries.[48]

First Peoples in Canada

To help reduce fire deaths and injuries among First Peoples in Canada, the Assembly of First Nations of Canada, in cooperation with NFPA and the Aboriginal Fire Fighters Association of Canada, obtained funding from the Canada Mortgage and Housing Corporation to develop *The Wisdom of the Fire—Learn Not to Burn®*,[42] an adaptation of NFPA's *Learn Not to Burn Programs* for children of First Peoples in grades K–2. The program's purpose was to blend technical knowledge of fire safety behaviors with First Peoples' cultural teachings and traditions emphasizing the respectful and constructive use of fire. The program teaches 22 key fire safety behaviors. It employs the use and development of thinking skills and action/doing skills. Each activity is marked with a single eagle for activities for students to do alone and a group of eagles for activities for children to do together. They are designated as follows: think it out alone; think it out together; try it out alone; or try it out together.[49]

The program addresses the differences that exist among First Peoples by including blank and completed templates to provide examples of First Peoples' community profiles, positive fire safety behavior, fire safety words for translation into original languages of First Peoples, and First Peoples' legends and teachings about fire. The eagle was selected as a generic symbol to represent the culture of First Peoples.

"Flying high above the earth, the eagle has been given the gifts of farsightedness, strength, and speed; it watches the movement of all creatures and guards the well-being of others."[49] Children using the curriculum are named Junior Fire Eagles to fit within this theme. About 80 new illustrations by a Navajo artist are used to demonstrate the behaviors for the total curriculum and the pre- and postknowledge tests for kindergarten and first grades. In the illustration in Figure 5.5.4, children are instructed to circle the part of the illustration that shows what to do if there is smoke in a room.

Navajo Nation

The Navajo Nation is the largest American Indian nation in the United States and is about the size of the state of West Virginia. It is located in parts of the states of Arizona, New Mexico, and Utah and is divided into 110 governing chapters.

When a manufactured-home fire took the lives of two children and their mother in 1996 in the Navajo Nation, the Navajo Nation Bureau of Indian Affairs Safety Office contacted the NFPA Center for High-Risk Outreach for assistance in establishing a coalition to help reduce fires among the people in the Navajo Nation. The fire was caused by an improperly installed wood stove, a leading cause of home fires on reservations in the winter. About 30 people representing various organizations of the Navajo Nation such as the Navajo Fire Department, the Red Cross, the Indian Health Service, and a Navajo tribe from

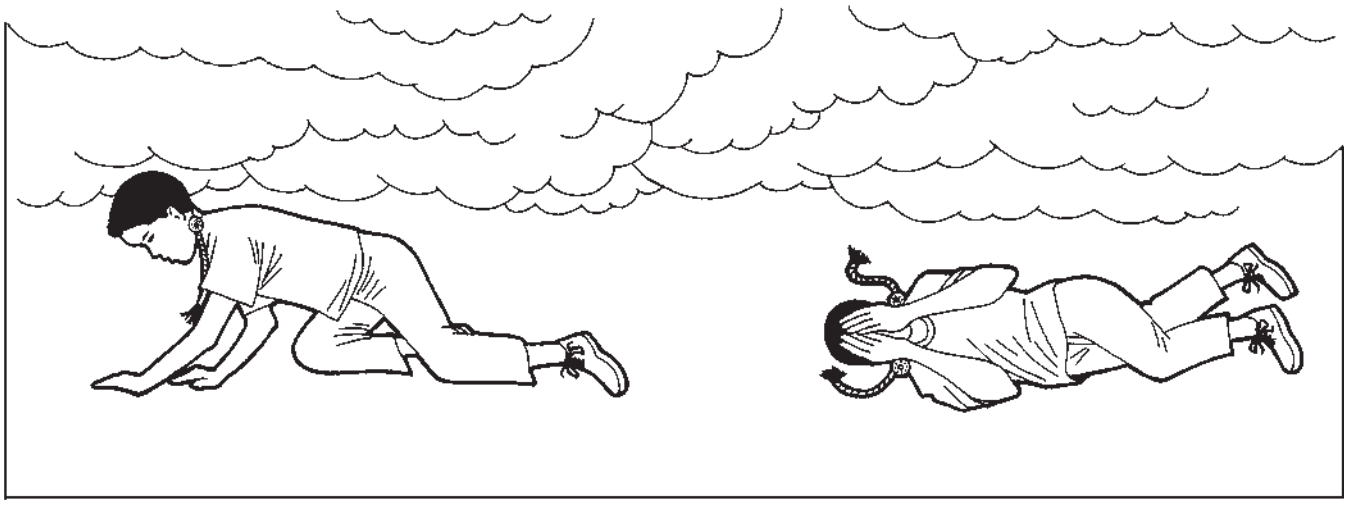

FIGURE 5.5.4 Artwork by Navajo Artist Irving Toddy, Used in the Knowledge Test for the *Wisdom of the Fire—Learn Not to Burn Program*

northern New Mexico and eastern Arizona attended a meeting. At the meeting the group learned that in 1995 there were 93 major home fires that left 400 people homeless in the Navajo Nation. Due to the lack of infrastructure of fire protection services in the Navajo Nation, 82 of the homes involved in these fires were completely destroyed. The group formed the Navajo Nation Fire Safety Coalition and began working on strategies to provide more fire safety programs for the 220,000 residents of the nation.

The coalition supported efforts in cooperation with the NPFA Center for High-Risk Outreach to implement the the *Learn Not to Burn Program.* Ten train-the-trainer sessions were conducted, reaching more than 350 teachers serving 6000 students. In addition the coalition implemented *Risk Watch* and *Remembering When* in selected chapters. In 1997 the Center for High-Risk Outreach conducted focus groups among Navajo people from the five major sections of the Navajo Nation: Eastern Navajo, Fort Defiance, Chinle, Western Navajo, and Shiprock. The purpose was to identify the needs, concerns, and cultural beliefs of the Navajo people and to educate attendees about various fire safety issues relevant to the Navajo Nation. Some recommendations resulting from the focus group included the following:

1. Make personal testimonies an important part of the program. House presentations should encourage people to talk about fire experiences and allow sufficient time for discussions.
2. Use public service announcements on KTNN, the reservation-wide Navajo radio station. Because many people do not have electricity, transistor radios are an important means to receive information.
3. Pair brochures, other written materials, and videos showing nonnative people with other materials depicting Navajos and using the Navajo language in addition to English.[50]

In 2005 with funding from a U.S. federal Fire Act grant, part of the Assistance to Fire Fighter Grant Program of the Department of Homeland Security, the Center for High-Risk Outreach worked in cooperation with the Navajo Nation Fire and Rescue. They trained dozens of trained installers who then installed nearly 10,000 smoke alarms in more than 3000 homes in the Navajo Nation. With the support of another Fire Act grant, the Center for High-Risk Outreach and the Navajo Nation Fire and Rescue planned to install another 8000 alarms in 2006 to 2007.

***First Nations Remembering When*™.** According to the Centers for Disease Control and Prevention (CDC), Native Americans age 65 and older are almost twice as likely to die in a fire than the general population of the same age. In order to address this need in 2005, the Center for High-Risk Outreach obtained funding from the Prevention and Safety Program Grant, part of the Assistance to Firefighter Grant Program of the Department of Homeland Security and the Office of Domestic Preparedness, to develop the *First Nations Remembering When* program to reach Native Americans age 65 and older. The program is an adaptation of *Remembering When: A Fire and Fall Prevention Program for Older Adults.*[51]

NFPA worked with a creative group that included fire department members, senior center directors, and older adults from the Navajo and Hopi tribes of New Mexico and Arizona, as well as the Fond du Lac Band of Lake Superior Chippewa to complete the *First Nations Remembering When* program for elderly people in tribes in the United States and Canada. The adaptation features Native American older adults from the various tribes demonstrating safety behaviors. Navajo artist Irving Toddy designed a logo and humor cards. The First Nations logo that Toddy created shows faces of elderly people woven together. The colors in the logo represent life, water/air, earth, and plants and when shown together signify the environment or the balance of man and mother earth.

The program includes several hands-on activities, checklists, and reproducible handouts. It also includes new reminder

sheets on wood stove and propane safety. An "Our History, Our People" trivia game highlights the history and accomplishments of First Nations people. The questions are coupled with safety questions aimed at reviewing the 16 key fire and fall prevention messages that form the basis of the program (Figure 5.5.5).

The program is implemented through the Indian Health Service, tribal senior centers, places of worship, community health representatives, fire service personnel, and educators.[51]

FIRE SAFETY FOR PEOPLE WITH DISABILITIES

According to a report released by the U.S. Census Bureau entitled "Americans with Disabilities: 2002," about 18 percent of Americans in 2002 said that they had a disability and 12 percent had a severe disability. That is approximately 51.2 million people who said they had a disability and 32.5 million who had a severe disability.[52] Persons have disabilities if they have difficulty performing a specific activity such as seeing, hearing, bathing, or doing light housework or had a specified condition such as Alzheimer's disease or autism. People are considered to have a severe disability if they are completely unable to perform one or more of these tasks or activities, need personal assistance, or have one of the severe conditions described in the report.[52]

People with disabilities also are much more likely to live in poverty than the general population. Median earnings for people with no disability are $25,000. The median income for people with a nonsevere disability is $22,000 and $12,800 for those with a severe disability.[52]

There are about 230 civilian deaths per year related to physical disability. Two-thirds of these deaths are to people age 65 and older.[53]

A person with a disability can be at greater risk to dying in a fire because it may be harder for the person to escape a fire. Or when a person is injured in a fire the particular disability the person may have may make him or her more likely to die from the injuries than the general population.

Since 1999 there has been a growing interest by the fire service for the issues of people with disabilities. In one of the NFPA Center for High-Risk Outreach free give-a-way programs fire departments and other organizations were required to fill out an application for a free version of the *Remembering When* older adults program. The form asked, "What new programs should NFPA develop?" One of the most frequent answers to this question was "develop fire safety education programs that fire departments could use to serve people with disabilities in their communities."

In the same time frame, the need to address the fire safety needs of people with disabilities came up in two symposiums entitled Solutions 2000 and Beyond Solutions 2000 that were organized in collaboration with the North American Coalition for Fire and Life Safety. These symposiums, held in 1999[54] and in 2001,[55] addressed the education, engineering, and enforcement needs of those who may not be able to take lifesaving action in a timely manner in the event of a fire, specifically young children, older adults, and people with disabilities. Leaders attending the symposiums who expressed the most dismay at there not being enough relevant programs were the group representatives of people with disabilities.

FIGURE 5.5.5 "Wear Safe Shoes" Fall Prevention Message from *First Nations Remembering When*™

To develop an action plan from the two symposiums, the Center for High-Risk Outreach and Oklahoma State University Fire Protection publications created the Fire Safety for People with Disabilities Task Force. In meetings held by the task force during 2002 to 2005 an action plan was developed, existing educational brochures and curriculum were reviewed with recommendations for inclusion and appropriateness for people with disabilities, education speaker sessions were conducted at NFPA World Safety Conferences, and new materials were developed to meet the needs of people with disabilities.

Among the criteria for public fire safety educators were the following:

1. Make materials accessible to all audiences both in format and design. Provide materials in alternate formats, such as Braille, audiocassette, interactive tactile (charts, games, props), music, close captioning, and so forth.
2. Make programs diverse and make art, content, and format sensitive to all areas of diversity, including socioeconomic status, ability, culture, and living situation. Include messages and pictures of people with disabilities integrated into general fire safety brochures addressing all people.
3. Make materials understandable. Illustrate what to do in photos or illustrations and use simple language. Provide explanations of pictures for people who are blind.
4. Make sure that information is not only technically accurate but also reflective of a variety of living situations.
5. Make materials compelling. Design and action should be practical and be convincing enough to motivate action.
6. Include experts in a variety of disabilities in all stages of the design and review of all materials.[56]

New materials that were developed on the recommendation of the task force included the "Fire Safety for People with Disabilities"[57] brochure (Figure 5.5.6) that gives tips on home fire safety and the "Workplace Safety for People with Disabilities"[58] information handout that gives both employers and employees with disabilities advice on escape planning in the workplace.

FIGURE 5.5.6 Representative Illustration from "Workplace Safety for People with Disabilities" (Illustrations by L. S. Pierce. © National Fire Protection Association)

Other successful fire and life safety education programs and materials that have been created for people with disabilities are described next.

Fire Prevention Program for Adults with Developmental Disabilities

Stacy F. Everson, executive director, Seeds Educational Services, worked with the University of Oklahoma Fire Protection Publications to develop a fire safety education program, *How to Be Fire Safe,*[59] for adults with developmental disabilities who live on their own. "There was a great need to create a fire safety curriculum that treats adults with developmental disabilities with dignity, respect, and provides correct information," explained Ms. Everson. "Understanding how people with developmental disabilities learn but not treating adults like children was crucial for communicating fire safety information to this audience."[60] Seeds hired a consultant with development disabilities to assist in a focus group to create the curriculum. The curriculum was then pilot-tested in California, Minnesota, and North Dakota. The program consists of a curriculum, a teacher's manual, a fire safety poster, and a fire assessment.

Content of the program includes smoke alarm maintenance and home escape planning. The poster that can be posted on the home refrigerator reinforces the material that has been taught through classrooms and individual home presentations. The curriculum has multiple pictures that enhance the presentations.

Presentations are given primarily through instructors of people with disabilities who understand people with disabilities. The curriculum requires four weeks to deliver. Three weeks of classroom instruction and one lesson right in the home are recommended. "My students don't generalize information; they need concrete in-the-home training," said Everson.[59]

There is a pretest and posttest assessment to gauge learning. A party is provided for participants at completion and graduation from the program.

Smoke Alarm Installation and Public Education Programs

People with disabilities may need smoke alarms with special features to ensure that they have early warning to escape a fire. People who are deaf or hard of hearing will often need to have smoke alarms with flashing lights to warn them. Generally, smoke alarms with flashing lights cost 5 to 10 times more than other smoke alarms. Communities that are conducting general smoke alarm programs will need to provide for those who will not be able to hear the regular alarms. Indeed, some smoke alarm programs have prioritized and focused their alarm installation programs on people who are deaf.

In 2004–2005 the Massachusetts Office of the State Fire Marshal in partnership with the Massachusetts Commission for the Deaf and Hard of Hearing (MCDHH) and the Massachusetts Department of Public Health (MDPH) secured a Fire Act grant to provide smoke alarms and fire safety education to people who are deaf or hard of hearing living in western Massachusetts. The Office of the Fire Marshal hosted a series of eight community meetings presenting general fire safety and instructions on how to install the detectors with strobe lights. The local partners provided applications for the detectors, liability waivers, gave out the smoke alarms, and arranged for a follow-up visit to check that the alarms were installed correctly and to instruct residents on how to test them.

A variety of communication methods were used in presentations to the audience. Presentations were delivered with assistance from both American Sign Language interpreters, certified deaf interpreters, and CART (Communication Access Real Time) readers.[61] CART interpreters type what is being said just like court stenographers and the text is projected onto a screen as for television except the interpreters also try to convey emotion, such as laughter. A PowerPoint presentation was designed with input from the Massachusetts Commission for the Deaf and Hard of Hearing for low English literacy that used many pictures. The project organizers also invited local fire department public education officers to the presentations in order to introduce them to people who are deaf and living in the towns they served.

There were 2300 alarms distributed to agencies and groups for installation. Data were received for 869 alarms installed in 428 homes.

Another smoke alarm installation program was sponsored by Fire Protection Publications and Oklahoma ABLE Tech, both at Oklahoma State University, entitled *Fire Safety Solutions for Oklahomans with Disabilities.*[62] This program provided installation of free smoke alarms not only for Oklahomans who are deaf or hard of hearing but also people who are blind or have low vision and people with mobility disabilities. Two types of alarms were used for this program: one using a strobe light and bed shaker for people who are deaf or hard of hearing and the other using a smoke alarm with a 10-year lithium battery that can be tested by using a television remote control for people with vision or mobility disabilities.

Installers also gave out several sets of educational handouts in large print on escape planning and prevention, tailored for people who have mobility impairments, persons who are hard of hearing, persons who are deaf, and persons who are blind or have low vision. The installers spent 1–2 hours in the home installing the alarm, helping draw up the escape plan, and reviewing the fire safety messages. The smoke alarm installation program reached people in 66 of Oklahoma's 77 counties.[63]

Other resources developed in this program included *Fire Safety for You at Home,*[64] an educational DVD in American Sign Language, and *Social Etiquette: For Fire Fighters Who Work with People with Disabilities,*[65] to help fire fighters better interact with people with disabilities. All these resources are available from Oklahoma State University, http://www.ifsta.org.

Fire Safety Programs for Children with Disabilities

Riley Hospital for Children has developed several programs to assist children with disabilities. With initial funding from the Department of Homeland Security, Assistance to Fire Fighters, Fire Prevention and Safety Grant, a hospital-based safety store and safe escape product distribution program was developed to ensure that children with disabilities or special health

care needs will escape safely in the event of a fire. During 2005, 700 families were provided adaptive fire safety products and education. Some of the fire safety items included smoke alarms with strobe lights and bed shakers, portable stretchers with hand grips to drag a child with mobility disabilities out in a fire, and fire-smothering blankets. Families with children with disabilities who visited the safety store got the free adapted fire safety products and fire safety education. Riley Hospital also provides free brochures and posters for parents of children with disabilities. In the poster and materials the message of "Stop, Lock, and Roll" is used for children in wheelchairs instead of "Stop, Drop, and Roll" for reaction to clothing fires.[66]

All communities have people of all ages with disabilities. If fire safety educators don't see them at presentations that they give it may very well be that the presentations have not been made accessible. The more that the fire service makes presentation forums accessible and that materials are provided in accessible formats the more likely that persons of all abilities will become involved and will become recipients of important fire and life safety messages.

HOME SECURITY AND FIRE SAFETY

People can become at high risk for fire as an inadvertent side effect of actions taken in good faith in response to other problems considered in isolation. An emerging example has been the elevated fire risk arising from certain steps taken for home security. One example is entrapment caused by bars on windows and doors installed to keep out intruders.

It is hard to measure the exact numbers of deaths and injuries that occur as a result of exits blocked by bars on windows and doors. Those observing the home security industry believe that more and more people are blocking themselves in their homes with bars or other measures, such as nailing windows shut or even blocking doors and windows with plywood or furniture. For example, four children perished in a fire in 1997 in Tampa, Florida; a family of five died in a fire in Bessemer, Alabama; and in East Palo Alto, California, nine people were killed in a fire. In 2002, an Alabama fire killed two adults and a 5-year-old. The same year, a Georgia fire killed three adults.[67] The Home Security and Fire Safety Task Force of the NFPA Center for High-Risk Outreach has worked on this issue since 1993, focusing on engineering, education, and enforcement approaches. The following are some of the key messages:

- Make sure windows open easily and fully enough to allow escape.
- Make sure all security-barred windows needed for escape have emergency-release devices and that everyone can open them (Figure 5.5.7).
- Make sure locked or barred doors operate quickly and easily and that everyone knows how to open them.
- Practice exit drills in the home and use them to identify and correct obstructions of doors and windows needed for escape.
- Have working smoke alarms on each level of the house and outside of every sleeping area.[68]

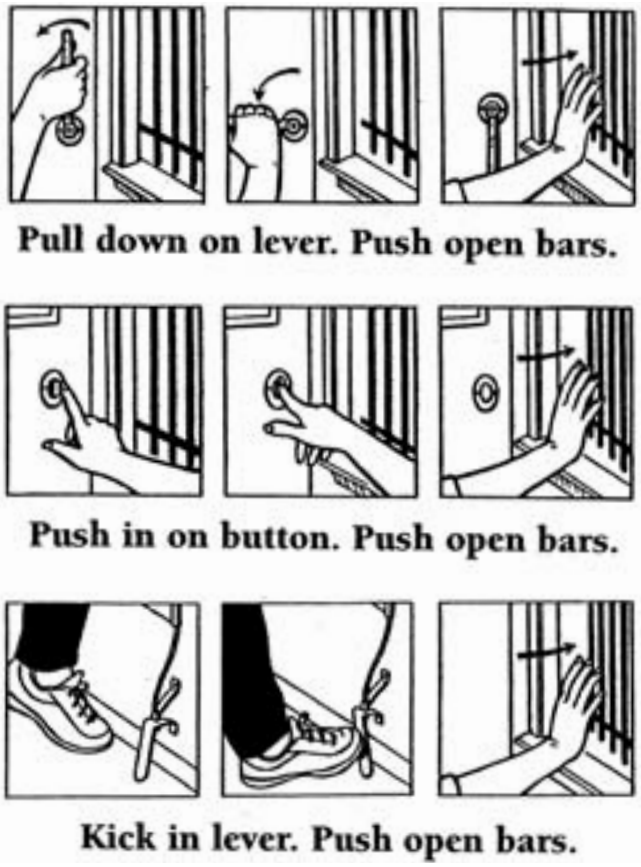

FIGURE 5.5.7 Types of Emergency Release Devices (Source: Exhibit S6.2, *Life Safety Code® Handbook,* 2006 ed.; illustrations by L. S. Pierce. © National Fire Protection Association)

Several cities have formed coalitions to provide retrofitting of security bars with emergency-release devices and community educational programs on fire safety and home security. One of the most comprehensive local programs was organized by Steve Kastner, fire marshal for the city of Ft. Lauderdale, Florida. This program was initiated by the combined Fire-Rescue and the Building Departments. The program was composed of public education, financial assistance, and enforcement. The department received $108,000 from a federal Community Development Block Grant to pay for the cost of retrofitting one window per bedroom of homes with security bars on the windows. Those grants were available to owner-occupied, single-family homes or duplexes for owners with low and moderate incomes. The Fire and Building Department identified a quality contractor to work for the city to retrofit the windows with bars.[69]

Community inspectors did sidewalk surveys to identify properties that had bars on windows. Building inspectors later visited properties and issued notices of violation. Property owners were given 30 days to initiate action. Since the program's inception in 1997, over 800 properties were cited. Of these, 80 percent went before the Code Enforcement Board and 50 percent had complied by May 2001.[69]

The education component of this program included the development of an informational brochure on security-bar hazards and code requirements and how to access financial assistance. This brochure was distributed to homeowner groups and civic associations. Presentations were also given to civic associations, targeted neighborhoods, and the city commission. In order for this program to succeed, the following internal and community partnerships were needed: the mayor, city commissioner, city manager, fire chief, fire marshal, building official, Council of Civic Associations, individual civic associations, homeowner associations, community service and action organizations, and other city agencies.[44]

In June 2005 the Home Security and Fire Safety Task Force decided to address the problem of other barriers to safe escape in the home. Some of those barriers included doors and windows painted or nailed shut, clutter, furniture, or appliances blocking doors or windows, plywood over windows, and hurricane shutters left in place after a hurricane is over. A new free literature piece titled "Clear Your Escape Routes!" was made available on NFPA's website.[70]

NATIONAL PROGRAMS IN THE UNITED STATES

National Center for Injury Prevention and Control (NCIPC) Smoke Alarm Programs

One of the best ways that communities can reduce fire deaths and injuries in high-risk communities is by implementing smoke alarm programs. Homes with smoke alarms typically have death rates about 40 to 50 percent less than the rate for homes without alarms.[29]

To reduce deaths in high-risk communities, the National Center for Injury Prevention and Control (NCIPC) of the Centers for Disease Control and Prevention (CDC) funds 18 states through three 5-year cooperative agreements with the state health departments to provide fire injury prevention programs. These programs provide installation of smoke alarms and education on fire safety and escape plans. Each state focuses on communities within their state that have fire incidence rates above the state average and mean household income below the poverty line. The state health department staff provides oversight and technical assistance to the local program officials and fosters partnerships between local communities and fire safety personnel. From October 1998 to December 2005, more than 382,000 homes have been canvassed through the program; 275,000 smoke alarms have been installed in 157,000 high-risk homes.[71]

Successful techniques learned in the CDC projects include the following:

- Partnering with local fire departments in the community (both paid and volunteer)
- Partnering with community-based organizations to assist in canvassing homes
- Getting support from community leaders
- Being flexible in the hours and days of the week that canvassing activities are conducted
- Advertising the program through all available media

National Fire Academy Class

Several organizations have recognized the need to reach those most vulnerable to fire and burns. In 2000, the United States Fire Administration in cooperation with the NFPA Center for High-Risk Outreach developed a new 2-week National Fire Academy Class, *Discovering the Road to High-Risk Audiences.*[47] The course takes an in-depth focus on topics that include the impact of social and economic diversity on the fire problem, fire and life safety for people challenged with disabilities, the aging process and fire risk, and the effect of fire on very young children.[72]

The class is designed for personnel who have responsibility for public fire and life safety education in their fire departments and who have more than 1 year in this functional area. The class discusses what factors make the audience vulnerable, ways to reach each group, and how to plan programs for them. Both the urban and rural audiences are woven into the course material. It uses evaluation methods such as small group learning exercises and case studies.

In 2006 the National Fire Academy added a new class titled *The Changing American Family at Risk.* It emphasizes the importance of and methods for reaching America's families to protect them from fire. The content includes the changing family structure in America, the means and methods of reaching families on the hazards of fire, and the relationship between the American family and fire risk.[73]

INTERNATIONAL PROGRAMS

Many innovative fire safety education programs are occurring outside North America in both developed and developing countries. Leaders of these programs have also found the importance of targeting their high-risk populations. A description of two of the initiatives follows.

South Africa

Factors that exist in South Africa that make people at greater risk include the use of paraffin (kerosene) for cooking and lighting, large number of security bars on windows and doors because of a high crime rate, poor housing construction, lack of fire-safe construction, and poverty. In the past the City of Johannesburg Emergency Management Services fire safety education program for children consisted of demonstrating fire safety skills to children by showing them how the fire department extinguished a fire.[74]

To provide a more successful delivery of fire and injury prevention education in the city, a public education division was developed for the Emergency Management Services. Several programs are conducted by the public education division, including the *Learn Not to Burn Preschool Program* and *Risk Watch*. Community Emergency Response Teams (C.E.R.T.) were developed to provide fire safety skills as well as to provide instruction on how to extinguish a fire in its earliest stage to people who live in informal settlements with a high incidence of fires.

In 2005 various injury prevention and health organizations formed the National Burn Prevention Reference Group to work

with NFPA to produce a South African version of the *LNTB Preschool Program.* The group adapted the eight fire safety behaviors for South African children and is working to make the program culturally appropriate for South Africa.[75]

For more information on the programs of South Africa, see Section 5, Chapter 2, "Fire and Life Safety Education Messages."

Australia

The 1991 census indicated that there were more than 2.7 million people (17.4%) age 5 and older in Australia whose first language spoken at home was other than English. In the state of Victoria, 22.6 percent of the population fell into this category; in the city of Melbourne in Victoria, 28.8 percent were in this category.[50] Fire departments have used a variety of strategies to reach this segment of the population, including translations of printed materials, advertisements, involvement in wider programs sponsored by other organizations, lectures, and use of radio stations targeted to ethnic audiences.[76]

One unique program implemented jointly by the Melbourne Fire Brigade and the Adult Migration Education Services in Victoria is *Flames—Better English Through Fire Safety Program. Flames* is a collection of activities that a teacher can integrate as a subtheme into a broader course in English as a second language. The materials are divided into levels of proficiency and focus on the themes of smoke alarms, escape from fire, fire hazards and prevention, and calling the fire brigade. Some of the materials used in the program are an audiotape with scripts, student work sheets, a reader, a quiz, and a board game.[51]

A fire fighter visit highlights the program. Fire fighters have been given preparation on how to talk to adults who are learning English as well as information about students' levels of English.[77]

SUMMARY

Many mainstream fire and life safety education programs fail to reach those who are at greatest risk. Programs implemented among the general population do not automatically trickle down to those at most risk—preschool children, older adults, the disadvantaged, and those who speak languages foreign to the country in which they are living.

This chapter presented characteristics of the various high-risk groups that put them at high risk to fire and provided samples of programs and strategies to reach those groups. It pointed out societal trends and demographic changes that help to anticipate new needs as communities grow or change. The chapter emphasized not only educational solutions but also samples of engineering and legislative changes that will make the total outreach program more successful.

arson, Dynamic-Behavioral Theory, fireplay, firesetting, Juvenile Firesetter Intervention Specialist (JFIS), public fire and life safety education

The fire service has known that children are accountable for many fires. In a small city in northern Pennsylvania, a presentation was being made on children and fire. The fire chief wanted to highlight their local fire museum and escorted a group to take a tour. On entering the museum, a fire department run-log from the late 1800s was displayed on a pedestal under a glass cover. The log was open to a handwritten entry describing a house fire with extensive damage. The cause was listed as "children playing with matches."

Prior to the mid-1970s, there were few, if any, programs or even concepts on how to change the behavior of children playing with matches. Some in the fire community took the view that "kids will be kids," treating firesetting by children as a normal and harmless stage of development. On the other end of the spectrum were those who believed that children who misused fire were psychologically disturbed. This view saw juvenile firesetting as neither normal nor harmless but still as unpreventable. Both views left the fire community with no effective intervention other than effective fire fighting.

The mid-1970s brought about major change. The fire service began working with mental health professionals to better understand firesetting behavior and evolve more effective intervention and prevention strategies. The past 25 to 30 years have brought about a much greater understanding of young people's misuse of fire and what can be done to prevent and minimize further incidents. This chapter highlights many of these findings and procedures that the fire service can implement to reduce fire incidents involving young people.

See also Section 5, Chapter 1, "Principles and Techniques of Fire and Life Safety Education."

TERMINOLOGY

An important aspect of understanding children and fire is being familiar with the language frequently used to describe this behavior. Different words and phrases are employed depending on perspective and position. Discussions on the standardization of terminology are currently ongoing among fire professionals and others involved in addressing this concern. Common use of terms would facilitate more precise statistics describing the magnitude of the problem as well as directing appropriate prevention and intervention strategies.

The primary distinction in labeling behavior is intent. Children who do not understand the consequences of their use and have no specific intent of starting a fire traditionally have had this behavior referred to as "fireplay." The terms *accidental* or *unintentional* have also been used to describe this behavior.

These terms have become quite controversial. Associating the concept of play with children's use of fire has raised concerns. Play is a positive aspect of child development and many have questioned whether using the term *fireplay* minimizes the risk and normalizes the behavior.

The term *accidental* formally implies a behavior or incident that could not be avoided or prevented. This notion when applied to children's use of fire also raises concerns because these incidents are not truly accidental. In fact, it is argued that almost no fire cause is "accidental." Enhanced supervision or storage of ignition materials can usually prevent these incidents. Advocates

Paul Schwartzman is a nationally certified psychotherapist with over 25 years' experience working with children and families. In 1981, while on staff at the University of Rochester, he and his colleagues in cooperation with the City of Rochester Fire Department began doing research on children and fire. This research led to the development of a model Juvenile Firesetter Program. He has a private counseling practice and consulting service in Rochester, New York.

of these perspectives prefer the terms *fire experimentation* or *fire starting,* believing that this phrase is more accurate and better describes the intent. Critics of these alternative terms, however, argue that *experimentation* and *starting* imply more conscious intent, deliberation, and knowledge than are typically present. So far, the search for a phrase free of misleading connotations has been unsuccessful.

The label of *firesetting* implies a deliberate effort to start a fire. The term *firesetting* is often associated with arson. *Arson* is a legal term that implies a deliberate intent to cause damage or injury. Similar to the concern involving the term *fireplay,* arson or firesetting carries an ominous tone and raises objections. Some feel that the use of these terms causes avoidance of the issue because of the stigma attached to these terms. Fire fighters are resistant to labeling a young child a firesetter or arsonist. In many jurisdictions, the legal age of accountability precludes young people from being charged and the terms are not applied.

Common terminology can go a long way to clarify and facilitate better responses to the problem of children and fire. It is not the intent of this chapter to establish a standard terminology. Doing so will require more dialogue among the various organizations to come to consensus. The terminology used in this chapter will echo common terms currently used in report forms and among fire service officers and line fire fighters.

MAGNITUDE OF THE PROBLEM

Based on fires reported to U.S. fire departments in 2002, there were 13,900 structure fires attributed to children playing with fire the latest year for which data were available. Children's fireplay resulted in 210 civilian deaths, 1250 civilian injuries, and $339 million dollars in direct property loss.[1]

Although this will be further explored later in this chapter, it is clear that a significant portion of fires involving young people goes beyond "child-playing" and is more intentional. Incendiary fires that are intentional can be considered arson. The Federal Bureau of Investigation (FBI) Uniform Crime Report for 2002 indicated that 51 percent of arson arrests were children under the age of 18, the ninth straight year that the juvenile share has been 50 percent or more. One-third of juveniles arrested for arson were under 15, and 3 percent were younger than 10[2] (Figure 5.6.1).

In 2002, 68,245 incendiary fires reported to U.S. fire departments resulted in an estimated 630 civilian deaths, 2030 fire injuries, and $1.9 billion in direct property loss. If half of these incidents and losses are assigned to juveniles, it means that 34,000 fires can be attributed to juvenile incendiarism, as can a death toll comparable to that for child-playing fires.

This does not include the many fires that never come to the attention of the fire service. Past studies have estimated unreported fires at 10 to 20 times the number of reported fires, although most are small cooking fires. Changes in the way that fires are reported and coded in the National Fire Incident Reporting System may also contribute to variations in the number of incidents. Putting the juvenile share (51%) of 2002 arson arrests together with the estimated total number of reported U.S. fires due to incendiary or suspicious causes, and then adding

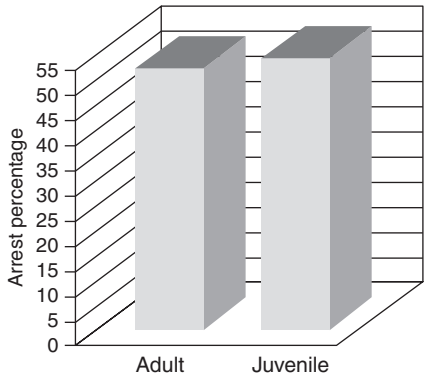

FIGURE 5.6.1 Juveniles Arrested for Arson as a Percentage of All Arrests, According to FBI Statistics

in the 2002 child-playing fires, the estimated total of reported fires started by children in 2002 is at least 50,000 fires, 545 civilian deaths, 2212 civilian injuries, and $1 billion in direct property loss. Precise numbers will remain elusive, but it is clear that juvenile firesetting remains a significant and dangerous problem.

The good news is that the total number of such fires and associated losses have consistently plunged since 1994. Mental health professionals assessing the problem of children and fire believe that a significant proportion of this reduction is due to the efforts of the fire service systematically addressing juvenile firesetting along with the introduction of a child-resistant requirement for lighters by the U.S. Consumer Product Safety Commission.

CHARACTERISTICS OF CHILDREN INVOLVED IN FIRESETTING BEHAVIOR

Age

In Rochester, New York, the city fire department tracked fire incidents over a nine-year period to determine youth involvement. The study identified children from 18 months to 18 years of age who had been involved in an incident that required a fire department response. The majority of fire incidents involved youth between the ages of 4 and 9 years.[3,4] Additional studies in other cities that systematically respond to fires with youth involvement have paralleled these numbers.

Preschool children under age 6 are disproportionately likely to be killed in child-set fires, accounting for more than 66 percent of deaths in child-playing home fires and about 15 percent of deaths in incendiary or suspicious fires, while accounting for only 9 percent of the population. Fireplay remained the leading cause of fire deaths among preschoolers. It is often not the children who were playing with fire who die. Very often it was a sibling or playmate. Most of the people killed by child-playing fires are under age 6.

The above-mentioned Rochester studies further determined that a third of youth involved in fire incidents were between 10

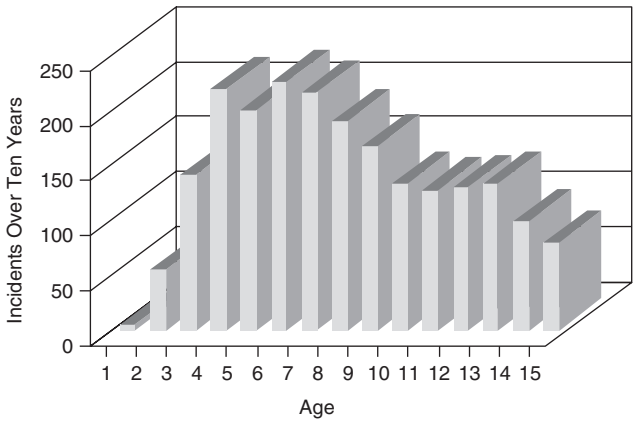

FIGURE 5.6.2 Age of Children Involved in Actual Fires, According to the Rochester Study

and 17 years of age, with 98 percent of these being under age 15 (Figure 5.6.2).

Gender

Firesetting is predominantly a male behavior. Studies tracking youth involved in fire incidents consistently report that young people who come to the attention of the fire service average 85 percent male and 15 percent female. This closely matches the gender breakdown for arson arrestees of all ages. Males tend to be more highly represented in risk-taking and acting-out behaviors of all kinds.

Interestingly, a developmental study[5] of school-age children looking at behavior with fire found a higher percentage of females. Children in grades 1 through 8 were asked if they ever experimented with fire. In this group, the male to female ratio was 2:1. Therefore, on comparing young people who come to the attention of the fire service because of a fire concern with a general population of school children who have not come to the attention of the fire service, the percentage of female involvement more than doubled (from 15 percent to 33 percent). When asked how they used fire, females stated that they lit matches and lighters, whereas males tended to use such implements to ignite other things, making their experimentation riskier and perhaps more detectable.

Family Type

Firesetting occurs in all family types but is somewhat overrepresented among single-parent households, as is the fire incidence in general. This is believed to be more a factor of increased stress and decreased time for supervision rather than family structure.

Socioeconomic Status

Poverty is highly correlated with firesetting. In a longitudinal study examining children who came to the attention of the fire department,[3] over 90 percent were found to be on a free or reduced lunch plan in school compared to 35 percent in the district as a whole. This indicates that the family falls below the poverty line. Families living in poverty typically have more difficulty providing structure, appropriate supervision, and effective parenting due to household chaos and chronic stress, evidenced by relationship discord and unemployment. Families in poverty typically have less education and are, therefore, less likely to possess the awareness and judgment to provide a safe environment. The same lack of effective supervision that makes ignition more likely also makes it more likely that fires will grow large enough to require fire department intervention and become reported fires. The inability of a poor household to readily absorb fire damage as a result of poor construction and high housing density may also make it more likely that their fires will come to the attention of the fire department.

Race and Ethnicity

Race and ethnicity are not associated with firesetting behavior, although they appear to be in studies that do not adjust for correlated socioeconomic conditions, such as poverty. Children are represented proportionately to the presence of their race or ethnicity in the general population.

MOTIVATION FOR FIRESETTING BEHAVIOR

Fire fascinates us all. Its power, beauty, and functionality parallel few entities existing on our planet. It is, therefore, natural that people of all ages express curiosity about fire. However, for young people with limited skills and understanding, turning curiosity into fire play can be deadly. Young people are motivated to use fire for various reasons. This section will present the underlying philosophy of how firesetting behavior develops and describe profiles describing different motivations or goals.

Dynamic-Behavioral Theory

At the outset of this chapter, it was mentioned that collaboration between the fire service and mental health community during the mid-1970s brought about new understanding. One of the major outgrowths of this collaboration resulted in a conceptual framework designed to explain firesetting behavior. This framework, known as the Dynamic-Behavioral Theory, was developed primarily by Dr. Kenneth Fineman, a clinical psychologist working closely with the Los Angeles County Fire Service and the United States Fire Administration.

The Dynamic-Behavioral Theory views firesetting as an interaction among the individual, the family, social circumstances, and immediate environmental conditions. The major contribution of this theory is that characteristics of firesetting youngsters can be organized and classified by using this conceptual framework and observed and measured. The Dynamic-Behavioral Model is an additive factor model. Models similar to this model have been used in all kinds of injury control studies and have wide acceptance.

Individual characteristics consist of demographic, physical, emotional, motivational, and psychiatric descriptors. Social

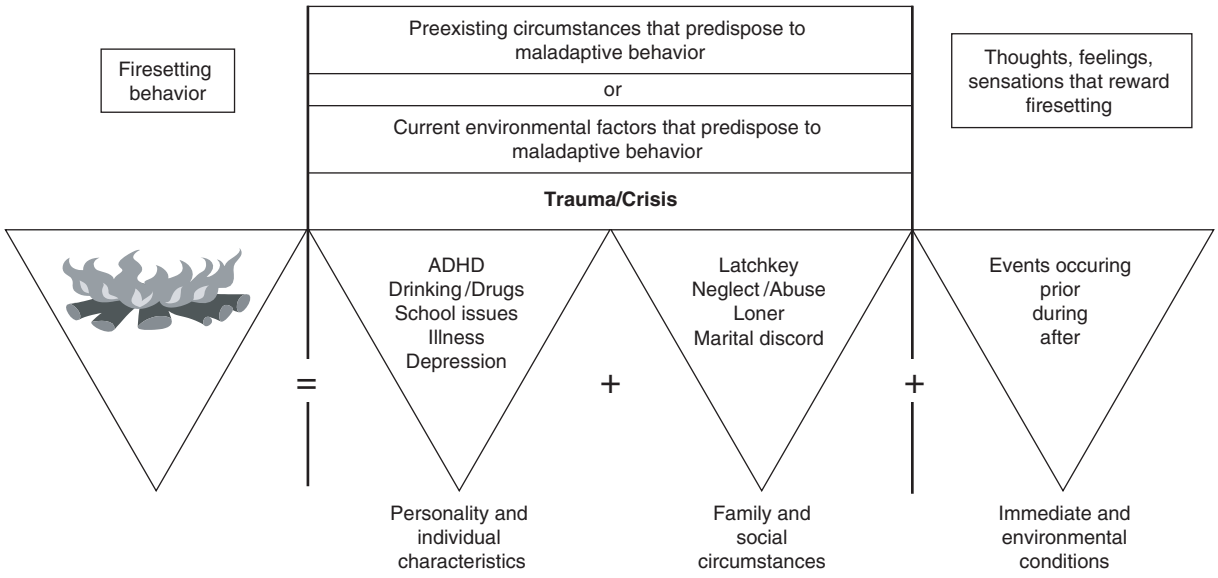

FIGURE 5.6.3 The Dynamic-Behavioral Model (Source: Paul Schwartzman and Ken Fineman)

circumstances are composed of family, peer, and social descriptors. Environmental conditions refer to events occurring immediately prior, during, and after firesetting. These variables interact to produce firesetting or increase the risk of firesetting. Figure 5.6.3 illustrates the sequence of how these dimensions may evolve to produce firesetting behavior.

Types of Firesetters

Many "types" of firesetters are listed in the literature concerning firesetting behavior. Researchers have categorized firesetters by focusing on a variety of personality and other factors, which specify a quality of the personality of firesetters and of their previously set fires. Any attempt to categorize the firesetter should serve the pragmatic purpose of helping describe the firesetter's risk level for future fire-related dangerous behavior and help guide prevention and intervention efforts. Dangerous in terms of firesetting are behaviors that destroy property or do physical and/or emotional harm. Another concern is the probability that the juvenile will set more fires.

It is important to understand that these categories are not exclusive. In fact, a firesetter may have multiple motives for his or her behavior. The following firesetter types focus on the firesetter's psychological state or diagnostic category, what is set on fire, or whether the fire is set as a function of the firesetter's need to bring attention to himself or herself or the need to use fire to direct attention elsewhere.

Curiosity Type. The most common profile describes children who act primarily out of curiosity and do not developmentally understand the consequences of their behavior. The few studies[3,4,6–8] that have examined representative samples of children converge on this point. The majority of children who start fires do so out of experimentation and may not have other psychological problems. Children motivated exclusively by curiosity tend to be young, primarily between 5 and 10 years of age, and to be involved in only one reported fire incident.

Although this curiosity-driven fire play is apparently not pathological, it is nevertheless potentially dangerous and a concern. Individual, family, and environmental factors predict whether children engage in fire play and serve as guides to preventive intervention. Access to ignition materials, momentary lapses in supervision, the perception that they would not be disciplined if they were caught playing with fire, and premature exposure to and responsibility for activities involving fire are all associated with curiosity fire play.[5] Children also often have an unrealistic sense of their ability to control a small fire. Teenagers trying to conduct science experiments could fall into this group.

Case Example. Jonathan, age 9, lives with his mother and father in a single-family house. One evening at about 7 p.m., Jonathan was in his bedroom while his parents were downstairs watching television. Jonathan's mother smokes and had left her cigarette lighter on the dresser in her bedroom. Jonathan saw the lighter on the dresser and took it into his room. He lit the cigarette lighter and touched the flame to some school papers he had piled in his room. The papers quickly ignited and Jonathan became frightened and dropped the papers on the floor near his bed. The flame spread to the bedding. Jonathan slapped at the flames with a nearby blanket and yelled for his father. Fortunately, Jonathan was able to put the fire out but not before singeing the bedding. His father arrived dismayed but glad that Jonathan was not injured and that there was no further damage. Jonathan was very remorseful and frightened. He was crying and apologetic and insisted that he did not mean to start a fire.

Cry-for-Help Type. The cry-for-help type includes children of all ages. These juveniles consciously or subconsciously wish to bring attention to an intolerable life stress, for example, a

personal problem such as feelings of depression or anger. It could also be associated with an interpersonal concern such as family stress and dysfunction, stressful life events, separation and divorce, and remarriage. This type of firesetting is more likely to continue without intervention. Physical and sexual abuse and chronic neglect are frequently associated with recidivism.[3,4,6–8]

Case Example. Mark, age 12, lived with his mother and stepfather. Mark had a younger brother, age 10, who was the birth child of his mother and stepfather. Mark frequently felt left out and believed that his stepfather treated him more harshly than his brother. Mark and his brother would argue frequently. During an argument, Mark's father became extremely angry and grabbed Mark and pushed him across the room, telling him that he would have to go live elsewhere if he did not stop fighting with his brother. Mark strongly felt that his brother was as responsible as he for these arguments, but his stepfather would not acknowledge this possibility and kept blaming Mark, claiming that he was older and knew better. Mark was sent to his room for the rest of the day. Shortly thereafter, a neighbor reported seeing smoke coming from the eaves outside of Mark's bedroom window and called the fire department.

Delinquent Type. The delinquent type usually involves adolescents between the ages of 11 and 15. Typically their firesetting is part of a larger constellation of conduct and aggression problems. This behavior most often occurs with other juveniles. An interest in vandalism and hate crimes is noteworthy. As juveniles manifesting this type, though frequently showing little empathy for others and little conscience, they usually avoid harming others with fire. Significant property damage is common. In this group, firesetting behavior is more easily extinguished than other personality and behavioral problems that usually accompany the firesetting.[3,4,6–8]

Case Example. Seven youths under the age of 18 began setting fires in dumpsters, then graduated to setting them in automobiles and vacant buildings. In March 1996, members of this group set a fire in an illegal tire dump beneath an interstate highway, resulting in damages estimated at $8 million to the overpasses. Commuter and interstate traffic was disrupted during the incident and for months during the repair. Various members of this group are linked to intentionally set fires in 18 vacant buildings in the same area.

Severely Disturbed Type. The severely disturbed type—the rarest type—includes young people who are suffering from serious mental health problems that may include paranoid and psychotic symptoms. Often, the firesetting may be reinforced because it creates a profound sense of elation or sensory reinforcement. Sensory reinforcement describes those for whom the sensory aspects of the fire are sufficiently reinforcing to cause fires to be frequently set. The reinforcement histories of many suggest an early fixation on fire. A subgroup of this type is the "self-harm" type, whose members use fire to harm or kill themselves. Prognosis is guarded with this severely disturbed group.[3,4,6–8]

Case Example. Lenny, age 7, was subdued by his parent after he attempted to set fire to his little brother. The police and fire department were immediately dispatched to the scene. The juvenile firesetter intervention specialist began talking to the young boy about his behavior. Lenny explained that he was directed to burn his little brother by the devil. When the fire investigator asked how he communicated with the devil, the boy stated that the devil was present in the room and that they had a regular conversation. Lenny was admitted to the child psychiatric hospital for further observation and treatment. Lenny had several firesetting incidents and was described by others to behave bizarrely.

Cognitively Impaired Type. The cognitively impaired type includes the developmentally disabled and the organically impaired types. This group, although tending to avoid intentional harm, lacks good judgment. Significant property damage is common.[7] The organic group includes those persons whose cognition ability or ability to control impulses is significantly affected by their neurological or medical state. Also included in this group are persons with severe learning disabilities and those who were affected by fetal alcohol syndrome or by drugs taken by their mothers during pregnancy.

Case Example. Ken, age 14, was referred to the fire department by his parents. The parents were afraid because Ken had started several fires in and around their home. Ken was severely learning disabled and impulsive. He attended a self-contained special education program to assist him with his learning disabilities and impulsive behaviors. Ken was also on several medications to control impulsivity and other behavior concerns. Ken had suffered from these behaviors since birth, and his parents stated that he needed constant supervision. Although they worked hard to control the environment and keep ignition materials from him, he was persistent. Ken is a very concrete thinker and when he does understand and accept an idea or concept, he internalizes it. Ken's parents hoped that the fire department might be able to provide information and education that Ken would find meaningful and affect his behavior.

Sociocultural Type (including the uncontrolled mass hysteria type, the attention-to-cause type, the religious type, and the satanic type). This category includes those who set fires in the midst of civil unrest and are either enraged and enticed by the activity of others and follow suit or set fires with deliberation in order to call attention to the righteousness of their cause. Those involved in uncontrolled mass violence frequently lose control and harm others, though initially the intent to do so may not be present.[7]

Case Example. The Earth Liberation Front is a group of older adolescents and young adults who are currently attempting to bring attention to a cause. This group targeted a ski resort in Vail, Colorado, by burning five buildings and four ski lifts because they believed that the development threatened the lynx. This group has also targeted housing projects in wildland regions because they feel these properties are infringing on nature. They justify their behavior with rhetoric, explaining the injustice imposed on others.

RESPONSE TO JUVENILE FIRESETTING

Juvenile firesetting is a community problem. The fire service is in a unique position to address it. Although specific responsibilities can be distributed among different agencies, depending on resources and demographics, the fire service is usually in the best position to manage the community response.

Successful program models have been examined for several years. An Office of Juvenile Justice and Delinquency Prevention (OJJDP) and United States Fire Administration (USFA) initiative to assess effective programs addressing juvenile firesetting identified seven critical components.[9] A recent review conducted by a group of researchers on behalf of the National Association of State Fire Marshals (NASFM) funded by OJJDP confirmed that these program components remain state of the art.[10] The components are as follows:

1. A *program management* component to make key decisions, coordinate interagency efforts, and foster interagency support.
2. A *screening and evaluation* component to identify and evaluate children who have been involved in firesetting.
3. An *intervention* services component to provide primary prevention, early intervention, and/or treatment for juveniles, especially for those who have already set fires or shown unusual interest in fire.
4. A *referral* component to link the program with the full range of community support agencies that might help identify juvenile firesetters and provide services to them and their families.
5. A *publicity and outreach* component to raise public awareness of the intervention program and encourage early identification of juvenile firesetters.
6. A *monitoring* component to track the program's identification referrals and treatment of juvenile firesetters.
7. A *juvenile justice* system component to establish relationships with the juvenile justice agencies that often handle juvenile firesetters.

Program Management

Effective programs need structure and standard operating procedures. In most instances, juvenile firesetter intervention programs (JFIP) are incorporated into ongoing department operations such as fire prevention, investigation, or inspection. It is recommended that JFIP efforts be incorporated into the day-to-day responsibilities of these programs, with specific responsibilities assigned to trained individuals.

Whether programs are located in a specific department is a matter of philosophy and personnel resources. Some juvenile firesetter specialists recommend locating programs in specific areas. Some propose that programs are better positioned within the investigation units so that fire circumstances can be more carefully reviewed and that the law enforcement aspects are preserved for incidents involving intentionally set fires. Figure 5.6.4 illustrates one way to locate juvenile firesetter programs within a fire department.

Other juvenile firesetter specialists propose that the educational aspects of children and fire need to be emphasized due to the primary motivation of curiosity and experimentation and that programs should be situated in fire education units. Both concerns are valid and essential. Most important is that programs include the components just listed and that the response to all concerns regarding children and fire be handled systematically and thoroughly, whether the response is to a big fire or to no fire at all.

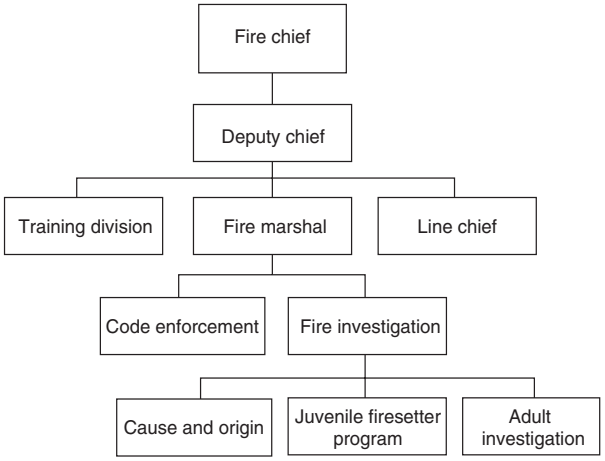

FIGURE 5.6.4 Sample Organizational Chart of a Juvenile Firesetter Intervention Program Within a Fire Department

Figure 5.6.5 illustrates the flow of a well-organized program. Referrals can be initiated from anyone with awareness or concerns regarding firesetting behavior. The process remains the same whether there is an actual fire or no fire at all. Therefore, a careful information-gathering procedure to assess motivation and direct interventions is needed. This is succeeded by a follow-up contact to assess the effectiveness of the intervention and the need for any additional services.

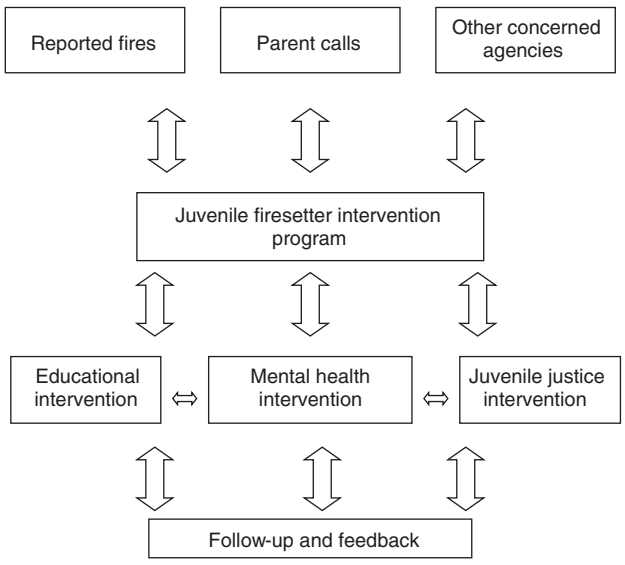

FIGURE 5.6.5 Referral Flow Chart

For the first time, the 2000 edition of NFPA 1035, *Standard for Professional Qualifications for Public Fire and Life Safety Educator*, includes two chapters outlining job performance requirements for Juvenile Firesetter Intervention Specialist I and Juvenile Firesetter Intervention Specialist II.[11] The standard is a resource to facilitate development of job responsibilities and procedures.

A Juvenile Firesetter Intervention Specialist I is an individual assigned with the day-to-day tasks of conducting a juvenile firesetter intervention program. This individual is responsible for keeping records of contacts, conducting assessment interviews, delivering educational interventions, and making referrals given the direction and feedback of a supervisor, but he or she does not have program management or oversight responsibilities.

A Juvenile Firesetter Intervention Specialist II is the program coordinator or manager. His or her responsibilities address key management concerns such as record management, compliance with government regulations, referral procedures, supervision of assessment and intervention personnel, establishment and maintenance of interagency networks, public relations, and program development and evaluation.

In a smaller program or department, it is likely that a single individual performs the role of Juvenile Firesetter Specialists I and II. In 2005, the Juvenile Firesetter Specialists I and II requirements in NFPA 1035 were revised to reflect the most current trends in the field (Table 5.6.1).

Screening and Evaluation

An essential component of an effective JFSI program is the screening and evaluation procedure to determine primary motivation and potential risk for future firesetting. This component typically includes structured interviews with the children and parents conducted by a trained juvenile firesetter intervention specialist. Most JFSI programs conduct the initial screening interviews themselves; if additional concern is generated, children are referred to identified specialists to conduct more comprehensive assessments. Some programs prefer to have all assessments initially conducted by an outside agency or professionals who are certified to work with youth and families.

The goal of the interview is to obtain background information about the child(ren), family, and fire behavior. Usually, the interviewer explains the purpose of the meeting, interviews the children and parents separately, and then reconvenes the family to explain the outcome and recommendations. Different programs based on philosophy and resources conduct this interview either at home or at an approved facility outside the home such as fire department administrative offices.

Both procedures have been demonstrated to be effective. There are advantages and disadvantages to each location. In the family home, the interviewer has the opportunity to assess the physical environment and observe the family interaction in their natural setting. However, the interviewer sacrifices an element of control in the home and sometimes children and families are more accountable in an "official" location.

The Federal Emergency Management Agency/United States Fire Administration (FEMA/USFA) has supported the development and distribution of manuals and community training materials.[12–17] FEMA manuals include copies of structured interview forms[18–20] and guidelines for their use. These interview forms were initially developed in the late 1970s by Dr. Fineman and are based on the Dynamic-Behavioral Theory mentioned earlier in this chapter. The manuals and the interview forms were revised in 2000 and are currently available from FEMA/USFA.

The revised FEMA manual includes a "short form," which is a subset of the complete interview designed to be a preliminary assessment. Figure 5.6.6 displays a page from the full assessment. Many practitioners have advocated a shortened procedure. This abbreviated interview is a relatively new procedure and will require a longitudinal study to determine its ultimate reliability. The initial caution is that any reduced inventory will possibly miss important information, but it might provide useful information to make a preliminary decision in the field by less experienced personnel.

The FEMA forms are not the only forms available. Well-established programs throughout the United States have taken the initial concepts and revised them to meet their own needs and procedures. Many of these programs have worked with local universities and researchers to establish reliability. A few examples of these are the Phoenix Fire Department in Arizona, the Portland Fire Department in Maine, the Monroe County Fire Bureau in Rochester, New York, and the State Fire Marshal's Office in Oregon. Most programs are proud of their efforts and welcome inquiries regarding their screening and assessment procedures.

The following is an example of the assessment procedure. The FEMA (child, parent, and family) forms are designed to assist in determining risk for additional firesetting behavior. The questions are scored and totaled to indicate the degree of risk. The scale ranges from little risk to extreme risk. The FEMA *Juvenile Firesetter Intervention Handbook*[21] defines the categories of risk as little risk, definite risk, and extreme risk.

Little Risk. Curiosity or experimentation accounts for the majority (60 to 65%) of children's involvement in fire in the little risk category. Most of these children are of little risk of repeating their behavior if they receive the proper supervision and educational intervention.

Definite Risk. Approximately 30 to 40 percent of children and adolescents fall into the definite risk category and are very likely to be involved in future fire behaviors. They are in need of interventions in addition to educational interventions. The cry for help and delinquent types described earlier typically fall into this category.

Extreme Risk. Less than 1 percent of children and adolescents fall into the extreme risk category. The severely disturbed types suffering from severe mental illness are most likely to be of extreme risk.

Interventions

Juvenile firesetting is a community problem requiring a community response. A comprehensive program is balanced between

TABLE 5.6.1 Professional Requirements for Juvenile Firesetter Intervention Specialists I and II

Job Performance Requirement (JPR) Group	*Juvenile Firesetter Intervention Specialist I*	*Juvenile Firesetter Intervention Specialist II*
Administration	**9.2.1** Assemble forms and materials, given approved forms, program policies, and procedures, so that the intake process is conducted according to those program policies and procedures. **9.2.2** Assemble interview tools and material resources, given tools and materials as determined by program policies and procedures, so that an interview with a juvenile and his or her family can be conducted. **9.2.3** Utilize personal work schedule, given contact name and requested time, so that all interviews are conducted on time and in a location agreeable to all parties. **9.2.4** Report case information to supervisor, given a case file that includes approved forms, the intake/interview information, and selected intervention(s), so that the supervisor can ensure that the intervention process meets all required program policies and procedures. **9.2.5** Record and secure data, given case information, approved forms and/or database, and program policies and procedures, so that statistical analysis can be completed.	**10.2.1** Formulate program policies and procedures, given a community needs assessment; program goals; community and agency resources, services, and organizations; so that the program policies and procedures match and support the goals of the program and the needs of the community. **10.2.2** Develop a program budget, given program policies and procedures, program needs, and revenue sources so that capital, operating, and personnel costs are determined and justified. **10.2.3** Identify and assign a JFIS I or other qualified personnel trained to conduct the intake/interview, given the program needs, resources available, and program policies and procedures, so that intakes/interviews are conducted according to the program policies and procedures. **10.2.4** Supervise the JFIS I assigned to the case, given program policies and procedures, so that a consistent body of information is collected, performance is evaluated, and continuous direction and feedback are given. **10.2.5** Maintain records and case files of each juvenile firesetter, given all data collection forms, program policies and procedures, and legal requirements, so that consistent and accurate documentation on process and content is available for each case, legal issues are addressed, progress is tracked, the program is evaluated, and federal and state/provincial reporting requirements are met.
Planning and Development		**10.3.1*** Develop an interagency network, given a current list of agencies, an interagency agreement, and protocol, so that roles and responsibilities are clarified; the mission, interagency agreements, and intervention are established; and duplication of services is avoided. **10.3.2*** Develop or select approved forms and materials, given existing forms or the option to create your own, so that the forms meet the needs of the program and follow the program policies and procedures. **10.3.3** Design a training program for program personnel, given a training curriculum, approved forms and materials, so that program personnel are able to perform intakes/interviews and interventions, including education, referral, follow-up, and evaluation. **10.3.4** Develop a community awareness program, given a mission statement, state/provincial program policies and procedures, and incident data, so that the community recognizes juvenile firesetter issues and available intervention resources. **10.3.5** Create a data collection system, given all approved forms and materials, legal requirements, and program policies and procedures, so that consistent and accurate documentation is maintained.

TABLE 5.6.1 Continued

Job Performance Requirement (JPR) Group	*Juvenile Firesetter Intervention Specialist I*	*Juvenile Firesetter Intervention Specialist II*
Education and Implementation	**9.4.1** Review a case file, given intake information, so that before speaking with the child and his or her family, the juvenile firesetter intervention specialist becomes familiar with the circumstances of the firesetting incident(s). **9.4.2** Initiate contact with the family, given the case file, so that the juvenile firesetter intervention specialist contacts the family; explains the program and its benefits; schedules a time, date, and place for the intake/interview; and advises the family of possible intervention options. **9.4.3** Conduct an intake/interview, given approved forms and guidelines, so that the juvenile firesetter intervention specialist can establish the purpose and limits of the intake/interview, establish rapport, gather relevant information, identify and intervene in any immediately life-threatening situations, report any suspected abuse or neglect, record and report observations, and summarize findings. **9.4.4** Determine intervention(s) and referral options with regard to educational, mental health, and/or possible legal consequences, given the case file, completed intake/interview forms, and knowledge of fire safety, so that specific educational material can be selected, mental health options explored, and legal consequences explained. **9.4.5** Implement educational, mental health, and legal interventions, given the case file, educational materials, and referral resources, so that the firesetter and his or her family complete the intervention(s). **9.4.6** Implement referral process, given current interagency network list and program policies and procedures, so that the juvenile firesetter and his or her family can expediently gain access to needed services and priority needs are met in a timely fashion.	**10.4.1** Deliver a training program for program personnel, given a training curriculum and approved forms and materials, so that program personnel are able to perform intakes/interviews, interventions, referrals, follow-ups, and evaluations. **10.4.2** Maintain a current interagency network, given established interagency agreements, so that responsibilities and program goals are met. **10.4.3** Deliver community awareness training to current interagency network members, given the training program, so that continued support is maintained for the juvenile firesetter program and juvenile firesetters are identified and referred to the program.
Evaluation	**9.5.1** Collect and record feedback from the juvenile firesetter and his or her family at designated intervals, given completed intervention(s) and referrals and approved forms and materials, so that the firesetter and the family have the opportunity to provide feedback. **9.5.2** Measure changes in juvenile firesetter and family behavior, given completed feedback forms, so that program results are documented.	**10.5.1** Evaluate the program, given program goals, feedback, records, and case files, so that program outcomes are determined and met. **10.5.2** Analyze the effectiveness of the program, given the evaluations, including information on recidivism, so that any necessary changes to the program can be made. **10.5.3** Prepare a program report, given evaluation results and program goals, so that the community and current interagency network are informed and support is generated for the program.

FIGURE 5.6.6 Sample FEMA Assessment Form (Source: K. Fineman, "Comprehensive Fire Risk Assessment," in Poage et al. (Eds.), *Colorado Juvenile Firesetter Prevention Program: Training Seminar Vol. 1,* Colorado Division of Firesafety, Denver, CO, 1997)

prevention and intervention services. This section will sample some fundamental intervention strategies and methods.

Primary Prevention. The goal of primary prevention is to reduce the likelihood of children and adolescents engaging in unsupervised activity with fire. As illustrated in Figure 5.6.7, primary prevention is a multifaceted approach based on the prevention triangle and the three E's: Educate, Engineer (sometimes called Environmental Change), and Enforce.

Education is the responsibility of the fire service, parents, teachers, media, community, neighborhood groups, and many others to provide relevant messages. Education messages that are aimed at children and fire should put emphasis on providing consistent supervision to children and adolescents, restricting access to ignition materials, teaching fire and life safety, and assigning age appropriate responsibility.

The developmental study[5] mentioned earlier explored the relationship between premature assignment of responsibility for tasks involving fire and subsequent unsanctioned use of fire. Premature assignment of responsibility may be defined as children cooking or building a fire in the fireplace before fully understanding the consequences or responsibilities of this action. Children who perceive their parents approve of this behavior feel a greater sense of control and permission and are more apt to be involved in unsupervised, nonsanctioned use of fire.

Effective prevention programs encourage the utilization and creation of products and environments that are engineered to prevent fire use or minimize the consequences from misuse. An excellent example of this is the manufacture of the child-resistant lighter designed to restrict the ability of preschool age children from igniting the flame on a disposable lighter. Additional examples range from the use of sleepwear and bedding with flame-retardant fabrics to the installation of residential sprinkler systems.

Intervention programs are designed to respond to actual concerns or incidents and can vary depending on the risk level determined in the assessment and the circumstances of the fire. Effective intervention programs have a range of interventions and include educational interventions, mental health counseling, juvenile justice consequences, and child welfare actions. Depending on the motivation and outcome of the risk assessment, one or all of these interventions might be implemented.

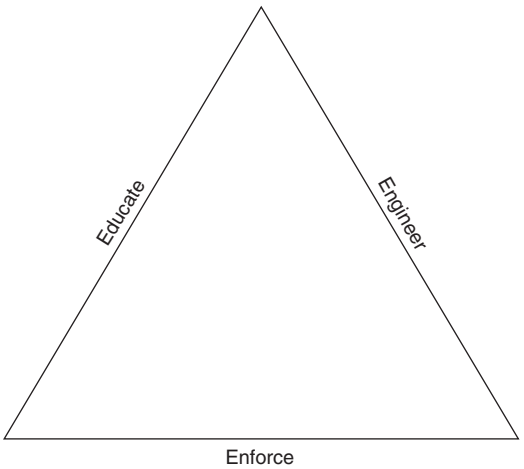

FIGURE 5.6.7 Fire Prevention Triangle

Educational Intervention. Educational interventions are recommended for most young people who demonstrate an inappropriate interest in or use of fire. The majority of presentations are going to be primarily motivated by curiosity. Well-constructed education programs are effective for changing this behavior.

Educational interventions need to be aimed at the youth involved in the incident as well as primary caretakers. Programs traditionally include reactive fire safety behaviors that teach what to do in the event of a fire such as "stop, drop, and roll" and "know two ways out." This information is clearly essential and saves lives, but it does not address the curiosity and misinformation that empowers young people to experiment with fire. Educational interventions need to be age appropriate. Information should be presented in a concrete manner and without scare tactics.

Table 5.6.2 illustrates objectives particularly appropriate for the listed age categories. Providers should feel flexible to amend objectives based on individual needs.

The priority for preschool children is to teach them that matches and lighters are for adult use only and that children should tell a grown-up if they discover matches or lighters in their environment. Preschool children are capable of learning basic life safety messages such as "crawl under smoke" and should be taught these skills. Caregivers should be included and encouraged to have children practice these behaviors so that the skills are rehearsed.

Many of the objectives are appropriate for adolescents as long as they are adjusted to be age appropriate. Many intervention programs include projects that require young people to create escape plans and home safety drills. Community impact statements have also proved successful in creating empathy and understanding. In a community impact statement, youth are required to complete a project that highlights the impact their actions have had on others.

The only exception to providing an educational intervention concerns the timing of the intervention rather than the omission of this procedure. In certain cases, children or

TABLE 5.6.2 Educational Intervention Objectives

Parents or Caregivers	*Ages 5–8*	*Ages 9–11*
Fire safety	Power of a single match	False sense of control
Limit access to ignition materials	How quickly fire spreads	Responsibility and fire
Supervision	False sense of control	Consequences of misuse
Age-appropriate responsibility	What burns	Personal vulnerability
Clear rules and consequences		Peer pressure

adolescents may be of imminent harm to themselves or others or may be in crises and, therefore, not able to process the information. When the situation stabilizes, it is suggested that an appropriately leveled educational intervention be implemented. Research at the University of Pittsburgh conducted by Dr. David Kolko specifically demonstrated the effectiveness of a structured intervention program that incorporates fire safety education for reducing the likelihood of future misuse of fire.[22] This was compared to a more casual intervention in which fire fighters make a brief visit to the home to discuss with parents ways to prevent children from using fire and to hand out educational materials.

Mental Health Intervention. As indicated in the Dynamic-Behavioral Theory and the crisis profile type, firesetting behavior is often motivated by the interaction of the individual with his or her family or social circumstances. Frequently, the individual lacks sufficient coping or problem-solving skills. Referral for individual and family counseling is imperative.

Counseling juvenile firesetters is not substantially different from interventions with others, but some critical aspects need to be understood and addressed. The specific mental health interventions are beyond the scope of this chapter but are generally built around a case management model, which allows for careful coordination of services and includes focus on the firesetting behavior. Mental health treatment for juvenile firesetters needs to be personalized to the firesetting type, motivation, and circumstances. Treatment tools include individual treatment, family counseling, cognitive techniques, behavior management, empathy and social-skill building, parenting skills, problem-solving methods, and relaxation techniques.

Referrals should always be made to mental health professionals who have specific understanding of juvenile firesetters. When knowledgeable mental health providers are not available, the fire service should facilitate access to training and information to develop these resources. A comprehensive overview of treatment strategies is available in the National Association of State Fire Marshal's Juvenile Firesetter Intervention Project Research Report.[10] This information is downloadable free of charge at the website www.firemarshals.org. The section is entitled "Juvenile Firesetter Mental Health Intervention: A Comprehensive Discussion of Treatment, Service Delivery, and Training of Providers," and comprises areas 1 and 2 of the overall report. The bibliography of the NASFM report references several resources that further address treatment concerns. The references at the end of this chapter also contain additional treatment resources by this author and others.

Social Service Intervention. It is well established that a critical predictor of repeat firesetting is documented incidents of neglect and abuse. In the Rochester study,[3,4] recidivism, or repeat firesetting, increased fivefold in families in which children were victims of chronic neglect and physical or sexual abuse. Juveniles who experience this in their lives feel powerless and helpless and sometimes use firesetting because of its power to bring attention to a serious concern in a dramatic way.

Dr. Alan Feldberg, director of Cornell Abraxis, a residential treatment facility in Pennsylvania, has conducted some initial case studies of the participants in his program who have all been adjudicated as juvenile firesetters with an average of 27 fires. Thirty-eight percent have a documented history of being sexually abused, 76 percent experienced chronic verbal abuse and humiliation, 78 percent were physically abused, and 100 percent suffered chronic neglect.

It is essential that a juvenile firesetter intervention program have an established relationship with the child welfare agency charged with responding to abuse and neglect. Parents and primary caretakers must be held accountable in these cases and children protected from further abuse. Social services agencies can assist with evaluation and help determine the need for placement and mandate services.

Referral Component

Juvenile firesetting is not just a fire service problem; it is a community problem. If there is any single aspect that can enhance the likelihood of success, it is the relationship among key stakeholders in a community. Effective intervention demands a comprehensive network of services, clear interagency communication, ongoing support, and follow-through.

Many juvenile firesetter intervention programs have established community advisory panels to facilitate the development and maintenance of their program. Perhaps one of the best established advisory panels based on its longevity and influence is the Phoenix Fire Department Community Advisory Panel.[23] Figure 5.6.8 displays the organizations represented on the Phoenix Fire Department Community Advisory Panel.

FIGURE 5.6.8 Phoenix Fire Department Community Advisory Panel (Source: Phoenix Fire Department)

The panel meets on a bimonthly basis to help determine actions and services necessary to address juvenile firesetters. The goals of the advisory panel are as follows:

- To utilize the members collective resources and expertise to reduce youth firesetting in the community
- To identify potential funding sources
- To increase the awareness of the program to its member agencies and to provide training
- To encourage ongoing collaboration in the community

The panel of community stakeholders is in the best position to help define what entails an appropriate referral to any given agency or service and the procedures to make the referral. Particular attention should be paid to necessary forms, funding, hours, feedback to referring party, availability, and waiting lists. All participants need to be trained in these procedures and kept abreast of any changes.

Confidentiality is frequently perceived to be a roadblock to interagency cooperation. This is often interpreted too narrowly. *Confidentiality is not intended to deter services.* It is critical that agencies serving children and their families share information that enables them to coordinate and provide more effective services. A failure to provide information generally results in fragmentation and duplication of services.[24]

In all circumstances, information can be shared with the consent of a juvenile's parent or guardian. A release of information signed by a parent or guardian allows information to be freely shared. Disclosures on a need-to-know basis can also be made when there is immediate need for information to prevent imminent harm to self and others. Children who are at high risk to start fires could be argued to fall under this umbrella.

Other arrangements can be made to facilitate communication between agencies. A memorandum of agreement can be established between two agencies that bind the providers in each agency to confidentiality under the regulations of each agency. Information can be provided when a school initiates legal action against a student or when a lawfully issued subpoena is presented.

Florida passed legislation designed to facilitate the sharing of information between entities. The state passed legislation to require the State Department of Juvenile Justice to establish an early delinquency intervention program with cooperation of local law enforcement agencies and community service agencies that work with children. Comparable laws exist in other states.[25]

It is beyond the scope of this chapter to detail all the circumstances in which information can be shared. Communication is facilitated in an environment where there is awareness, trust, and ongoing relationships to clarify how information is to be used. Confidentiality is not intended to hinder effective interventions when trying to help young people.

Publicity and Outreach

Generally, a program is only as successful as its reputation. Awareness of the program goals and how the public and relevant agencies can access the program should be regularly disseminated. The advisory panel is an excellent body to help distribute information among its members and outside. Public service announcements can be a useful method to reach a broad audience. The United States Fire Administration has developed brochures and videotape-based programs that can be used for presentations to service organizations, schools, and other community groups to increase awareness.

Publicity and outreach programs should be designed to fit the profile of the community so that the messages clearly define the problem in terms of types of fires, who is at risk, demographics, and cultural influences. Messages should be designed to inform and not frighten the community. More diverse communities should design outreach that is multilingual and fully utilizes the media to maximize exposure.

There is plenty of room for creativity to extend reach at low cost. One community in upstate New York arranged to print messages regarding match and lighter safety with program contact information on the grocery bags of a major grocery chain, thus enabling the message to reach thousands without any direct cost to the program.

Monitoring

Careful record keeping to measure program utilization and results can help programs survive in environments where resources are highly sought after or scarce. Feedback of this nature also helps managers structure programs to best meet the needs of the community. Program personnel should monitor at least the kinds of referrals that come into the program, the basic demographics of clientele, types of firesetting behavior, source of referrals, and referral dispositions.

It is also recommended that program personnel document their activities. Keeping track of presentations, interventions, program development activities, and interagency networking will help to ensure that adequate resources both in personnel and monies are allocated to the maintenance of the program over time.

Methods of tracking these data should be carefully considered. It is generally recommended to collect information as individual data points and not in a summary or aggregate form. Data can always be grouped to generate a summary but cannot be unbundled once aggregated.

Program managers should decide whether program activities and data will be tracked specifically to the program or whether there will be a central system for collecting and storing information within the department. Regardless, data should be easily retrievable.

Program personnel will want to determine whether an individual has had prior contact with the program as well as generate reports for reporting and monitoring systems. Computerized data management systems are available. Dr. Fineman and the Orange County Fire F.R.I.E.N.D.S. (Firesetter Regional Intervention Education Network and Delivery System) have recently developed a Web-based data system based on the FEMA forms. The database covers all aspects of the incident as well as individual and family data. The database has specific data fields with many drop-down menus that encourage systematic data collection and accuracy. This system is available to programs that are registered with this group and that are willing to

share aggregate data toward the development of a national data collection system. Many fire departments around the United States have developed custom systems using desktop computers. Some departments have adapted the National Fire Incident Reporting System to store information and some still utilize the old-fashioned method of file folders and index cards.

Programs with several years of history and documentation in states such as New York, Oregon,[26] Arizona,[23] Massachusetts, Indiana, and Illinois[27] consistently demonstrate reductions in rates of repeat firesetting among young people who have come to the attention of their programs. Communities that have established primary prevention programs document reductions in the numbers of fires and resulting loss of young lives and property, especially among preschool age children.

Juvenile Justice

Children and adolescents need to be accountable for their actions. In the earlier referenced developmental study,[5] it was demonstrated that children are less likely to misuse fire if they perceive that their behavior will have a consequence. The juvenile justice system has a critical role. The juvenile justice system has the power to mandate services and to hold juveniles and their families accountable.

The juvenile justice system usually comprises the juvenile unit of the probation department and family court. Family court is designed to address behaviors that would be considered crimes if committed by an adult. The ages of culpability (age at which a child can be held accountable) vary from state to state and typically range from 7 to 16 years of age. Children older than 16 may be treated as adults in many areas of the United States. Given the chaos in the lives of many cry-for-help and delinquent-type firesetters and the risk to the community, this power is a pivotal factor in addressing juvenile firesetting.

Effective juvenile justice programs maintain graduated sanctions. These sanctions consist of mandated counseling interventions, restitution, accountability, and community service on an initial level; and secure confinement in community settings, training, and aftercare on more severe levels. The juvenile justice system in each community needs to work with the juvenile firesetter intervention program to aggressively support programs that address juvenile problems through a continuum of services and sanctions that consider youth needs, family needs, community safety, and victim restoration.[28,29]

PITFALLS

Clearly, juvenile firesetting is a serious concern requiring a systematic response that is institutionalized and supported. The following comments are intended to highlight common pitfalls that can undermine programs or prevent them from being maximally effective.

Too often juvenile firesetter programs are initiated by an individual who appreciates the problem and has a passion to do something to help. Although it is true that an individual's efforts can start something that can make a difference, attempting to maintain a program single-handedly threatens the life of the program over time.

When a program is generated and maintained by an individual, it is unusual to find replacements that have the same level of energy and ownership to carry on these efforts. Individuals retire, get promoted, reassigned, or simply burned-out and with these changes go the program. Individuals who have a passion to work with juveniles involved with fire will best serve the mission by making a concerted effort to institutionalize the program so that the program's longevity can be their legacy.

Programs need to be recognized and supported from top to bottom within a fire department. It was stated earlier that juvenile firesetting is not just a fire service problem but a community problem. However, when attempting to establish and maintain a program within the fire department, it needs to be acknowledged that this is not just the responsibility of the prevention or investigation unit conducting the program.

TRAINING

Training opportunities are widely available. The National Fire Academy in Emmitsburg, Maryland, has established a series of courses focusing on Juvenile Firesetter Intervention Specialists I and II as defined by NFPA 1035. These courses are offered at the academy and regionally around the United States. A leadership curriculum has been developed to correspond with these courses. The United States Fire Administration has revised and reissued its manual and forms. Statewide coalitions in states such as Oregon and Massachusetts conduct annual conferences with comprehensive seminars on a wide variety of related topics.

The National Fire Protection Association provides training and awareness via the annual World Fire Safety Conference and Exposition in June. In addition, several training entities are establishing certification programs based on NFPA 1035 in cooperation with state certifying bodies. Many of the consultants and providers who helped establish these programs are available to work with individual communities to assist in developing personalized training, program development, and evaluation services. Distance-learning opportunities have also spawned Web-based courses on juvenile firesetting and related areas. A number of professional publications have also been published in the past few years and a comprehensive book on treatment of juvenile firesetters by this author and colleagues is being readied for publication.

Awareness of the juvenile firesetter issue needs to be incorporated on an ongoing basis at all levels of training and professional development within the fire service. The Rochester, New York, Fire Department has its juvenile firesetter intervention specialists present an overview of the issue and the intervention process to every graduating class at its fire fighter training academy. In this way, all new recruits begin their careers with a basic understanding of children and fire. Officer training programs should adopt this model as well.

Effective juvenile firesetter intervention depends on suppression, prevention, investigation, and inspection divisions all working together. It is the responsibility of every line fire fighter and officer to be sensitive and alert to the possibility of juvenile involvement and to initiate intervention.

Programs that are highly successful have support not only from the hierarchy within the department but also from the entire fire service ranks. Oregon established an infrastructure that supports juvenile firesetter intervention statewide. The Oregon State Fire Marshal established a full-time coordinator responsible for supporting juvenile firesetter intervention programs, which includes facilitating all the program elements illustrated earlier.

Although the importance of establishing formal programs within the fire service is advocated, it is also important to acknowledge that programs should be designed to meet the demand however large or small. Programs can be undermined when they are underutilized. Program managers need to be sensitive to the size of the community and to the potential number of referrals. Rural communities may not want to put extensive resources into maintaining an individual program but may want to combine personnel and resources between a few departments to establish a regional or county-based program.

At the opposite end of the continuum, programs that are understaffed will also be undermined. Program credibility will be lost in the community if referrals cannot be responded to in a timely or comprehensive manner. Staff turnover will increase if personnel perceive that they are not able to protect children and their families due to inadequate support or feel they cannot perform their duties competently.

INFORMATION RESOURCES

Fire departments can build on the experience of many established programs throughout North America. Technology allows the transfer of information and materials unlike that in any period in our history. Several websites have been established solely for supporting efforts to address juvenile firesetting. Many of these sites offer links to other sites and provide references for materials, training, and speakers (Table 5.6.3).

In addition, several state coalitions and providers have established newsletters and publications that are published regularly. Perhaps the best known is *Hot Issues,* published by the Oregon State Fire Marshal's Office for Juvenile Firesetting. The newsletter is published quarterly and features program issues, treatment recommendations, current research, and resources.

SUMMARY

The fire service has never been in a better position to be the leader in addressing the problem of juvenile firesetting. Juvenile firesetter intervention programs work. Years of collective experience and research have proven that the fire service is in a unique position to make a critical difference and to do what it has always been recognized for doing—saving lives and protecting property.

Our communities are struggling with many complex and frustrating problems and challenges endangering our youth. Clearly there is always room to grow and perfect our understanding, but the problem of children and fire is one that we have considerable knowledge about and the immediate ability to impact.

Chapter 7

Using Data for Public Education Planning and Decision Making

John R. Hall, Jr.

Chapter Contents

The Role of Data in Community Fire Education Planning
Problem Definition
Intervention Strategies
Target Audience Considerations
Mapping Program Delivery
Was the Target Audience Reached?
Did the Strategy Work?

Key Terms

high-risk audience, program, public fire and life safety education, risk, strategy

Successful fire and life safety education begins with good decisions by the managers of fire and life safety education—decisions that identify the major fire problems and target audiences, design a program best able to address those problems with that audience, and deliver the right program to the right people. At every stage of this process, good decisions depend on the proper use of good data.

See also Section 3, Chapter 1, "An Overview of the Fire Problem and Fire Protection"; Section 3, Chapter 4, "Use of Fire Incident Data and Statistics"; and Section 5, Chapter 8, "Evaluation Techniques for Fire and Life Safety Education."

THE ROLE OF DATA IN COMMUNITY FIRE EDUCATION PLANNING

Community Fire Education Planning

Community fire education planning is a way of making necessary decisions within a structure and specifically using a five-step process developed by the U.S. Fire Administration:

Step 1: Conduct a community analysis.
Step 2: Develop community partnerships.
Step 3: Create an intervention strategy.
Step 4: Implement the strategy.
Step 5: Evaluate the results.

Steps 1 and 5 are primarily data-driven exercises, and the other three steps may also benefit from data analysis in some respects. The uses of data may be grouped into the following six sections, which will be used to organize this chapter:

- What is the problem to be addressed? (This is the question for which Step 1, the community analysis, is conducted.)
- What is the strategy to address the problem? (This is the question for which Step 3 is conducted, and there may be additional analysis to refine the strategy during implementation as part of Step 4.)
- Who is the target audience? (Step 2, development of community partnerships, will reflect both the choice of strategy and the identified target audiences, because these two choices will suggest appropriate groups and agencies for partnership.)

John R. Hall, Jr., Ph.D., is assistant vice-president for fire analysis and research at the National Fire Protection Association.

- Was the target audience reached by the strategy? (Step 5 includes answering this question.)
- Did the strategy change the target audience as intended? (Step 5 also includes answering this question.)
- Did the fire problem decline? (Step 5 also includes answering this question.)

The first three question groups give the design for the program. The second three question groups indicate what was accomplished. Because most programs are not one-time affairs, the lessons learned regarding accomplishments will then feed into the next cycle of program redesign decisions.

This chapter addresses matching the right data with the questions posed, interpreting that data correctly, and eventually using data and all other available resources to save lives and property. Many of the issues and themes of this chapter have counterpoints elsewhere in this handbook.

The reader is particularly encouraged to read Section 3, Chapter 4, "Use of Fire Incident Data and Statistics," which provides additional guidance on techniques of data interpretation for fire safety not limited to public education; Section 5, Chapter 8, "Evaluation Techniques for Fire and Life Safety Education," which provides more detailed guidance on question groups four through six than will be provided here; and Section 5, Chapter 5, "Reaching High-Risk Groups," which provides more information for those (common) occasions when the target audience includes a number of high-risk groups.

Data and Public Fire Education

This chapter does not propose that analysis of readily available data is necessary or sufficient to answer all questions in the design and evaluation of public fire and life safety education programs (or any other kind of program). It is claimed that answers are sounder when they reflect the best data available and are ill-advised if they contradict, without engaging, the best data analysis.

Use data to challenge assumptions, even the ones that seem most obvious. If the data are not strong enough or detailed enough to dictate the specific answer needed, then use the data to reduce the range of possibilities before applying judgment to make the final choices. Do not be afraid to use data to support choices and persuade third parties; however, do not confuse that exercise with the use of data to shape and assess choices. Decision making and advocacy of decisions are both essential, and both can be done better with data analysis.

For advocacy purposes, representative statistics may be less effective than more specific examples that allow people to put a human face on the fire losses and the program activities. Match appropriate data to the target audience. Supervisors, managers, local legislative officials, and budget officials tend to want hard numbers, although even they will have an easier time grasping the need and the plan with examples. The general public, the press, and organizations outside the fire safety arena may relate primarily to the examples. Additional resources at the end of this chapter, particularly the National Fire Protection Association (NFPA) "One-Stop Data Shop," can help locate accurate statistics and relevant case histories.

PROBLEM DEFINITION

This first stage requires the fire safety education team to define the objectives explicitly. What aspects of the fire problem should be addressed? What scales measuring fire loss is the team willing to use to measure success and hold the team accountable for results? The answer may appear obvious—save lives and prevent injuries, for example—but here, and at every other stage in the data use process, the team will learn a great deal about real objectives as it wrestles with the problem of setting performance criteria that are measurable, meaningful, and realistically achievable.

Start with the basics. Is the team comfortable being judged by changes in the size of the fire problem? If so, team members will be taking responsibility for outcomes that are not totally under their control. Fire safety or risk is affected by both the behaviors people learn and the products and other physical aspects of their environment. Education directly affects only the behaviors. On the other hand, if success is measured only by the number of children taught or the fraction of all children reached, then the team can guarantee success, given sufficient resources. But reaching children does not necessarily mean teaching children, and learning does not necessarily mean safety.

The following three examples are different ways to fail, relative to the only criterion that ultimately matters—are people safer? And yet each of these examples of unequivocal failure would be judged a success by some, even many, methods of evaluation:

1. To take an extreme example, an educator can stand in front of a class full of sight- or hearing-impaired or non-English-speaking children and deliver a standard fire safety education program. Although this may add 20 to 25 children to the tally of people reached, one can say with confidence, based on the mismatch between the standard medium of delivery and the special needs of these audiences, that the behaviors of this target audience will not change at all.
2. Or, an educator can deliver a program to a classroom of children who pass the test at the end of the day with "flying colors" but who forget everything they learned by the start of the next day's classes.
3. Or, an educator can teach a program that stays with the children for the rest of their lives, changing their behaviors as intended, but that somehow misses the behaviors that will prove to be most important in coping with the fire hazards they will face as adults.

Why address evaluation/success at this early stage? Because the design of a program—and the data appropriate to help design the program—should anticipate the way it will be evaluated. That is, at the very end, when evaluating whether the "problem" was reduced, it should be the same problem identified at the outset that inspired the design of the program.

Type of Loss

There are four principal measures of home fire loss:

- Fire incidents (count each fire once)
- Deaths
- Injuries
- Monetary loss

In settings other than homes, other measures may be of particular value, such as environmental impact, continuity of operations, and protection of cultural resources. The latter two measures are increasingly important in commercial settings. If a particular education effort leads to, for example, presenting a training session at the local chemical plant that employs a large number of the community's people and provides a large part of the community's tax base, then the educator may be less concerned about preventing a "typical" $10,000 fire at the plant than about preventing a catastrophic fire that might put thousands out of work and release a vapor cloud that could force evacuation of thousands more.

Choosing the Type of Loss to Measure. Which is the right measure to use? Most fire and life safety educators have a principal concern with saving lives, so deaths should be a measure of fire loss of concern to them. But should it be the only measure used?

Injuries are another measure of loss often targeted by fire safety educators. Injuries are several times more common than deaths, and some injuries are extraordinarily expensive, painful, and tragic. Most people value reducing the risk of death much more highly than reducing the risk of injury. However, injuries are more common, which means that injury statistics can provide significant, hard evidence of a program's positive effects much sooner. For that reason, measuring success by fire incidents, regardless of severity, also has advantages.

In the end, decisions must be made on which measure(s) of loss will be used. For each measure of loss, there needs to be an explicit rationale for the measure, which will provide guidance on how to interpret it and how much importance to attach to it. Different measures of loss will yield different priorities and multiple measures of loss can pull in different directions. For example, child-playing and smoking fires are major contributors to deaths and injuries, but only minor contributors to fire incidents (Table 5.7.1). Cooking fires are major contributors to fire incidents and injuries, but much less so to deaths. Smoke alarms have major impact on the risk of death but very minor impact on the risk of injury. And so on. Design the education program to

TABLE 5.7.1 Leading Causes of Structural Fires in Homes, 1999–2002 Annual Averages

Cause	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*	
Cooking equipment fire	105,400	(28%)	270	(9%)	4,230	(28%)	519	(10%)
Identified cooking equipment	*75,600*	*(20%)*	*270*	*(9%)*	*3,750*	*(25%)*	*509*	*(9%)*
Confined cooking fire	*29,800*	*(20%)*	*0*	*(0%)*	*470*	*(3%)*	*10*	*(0%)*
Heating equipment	53,700	(14%)	320	(11%)	1,270	(8%)	637	(12%)
Identified heating equipment	*40,300*	*(11%)*	*320*	*(11%)*	*1,240*	*(8%)*	*628*	*(12%)*
Confined chimney or flue fire	*10,600*	*(3%)*	*0*	*(0%)*	*10*	*(0%)*	*7*	*(0%)*
Confined fuel burner or boiler malfunction or fire	*2,900*	*(1%)*	*0*	*(0%)*	*10*	*(0%)*	*2*	*(0%)*
Intentional	34,400	(9%)	550	(19%)	1,500	(10%)	738	(10%)
Electrical distribution or lighting equipment	32,400	(9%)	220	(8%)	960	(6%)	679	(10%)
Smoking materials	24,800	(7%)	850	(29%)	1,900	(12%)	455	(8%)
Candle	18,200	(5%)	160	(5%)	1,640	(11%)	392	(2%)
Exposure to other fire	15,800	(4%)	30	(1%)	90	(1%)	319	(6%)
Playing with heat source	14,000	(4%)	220	(8%)	1,360	(9%)	249	(5%)
Clothes dryer or washer	13,300	(4%)	10	(0%)	280	(2%)	97	(2%)

Note: These are the leading causes, obtained from the following list: intentional (from the NFIRS field "cause"); playing with fire (from factor contributing to ignition); confined heating (including confined chimney and confined fuel burner or boiler fires), confined cooking, and contained trash or rubbish (from incident type); identified heating, identified cooking, clothes dryer or washer, torch (including burner and soldering iron), electrical distribution and lighting equipment, medical equipment, and electronic, office, or entertainment equipment (from equipment involved in ignition); smoking materials, candles, lightning, and spontaneous combustion or chemical reaction (from heat source); and mobile property involved (from mobile property involved in ignition). The statistics on smoking materials and candles include a proportional share of fires in which the heat source was heat from an unclassified open flame or smoking material. Exposure fires include fires with an exposure number greater than zero, as well as fires identified by heat source or factor contributing to ignition when no equipment was involved in ignition and the fires were not intentionally set. Because contained trash or rubbish fires are a scenario without causal information, they are shown at the bottom of the table if they account for at least 2% of the fires. Causal information is not routinely collected for these incidents. The same fire can be listed under multiple causes, based on multiple data elements.

These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest hundred, civilian deaths and injuries are rounded to the nearest ten, and direct property damage is rounded to the nearest million. Property damage has not been adjusted for inflation.

Source: NFIRS and NFPA survey.

produce results on the measures that matter most, not the measures that will show results the soonest. For example, suppose the team chooses to measure fire incidents as early evidence of program success and fire deaths are the measure of the real objective. Then the team should design the program not for its leverage on the rate of fire incidents but only for its leverage on fire deaths.

Refining the Measure. Even after a measurement scale is chosen, more decisions are needed to select a specific measure. For example, suppose fire deaths are chosen as a measure of fire loss. This can be translated into four very different specific measures: (1) deaths in fires, (2) fatal fires, (3) multiple-death fires, or (4) deaths in multiple-death fires.

Counting fatal fires rather than total deaths reduces the emphasis on deaths occurring in multiple-death fires. Under what circumstances might this make sense? Imagine a fire and life safety education manager in Las Vegas in the early 1980s. The MGM Grand Hotel fire caused more deaths in one fire than the city had experienced in all other fires combined in many years. In that kind of situation, counting deaths individually—and targeting programs accordingly—will mean devoting all educational resources to ensuring that the city never has another fire like the MGM Grand Hotel fire. This is a worthy goal, but it is not the only worthy goal. How many lives would be worth losing in ordinary home fires in order to ensure, say, that the odds against another MGM Grand–sized fire were a billion to one instead of only a hundred million to one? A similar argument would apply to office or high-rise fires in New York City because of the World Trade Center tower collapses, or to wildfires in Los Alamos, New Mexico, or to nightclub fires in West Warwick, Rhode Island, or in the entire state of Rhode Island. In each case, a single event of historic severity can justify expanded attention, but not exclusive attention.

Alternatively, the team could decide up front to concentrate exclusively on multiple-death fires. The public often seems to be far more upset by one fire that kills five people than by five fires that kill one person each. If the intention is not so much to increase safety as to increase feelings of safety or to reduce public distress over gaps in safety, then the team might devote more attention to boosting the safety factors of programs that prevent large fires rather than programs more likely to save people in the circumstances in which deaths are actually occurring.

Sometimes, there are multiple measures of loss that each seems to point in a different direction in terms of defining the problem. Table 5.7.2 shows the five primary types of space heating equipment, ranked in descending order by fire death rates relative to population, rates relative to population of deaths due to either fire or unvented carbon monoxide, and total fire deaths not adjusted for usage population.

The inclusion of carbon monoxide makes electrically powered equipment look better than any fueled equipment, and sorting by death toll produces a ranking almost exactly opposite the ranking by fire death rates. Portable liquid-fueled devices have the highest rates on the two rankings by deaths per million population, but they would have ranked second to fixed gas-fueled devices if 1985–1990 fire data had been used instead of 1995–1999 data. Only fixed, electrically powered devices consistently rank lowest, and this is one of the least used types of equipment of the five.

TABLE 5.7.2 Measures Related to Risk of Death for Five Leading Types of Space Heaters

Fixed vs. Portable	*Fuel or Power*	*Civilian Deaths*
1995–1999 Fires; 1997 High and Low Usage—Deaths per Million Households		
Portable	Liquid (e.g., kerosene)	9.93–12.41
Portable	Electricity	5.95–7.11
Fixed	Gas (e.g., LP-gas)	4.49–5.35
Fixed	Solid (e.g., wood)	3.32–3.91
Fixed	Electricity	0.65–1.42
1995–1999 Fires and Deaths Due to Unvented Carbon Monoxide; 1997 High and Low Usage—Deaths per Million Households		
Portable	Liquid (e.g., kerosene)	12.02–15.02
Fixed	Gas (e.g., LP-gas)	9.70–11.56
Portable	Electricity	5.95–7.11
Fixed	Solid (e.g., wood)	3.69–4.34
Fixed	Electricity	0.65–1.42
1995–1999 Fires Deaths Not Adjusted for Usage		
Portable	Electricity	90
Fixed	Solid (e.g., wood)	60
Fixed	Gas (e.g., LP-gas)	60
Portable	Liquid (e.g., kerosene)	40
Fixed	Electricity	10

Note: Deaths shown to nearest ten.

Source: NFPA analysis of data from NFIRS, NFPA survey, and U.S. Department of Energy.

Sometimes the message of the data is that all parts of the problem are worthy of attention by some relevant criterion, and so it makes sense not to narrow or target the problem.

Differences in Fire Risks Around the World

In Japan young children are not a distinctively high-risk group for fatal fires. Their rate of fire deaths per million population is nearly the same as the rates for their parents and for older children. By contrast, in the United States, preschool children face a risk of dying in fire that is considerably more than double the risk for everyone else.

At the other end of the age spectrum, however, Japan faces a much more severe problem than does the United States. The gap between fire risks for older adults and those for everyone else is much wider in Japan than in the United States. There may be lessons here for both countries. Child-rearing and child-supervision approaches in Japan may deserve some credit for their better experience in protecting the youngest of their people, whereas the better experience in protecting older people in the United States may reflect some of the distinctive U.S. practices. Only in-depth research can establish a credible link between differ-

ences in practices and differences in outcomes, because usually there are more than enough of the former to explain the latter.

In Russia and much of Eastern Europe, fire death rates overall are higher than they are in North America (the United States and Canada, in particular), Western Europe, and the Pacific Rim (particularly Japan). An obvious explanation is that the use and abuse of alcoholic beverages appears to be higher in Russia and Eastern Europe as well, to the extent that available statistics can be trusted to quantify such behavior. Two-fifths to one-half of U.S. adults who die in fire each year are legally intoxicated at the time; therefore, there is no doubt that abuse of alcohol is associated with elevated risk of fire death.

The use of smoking materials is also a point of distinction. In Europe, the percent of the adult population who smoke—and the range of places where smoking routinely occurs—is much larger than it now is in North America and is in fact reminiscent of the 1950s in North America. Coupled with better European success in preventing or mitigating many other types of fires, this distinctive behavior with regard to smoking is, not surprisingly, associated with a much higher percentage of fire deaths being attributed to smoking materials.

As around the globe, so within the United States, local differences in the problem to be solved should be identified early and incorporated into the design of an appropriate fire safety program.

Prioritizing by Risk

Choices and Concerns of Prioritizing by Risk. A similar set of choices arises in choosing the properties of interest. Suppose the concern is with fire deaths, and the community, like most, suffers 80 percent of its fire deaths in home fires. This situation clearly argues for special attention to homes. But should the team target all homes and should homes be the only target? If not all homes, which homes should be targeted? If not exclusively homes, what other properties should be targeted?

Data on the fire problem will indicate where to target programs if targeting is done, but the same data will indicate the high price paid for targeting of any kind. Targeting based on fire problem data will mean targeting high-risk places and people. However, targeting the highest-risk places and people may mean giving up in advance any chance of reducing the large share of the fire problem cumulatively accounted for by places and people having less than the highest risk. It may be that 1 percent of the community accounts for 20 percent of fire deaths, for example, but if that group is targeted exclusively, then 80 percent of fire deaths will be left untouched, even if the program works perfectly on its targeted group.

In addition, there are other legitimate concerns, many of which also have data that can be used in choosing the types of properties to target. For example, there are costs involved in delivering the program. If there is need to travel to selected sites (e.g., schools, homes) to deliver the program (e.g., school-based fire safety education, home inspections), then those costs are likely to be sensitive to the scatter of locations of targeted properties. It will cost much less, for example, to go to the highest-risk block in the city than to go to the 25 highest-risk households in the city. Also, the program itself needs to have multiple parts if it is to address several very different property types. After homes, the property class that accounts for, by far, the largest share of fire deaths is road vehicles. But the fire problems of cars and trucks are far different from those of homes. An educational program designed for homes would be much easier to adapt to other residential properties—or to any group of buildings—than to vehicles, where the educator might as well start over from scratch.

In fact, it is difficult to find any fire safety educational program designed for vehicles, and this challenge brings up another problem. Data analysis may do more than help choose among alternative educational programs. It may indicate a need to go beyond education in designing an effective prevention or mitigation program, for example, through codes and standards or other means for changing the physical characteristics of an engineered environment.

Public Priorities. Public priorities do not always follow patterns of risk, either. The public wants most of all to be protected from fire risks associated with strangers, even though they are much more at risk from themselves and their families and friends. Risks are less acceptable when they are unfamiliar or involuntary, hence, the tendency to focus on strangers.[1] Homes and private vehicles account for more than 90 percent of all fire deaths, but they account for much less than 90 percent of people's exposure, as measured by, say, time.[2] The public worries about fire risks to children, even though school-age children are the lowest-risk age group in the population.

Much of the public worries about fire risks to people like themselves more than they worry about fire risks to people in other social groups.[3] Hence, programs targeted on the comparatively small high-risk groups may draw less public support than programs that make people with average-to-low risk even safer. This question may seem purely philosophical or ethical, but most fire safety educators are able to operate only because other people decide to give them funding and other resources. A program designed with an eye to the special concerns of the people who control the resources is more likely to obtain the resources it needs to succeed.

Questions to Consider When Prioritizing by Risk. All of this needs to be considered, and all of it can be reduced to data. Should the educator target properties with a history of fire deaths? Or places with unusually vulnerable populations (e.g., schools, nursing homes, hospitals), even if their actual fire history has been extremely low? Or places with high occupancy (e.g., arenas, high-rise buildings), just because of the number of people potentially exposed to fire? Or places with unusual hazards, because the complex knowledge and behaviors required for their fire safety are the furthest from simple common sense? Should only buildings be targeted? Are other agencies or organizations being implicitly expected to address the fire safety needs of places not targeted?

Trend Versus Current Size

Another point to examine in data analysis to define the fire problem is the question of trends. From a national perspective, for

example, total fire deaths have been declining, and the risk of death from fire relative to the size of the population has been declining even faster. Trends for fire deaths involving particular fire causes, however, have shown different trends.

In 1980 the top two major fire causes, in terms of home fire deaths, were (1) smoking and (2) heating. Since then, these two causes have been among the fastest declining.

Confirmed and suspected arson declined in terms of fire deaths, but not so steadily and not so steeply, and it moved past heating as the second leading cause of home fire deaths in the late 1980s. Child-playing fire deaths rose in terms of share of fire deaths, ranking fourth in 1993 behind smoking, arson and suspected arson, and heating. With the help of the new child-resistant lighter standard, introduced in 1994, however, child-playing fire deaths plunged. In recent years, child playing has consistently fallen below 10 percent of fire deaths. Which cause should a new educational program target first? Should it be smoking, which is still, as far as the most current statistics indicate, the leading cause of fire deaths? Should it be arson and suspected arson, which could be the leading cause in a few years? Should it be heating, which of all the leading causes involves behaviors that are easiest to change through education and so might still produce the most lifesaving value for a given level of effort? Or should it be cooking, which has had the least favorable trend of the four leading causes?

There is no one best answer to these questions. Any declining problem that is given priority in a new program may turn out to be a case of overkill. Any increasing problem that is given priority may turn out to have been varying around a constant or even declining trend line; that is, the "increase" may turn out to have been an artifact of when and how the baseline statistics were analyzed. Then again, any problem *not* given priority may suddenly "take off" and, once increasing, may lead to considerable loss and suffering before it can be controlled. For example, heating fire losses increased from the late 1970s to the early 1980s before intensified educational efforts, combined with other factors, brought that fire problem back under some degree of control.

Figure 5.7.1 shows that in the early 1980s, fires started by children playing with matches far exceeded fires started by children playing with lighters. The death toll with matches, not shown on the graph, also was usually higher than for lighters.

In the mid- to late 1980s, some fire safety advocates noticed that the match component was declining rapidly, while the lighter component was not clearly declining at all. This situation led to support for changes to lighters to make them more child resistant. A counterargument at that point was that matches still seemed to be the larger problem, at least in terms of fires and deaths and possibly as rates relative to numbers of uses of the two products. For these opponents, the danger was that, by chasing the problem with a less favorable trend, we might shift people to a product (match) that might be riskier, leading to an increase in fires and deaths.

In a case in which the good data do not all point in the same direction, the ideal response is more research and more data. Research found that children playing with lighters tended to be younger than children playing with matches—too young to be reached with confidence by educational programs. Further data from the early 1990s showed the lighter component passing the match component, first in fire deaths and eventually in fires.

As noted earlier, the introduction of the child-resistant lighter requirement in 1994 produced an immediately and substantial trend reversal, which has been sustained and extended through a number of years. Unexpectedly, this change in lighter design coincided with a resumption of the dramatic decline in fires due to children playing with matches. This decline sug-

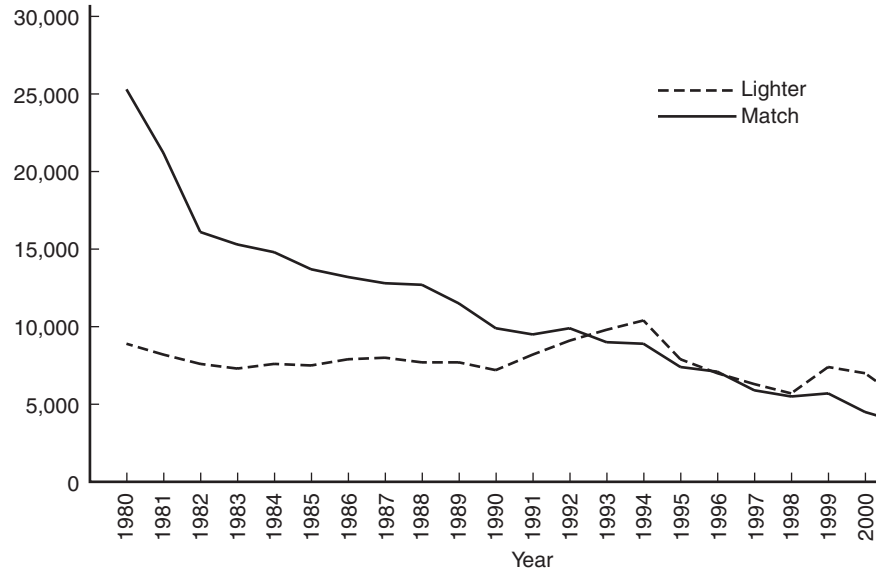

FIGURE 5.7.1 Child-Playing Home Structure Fires Involving Matches or Lighters. For 1999 and later, all fires attributed to "playing" are included, and so statistics may not be limited to fire play by children. (Source: NFIRS and NFPA survey)

gested some positive changes not fully explained as intended effects of the product change. In fact, the most obvious explanation seems to be that educators put more emphasis on educating parents and other caregivers about the dangers of these fires, and that awareness and education in turn both reinforced the positive effects of the product change and produced positive results of their own on matches.

Putting It All Together

The previous paragraphs were heavier on questions and issues than on answers. For those who prefer answers and guidance, the following tips may provide a reasonable way forward.

Design the program to reduce the risk of fire death among the people whose safety is the responsibility of the educator's team, which may be a community, an age group, a company's employees, an organization's members, and so on. Treat every death as equally important and potentially preventable. Although fire deaths should not be the only measure, because they take too long to show statistically significant effects, deaths should be regarded as the primary measure of success.

As an example of how long it takes to show success, measured by fire deaths, however, consider the Louisville, Kentucky, home smoke alarm campaign of the 1980s (Figure 5.7.2). Louisville fire officials properly used a 5-year baseline that stretched back before the program began. The average fire death toll in that period was 15, including a declining trend in the last 3 years of the baseline. The first year of the program showed a death toll of 10, well below any year in the baseline and even below the improved level one might have computed from the baseline trend. However, a prudent program manager would want to see multiple years of data in order to determine whether the excitement surrounding the program had produced a first-year improvement that could not be sustained or whether some other fluke or normal variation asserted itself. With 4 years of post-program data, it seemed clear that a substantial (more than one-quarter) decline in fire deaths had occurred.

But suppose the 1987 death toll of 16 had occurred in 1985. That statistic would have presented a real blow to the program and might have prematurely aborted it, even though time would show that it was a fluke. Or, suppose someone put forward a theory based on changes already in the works in 1982–1984 and claimed that the 1985–1988 success was only a continuation of that earlier trend and not a result of the program. It might have taken much more analysis or more years of data to sort out these conflicting claims.

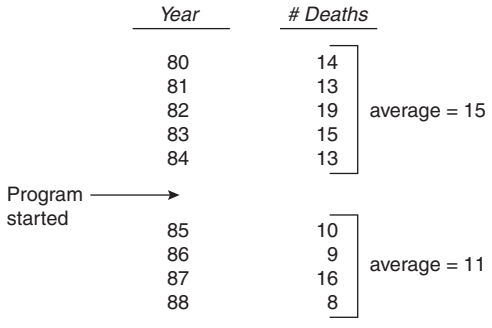

FIGURE 5.7.2 Louisville, Kentucky, Fire Deaths and a Home Smoke Alarm Program (Source: Philip Schaenman, et al., *Proving Public Fire Education Works,* TriData Corporation, Arlington, VA, 1990, pp. 92–93)

As it is, the substantial difference between 15 deaths a year in 1980–1984 and 11 deaths a year in 1985–1988 is not yet statistically significant. The difference between the two averages (15 and 11) is about 1.2 standard deviations, if the entire nine years is treated as one set of years with death tolls randomly chosen from what is assumed to be a constant risk of fire death, subject to variation. Statisticians usually look for at least 1⅔ standard deviations for significance in a one-sided test. A trend line analysis might look better, given that three of the four lowest years came after the program was begun, but it would still probably take quite a few additional years of progress to satisfy a classical test of statistical significance.

This illustrates the special challenge involved in focusing on fire deaths as an outcome measure.

When extending the scope to include injuries, property damage, or some other objective, treat all such objectives as secondary to the risk of fire death. That is, design the program to achieve a reduction in the fire death toll, and only then, if some latitude in the design of the program exists (i.e., room for a few more behaviors to be taught), look for program design features that will address the other objectives. The reason for this is that, even though other kinds of losses are more frequent, deaths are preemptively more important.

Use at least a 5-year baseline of the community's or organization's fire experience for analysis as was done in Louisville. More years will be needed if the community or organization has fewer than 100,000 people. If the target population is closer to 10,000, or even less, the community or organization's own data will comprise too small a base to analyze or track success by the fire death toll in any reasonable period of time. In that event, use historical national fire death data—or, if obtainable, state data or data on a group of similar communities—for analysis to design the program.

Many fire safety education programs are aimed primarily at fire prevention, as opposed to mitigation after fire starts, as is true for programs based on home smoke alarms or sprinklers. If so, it is appropriate to use fire incidents, rather than fire deaths, as the primary outcome measure. Because fires are 50 to 100 times as common as fire deaths, a shift from deaths to fires greatly improves the analyst's ability to quickly confirm statistically significant program impacts. Figure 5.7.3 is an example of such a tracking, in which a Waterford, Connecticut, school-based education program covering several fire safe behaviors was used to reduce the number of reported fires (excluding vehicle fires, which were considered outside the range of impact of the behaviors included in the program).

Note, too, that there is still room for interpretation and debate. The program in Waterford was introduced at the end of a two-year period of increases in the number of reported fires, which followed a two-year period of decreases. The program appears to have been successful. An immediate and substantial drop in the number of fires occurred, followed by

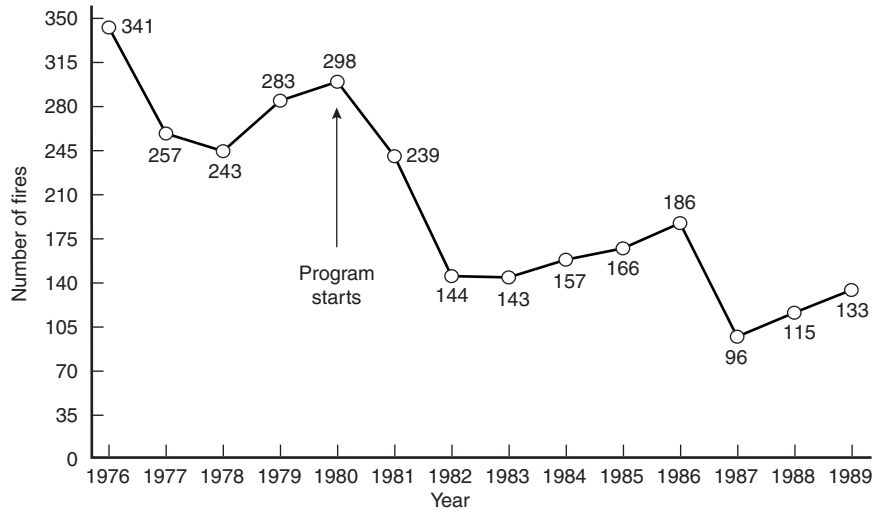

FIGURE 5.7.3 Waterford, Connecticut, Fires (Excluding Vehicles) and a School-Based Education Program (Source: Philip Schaenman, et al., *Proving Public Fire Education Works,* TriData Corporation, Arlington, VA, 1990, pp. 39–41)

an even larger decline the next year. These gains have been largely sustained through the seven years that followed. But as with the other examples, one could make the case that the 1976–1978 decline was the real long-term trend, that the 1978–1980 increase was a temporary fluke, and that the 1980–1989 declines were therefore more attributable to a resumption of the already established declining trend and not so much to the new program.

In a situation like this, in which the data are not conclusive, the obvious, simple interpretation is also the one that favors the program, and a positive impact from the program is what everyone would have expected. Nevertheless, if there were already some well-defined programs underway in the mid-1970s and a good case could be made that their full effect had not yet been achieved, one would want to make sure that the older programs were kept in force alongside the new program, thereby assuring that the favorable impact on fire rates continues, no matter what the principal factors in the trend might really be.

Analyze the historical database for major patterns that will be useful in selecting or refining programs or in targeting or reaching selected audiences. (See the following two sections.)

Do a "snapshot" analysis of the baseline, that is, one that ignores trends. Then, only after the initial conclusions have been set, look at major trends and consider making a few adjustments based on the trends. Minimizing use of any apparent trend information other than major trends will (1) avoid the dangers of overreacting to statistical fluctuations that are not real trends and (2) avoid the temptation to change the program before it has finished "doing its job" (which is analogous to stopping the antibiotics as soon as symptoms improve).

Figure 5.7.4 shows a trend line of civilian fire deaths involving children playing with lighters, showing eight years before and after 1994, the year when the child-resistant lighter requirement was introduced by the U.S. Consumer Product Safety Commission. This is as close as we will ever come to a program showing immediate and sustained, substantial improvement. Given that disposable lighters turn over frequently, it is not surprising that the improvement was immediate, as would not be expected with a long-lived product such as a mattress. Even for a program with immediate, sustained, substantial improvement, however, the effects show signs of leveling off with what is still a high death toll.

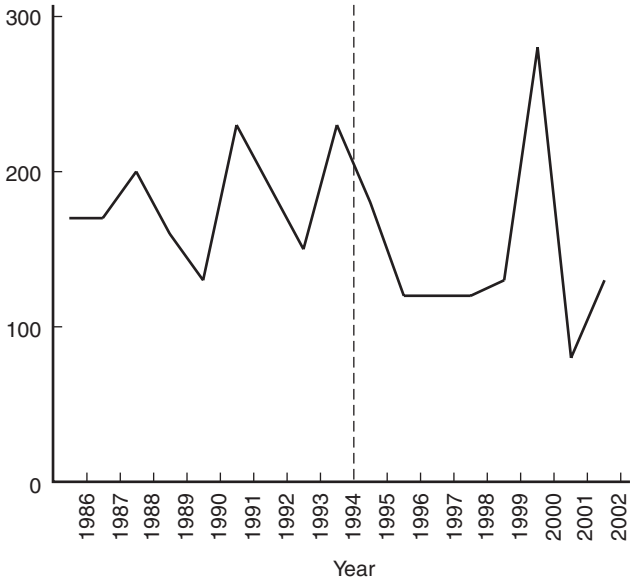

FIGURE 5.7.4 Deaths in Child-Playing Home Structure Fires Involving Lighters, 1986–2002. For 1999 and later, all fires attributed to "playing" are included, and so statistics may not be limited to fire play by children. (Source: NFIRS and NFPA survey)

INTERVENTION STRATEGIES

The purpose of data analysis is to set the stage for design or selection of a program that will reduce the fire problem as defined. However, many programs already exist; so do not "reinvent the wheel"—or any other parts of the car. This fact means the analysis will be most useful if it identifies patterns in the fire problem that favor some strategies and programs or help to set specifications for the selected strategies and programs.

For example, if the education team has data on fire deaths by home smoke alarm status (e.g., how many fires were in homes with no smoke alarms, how many in homes where smoke alarms were not working, how many in homes with an insufficient number of smoke alarms, how many in homes with smoke alarms in the wrong place) or related variables (how many in homes where there was no escape plan), then the team will have a much better idea whether to build the program around home smoke alarms, and if so, what specific points the education should address. Some of the data cited in this example will be retrievable from a typical state or local fire department database on fire incidents. Other data might require a survey. The analysis done will depend on the data available. If data specific to the target audience are not available, analysis based on national data may be available and used.

Fire cause data is similarly of interest because each cause corresponds to specific fire prevention behaviors that may be emphasized if the cause is a major concern.

A key danger at this stage lies in committing oneself too early to a particular approach. For example, if fires are analyzed by cause—and only by cause—this may lead to an education emphasis on prevention, to the exclusion of the kind of education that can save lives even when fire occurs. It is far better to develop at the outset a comprehensive view of all the programs one could pursue, and then let the specifics of those programs guide the selection of analyses that will help decide the best programs and refine them to best fit the team's particular circumstances.

Keys to Program Success—Reach and Effectiveness

The central point to remember when setting priorities is that success requires substantial leverage, which comes from two equally important sources:

1. The educational program has to be effective enough to make a major difference in the fire risks faced by everyone the program reaches.
2. The program has to reach most of the people, representing most of the existing fire risk, or else even a highly effective program will have little effect on the size of the total fire problem.

People cannot be saved if they are not reached or if they are reached by a program that makes little or no difference. Frequently, the need to reach a large audience and the need to be effective with those reached will compete with one another. One can affordably reach many people with billboards and radio public service announcements, but it is not clear that such media, by themselves, make much difference. The educator can dramatically reduce the fire risk to people by using a comprehensive fire safety curriculum, but it takes significant resources to do so, and even then, such a program directly reaches only school-age children. A full unintentional-injury curriculum provides high effectiveness over a wider range of injuries, but it poses the same challenges in achieving reach to the full target population.

Effectiveness, in turn, can be assessed only against a clearly stated objective, and a single program may be used to achieve many distinct objectives. What are the objectives with a school-based program, for example? (1) Is the program objective to teach the schoolchildren how to be more fire safe during their school-age years? (2) Is the program objective to teach them fire safety for the rest of their lives? (3) Is the program objective to have them deliver fire safety to their families?

The first program objective involves a narrow reach (only the students and only for a limited time), but a high degree of effectiveness that can be readily measured. The second objective involves a wider reach (only the students but for their entire lives), but a lesser degree of effectiveness (many will forget what they have learned without practice) or a need to expand the program (how can fire safety refresher training be given to adults who learned fire safety in schools as children?). The third objective involves the widest reach (potentially everyone who knows a school-age child), but the least effectiveness (a lot will be lost in translation before the students can pass on their knowledge to their families).

To evaluate the impact of a program, a baseline is needed that addresses all the objectives. If the educator intends to teach the schoolchildren only while they are present, only a pretest and a posttest are needed to check gains in knowledge, what fraction of the class learned all behaviors, and so on. However, if the goal is to teach children for life, methods must be found to test adults five, ten, and so on years out of school, to determine their retention levels. And if the goal is to teach families through their children, then pretests and posttests are needed for family members as well as for schoolchildren.

Selection and refinement of the program using data analysis require application of the data collection protocols that support the kinds of evaluation implied by the objectives set.

Programs Implement Broad Strategies

At this stage, consider the difference between the strategy and the program. For an educational program, the strategy is to impart specific knowledge and change specific behaviors for a designated target audience. The program includes the materials used to accomplish that end, the people taught, and the people they teach, together with the materials they have to use. For example, the city of Portland, Oregon, won a national fire safety award for a program that involved targeting high-risk neighborhoods by working through respected, trusted neighborhood groups.[4] The fire department taught the church leaders, who took the lead in teaching the neighborhood.

Fire code inspection programs are also education programs. NFPA research conducted in the 1970s indicated that the successful fire code inspection programs are the ones that have nearly universal reach and that educate and motivate building

occupants to make changes, even when the inspector is not there.[5] Most fires and losses involve behaviors and transitory hazards that may not show up in an annual inspection. Unless the occupant has been convinced to act as a year-round inspector, which means education, the value of the inspection wears off very fast, even if the inspector is very thorough and enforcement is very effective.

Six General Approaches to Prevent Fire Loss

During development of the initial list of candidate educational programs, for which objectives will be assigned and reach and effectiveness assessed, it may be useful to use the following set of categories, introduced in Section 3, Chapter 1, "An Overview of the Fire Problem and Fire Protection." They are (1) prevention, (2) slowing the rate of growth of initial fire, (3) early detection, (4) early suppression, (5) preventing unusually rapid spread of fire or its effects, and (6) evacuation. Each of these categories has engineering and educational approaches, which ideally should work together. And each can be pinpointed as a possible priority through data analysis.

Analysis of fire deaths by major causes, defined in terms of behaviors and heat sources, can identify a number of possible priorities for prevention education. Most educational programs include a number of prevention-oriented behaviors and so can benefit from an analysis by major causes. Bear in mind, however, that conventional educational techniques are of limited or unproven effectiveness in dealing with some leading causes of fatal fires; for example, smoking, arson, and children playing with fire. Before assigning a high effectiveness to the program, make sure it will be effective on a large fraction of targeted fires and consider product changes as a strategy. For example, a serious program to address smoking fires includes consideration of efforts to pass a state law mandating reduced-ignition-strength cigarettes (commonly called "fire-safe cigarettes"). The state level approach is suggested, because it is not practical to try to make such cigarettes mandatory, or even available, in a single community.

Analysis of fire deaths by the first burnable item ignited may shed some light on the problem of rapid early fire growth. Flammable and combustible liquids and gases can promote such rapid growth, as can large pieces that are ordinary combustibles, such as upholstered furniture. Most educational programs contain some guidance on storage of such materials, on limiting quantities, or on the use of potential heat sources near them, but the educator might also consider guidance on selecting items to reduce risk (e.g., choosing upholstered furniture made to the industry's voluntary standard on resistance to cigarette ignition) and on positioning items (e.g., how close are furniture pieces to walls and to each other?).

National analyses of fire deaths by detector performance typically show the value of home smoke alarms and of keeping them operational. So will analysis by sprinkler performance, which should be included as an option in any fire safety program.[6] Analysis of fire deaths by extent of flame damage—and, in particular, whether or not fire is confined to the room of fire origin—will always show the importance of blocking fire spread. For an educational program, the analysis will be enough to justify including guidance on the need to avoid creating avenues of rapid flame spread (e.g., untreated wood paneling on walls, especially on stairway or corridor walls).

Analysis of fire deaths by the victim's condition before fire began and activity at time of fatal injury will give some insight into the importance of evacuation issues. Typically, most victims never get as far as trying to escape. They were asleep, impaired by drugs or alcohol or disability, or too young or too old to act effectively. Every such finding translates into a point for education, but be realistic about what can be achieved. The educator probably cannot convince people not to get drunk—and certainly cannot change disabilities or the limitations associated with various ages—but he or she may be able to convince people to develop and practice escape plans that are tailored to their circumstances.

Putting It All Together

Assemble and brainstorm a list of promising educational programs. Include any available evidence on these programs' track record of effectiveness. Lacking such evidence, try to develop some estimates, for example, by asking for quantitative estimates from a variety of national experts and others familiar with the programs.

Set up a flowchart showing how specific actions will lead to changes in and actions by other parties, and from them to changes in the target audience, and from those changes to reductions in fire deaths and other forms of fire loss and risk. Fill in anticipated effects of changes at each stage and how effective the changes will be, based on the predicted effects.

Based on a review of available resources (and other considerations in the following section), rough out how large a version of each program can be launched. Translate that into an estimate of reach, that is, the fraction of the target audience that can probably be reached.

Despite the emphasis on data analysis throughout this exercise, it is important to think qualitatively more than quantitatively. Look for big differences in likely impact, and do not be too wrapped up in small percentages. It should be obvious by now that much of the information will involve best guesses. Pay particular attention to any points in the flowchart at which there is a real risk that the whole program will go "off track" if some key group does not do its part.

For programs that still look attractive after this analysis, use data analysis of fire experience to specify program details (e.g., which prevention behaviors will be emphasized?). Based on these details, estimate what fraction of the total fire problem the program will target.

Even program details such as timing can be informed by data. If your program includes a component for heating equipment fires, develop a graph like Figure 5.7.5, showing such fires as they vary over time. By refining the graph (or table), you can find the week(s) when heating equipment fires traditionally begin climbing. Or, if you are very ambitious, you can plot daily temperatures (peak, low) and estimate the trigger temperature for widespread activation of heating equipment and onset of related fires. With this information, you can time a public awareness campaign that will hit just when most members of

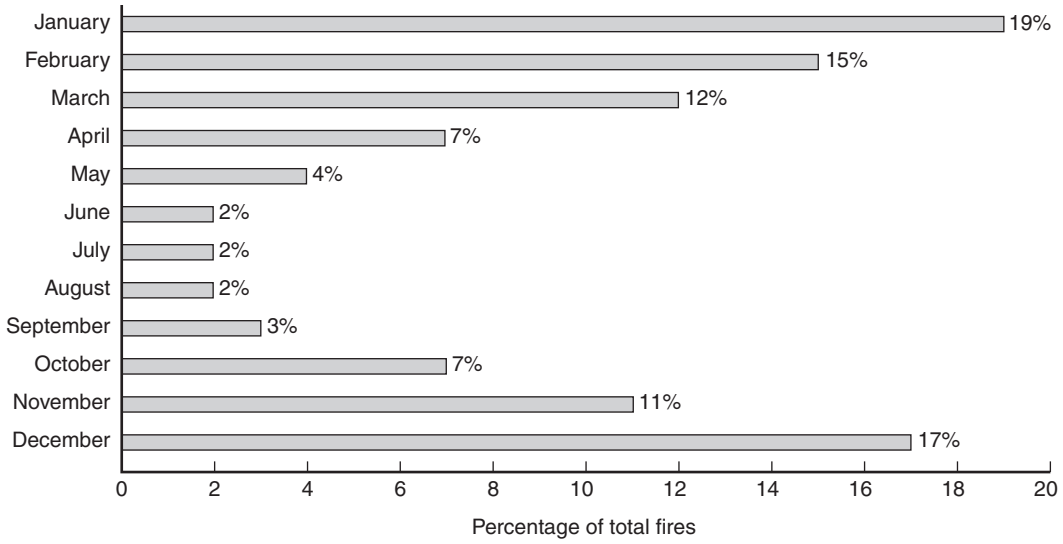

FIGURE 5.7.5 Home Heating Equipment Fires by Month, 2000–2004 Annual Averages

the community are already beginning to focus on their heating equipment and the need to bring it back in service.

TARGET AUDIENCE CONSIDERATIONS

Types of Audiences

Most public education programs target one of the following four groups: (1) the general population, (2) high-risk populations, (3) schoolchildren, or (4) people where they work. The first two are targeted because they represent all or a large share of the total fire problem, which gives the program a large reach. The second two are targeted because they find people under circumstances in which they can and will spend significant time in an ideal learning environment, able to listen to lessons, practice behaviors, and be tested for what they learn. Conversely, the first group is hard to reach in ways that are highly effective, and the second group is just hard to reach. The last two groups have below-average fire risk to begin with, which may mean that high impact requires extending the reach of the program.

For programs aimed at the general population, serious questions have to be asked at the outset as to how effective the program will be. It is almost impossible to devise a program for the general population in which the participants practice fire safe behaviors. Can the program even ensure that everyone will read or hear the lessons? Mailed materials and materials dropped off by people on rounds will often be discarded without being read. Billboards and public service announcements are within viewing range of only a fraction of the population and will be ignored by many of those.

Cost alone is usually enough to force a program to target only a fraction of the general population, in which case the program should be targeted at high-risk populations. If forced instead to target a partial program based on greatest ease or lowest cost, the education will almost inevitably, albeit inadvertently, end up targeting low-risk populations, the people who need the program least. The safest neighborhoods for home inspections, the most receptive neighborhoods for community meetings, the participants in fraternal organizations and other social groups, and the best and most receptive schools, all tend to favor the more affluent, better educated, and lower fire risk people.

It takes a great deal of work to hit the target of high-risk populations, so much so that Section 5, Chapter 5, "Reaching High-Risk Groups," is devoted to that topic alone.

High-Risk Audiences

Once the decision to target high-risk populations is made, they must be identified and creative ways must be determined to reach them. If high-risk populations are defined by where people live, use actual fire history to find parts of the community where fire rates and fire death rates, relative to population, are unusually high. This will lead naturally to programs that deliver fire safety within those neighborhoods. (High-risk areas can easily have rates several times the community-wide average. Again, do not focus too much on small differences, such as slightly above-average fire rates.)

At this stage, effectiveness considerations, already discussed, will become as important as extent of coverage, or reach. Door-to-door programs offer more potential for substantial learning but are very resource intensive. How many can the program afford to reach in this fashion? Assembling people through the guidance of some community group is more cost-effective but permits less individualized teaching and therefore may not result in as much practice of behaviors by the entire target audience. Such programs also tend to draw disproportionately from the lower-risk occupants of even a high-risk neighborhood. Mailing or dropping off materials is even more affordable and even less likely to change behavior. Use available data on effectiveness with estimates of projected numbers of people reached to compare different programs.

Older Adults. High-risk populations need not be defined by neighborhood or community, however. Older adults are a high-risk population, for example. Use data analysis to check every assumption for these programs.

For example, in 2000 (the latest year for which published data were available from the U.S. Census Bureau, at press time), there were 2.0 million resident patients in nursing homes, compared to a total of 35.0 million U.S. residents who were age 65 or older.[6] That is, there were about 16.5 older adults living at home for every one living in a nursing home; therefore, any program intending to target older adults as a high-risk population would only "scratch the surface" by targeting the nursing home population.

Further, older adults living in nursing homes already may have much lower fire risk than older adults living at home, because of the much greater built-in fire protection and supervision afforded in nursing homes. The population ratio may have been 16.5:1, but the ratio of fire deaths in the same period was more like 100:1. Therefore, within the high-risk older adult population, the people living in nursing homes need additional fire safety least.

With creativity, an educator might try to target a program for older adults in homes but without ignoring nursing homes altogether. For example, nursing homes or like facilities could be used as magnets to draw in older adults from homes throughout the community.

The need for data analysis lies in the need to check assumptions, because assumptions are an inevitable part of crafting a fire and life safety education program to fit within limited resources. The example just discussed started with a (presumed) fact: it is not affordable to target everyone in the population, and so limited program resources should be applied where they will do the most good. That means large reach and/or high effectiveness. Targeting high-risk populations gives the most reach (in terms of share of the fire problem) per population reached. First assumption: older adults are a high-risk population. Data confirm this; they have more than twice the fire death rate of the general population. Second assumption: nursing homes are a compact, efficient way to reach older adults. Data disprove this, as shown. Third assumption: a program can be devised with enough effectiveness to produce high impact when targeted to older adults. Data can best address this only after the program is specified (targeting nursing homes did not work) and alternative programs are specified, against which to compare the older-adult program.

If targeting nursing homes had proved to be a good idea, it would still be necessary to be creative, challenge assumptions, and analyze data to specify details of a program. For example, should the educational program target the patients or the staff? Both are possibilities, and both types of programs may have data on effectiveness. Or would a mixed program, targeting both groups, be best (where "best" takes account of affordability, too)?

Fire-Related Characteristics and Target Audiences. In fact, every fire-related characteristic can be examined as a basis for identifying high- versus low-risk populations, and, hence, for targeting fire and life safety education programs. Smoking material fires lead the list of causes of fatal fires. How about an educational program that works through points of sale of cigarettes? Heating equipment fires still rank fairly high. How about educational materials distributed where portable or fixed space heaters are sold, serviced, or maintained? These are examples of what can be an iterative process, wherein data help in design and selection of existing educational programs but also suggest unmet needs that may spark ideas for entirely new kinds of educational programs. Data analysis can be a stimulus to that kind of creativity as well as a reality check on assumptions about what will work and who most needs attention.

Targeting schools or workplaces presents its own set of questions, similar in form but different in specifics. Does the program provide that participants will practice fire safe behaviors, or (less effective) take a written or oral test after being taught about fire safe behaviors, or (even less effective) be lectured on fire safety with no testing or interaction, or (least effective) be notified of the availability of materials on fire safety?

Note the variations implied by this question. After a target audience and a set of information to be used in an educational program are specified, success (effectiveness) in getting the audience to learn, know, and be able (and likely) to act on the information may depend on the manner and intensity of the interaction. The easier it is for the audience to "drop out" of the exchange, by ignoring the materials or even by not examining them at all, the more likely it will be that many people will not be educated.

And reach takes many forms. Do all classrooms in the school, all schools in the system, all areas in the workplace, and all facilities in the industry participate? Or do only the most motivated, self-selected ones, who probably have the lowest fire risk already, participate?

MAPPING PROGRAM DELIVERY

Divide your community into areas on a map. The areas could be large, like a census tract, or not so large, like a census block, or small, like an individual building, or very small, like an individual occupancy (e.g., one apartment in an apartment building, one store in a mall, one tenant in an office building). When choosing how small to make the areas—how fine to make the grid—think in terms of how much ground you can cover with program delivery in a day or a week. Or, think in terms of the smallest unit in which it could make sense to deliver the program to that area and not immediately move on to the neighboring area. Visiting one apartment unit and then leaving the building makes no sense, even if there is a huge difference in risk between one household and all the others. On the other hand, breaking off at the major highway that borders a census tract could seem quite natural.

Loss Value

Next, for each area, enter the area's loss value—such as average fires or fire deaths over the past five years. Do not include losses in properties your program will not visit; for example, a home inspection program will not include a grocery store in the neighborhood. Next, if you deem it appropriate, discount the loss value by your predicted success rate in reaching the area's population and effecting change. For example, you might

predict more cases of finding no one home in one type of neighborhood (e.g., where nearly everyone works or attends schools) than another (e.g., with more retired people or stay-at-home parents). Or, you might predict more success in changing behavior in one neighborhood than in another (e.g., where few people speak English or more people are too poor to make changes called for in your program).

The resulting estimate is the fire safety benefit of delivering a program to that area. You now need a cost value to go with the safety benefit. Estimate the total cost of delivering the program to the area, and you may want to use more than one dimension (e.g., person time, out-of-pocket costs) for resources that have separate limits and cannot be traded off with each other.

Cost-Benefit Ratio

Finally, divide the area cost into the area benefit. Use these cost-benefit ratios to make a preference ordering of the area in the community. Draw a line below the last area you can fit into your overall budget. If you have separate budgets for different resources (e.g., time, money), then you may need to develop multiple lists (or use mathematical techniques for what are called "packing problems" in the field of operations research).

If this effort seems like a lot of work for limited program benefit, it well may be. Many communities have a single, compact high-risk area, which is so distinct from the rest of the community that everyone knows about it even before analysis is conducted. Nevertheless, many communities have more complex layouts, including different areas with elevated risk for different reasons. For these communities, a more sophisticated analytic approach may be worth the trouble.

WAS THE TARGET AUDIENCE REACHED?

At this stage, data are used not to design or select the program but to evaluate its impact. That evaluation may lead to some redesign, in which case it is necessary to move back to an earlier point, as appropriate. This first step in evaluation corresponds to the first effects the educator can hope to measure. It relies on *activity* measures—measures of the work already done.

The earlier discussion of intervention strategy selection called for estimating the likely reach of programs and strategies as a basis for choosing those to be implemented. After program implementation, it is necessary to measure the reach that was actually achieved.

To do this, begin with data on people and groups to whom the program was delivered. For example, which schools were sent materials? Usually, the materials will not have been sent directly to the target audience, and so it will be necessary to survey the addressees to determine how many of them passed on the materials, and to what fraction of the target audience members within their organization. Then it may be necessary to survey those individuals to determine how many of them used the materials.

Take the school materials example again. The program data will indicate which schools were sent the materials, but the educator will need to survey the principals to determine which classrooms took the materials, then survey the teachers from those classrooms to determine which ones used the materials and to what extent, and finally survey the teachers or the students to determine how many students in the classrooms participated in the exercise (e.g., omitting students who were sick or excused for other reasons).

Whatever method is used to build up the database, the goal is to estimate the fraction of the original target audience that was actually reached. Therefore, count people, not some more convenient distribution unit, such as classrooms, schools, workplaces, and so on.

This evaluation needs to be this thorough so that a realistic view of what was achieved can be obtained. There are many steps in a program in which targeted people may be missed, and so any such step not evaluated is a place where one might inadvertently overestimate the effective reach of the program.

DID THE STRATEGY WORK?

Measuring Change

This evaluation step corresponds to the design step that specified the strategy. It usually involves pretests and posttests of knowledge or learned behaviors for the target audience. This step calls for *change* measures—the most direct measures possible of the difference the program has made. Table 5.7.3 summarizes types of evaluation measures.

This comes later in the time sequence because, for most programs, the program objectives will imply a goal of long-term learning. The educator needs to ensure that the program has effects that last past the end of the program. This means, ideally, a sequence of posttests, for example, immediately after the program, one year out, five years out, and so on.

In time, enough may be known about patterns of retention of fire safety knowledge that it will no longer be necessary to conduct elaborate posttesting regimens for specific programs; but, at present, such information is quite useful.

Even at this stage, look primarily for changes that are substantive and closely linked to how lives are saved. Measure changes in knowledge (pretests and posttests) and behavior (by surveys, interviews, and other sample observation techniques). It may be interesting to note, for example, that school officials and fire officials are working together more now than before or that they enjoyed participating in the program or that they believe it made a difference; but these kinds of changes are too far removed from the hard evidence of program impact to deserve much emphasis in the evaluation.

Were Lives Saved or Losses Reduced?

This is the ultimate measure of benefit and impact—and the only one that truly matters. It is the evaluation counterpart to the design step that asked what the problem was. It involves comparing fire death rates and other fire loss rates after the program to those before the program. This step calls for *outcome* measures.

These are change measures, too, but they are measures of the intrinsically valuable changes to which all the work was meant to lead. If people learn more or know more, that

TABLE 5.7.3 Types of Evaluation Measures for Public Fire and Life Safety Education Programs

Type of Measure	*Purpose*	*Timing*	*Examples*
Activity measure	Determine whether the target population was reached with something.	Measure can be calculated based on plans and scheduled activity, before or during program delivery.	1. Number of schoolchildren contacted. Weak measure because it does not indicate fraction of total reached, any bias in selection of children reached, or possibly even whether contact stopped short of program delivery. 2. Percentage of schoolchildren taught, overall and by school, by grade, by part of community (distinguished by high vs. low fire risk). Strong measure because it indicates relative achievement of goal and checks for bias. 3. Breakdown of above measures by different risk populations (e.g., by income, gender, ethnic, or cultural grouping). Measures are to look for differential input and reasons for it.
Change measure	Of the people reached, determine whether learning occurred or whether behavior changed as a result.	Measure of learning can be calculated at end of program but should also be calculated 6–12 months later to check for decay in learning. Measure of behavior change takes time to measure but can also be calculated just after the end of the program and 6–12 months later.	1. Percent correct answers on posttest. Weak measure because it shows knowledge other than learning. 2. Percent correct on posttest minus percent correct on pretest. Better measure but still needs to be calibrated or interpreted by how much learning was needed. 3. One minus [(percent correct on posttest) / (percent correct on pretest)]. Measure addresses learning achieved, calibrated by learning needed. May still be misleading if very little learning was required, and form of the measure is sufficiently unfamiliar and complex that it will take educators a while to get comfortable with it. 4. Analogous measures can be applied to behavior, if a system can be established to observe representative samples of behavior. For example, bicycle-helmet-wearing behavior in school can be checked unobtrusively before and after program. 5. Breakdown of above measures by different risk populations (e.g., by income, gender, ethnic, or cultural grouping). Measures are to look for differential input and reasons for it.
Outcome measure	Determines whether enough people at risk were reached by a program with enough effectiveness or the knowledge, skills, and behaviors most important to that risk, resulting in reduced human losses (i.e., deaths and injuries)	Statistically significant data will require years to accumulate. Even more time will be required if analysis focuses on deaths and injuries involving the specific skills, knowledge, and behaviors targeted by the program.	1. Number of deaths and injuries among the target population, baseline vs. after program. Good measure of what the program is intended to affect, but not calibrated for program reach or effectiveness. 2. Number of deaths and injuries among the population taught vs. target population not reached, baseline vs. after program. Better measure calibrates for reach but not for effectiveness. Also useful to use population not reached as a control group. 3. Breakdown of measure No. 2 for deaths and injuries involving knowledge, skills, and behaviors targeted by program vs. deaths and injuries not involving those. Measures are not to gauge impact but to sort out reasons for impact or lack of impact. Does the program have limited impact or limited reach (among target population, among critical behaviors and risk factors) or both? 4. Breakdown of above measures by different risk populations (e.g., by income, gender, ethnic, or cultural grouping). Measures are to look for differential input and reasons for it.

is valuable only if they have fewer fires and fewer of them die (or are injured or whatever the chosen loss measure[s] for the objectives may have been). At the same time, these change measures may be affected by more than just the program. Time has passed since the baseline period. People may have gotten poorer or richer, smarter or less knowledgeable, more mature or more impaired by advanced age. And other groups will have been conducting programs: some directly and deliberately focusing on fire safety; others not intending to address fire safety but having some impact on it nevertheless. Therefore, although these measures are more directly indicative of the program objectives, their changes or lack of changes may reflect more than the program under scrutiny.

Therefore, it is useful to apply experimental techniques that can isolate the fire safety program from other influences. Some common phenomena should be checked, as described below.

Fire loss rates, including death rates, will vary randomly over time, often significantly. If the educator introduces a program at a time when those variations have pushed loss rates up to historically high levels, then significant reduction relative to that baseline can be expected, even if the program itself has no effect. Loss rates will return to "normal" levels or trends, and that return will look like an improvement. Because a random variation pushing up loss rates looks the same as a problem "spinning out of control," in need of immediate special attention, it is not unusual for programs to be launched at the top of one of these artificial peaks. Consider that possibility when interpreting data.

Consider, too, the Hawthorne effect. First noted in studies of industrial productivity, the Hawthorne effect refers to the tendency of populations to do better just because someone is paying more attention to them. Just being in a fire and life safety program may inspire participants to be more fire conscious, and so more fire safe, even if they really have not learned anything more. These motivational effects rarely outlast the program, or even the experimental phase of the program when publicity is most intense, so this possibility is another reason to check for effects over the long term. (It also can be checked by running a "placebo" program that has no educational content but delivers to a control group all the attention of being part of a program.)

Analyze data not only for how much impact a program produces but also for how the program achieves its impact. It is not unusual for a successful program to produce effects differently than expected. This analysis is important for design choices when moving from pilot programs to full-scale programs or from experimental programs to institutionalized programs, because it is crucial to emphasize those features that actually produced success.

One classic example was a fire department home inspection program whose introduction coincided with a large decline in home fire rates.[5] Detailed analysis, however, showed the decline often preceded the arrival of inspectors in a particular neighborhood, suggesting that the fire safety effects were produced more by the motivational effects of the program's introduction and the desire to "look good" for the inspectors when they arrived. This effect had implications for the program, because it suggested a need to emphasize mass-media publicity in support of the program on a continuing basis and to look for ways to encourage people to "clean up for the inspectors" rather than relying on the inspectors to find hazards on the spot and have them corrected.

See Section 5, Chapter 8, "Evaluation Techniques for Fire and Life Safety Education," for more detailed guidance on measurement techniques and guidelines for interpretation of these last three sections.

SUMMARY

Much of the design and evaluation work needs to be based on local data; these data include data specific to the team's program, community or organization, and target audiences. But a fair amount of the design work can be done on the basis of existing national data analysis, and even the evaluation can take advantage of existing data analysis already done on similar programs.

Guidance on analysis methods is given in Section 3, Chapter 4, "Use of Fire Incident Data and Statistics." For more details on sophisticated statistical analysis and modeling techniques, consult the *SFPE Handbook of Fire Protection Engineering,* published by NFPA.[7]

The most important caution to keep in mind regarding methods is this: the key weakness in most databases is not the quality of the reporting but the representativeness of the coverage. Databases do not have to be complete to be comprehensive; if they are properly representative, statistical methods will allow valid projection of totals from samples. Databases do not have to be totally accurate within each record to be very accurate for statistical analysis; errors usually balance each other out, as one person's miscoding is offset by an opposite miscoding by someone else.

The best national data for public education program design consist of what are called national estimates based on two national fire-department-based databases—the U.S. Fire Administration's National Fire Incident Reporting System (NFIRS) and NFPA's annual fire experience survey. Through the "One-Stop Data Shop," NFPA maintains a listing of dozens of reports covering all aspects of the home fire problem, including patterns, trends, comparative risk factors, major causes, victim patterns, and detection and suppression equipment roles in fire safety. NFPA encourages educators to seek this support.

The U.S. Fire Administration's National Fire Data Center (NFDC) is another valuable data analysis resource. In addition to its role in maintaining and distributing NFIRS to all fire data users, the NFDC has done more than any other organization to develop analyses at the state and local levels. NFIRS is not a complete database, having data on about half of all reported U.S. fires each year, so analyses below the national level are not possible for all areas; however, the NFDC is an excellent resource.

Another major source of fire data analysis at the national level is the U.S. Consumer Product Safety Commission (CPSC). In addition to a wide range of national estimate analyses focused on home fires—and a key role working with NFPA analysts in standardizing the methods used for making national estimates—CPSC is the nation's leading organization for special data collection and analysis projects applicable to home fires.

Watershed analyses of home electrical fires and smoke alarm usage and problems are only two of the best-known examples. CPSC's Hazard Analysis Group conducts these analyses and can describe what is available.

The best compilation of data-based evaluations of fire safety education programs is still a report by TriData Corporation. Anyone interested in evaluation of fire safety education programs should read *Proving Public Fire Education Works,* TriData Corporation, 1990.[8] This valuable report is no longer in print, but photocopies can be obtained from TriData, and many fire libraries have copies available for consultation or interlibrary loan.

Finally, the roughly 30,000 communities in the United States are resources for each other. Remember that, when creating programs or analyzing data for programs, it is likely that some other community has done so already and learned some useful lessons. NFPA's Champions program is building a network of leading-edge communities that have not only successfully demonstrated fire safety education programs but also committed themselves to sharing their knowledge and methods with others. Contact NFPA Public Education for more on the Champions network.

Chapter Contents

The Evaluation Process
Formative Evaluation
Process Evaluation
Impact Evaluation
Outcome Evaluation
Handling Uncontrollable Factors
Uses for Evaluation

Key Terms

formative evaluation, impact evaluation, juvenile firesetting, process evaluation, public fire and life safety education, *Risk Watch*®

Injuries from fire and other causes account for a significant number of deaths in all age groups in the United States, and unintentional injury is the leading cause of death in children aged 1–14.[1] In recent years scientists have come to better understand the risk factors involved in injuries and the potential of a wide range of engineering and education measures to successfully reduce injury occurrence or severity.[2] Proven interventions, such as smoke alarms, child safety seats, and bicycle helmets, can substantially reduce the number of fatal and nonfatal injuries and decrease the enormous dollar loss associated with these injuries, premature death, or long-term disability.[3]

However, these measures must be successfully implemented to be effective. Selecting the most effective strategies—or the best strategies one can afford—requires evaluation. Designing a chosen strategy for greatest impact requires evaluation. So does successful implementation.

Every reader or user of the *Fire Protection Handbook* section on fire and life safety education has to make decisions about educational programs. They may be decisions about whether to adopt an educational program in a community or school that has none. They may be decisions about how to modify or reinforce elements of an educational program to reflect the special needs or capabilities of a particular group of students. They may be strategic, tactical, or operational decisions. But in the end, every decision comes down to good information about better versus worse, about more versus less effective. *Evaluation* refers to any systematic process for gathering information about better versus worse.

The term *evaluation* means different things to different people. That leads to various concepts of how to evaluate a public fire and life safety education program. Some people evaluate programs based on how well the public education program is accepted and used by teachers, or how well it is liked by the target audience. Others evaluate a public education program from the point of view of features that are thought to constitute a good program, such as whether it has good graphics, is well targeted, and has input from various community groups.

Another type of evaluation asks whether a program causes "institutional changes," such as getting additional funding for public education materials, obtaining additional slots for public fire and life safety educators in the prevention bureau, having public education incorporated in the school curriculum, or stimulating local businesses and service organizations to participate in public safety education.

All of these concepts of evaluation are useful. All help indicate the path to program success. But they are several steps removed from being able to prove that public fire and life safety education works in achieving its main purpose: reduction of deaths, injuries, and dollar loss from fire.

John R. Hall, Jr., Ph.D., is NFPA's assistant vice-president for fire analysis and research.

Michael W. Weller is fire and life safety education officer for the city of Hagerstown, Maryland. He is a graduate of the University of Maryland and has coauthored much of the risk reduction curriculum presented at the National Fire Academy. He is also affiliated with the Fire Protection Publications division of IFSTA at Oklahoma State University.

Many programs have side effects, secondary missions, or even hidden agendas. Public education, for example, can enhance the image of the fire department, demonstrate a caring city administration, and raise or lower public fears.

A sophisticated, comprehensive set of measures of effectiveness of a public program would consider such issues, which often are important in the minds of managers under their day-to-day political pressures. But the main purpose of public fire and life safety education is to improve safety, and unless one can demonstrate that a program is achieving this goal, it will be hard to convince decision makers in the long run that the program should be supported. Sooner or later questions will arise about the bottom line.

The purpose of this chapter is to present an overview of the evaluation process and a hierarchy of evaluation measures. In addition, the chapter will illustrate the evaluation process and hierarchy through examples based on the NFPA *Risk Watch*® curriculum.

Although these evaluation techniques are designed for use on public fire and life safety education programs, they can be applied just as well to more broadly based fire and life risk reduction strategies, in which educational programs are combined with engineering and enforcement strategies to provide the best possible leverage on the problem. Increasingly, fire departments are being asked to place their many fire safety programs, including public fire education, code enforcement, and special legislative initiatives, into a broader risk reduction context.

See also Section 3, Chapter 4, "Use of Fire Incident Data and Statistics"; and Section 5, Chapter 7, "Using Data for Public Education Planning and Decision Making."

THE EVALUATION PROCESS

Evaluation is the process of determining whether a curriculum, educational program, or community initiative is effective and appropriate, and it may indicate whether a program has unexpected benefits or creates unexpected problems.[4,5] Because evaluation is a process, it begins early, in the initial stages of program design, and continues throughout the development and implementation of the program.

Many injury prevention programs have been developed, but few have been rigorously evaluated and shown to be effective in reducing injuries. Reasons for this may include a lack of funding to support evaluation efforts, a focus on implementation and service delivery rather than evaluation, or a lack of understanding of the importance of evaluation. Target populations may be too small, or the injury event and safety behavior too rare to demonstrate significant effects, and in some cases program developers are simply unaware of evaluation techniques to use.[4]

When developing a safety program, one must remember that evaluation is an ongoing process: it begins with identification of goals and objectives, and continues throughout the program development cycle. As the program is implemented, final assessment is completed to determine the effectiveness of the program in meeting the stated goals and objectives.

Stages of Evaluation

Successful evaluation involves a series of steps, each of which must succeed in order for the goal of fire and life safety education—a changed human being whose behavior produces less risk and more safety—to be achieved. Professional program evaluators have developed a staged approach to evaluation, summarized in Table 5.8.1, which addresses these steps in a logical order. Table 5.8.2 provides several types of candidate evaluation measures and the evaluation steps they could support.

Formative Evaluation. Formative evaluation is qualitative, whereas process, impact, and outcome evaluation are quantitative; that is, they measure. The educational program has to be designed to target the behaviors associated with the most common or severe forms of harm. Teaching everyone how to safely operate a tractor, for example, would be mostly ineffective because most people will never have use for that information. However, teaching everyone how to select safe floor coverings to avoid unusual risks of falling will benefit nearly everyone.

TABLE 5.8.1 Stages of Program Evaluation

Stage	*Description*	*When Used*
Formative evaluation	The process of testing program plans, messages, materials, strategies, and activities for feasibility, appropriateness, acceptability, and applicability	During development of new program or modification of existing program
Process evaluation	The mechanism of testing whether a program is reaching the target population, such as by counting the number of people or households reached	From the start of program implementation throughout the life of the program; results used to fine-tune a program during implementation
Impact evaluation	The mechanism of measuring changes in the target population's knowledge, attitudes, beliefs, or behaviors associated with the program	Before program implementation and during and/or following the program
Outcome evaluation	The mechanism of determining how well a program achieves its goal of reducing morbidity and mortality; requires a large study population and analysis of the same data for a similar population that did not receive the program (control group)[6,7]	Before program implementation and after program completion

TABLE 5.8.2 A Hierarchy of Evaluation Measures for Public Fire and Life Safety Education

	Aspect Measured	*Examples of Evaluation Measures*
Outcome evaluation	End results (strongest proof)	• Number of deaths, injuries, dollar loss, or fires per capita • Anecdotes of saves linked to programs
Impact evaluation	Behavior or the environment	• Percent of households with a working smoke detector • Percent of households sprinklered • Percent of chimneys cleaned at least annually
	Awareness, knowledge	• Percent of public who know how to extinguish a grease fire • Percent of public who know how to use extinguishers • Percent of public aware of need to crawl low in smoke
Process evaluation	Extent of program outreach	• Percent of population (or a subgroup) receiving public education materials • Percent of elderly receiving safety lecture • Percent of schoolchildren with *x* hours of safety instruction each year
	Likeableness and usage of programs	• Percent of teachers who think program materials are good and use them
	Institutional change	• Introduction of safety curriculum in schools • Addition of service organization to aid dissemination

The educational program has to be designed to be effective for its intended audience. The key behaviors for the intended audience may not be the same as the key behaviors for the general public. If the audience were a high school in a farm community, for example, teaching members of the audience how to safely operate a tractor would be appropriate. If the community includes a large population of immigrants from non-English-speaking communities, then an effective program will need to deal with language issues.

Process Evaluation. Once the content of the program is selected and evaluated for its potential to make a difference, the next step is to evaluate the program's effectiveness in reaching its target audience. This step is dependent on program resources and the skill with which they are deployed. *Process evaluation* measures the adequacy of the program resources, delivery approach, and implementation plan generally to achieve its goal—the process for educating the target audience. There are all kinds of ways of targeting a program to achieve the maximum bang for the buck. But even with these targeting methods, too few bucks will mean too little bang. This situation is where evaluation of some secondary program goals cited earlier—obtaining additional funding or additional personnel slots, for example—may also be appropriate as part of program evaluation against the primary goal of reducing harm to people. But there are all kinds of reasons other than insufficient resources why a program may fail to reach its audience.

Impact Evaluation. If the program has targeted the key behaviors in a manner appropriate to the target audience and has been delivered effectively to that audience, it is now time to ask about direct educational effects. *Impact evaluation* measures changes in knowledge, attitudes, and beliefs. If those are confirmed, it goes on to measure changes in behavior.

As with the earlier stages of evaluation, there are many reasons why a program that has shown nothing but success in the prior stages of evaluation might nevertheless demonstrate serious problems in this stage. The specific educational content might prove ineffective with the audience. The audience might already have a high degree of relevant knowledge but might have deeply ingrained attitudes or beliefs that prove resistant to change.

At this point, if not before, it is useful (some would say necessary) to have a model of how people learn and how and why they change behavior. Table 5.8.3 describes three widely used and highly general examples.

Impact evaluation may also be the stage where the design and implementation of good measures is the most difficult. It is relatively straightforward to segment parts of the fire problem and characteristics of target audiences for formative evaluation, and data on these are often plentiful. It is entirely straightforward to count people reached for process evaluation, even though the information necessary for proper context and in-depth examinations can be more challenging.

But measuring overall changes in knowledge—based on a brief test with a few questions—can be done in many ways, none of them obviously the best. Measuring changes in attitudes and beliefs is notoriously difficult, because many people are not articulate or even fully aware of all their critical safety-related attitudes and beliefs, and some attitudes and beliefs are known to be widely disapproved and are likely to be concealed. In addition, measuring change in behavior is very difficult outside structured situations, when what is important is behavior in the places and at the times when the choice between safe and unsafe behavior will be done automatically, based on learning, and not with a heightened and artificial sensitivity to the needs of a test.

Outcome Evaluation. If impact evaluation is successful—if it is established that the target audience has received the education, learned new knowledge and new attitudes and beliefs, and modified its behavior—then it is time for the final, decisive stage of evaluation, which is *outcome evaluation.* Although the basic

TABLE 5.8.3 Selected Health Behavior Frameworks Used in Community-Based Interventions

Model Type	*Description*	*Comments*
Health Belief Model[8]	An individual's readiness to alter behavior depends on four conditions: • Perceived threat or susceptibility to the condition • Perceived severity of the condition • Perceived benefits of the health action • Perceived barriers or personal costs of the health action	Community-based interventions should be designed to convince the target population of the threat of injury and their risk while simultaneously instilling confidence that a particular action is effective in reducing their risk.
Social Learning Theory[9]	Behavior change occurs within a social context and is influenced by both active involvement in the learning process and identified consequences of the behavior change.	Strategies such as modeling behavior (i.e., having someone physically demonstrate the desired behavior) and promoting external reinforcement (e.g., offering money) or internal reinforcement (e.g., instilling a feeling of pleasure or pride) are key to successful behavior change. The ways in which social groups alter behavior support social learning theory; members change their behavior as a result of modeling or reinforcement by others, or by their own active involvement in the group.
PRECEDE Model (an acronym for Predisposing, Reinforcing, and Enabling Constructs in Educational Diagnosis and Evaluation)[10]	Predisposing, Reinforcing, and Enabling constructs work together toward behavioral change.	*Predisposing factors* include attitudes, beliefs, and values of the target population. *Reinforcing factors* include support for behavioral change, such as support from family, peers, teachers, or health care providers. *Enabling factors* consist of the individual skills necessary to adopt the proposed change, as well as the availability and accessibility of external resources to facilitate change. The *educational diagnosis* is the examination of predisposing, enabling, and reinforcing factors in the specific context of the proposed behavioral change. *Evaluation* is the quantification of the program's impact.

measures for outcome evaluation are in many ways simpler than those for impact evaluation, proper interpretation of the data can be enormously complex. The measure of a program's success is not simply the outcomes and events in the lives of its target audience; it is the change in those outcomes and events attributable to the program. Determining success means comparing outcomes to baseline experience prior to the program. It means considering preexisting trends and what they say about how bad or how much better experience would likely have been in the absence of the program, if other changes already underway had simply continued without additional intervention. Or, if simple extrapolation is considered unreliable, it may mean comparison of the educated group and its progress to a control group not exposed to the program.

FORMATIVE EVALUATION

Overview of Formative Evaluation

Formative evaluation is like a very thorough technical review; formative evaluation is qualitative rather than quantitative. It involves checking embedded assumptions against available relevant data. Are the hazards targeted the leading ones in this community, or are they the equivalent of tractor safety in Manhattan? Is there experience elsewhere with these materials and activities, and does the proposed approach fully incorporate lessons learned in those prior implementations? What are the key characteristics of the target audience, and are those fully reflected in the program's specific design? Has a diverse group collectively representing all relevant perspectives and types of expertise reviewed the program, and have their comments all been addressed? Are there issues of acceptability for the students, the teachers, or the community?

Formative Evaluation of *Risk Watch*®: An Example

Risk Watch®, designed for students grades pre-K through 8, is the first injury prevention program for children that is comprehensive in scope, addressing eight high-risk areas, including motor vehicle safety, bicycle and pedestrian safety, fire and burns, poisoning, choking, falls, water safety, and firearms safety. Developed in collaboration with injury prevention experts and educators, *Risk Watch* is a school-based curriculum designed to be

implemented as a community-based injury prevention initiative, emphasizing community participation and involvement.

One very important component of *Risk Watch*—the use of community volunteers (firefighters, EMS personnel, law enforcement officials, and health care providers) to visit classrooms to present and demonstrate safety messages to children—was the direct result of formative evaluation, in which teachers indicated their strong preference for the direct involvement of community helpers. The benefits of using community volunteers are twofold. First, children are presented important safety messages by front-line community role models.[11] Second, volunteers themselves become more involved in promoting the health of the community.

Before the *Risk Watch* curriculum could be evaluated in terms of impact—that is, effectiveness in improving children's safety knowledge and behavior—it first had to undergo a formative evaluation to assess core activities and safety messages. If the curriculum could not be easily taught by schoolteachers, or if the safety messages were inappropriate for the target age group of students, then one would not expect to see positive results in terms of knowledge gain or behavior change. The *Risk Watch* curriculum had been developed by injury experts, who suggested appropriate safety messages to relay to children, and by developmental specialists, who "translated" these messages into lessons that children of different ages and developmental levels could comprehend. For example, many songs and chants were used for young children grades pre-K through kindergarten, whereas story writing was used for older children in grades 6–8. Focus groups of teachers and educators were formed to discuss the appropriateness of the lessons and messages, and scripted interviews were administered to a large sample of teachers to obtain additional feedback. The information obtained from these studies constituted the formative evaluation and was used by curriculum writers to revise the lessons, clarify safety messages, and assure a user-friendly manual.

The next step in the *Risk Watch* development cycle was to complete a comprehensive field test of the curriculum. The purposes of the field test were to gather additional formative data (that would allow further "fine-tuning" of the program) and to begin to assess its effectiveness in terms of student knowledge gain. Five geographic test sites were chosen, with several schools participating at each site. A sample of teachers representing all grade levels from each site was trained, as were community volunteers who came into classrooms to augment the teachers' safety lessons. After teaching *Risk Watch* lessons, teachers completed surveys with questions relating to acceptability and usability of materials, as well as perceived learning by students. Results of end-of-lesson surveys and end-of-program surveys completed the formative evaluation. Many teacher suggestions and recommendations were incorporated into a new, revised *Risk Watch* curriculum.

Formative Evaluation of Hagerstown Programs: An Example

Hagerstown, Maryland, provides a case study of the uses of evaluation in a fire safety program based in a local fire department. Nearly 250 years old, Hagerstown is a small city whose 2000 population was just under 37,000. Located in western Maryland, it has recently experienced a high rate of residential development as well as rapid growth in adjoining suburban areas of Washington County.

In the mid-1980s the fire department assigned an officer full-time responsibility for designing, implementing, leading, and evaluating a comprehensive risk reduction strategy. After subject-matter training through the nearby National Fire Academy, author Weller designed and implemented a program that has now run for more than a decade.

Formative evaluation is a qualitative stage of testing a program to see whether its design features and target audience give it a good expectation of success. Most local fire and life safety educators will design a program by adopting and adapting model programs that have already been tested elsewhere. This situation means there is no need for a formal step of formative evaluation, but there is still a need to select program elements and decide how to adapt them.

Typically, a risk reduction officer will find that his or her community, like the nation as a whole, suffers most of its fire deaths and injuries in homes. It is advisable to review fire experience data to determine whether there are any nonhome areas worthy of attention, but the decision to target homes will usually be supported by such a data review.

Also, the officer may discover that the most readily implemented programs are educational programs, specifically those designed to improve prevention behaviors and use of smoke alarms. Changes to engineered products or to common fire protection and mitigation practices (e.g., use of fire sprinklers) tend to be implemented through building and fire codes or the actions of the U.S. Consumer Product Safety Commission. Therefore, even though some such programs can be quite effective, they are likely to be considered outside the scope of the risk reduction officer's authority and influence.

Using this framework, Hagerstown examined a decade of fire response data for leading causes of fire and the typical sequence of events leading to these risks. Hagerstown confirmed a significant share for all the national leading causes: cooking, intentional fires, electrical distribution equipment and electrically powered appliances, candles, heating, and smoking. Further analysis led Hagerstown to focus on cooking.

Cooking Fires in Hagerstown. The decision to focus on cooking was based on three approaches to interpreting Hagerstown data. First, cooking fires in general and unattended cooking fires in particular contributed a large or leading share of local fires. Therefore, it was the natural first choice if one cause were to be emphasized. Similarly large shares were seen in available national data, which supported the idea that Hagerstown was seeing something real and not some one-time fluke.

Second, the large shares for Hagerstown were larger than the local people had expected prior to the analysis. Therefore, their sense of the degree to which this problem was under control changed.

Finally, an informal check with neighboring towns suggested that Hagerstown's cooking fire shares might be higher. Ideally, one would go beyond impressions to a comparative analysis, and as local databases suitable for analysis have

become ever more widespread, this formal step has become easier to do than it was perceived to be at that time. It could be that the impressions of neighbors regarding their cooking shares would have been found to be low, just as the impressions in Hagerstown were found to be when the analysis was performed. However, this informal check was at least consistent with the direction provided by the other analysis, namely, a focus on cooking made sense for Hagerstown, at least because it had a large cooking fire problem, at most because it may have had an unusually large cooking fire problem.

Having decided to focus on cooking fires, Hagerstown next asked for more specifics on target behaviors and target audiences. Local and national data indicate most cooking equipment fires involve stovetop cooking, and both the Hagerstown data and national data showed no reason to focus more on gas or electric stoves.

The occurrence of the problem was distributed city-wide, with an expected higher rate of incidence in the greater downtown area where poverty was of significant concern.

Hagerstown Goals and Approaches. Hagerstown was now in a position to specify its goals and its programmatic approach. The goals were reducing cooking fires by 30 percent and improving smoke alarm usage to 90 percent, both within 10 years. The programs were to involve increases and improvements in the K–12 school education efforts and a door-to-door awareness and smoke alarm installation program, the latter at a targeted pace of 4000 homes per year, conducted during the spring season. (Spring meant more daylight hours than winter, and experience had shown that resistance was more likely after dark or on weekends, including Friday evenings. Daylight hours during summer can be quite hot, and this factored into the decision to avoid summer. In the same spirit, fall would have meant competition with the staff time required for the school-based part of the program.)

Local data not available on a national basis provided detailed insights into why unattended cooking was unattended. The primary behavior identified was leaving a pan of grease unattended on a stove after being distracted by things such as children, TV, phone, Internet, neighbors—or just thinking one had time to go do other things while the grease heated or the food fried. Additional local-only data indicated what kind of inappropriate fire-fighting techniques were being used and helped to explain injuries suffered while fire-fighting. All of this extra detail was available to inform choices about educational messages and model programs to be used.

Neighborhood tours of burned homes, conducted by fire fighters, were incorporated as part of the door-to-door effort. And an all-media awareness campaign, focused on cooking fires and smoke alarm usage, completed the program design.

Finally, Hagerstown used testing by local focus groups to select among the specific candidate educational materials to be used within its general approach. This testing was the part of formal formative evaluation that made sense for a local program using already-tested national model program components. The fire department enlisted help from professional educators, marketing specialists, and citizens. By having members of target populations review proposed materials and initiatives, Hagerstown obtained a good idea of what might lead to successful impact and outcome over time.

This strategy worked well as several concepts that proved ineffective during pilot testing were deleted in favor of those exhibiting stronger potential for success. One example was a door card that showed fire fighters extinguishing a grease fire. It was deleted in favor of an image of responding fire apparatus with the slogan "Don't Invite Us to Dinner—Stay in the Kitchen When Cooking."

PROCESS EVALUATION

Process evaluation involves more than just counting students taught or households reached. It involves more than comparing such numbers to the size of the target audiences and determining the degree of coverage, penetration, or reach. It involves evaluating the reasons for shortfall and also information on reactions that may bear on the program's likely acceptance if its target audience is broadened. In other words, the *process* of delivery of the material needs to be evaluated.

Process Evaluation of *Risk Watch*

Figure 5.8.1 is part of a process evaluation questionnaire for *Risk Watch.* The first question, on time allotted per lesson, is one of many that may provide insight into hidden problems with the quality of delivery. The second and third questions, on enthusiasm from the students and teachers respectively, may give insight into sources of resistance down the road or help explain why teaching might occur and learning still not occur.

Process Evaluation of Hagerstown Programs

Hagerstown got the baseline information it needed through a household survey of most of the city and through school-based knowledge tests at various grade levels, to see what school age students knew about fire safety.

The face-to-face survey of 7000 citizens asked what they knew about Hagerstown's fire problem and how to prevent it:

- Citizen knowledge of the leading causes of fires in the community
- Citizen knowledge of how to best prevent stovetop fires
- Citizen knowledge of how to best extinguish a grease fire
- Presence, location, operability, and overall condition of smoke alarms in homes

Unattended cooking was identified by 24 percent of respondents as the leading cause of fire and related injury. Although this indicated a need for greater awareness, it is not a bad starting point. (The size of the group surveyed far exceeded the number needed for statistically significant results, but Hagerstown chose to use the survey not only for its informational content but also as a first step in outreach to the community.)

More disturbing in the survey was the discovery that only 60 percent of households contacted had smoke alarms, a level far behind the reported usage levels nationally at that time. People without smoke alarms were asked why, and as with similar national surveys, the dominant answer was a lack of perceived

Representative Teacher Survey Questions

1. On average, how much classroom time do you spend teaching a *Risk Watch*® lesson? (Select only *one* response)

   ☐ Less than 30 minutes
   ☐ Thirty minutes
   ☐ Forty-five minutes
   ☐ One hour
   ☐ More than one hour

2. How enthusiastic about each lesson were your students? (Please answer on a scale of 1 to 10 with 1 being NOT enthusiastic and 10 being VERY enthusiastic.)

	Not enthusiastic									Very enthusiastic	
Lesson 1: Motor Vehicle Safety	1	2	3	4	5	6	7	8	9	10	n/a
Lesson 2: Fire & Burn Prevention	1	2	3	4	5	6	7	8	9	10	n/a
Lesson 3: Choking, Suffocation, & Strangulation Prevention	1	2	3	4	5	6	7	8	9	10	n/a
Lesson 4: Poisoning Prevention	1	2	3	4	5	6	7	8	9	10	n/a
Lesson 5: Falls Prevention	1	2	3	4	5	6	7	8	9	10	n/a
Lesson 6: Firearms Injury Prevention	1	2	3	4	5	6	7	8	9	10	n/a
Lesson 7: Bike & Pedestrian Safety	1	2	3	4	5	6	7	8	9	10	n/a
Lesson 8: Water Safety	1	2	3	4	5	6	7	8	9	10	n/a

3. Overall, how much do you like teaching *Risk Watch*?

1 2 3 4 5 6 7 8 9 10

Do not like teaching *Risk Watch* — Like teaching *Risk Watch*

FIGURE 5.8.1 Representative Teacher Survey Questions

need. A smoke alarm distribution program needs funding beyond the normal budget of the fire department to succeed. Hagerstown was able to fund its program with support from the U.S. Department of Housing and Urban Development.

The downtown area, with its higher fire rate, was split in two, with half to be covered every 2 years. The rest of the city was to be covered every 6 years, based on 2 out of 12 census tracts per year. "Covered" meant that every home in the target zone was approached. About 40 percent were successfully contacted. This could mean the cycle time for contacting everyone would move up from 2 and 6 years to 5 and 15 years—or worse, if some of the missed households constitute hard-core, chronic refusals. This is why contact rates are critically important statistics in process evaluation.

Quality control for the large team of fire fighters acting as educators was provided by random surveys of contacts. It was important to ensure that variations were minimized from one fire fighter to another in what information was being disseminated (e.g., educational messages) and what information was being collected (e.g., knowledge tests, smoke alarm usage).

IMPACT EVALUATION

Impact evaluation usually proceeds in two successive steps. First is evaluation of changes in knowledge, attitudes, and beliefs. Second is evaluation of changes in behavior.

Measuring Change in Knowledge

One of the most common types of evaluations of fire safety education is the classic multiple-choice test. Often such tests are given before a program starts, or at the beginning of the first class, and then repeated at the end of the training using the same test instrument. Sometimes the "after" test uses a slightly

different set of questions. The results of the "before" test not only establish a baseline but also give insight into exactly where the group is weak. The "after" test shows the increase in knowledge.

Pre- and posttests do not have to be elaborate. Sometimes a few well-chosen questions can suffice.

Figure 5.8.2 shows profiles of test scores before and after a class that was conducted over a four-day period. The graphs show the profile of scores for different questions. It is very clear that the class dramatically improved. Although this example was drawn from a class of fire fighters taught about fire safety education, the data could have been for a classroom of children or a group of elderly.

In addition to the graphic presentation in Figure 5.8.2, the average score and the range of scores for the pretest versus the posttest describe the change quantitatively. This type of evaluation can be done separately for each class or group of people, or all classes can be lumped together. The separation by class is especially useful when there are differences in the composition of the classes or when the classes are taught by different instructors.

Retention Tests. Giving a posttest immediately at the end of training may reflect only short-term retention, though the test itself may promote retention. It is desirable, therefore, to administer another test several weeks to a year after the last training session. That test would measure retention and present an opportunity for a "booster shot" or reminder of the safety lesson to the students.

Practical Tests. Another testing problem is that a paper test may not reflect what a person will remember or do in a crisis. Physical, hands-on training and demonstrations of competence may be better indicators of actual performance. Few people would certify someone as competent in cardiopulmonary resuscitation (CPR) or first aid based solely on a multiple-choice test, yet this can occur in fire safety program evaluation.

Different Pre- and Posttests. When the same test is used for pre- and posttesting of the same group, there might be some improvement in the score even if nothing were taught, due to increased familiarity with the questions and discussion of answers among the students. This situation is not necessarily detrimental—the test itself can be part of the learning experience. But there are ways to circumvent the problem:

1. Slightly different wording of questions can be used in pre- and posttests, though some of the changes measured might result from differences in the test wording rather than changes in knowledge.
2. Test one group before it is taught the prevention material, and test another group after it is taught the material. If the groups are reasonably similar in composition, the differ-

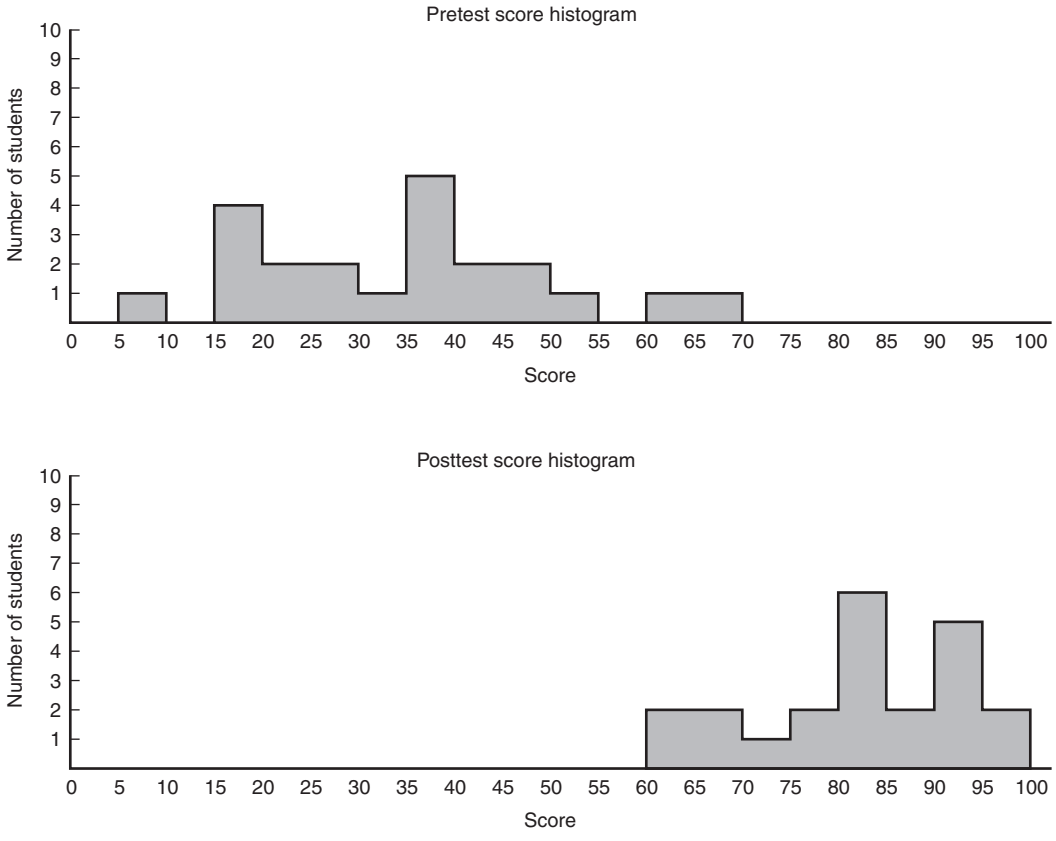

FIGURE 5.8.2 Profile of Test Scores Based on Bolitin/Histogram

ence in test results will show the effectiveness of the program in improving knowledge, while requiring only one test per class and allowing all students to receive the prevention material.

This approach works particularly well when a large number of reasonably similar classes are to be taught the same fire and life safety material, for example, all grade 5 classes. The test might be given to every other class before the material is taught, with the remainder given the posttest. The large number of classes is likely to make the difference between the two groups unimportant. To take the other extreme, one would not want to use this approach on only two classes, especially if one were a "slow" class and the other an honors class.[12]

Impact Evaluation of *Risk Watch*

NFPA worked with an external evaluation firm to conduct a three-year analysis of the impact of *Risk Watch* on children's knowledge of safety behaviors. The field test was designed to gather impact data, and instruments were developed to measure knowledge change in children exposed to *Risk Watch.* A pretest/posttest methodology was used, comparing knowledge gain of students exposed to the curriculum (study group) with knowledge gain of students who did not experience *Risk Watch* in their classrooms (control group).

Pretest/Posttest Methodology. Pretest/posttest exams had to be created with developmental characteristics of the audience in mind, such as children in the youngest classrooms (pre-K–1) who were nonreaders. Teachers in the latter classrooms administered exams verbally and by using pictures, whereas exams for older children consisted of short answer questions and multiple-choice type questions, each of which had three answer choices.

After teachers in the pilot site classrooms conducted a pretest of knowledge with students, *Risk Watch* was implemented by using the NFPA collaborative model. A team approach was used to deliver course content to students, with representatives from fire and police departments, EMS, and numerous other community resources augmenting the work of teachers in presenting *Risk Watch* lessons. After all lessons were completed, a posttest was conducted. A comparison of the pretest and posttest scores was used to indicate knowledge gain within each risk area. This incremental change was then compared to a control group who received the same pretest and posttest as the experimental group did without receiving *Risk Watch* lessons.

Analyzing Initial Pretest/Posttest Data. NFPA's evaluation researchers analyzed data from pilot sites, using t-tests from the Statistical Package for the Social Sciences (SPSS) to determine the equivalence of the *Risk Watch* (study site) students and comparison (control site) students in terms of their pretest knowledge.[13] This important concept should be considered when using a pretest/posttest design to measure impact on knowledge, because if pretest scores are very high, students will not be able to show much growth in knowledge from pretest to posttest. This situation occurred with the initial *Risk Watch* knowledge tests. Students, even with no exposure to *Risk Watch,* got the great majority of test items correct. This occurrence makes it almost impossible to demonstrate change, or growth in knowledge, as a result of participating in *Risk Watch.* Either the initial tests leaned too much on widely shared safety knowledge, in which case more difficult tests would show the value of *Risk Watch* as these initial tests did not, or *Risk Watch* was teaching children only what they already knew and was not an effective program.

Redesigning Tests. NFPA's evaluation researchers developed new, more difficult knowledge tests that were administered to children in a pretest/posttest style, as had been done in the field test. Results demonstrated statistically significant gain in knowledge between pretest and posttest scores of children exposed to *Risk Watch.* Although comparison (control) group scores also improved, the increases in score were greater for the *Risk Watch* students in all grade levels.[14] Table 5.8.4 displays the differences between target and control groups, using the redesigned test.

There were statistically significant improvements in both the test group and the comparison group. For *Risk Watch,* the important result is not the significance of the differences. Rather, it was important that the *Risk Watch* student gains were larger, by enough of a margin that it was considered statistically demonstrated that the superiority of the *Risk Watch* students over their comparison group was real and not due to chance. However, this gain also demonstrated that students learning safety outside a structured program, and a less sophisticated evaluation, might well have overestimated the particular contribution of *Risk Watch.*

Previous studies have suggested a link between knowledge gain and behavior change, and several educational interventions have been shown to increase a safety behavior (use of motor vehicle restraints) of preschool children.[14,15] For some safety behaviors, there is also evidence that adoption of the behavior

TABLE 5.8.4 Comparison of *Risk Watch* Target and Control Groups

Target Group	*Pre-K–K*	*1–2*	*3–4*	*5–6*
Gain (in items)	3.10	1.26	2.0	1.97
Gain (in percent)	9	6	8	8
Significance	<.0001	<.0001	<.0001	<.001
Sample size	74	114	83	78
Control Group				
Gain (in items)	1.32	1.05	.82	.75
Gain (in percent)	4	5	3	3
Significance	<.0001	<.0001	<.05	<.05
Sample size	65	135	67	71

(such as wearing a bicycle helmet) is strongly associated with a decrease in injury rates (such as head injury).[16] Several observational studies have reported beneficial effects of increased use of safety practices on childhood injuries.[17,18]

Nontest data collection strategies have been designed to determine whether student behavior changes as a result of participation in *Risk Watch.* This determination is a difficult undertaking, for although direct observation is a natural technique for identifying behavioral changes, fully half of the topics covered in *Risk Watch* are almost impossible to observe. Many of the safety behaviors associated with *Risk Watch* do not occur in the school environment, where researchers could easily complete observations of all children. If researchers move off site from the school, they would need to be sure that every child they were observing were exposed to *Risk Watch* in the study area, and every child they observed in a control area had not been in a *Risk Watch* classroom. With so much crossover in school populations (i.e., children attending "magnet" schools out of district or attending private schools some distance from their homes), this control would be difficult. Further, many of the behaviors taught in *Risk Watch* occur relatively rarely, making observation of such behaviors difficult.

As a simple example, the chance of one student participating in a *Risk Watch* evaluation study being involved in a fire during the time period of the study is, fortunately, small. The chance that enough students would be involved in fires to allow valid conclusions to be drawn about their response to such an emergency situation is, just as fortunately, nearly infinitesimal. Although no observational studies have yet been completed to evaluate the effect of *Risk Watch* on behavior change, several have been designed and can serve as examples of additional evaluation techniques. One such study was designed to include children and households in a rural, high-risk geographic area. The evaluation uses a pretest/posttest design in an intervention community and a control community. Data collection was accomplished by direct observation of the behavior of children in the areas of motor vehicle safety, bicycle safety, and pedestrian safety. In addition, home visits are planned to complete a safety survey. These observations were recorded prior to the implementation of *Risk Watch* in all classrooms of the intervention community's schools. Repeat observations will be completed in both the study county and a control county after the school year has ended to gather postintervention data.

Measuring Impact on Behavior Through Inference: An Example

Direct observation of natural behavior with safety implications is extraordinarily difficult. In even the best evaluated programs, evaluation is likely to be limited to some behaviors in artificial environments and some other behaviors that lend themselves to unobtrusive observation in a natural setting, but may not be collectively representative of the range of behaviors covered by the educational program.

One method of compensating for the lack of direct observational data is inference from established research demonstrating the conditions linking knowledge to behavior change for similar educational programs on other matters of safety or health. The developers of *Risk Watch* have used this technique on at least a temporary basis, to strengthen their impact evaluation.

Impact Evaluation of Hagerstown Programs

Pretest and posttest scores on school-based programs were monitored. During every annual neighborhood canvass, citizen knowledge of fire causes was evaluated and the number of homes equipped with smoke alarms carefully tracked.

These tests all showed slow but steady and cumulatively significant progress. Baseline and postprogram fire safety knowledge grew among schoolchildren. Citizen knowledge of the cooking fire problem grew in some neighborhoods by as much as 50 percent (e.g., a baseline of 16 percent knowing that cooking was the leading fire cause might grow to 24 percent, which is 50 percent higher than 16 percent, $(24 - 16)/16 = ½ = 50\%$).

OUTCOME EVALUATION

For outcome evaluation, it may be assumed that the general measures of interest are deaths and injuries due to the targeted hazard, that is, fires and falls. The more detailed guidance in this section has to do with techniques and issues in using anecdotes as evaluation evidence, selecting focused outcome measures to better fit the programs, and using basic approaches to making comparisons.

Using Anecdotes

One of the favorite means of evaluating public education programs is through anecdotes of survivors who testify that they learned a safety behavior from a public education program, and it saved their own life or that of another. Anecdotes are wonderful human interest stories and can attract the attention of the media. To most people, including decision makers, they are more interesting and more understandable than statistics. But anecdotes alone can be dismissed as weak evidence, especially if there are only one or two. Despite the frequently made statement that "this program is worth it if only one life is saved," politicians and budget managers do not always see it that way.

Nevertheless, anecdotes are a legitimate form of evaluation, especially when used in conjunction with statistics. An anecdote provides insight into a program and proves that at least in one case the program worked. Multiple anecdotes are much stronger evidence than single anecdotes, because one event might be considered a fluke.

Anecdotes are most credible when documented in writing by survivors or firsthand witnesses and when they describe not only an appropriate behavior but also where that behavior was learned. Preferably the anecdote should be verified by at least a telephone call or second witness. The more anecdotes on a program, the better. NFPA's *Learn Not to Burn*® curriculum[19] has accumulated more than 202 documented cases where its messages saved lives or reduced injury to 554 people. Similarly, there are 15 *Risk Watch* documented incidents in which 31 lives were saved. Anecdotes are also more impressive when at least some of them are fresh (because programs and program delivery change) and when there is a series of anecdotes, indicating consistent, long-term results.

Because it is virtually impossible to collect anecdotes for all saves associated with a program, one needs the relevant overview statistics as well. A budget manager is much more likely to continue to fund a public education program where fire deaths decreased by ten over the previous year and anecdotes were used to show that the program was a factor in the decline, than where only the statistics or only the anecdotes are used. Together the picture portrayed is much more convincing.

Some people belittle the use of anecdotes because they do not add up to statistical "proof." But at the local level or even nationally it does not take that many anecdotes to drastically change the fire loss picture. If public education programs reached half the people in each community and saved more persons per 100,000 people reached by public education per year than at present, the nation's fire death rate would be cut in half. (To see this, consider that one out of 100,000 is equivalent to 2500 saves out of 250,000 people and the annual fire death toll per year has been about 5000.)

Selecting Focused Measures

When a fire safety education program is targeted at a particular type of fire, such as grease fires on the stove, Christmas tree fires, or kerosene heater fires, the evaluation, too, should focus on how that type of fire changes over time and how it compares to other types of fires for which there was no current program. Sometimes focusing on one type of fire may raise awareness and have a beneficial effect on many types of fires, and so the overall change in the fire problem needs to be monitored, too. But the primary focus should be on the type of fire that was the target of the program. The same philosophy of targeting the evaluation properly applies to programs aimed at changing people's response to fire, such as escaping quickly or closing doors or using extinguishment methods properly.

Unfortunately, those attempting to undertake evaluations often look for changes only in the larger universe of fires rather than in the target group they were after. They measure the change in all fires when a program was targeted just to residences, or they measure the change in all residential fires when the program was aimed solely at cooking fires, or they look at all cooking fires when the prevention message was targeted solely at grease fires.

The chance of detecting results increases if one keeps the focus as narrow as the category the program message addresses. Otherwise, the results are diluted amid a larger pool of fires, and one may not be able to detect them.

Table 5.8.5 gives examples of some targeted messages and associated measures of their effects. In each case one also should compare the change in the targeted type of fire to the change in other types of fires, or fires in general, as a control. If cooking fires are targeted and they dropped in number, check whether heating and children-playing fires dropped, too. And check whether cooking fires dropped in nearby communities where there was no program. If there were reductions in other types of fires or in other communities, forces other than the education program may be at work. Or the program may have broader impact than what it targeted.

It may be difficult to obtain the data for exactly what one wants to measure. Therefore, it may be necessary either to (1) retreat and find a surrogate measure or (2) measure the impact on the next larger category that includes the type of fire or behavior targeted. For example, one runs a public service announcement (PSA) about sliding a lid on grease fires, but cannot easily measure the number of grease fires; therefore, the number of cooking fires might be used instead. Further, if a school program is focused on the need for children to escape quickly from home fires, but one cannot measure the number of injuries from not escaping quickly, it might still be useful to track the number of injuries to children in home fires.

TABLE 5.8.5 Sample Measures for Specific Education Focuses

Education Theme	*Examples of Measures to Use*
Use of smoke detectors	Number of households with detectors Number of reported fires (early detection leads to occupant extinguishment and fewer reports) Number of fire deaths
Getting out quickly from residential fires	Number of injuries while attempting fire control in residential fires Number of fire deaths Number of severe injuries
Need to clean chimneys	Number of chimney fires
Careless smoking	Number of fires or deaths involving careless smoking
Safe storage of flammable liquids at home	Number of nonarson fires where flammable liquid was material first ignited
Children playing with lighters or matches	Number of residential fires where heat of ignition was a match (or lighter) and ignition factor was "children playing" Number of children injured in above type of fire

Using Basic Approaches to Making Comparisons

This section presents a short, condensed summary of the complex subject of data measure evaluation. A more in-depth treatment on evaluation in general is available from the Urban Institute's book, *Public Program Evaluation.*[20] Another excellent reference specifically on evaluating public fire education is the National Fire Academy's fire education evaluation guide.[21]

Perhaps the most basic concept of an evaluation is to demonstrate that some benefit can come from having a prevention program compared to not having it. There are several approaches to making the desired comparisons:

1. Compare the targeted community's experiences over time to see if there is a difference after a program started compared to the "baseline" before it started. (Changes in the community that occurred during the period used in the

comparison and that could affect the results must be taken into consideration.)

2. Compare one part of the community to another, to see whether there is a difference between areas that have public education programs versus other areas that do not yet have the program, or had it for a shorter time or with less intensity.
3. Compare the community to other communities, especially to similar communities that have not had a comparable public education program recently. A variation is to compare like parts of different communities, such as inner-city neighborhoods or high-rise dwellers.
4. Compare changes in a targeted type of fire or hazard (or safety behavior) to the trend in other types of fires or hazards (or other safety behaviors). For example, consider the change in cooking fires versus the change in heating fires after a campaign that targeted cooking fires.

Measuring Change over Time. The most straightforward way to show that a public fire education program has had an impact is to demonstrate improvement after the program started (Figure 5.8.3).[22]

In some cases, the effects are not immediate, and time must be allowed to observe results. In other cases, the effect is expected to be immediate and wear off with time, in which case speed of measurement is necessary. In yet other cases, the changes result from uncontrollable factors outside the program. All of these issues must be addressed.

Although ideally a public education program produces a drop in hazardous events, injuries, or deaths, the impact sometimes may be to reduce the magnitude of an increase, or change the rate of an increase. Data from statewide fire and life safety education programs in South Carolina provide further information (Figure 5.8.4).[22]

Often, there are random fluctuations in fire experience; these are especially noticeable when the community is small and the number of fires few. It may be necessary to observe data that zigzags for weeks or years before being able to discern the trend (Figure 5.8.5). There are sophisticated statistical analysis tests that can help.

Also, patterns may be more apparent visually if one uses rolling multiyear averages (e.g., 1995–1997, 1996–1998, 1997–1999, 2004–2006). The speed with which a prevention program has impact varies with the fire safety behavior being targeted, the frequency and timing of the message, and the receptiveness of the audience. It also may vary with the size of the audience reached. For example, if one-third of the population of a city is reached by a PSA associated with a popular television show—a very large audience for television—one might expect an immediate drop in the type of fires targeted. If instructions in the PSA were on how to prevent and extinguish a cooking fire, and the city averaged nine reported cooking fires per week, it might be reasonable to expect an average of six or fewer after the broadcast, if the program was designed to reach a broad cross section of households. The behavior change can be immediate for those who saw the PSA. It does not require any accumulation of knowledge over time, because the message is simple.

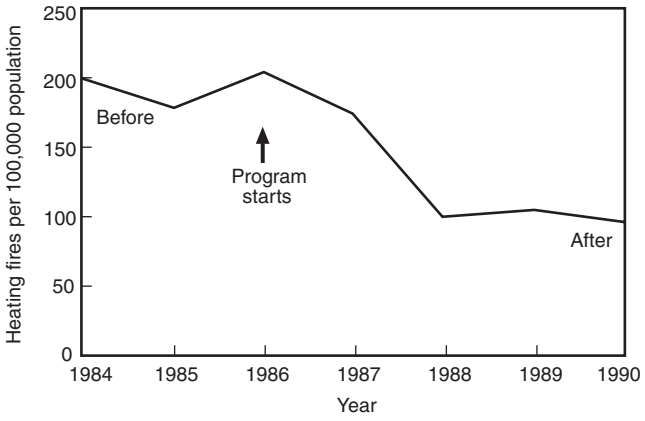

FIGURE 5.8.3 Hypothetical Example of a Change over Time Showing a Successful Program's Impact

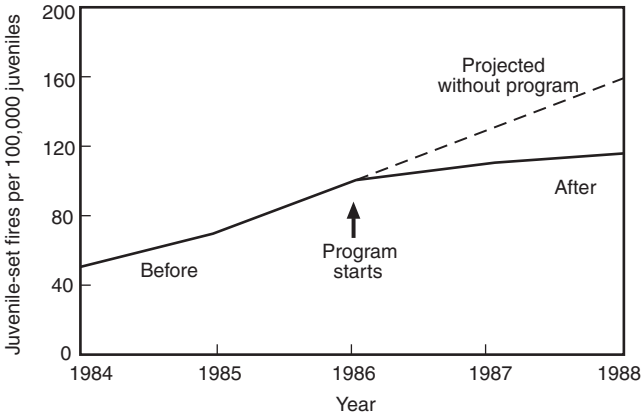

FIGURE 5.8.4 Hypothetical Example of a Change in the Rate of Increase Showing a Successful Program's Impact

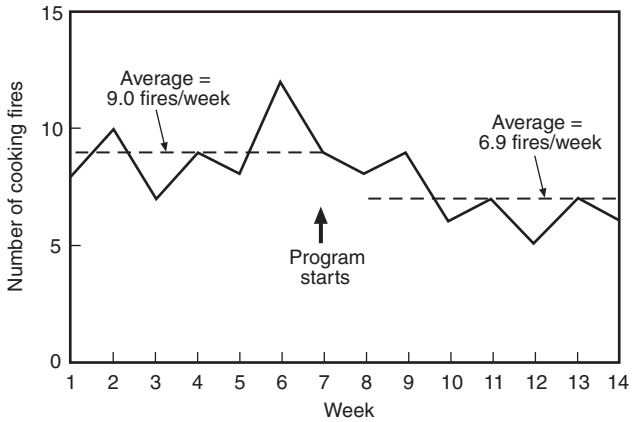

FIGURE 5.8.5 Hypothetical Example of a Change in Trend Visible Even with Fluctuating Data

Effects of a program may be delayed when the safety behavior being sought takes time and money to implement. For example, when people are instructed to test their detectors and replace the batteries, it may take some time before they get around to doing the test, then buying the batteries or alarms, and then installing them. In contrast, there is no delay in being able to implement "crawl low under smoke" or "slide a lid on a grease fire."

The speed with which a prevention program has an impact also depends on the nature of the audience. If the audience comprises mostly "safe households" with a low incident injury rate, it may take a while to see any further impact.

In contrast, a PSA targeted to areas with disproportionately high fire rates may impact faster, because there is more opportunity to create a larger change. However, if these households tend to ignore safety information, there could be no change. One needs to consider the status of the audience in assessing program impact, especially when comparing different programs or the same program in different areas.

The effects of a program also may be delayed when the target audience is young. For example, teaching students in junior high school to slide a lid on a grease fire may not have its full effect until they begin cooking more for themselves (though they may pass the information to other members of their households or intervene in a fire themselves).

Measuring a drop in reported hazardous events as a result of a public education program can be thwarted due to the unpredictable effects publicity can have on people's likelihood to report a fire. It is known that many fires go unreported. Almost all of the unreported ones are small, though they include fires that injure and that cause hundreds or even thousands of dollars in damages.

When a fire and life safety education program brings attention to a fire problem, more of these small fires might get reported than is usual, making it appear to the fire department that the problem is worsening when it actually is not. For example, encouraging people to evacuate their home quickly may cause some who previously would have extinguished their own fire and not reported it to leave and report the fire. The education program thus could cause an upsurge in reporting of fires. As another example, asking people to refer children who set fires to a juvenile firesetter program could encourage reporting of fires that might otherwise have gone unreported because of the perceived futility of reporting them.

The only way to know for sure whether a surge in reported fires is due to reporting of previously unreported fires is to periodically survey the population to determine the degree of their underreporting and the reasons for it. Then one can determine whether fires are being shifted from being unreported to being reported or are truly increasing in number.

Increasing Chances for Identifying Changes. Although there are a number of reasons why it may not be easy to see a change in trend as a result of public education, there are several ways to increase the likelihood of detecting a success.

One way is to use more sophisticated statistical techniques to see whether there is some signal of a change amid the noisy, erratic data coming from the outside world. Some fire departments have people on their staff or from nearby universities or other organizations who have training in statistical analysis. Modern, easy-to-use statistical computer software packages may help too. By all means use them if available. But if it takes extremely sophisticated statistical techniques to identify a change caused by a program, the program is not likely to be having a large effect. That is, if one cannot see the effect of the program looking at the data with the "naked eye," chances are that the effect is probably not very large. There are exceptions, and even if a change is small, it may be cost effective if only a correspondingly small effort were required to produce it.

An easier approach than employing sophisticated techniques is to collect more data over time. Average the data before the program started and compare that to the average after the program starts, as in Figure 5.8.5. The averaging will take out some of the random fluctuations, and some of the problems inherent in having only small numbers of deaths, injuries, or fires for smaller areas. Compute the trend lines (Figure 5.8.6). Look at fires, not just deaths, because there are usually about 100 times more fires than deaths. The impact of a program aimed at ignition prevention will show up sooner and more clearly for fires than deaths. If the program is directed toward education about escape or preventing bodily harm after a fire starts, rather than preventing or mitigating the fire itself, look at the number and severity of civilian injuries, and not just deaths. There tends to be about four times more injuries than deaths, and again the effects of a program may be more readily detected.

If the targeted community's population has not remained constant over the period of analysis, look at the data per 10,000 or per 100,000 population. (One also should look at the data on a per capita basis when comparing the community to others.) If the targeted community's population is increasing but the number of fires or deaths remains approximately the same, the rate per 10,000 people will be going down. That is, when more people are at risk but the community is not experiencing more fires or deaths, that can be an indication of a successful program.

Comparing Different Parts of the Community. As an evaluation tool, comparing parts of the community against each other

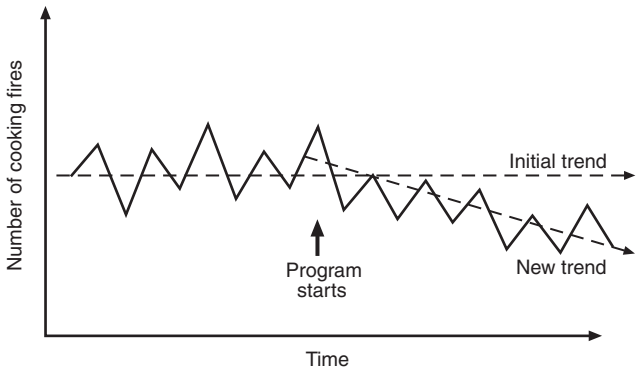

FIGURE 5.8.6 Hypothetical Example of Plotting Trends in Noisy Data

is most useful when a program is introduced to one area of the community and not to the others. Then one can compare the "treated" population to the "untreated" population, as is done in medical research (Figure 5.8.7).

For example, an educator might introduce to the schools in one neighborhood a program directed at getting smoke alarms tested and properly installed. The students might be asked to count the number of smoke alarms they have at home and to test them. This can be a homework exercise. Then the students can be taught the importance of maintaining alarms and periodically testing them. Results can be monitored for the next three months by looking at fires in that school area, and determining the percent of fires in which alarms were found working versus how that area did prior to the program, and how it compares to the areas of the community without the program. If the program appeared successful immediately, it could be tried in other areas. If not successful immediately, the material might be repeated and monitoring of results continued. An attempt might also be made to determine whether any outside factors were causing a counter, that is, negative, impact.

As another example, for one year one might equip the schools in a selected neighborhood or district with a fire safety curriculum. Results would then be monitored for the trial neighborhood versus the rest of the community. If the program shows some success, perhaps in a few types of fires such as "children playing," then it might be implemented in the rest of the community. Chances of getting expanded implementation are much greater if one can show quantitatively that the program really made a difference in the area of the trial.

Sometimes a program applied in one area of a community inadvertently may have effects on the whole community. A notable example came from Edmonds, Washington, where a door-to-door home inspection program in the mid-1970s using paid elderly women to make the inspections was found to have had about as much impact in the census tracts that had *not* been visited by the program as in the census tracts that had been visited. The suspicion was that the publicity attendant to the program caused people to "clean up their act" in anticipation of having a stranger inspecting their house. The program raised awareness of fire safety even in areas that did not receive the door-to-door inspections. If one compared the areas visited by the program to the areas not visited by the program, it could be concluded that the program was not very effective, when in fact the overall impact of the program was a drop in fire incidence by a remarkable two-thirds. The before-and-after comparison for the city as a whole made clear what had most likely happened.

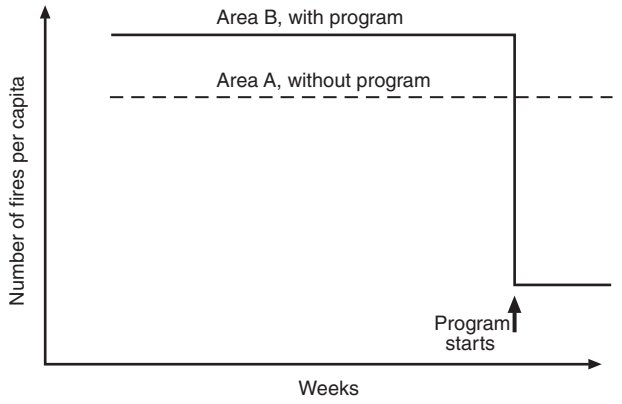

FIGURE 5.8.7 Hypothetical Example of Comparing Area with Prevention Program to Area Without Program

It is sometimes politically difficult to run an education program in one area of the community and not in others unless (1) it is clearly labeled a pilot program and (2) a plan exists for subsequently introducing the program everywhere. Nevertheless, whenever possible, introduce a program in one area first, and test the results in that area versus the rest of the city. Even for proven programs this initial test can help the educator make adjustments in the program before introducing it everywhere.

When comparing different parts of the community, one should compare *like areas,* if possible. For example, compare a program in a low-income area against how other low-income areas are doing without the program, or compare a moderate-income area to other moderate-income areas. This is especially important if all similar areas have been trending in the same direction, and the impact of the program is to reduce the rate of rise or accelerate the drop in fires or casualties.

Comparisons among areas are best made over a period of time. Data are needed for each area from before and after the time when a program was first started, to know whether differences between areas result from differences in their characteristics or differences in the program.

Comparing the Community to Other Communities. Similar in principle to comparing different areas within a community is to compare the community to other communities—especially to other communities that are generally similar to the target community. A variation on this is to compare the community's experience to that of its state. Comparisons among communities (or areas) should be made on a per capita basis or in terms of percentage changes or trends in the magnitude of the problem. Otherwise, differences observed in the numbers of fires or casualties may be due to differences in the numbers of people protected rather than from the results of the program.

Outcome Evaluation of Hagerstown Programs

The number of homes having smoke alarms rose to nearly 99 percent overall and at least 97 percent in every census tract, from far worse than the national usage rates to much better than those rates. Cooking fires declined by one-third over a decade, which is a larger reduction than the national data show over more than two decades (Table 5.8.6).

As with any program or survey, not all homes were reached. The successful contact rate was about 40 percent, and it would not be surprising if the noncontacted homes had a lower smoke alarm usage rate, perhaps closer to the 1997 baseline. Even if this possibility were true, the success of the program against a 90 percent target usage rate would not be in question. And there have been programs that have documented large progress in both the contacted and noncontacted target properties, perhaps because of other trends, perhaps because of the motivational

TABLE 5.8.6 Hagerstown Outcomes (Smoke Alarms) by Census Tract

impact of publicity surrounding the program and the desire of many households to be part of something. In any event, program evaluations need to consider contact rates and other sources of uncertainty in the program statistics when drawing conclusions about the program's relative success.

With these successes, the program could now shift focus to secondary outcome measures, such as the percentage of households with fully compliant, working smoke alarms. Hagerstown has documented deficiencies in up to a quarter of the households visited. Deficiencies are noted if a home does not have working smoke alarms less than 10 years of age on all levels; see the last column of Table 5.8.6. The most common deficiencies have been aging alarms and alarms with dead batteries. To help address these issues, the program has begun using long-life lithium-battery alarms that feature a tamper-resistant design.

In addition to reducing loss, Hagerstown's *measurable* prevention strategies began generating side benefits. School administrators, government decision makers, and citizens began to view the department as a true subject-matter expert in the field of risk reduction. This credibility led to additional staffing, an increased prevention budget, and the receipt of numerous federal grants. These benefits were realized because the department invested the time to plan and evaluate its overall prevention strategy carefully.

HANDLING UNCONTROLLABLE FACTORS

It often is not enough to show that there was a change in knowledge or behavior or in bottom-line measures, such as injuries or dollar loss. One also needs to demonstrate that the observed changes were caused by the education program and not by other factors, such as an unusually warm winter that caused fewer heater fires or a dramatic national fire in the news that raised awareness. Likewise, one needs to check whether positive effects of a program may have been masked by uncontrollable factors, such as a weakening economy that leads to an increase in vandalism and arson fires during the implementation of an arson control program.

The sociology of fire is complex. There are many causes of fire and many uncontrollable factors that may affect the environment or behaviors leading to fires. A social scientist or statistician might never be totally satisfied with the degree of rigor of most evaluations that are practical, because it is difficult to account for all of the uncontrollable variables without much effort, and perhaps not even then. Nevertheless, evaluations can be useful if undertaken with a little care, because they generally lead one in the right direction.

Table 5.8.7 lists some of the factors that might affect evaluation results. The first column in Table 5.8.7 contains variables that are largely out of the hands of the fire and life safety educator to affect. The most classic examples perhaps are the weather and the economy. The second column has factors that may not be controllable in the short run, though they may be affected by codes and other prevention efforts in the longer run. The third column has the initial conditions that need to be considered, even though they can be affected by public education.

Evaluations can be made more meaningful by comparing results for situations in which these external variables are reasonably similar, or at least by acknowledging the possible influence of these variables.

The need to consider uncontrollable variables can cut more ways than one. A modest reduction in the number of wood-burning stove fires that would have followed the introduction of an intense education program on the need to clean chimneys might be masked or negated by an unusually severe winter. The colder temperatures might cause a sharp increase in the use of stoves and a corresponding increase in fires that overwhelms the decrease from more people cleaning their chimneys. But the increase might be less than in earlier years when no prevention effort took place, which could be a demonstrable positive impact of the program. If there were a decrease in chimney fires in spite of a particularly cold winter, that would suggest that the

TABLE 5.8.7 Examples of Factors Affecting Evaluation Results

Uncontrollable Factors	*Semicontrollable Factors*	*Starting Conditions*
• Age profile of population • Income distribution of population • Education level of population • Geographical scatter of population • Ethnic groups in population • Weather or climate change • Economic changes • Migration of people in or out of community • Nature of local business and industry • Changes in fire reporting procedures	• Condition of housing • Architecture of the homes • Hazards of new technology	• Severity of fire problem (fire and death rates) • Previous exposures of population to fire safety information • Current level of detector usage and condition

program was being extremely effective, not only in reducing the normal toll, but doing so in the face of increased stove use.

The reverse situation is also possible: an ineffective public education program might appear to be effective if chimney fires drop because the winter is relatively mild and the use of stoves decreases. That type of external factor has to be considered before one starts claiming success. It should be noted, however, that the chimney fire situation is a somewhat difficult example because relatively mild winter weather can cause people to reduce airflows to the firebox to reduce the intensity of the fire, which in turn can increase creosote buildup and lead to more house fires, instead of fewer.

To understand whether changes in fire incidence or casualties are due to the public fire and life safety education program or to climate change, one needs to look at the data on the weather in the period in question, and perhaps some nearby communities that did not change their public safety education programs but had the same weather. Looking at the data averaged across several winters may also reveal whether a program is having an impact independent of fluctuations in climate (unless the climate takes a several-year shift in one direction).

Another approach is to compare the data from years when the uncontrollable factor—in this case the climate—was the same. Nebraska's Forest Service provided a brilliant example of this approach. Fire rates in years of relatively similar dryness were compared with respect to the intensity of the prevention programs in those years. Comparing results from years with similar weather allowed the impact of the program to stand out. Otherwise the fluctuations in dryness masked the effects of the fluctuation in the intensity of the program.

Besides considering factors that are uncontrollable by the fire department, evaluation of public education programs needs to consider the relevant preexisting fire situation in the community. This is especially important to do when effectiveness is compared to resources expended; that is, when productivity is to be measured. Table 5.8.7 includes a list of several starting conditions to consider. The existing level of smoke alarm usage, for example, will affect the apparent effectiveness of a new effort on smoke alarms. It is easier to get the middle 20 percent of households to install smoke alarms than the last "hard-core" 20 percent. It usually is easier to reduce a high fire death rate than it is to further reduce a very low death rate. It is easier to maintain new alarms than old alarms, because the new ones use less expensive batteries, begin with fresh batteries, and are less worn out. Although one may use the change in the percent of households with working smoke alarms as a measure of effectiveness, it must be realized that it gets harder and harder to reach the last 10 households.

Measuring Change in Juvenile Firesetter Programs: An Example. Juvenile firesetter programs are different in nature from other prevention programs, and their evaluation requires some special considerations. First, juvenile firesetter programs often are aimed both at the curious child and the disturbed or malicious child. The "bottom-line" effect of the program is manifested by whether there is a reduction in (1) children-playing fires and/or (2) arson. Both of these categories need to be monitored, because sometimes fires are simply relabeled and shifted from one category to the other rather than truly reduced. A "get-tough" policy with children can result in labeling fires as arson that previously would have been called "children playing." Conversely, a more sympathetic attitude toward juvenile firesetters could cause a shift from labeling fires as "arson" to "children playing." Differences in legal definitions between jurisdictions also can muddy intercommunity comparisons if both categories of fires are not considered.

Second, a common practice in evaluating juvenile firesetter programs is to consider "recidivism rates," that it, the rates of repeat fires from children who have been treated by the program. Recidivism rates usually are quite different for the curious firesetter than for the disturbed or malicious firesetter. It is easier to "cure" the curious child than the disturbed child. Rates therefore should be measured separately for these two categories. If not, one program can appear to be more successful than another, simply because one has a greater proportion of the easier-to-cure, curious-child cases.

Also, curious firesetters may have a low recidivism even without any program. A truly fair evaluation would consider their recidivism rates, with and without the program. A recidivism rate of 5 percent might appear good at first, but would not be so good if the rate without the program were 4 percent.

Statistical Change—Determining Whether Change Is a Fact or a Fluke. The evaluator often must address factors that

confound simple statistical approaches. The majority of fire departments do not have a trained statistician, though many departments have someone with some knowledge of formal statistical techniques. Unfortunately, real-world statistical situations often require considerable expertise to be able to say that "with such and such a confidence level" the impact of a program is real.

Standard statistical formulas actually may be invalid for many situations, such as when the samples collected are not truly random samples and the assumptions behind the formulas are not met. It is recommended that fire departments seek statistical expertise either from among their own personnel or from outside sources, such as local universities or statistical consultants, to assist in their evaluations.

Despite these caveats, some basic idea of statistics can give at least a rough, "ballpark" feel for whether observed changes are likely to be significant.

What many statisticians do not like to reveal is that, in many cases, common sense and good judgment are needed to say whether a change is likely to be real or not, and not just complex statistical formulas.

It is also useful practice to periodically review previous evaluations to see whether initial findings about effectiveness or lack of effectiveness held up over time. Sometimes what seemed like a true program impact may appear to be a fluke after a few years of data are collated. Sometimes it goes the other way; a program with little impact initially starts to have a large cumulative impact after a year or two.

Another kind of statistical evaluation problem comes when trying to separate the impacts of two or more programs that overlap in time. For example, it is difficult to separate the impact of fire department programs on smoke detector purchases versus the impact of television ads. Comparing communities with and without fire department programs but exposed to the same television ads may give some insight into whether the programs in question add anything. Sophisticated statistical techniques can be applied but are virtually unusable without expert statisticians. Suffice it to be flagged as a complex problem here.

Unintentional Impacts

The evaluation of a program should include a check for unintentional impacts along with expected desirable results. Some common unexpected side effects are the following:

1. *Greater reporting of minor fires that previously went unreported.* Encouraging the public to flee a fire and call 9-1-1 instead of trying to put it out can lead to an increase in reported fires. Other positive aspects of a public education program sometimes are partly or entirely masked by this surge. Looking at the number of small fires apart from large fires can be a check on this.
2. *Increase in fires set by children.* Sometimes raising the subject of fire to children boomerangs and greater curiosity is generated instead of being lessened.
3. *Scares, nightmares, and other psychological problems.* Young children can have a new fear added unwittingly by a program that is too scary for their age group. Children may become fearful instead of careful.
4. *Intrusion into parents' lives.* Getting a child to harass parents to improve home safety or to purchase safety devices the parents feel they cannot afford can lead to complaints by the parents. Usually this is outweighed by positive feedback from parents whose safety consciousness is improved. But complaints should be taken seriously, and the curriculum and instructors reviewed to see whether the safety message can be delivered effectively without unwanted side effects.

Proving Effectiveness After a Program Is Terminated

Sometimes the value of a program is not evident until after it is gone. Proving that there was a real loss of benefit after a budget cut or reallocation of resources causes the demise of a program is one way to fight for its restoration. It also is a valuable type of hindsight from which the profession can learn.

Just as a drop in fires, fire casualties, or dollar loss after a program is initiated can prove it worked, so can a rise in these measures after the program is dropped. Likewise, drops in smoke detector maintenance, drops in fire safety knowledge, and increases in numbers of hazards found per home after a program terminates can all indicate the effectiveness it had.

Of special importance after a program ends (or after an initial test of a program in one area) is to see how long the good results last. One might be able to show, for instance, that half of the people exposed to a public service announcement continue to test their detectors for three months after seeing it and then begin to forget and stop testing. Information on how fast the initial effect wears off is highly valuable for identifying the minimum repetition frequency a message needs to have to produce a continuing impact on the majority of those who receive it. This information can be used to optimize the use of scarce prevention resources.

The problem of unintentional injury is one of the most significant public health issues facing society today, and effective injury prevention programs need to be developed and implemented to address this problem. Evaluation is a key component of any program and should include assessment of the program's feasibility, cost-effectiveness, and efficacy. Data gathered early in the development cycle can be used to help create better programs, modify implementation strategies, revise interventions, and monitor progress toward goals and objectives. Outcome data can be used by policy makers, funders, and practitioners to expand successful programs to larger populations.

Education is an important component of safety and prevention programs, but acquiring knowledge is just one step in reducing injuries. Successful programs use multiple strategies, such as teaching children in schools, involving families and communities, and promoting changes in the home or community environment. *Risk Watch* is an example of such a program. Recent reviews have shown that many communities have the commitment, desire, and ability to share the responsibility for reducing unintentional injuries. In consultation with community leaders, future studies should continue to evaluate the effectiveness of well-designed community-based approaches aimed at improving safety behaviors and reducing injuries.

Hagerstown Case Study—Next Steps

Part of the ongoing monitoring was the identification of new fire problems that were now of greater relative importance, because of the success in reducing cooking fires or because of unrelated adverse trends in those fire problems. The next round of programs for Hagerstown would need to address emerging fire problems involving children playing with fire, candles, and smoking. Some of these problems showed up particularly in a recent adverse trend in fires causing at least $100 in damage, a threshold used locally to identify more serious fires.

Another part of the ongoing evaluation has tracked any contrary trends that threaten to undercut the program's successes. This tracking would include evidence of the disabling of smoke alarms installed by fire fighters.

The disabling problem led to a refinement of the program, focused on renters. The 2000 Census showed that 58 percent of Hagerstown housing units are renter occupied, and these homes account for roughly 90 percent of Hagerstown's home structure fires. Hagerstown also recognized that some of the lowest percentage gains in knowledge were registered in the low-risk neighborhoods where transient professionals occupy predominantly rental housing. Although some of these low gains could reflect the fact that higher initial scores left these households with less room for improvement, part of the reason was that the high turnover of busy people made for a lower contact rate (i.e., fewer people at home when contact was attempted) and far less potential for long-term impact, because new occupants would mean a need to start all over again.

All these findings encouraged Hagerstown to look for ways to work through landlords rather than just occupants. Hagerstown realized that certain options for dealing with landlords are even stronger than those for dealing with owners of owner-occupied housing.

As a financial incentive in this new approach, property owners are provided with free smoke alarms. In return, property owners are required to install the alarms and instruct tenants how to test and care for smoke alarms. They also educate tenants about the leading causes of fire in Hagerstown and solutions to current challenges. Tenants also are given printed and visual materials that reinforce the information provided by property owners. Property owners are also encouraged to incorporate a 12-point fire safety contract into their leases with tenants. Violation of the terms by a lack of fire safe behavior results in the possibility of financial sanctions levied by owners on tenants in the event of a fire.

The last problem still awaiting a fully developed programmatic response is dynamic. As noted earlier, development has been rapid in areas adjacent to Hagerstown. Like many cities of all sizes, Hagerstown has seen a disproportionate outflow of affluent, lower-risk households to its new suburbs, leaving behind a higher concentration of more challenging households. These dynamics change the landscape to which programs are tailored. Sometimes, they provide more reasons to work through landlords more than through occupants. Sometimes, they create a need to identify new established local networks and local opinion leaders. But regardless, they show the value of evaluation as a source of information to continually reshape the program to best build on past successes.

USES FOR EVALUATION

As demonstrated above, the evaluation of public fire and life safety education programs requires effort—effort that might seem out of reach to the busy educator. Because evaluation is central to improved fire and life safety education, as reflected by its inclusion in NFPA 1035, *Standard for Professional Qualifications for Public Fire and Life Safety Educator,* it is useful to review the many uses of information gained during the evaluation process. Uses included those directly related to the fire problem, those related to target audience, and those related to process, impact, and outcome evaluation.

Uses for Evaluation Related to the Fire Problem

National data can be obtained by contacting organizations such as the Centers for Disease Control and Prevention, the Consumer Product Safety Commission, the NFPA, and the U.S. Fire Administration's National Fire Data Center. Local data can be collected from emergency services reporting systems, local hospitals, and health departments. These data can be used to do the following:

- Identify and prioritize local risks
- Identify where, when, and how often problems are occurring
- Identify who is causing the problem
- Identify who is being affected by the problem
- Identify what the problem is costing the community
- Identify the sequence of events leading to the occurrence of leading risks
- Develop a community risk profile
- Prioritize local risks based on objective data
- Develop comprehensive intervention strategies to address priority local risks

Uses for Evaluation Related to the Target Audience

National, state, and local data can be used to accomplish the following:

- Identify the demographics of a community
- Understand how human behavior is contributing to a risk issue
- Identify high-risk populations such as toddlers, elders, people with disabilities, and people affected by poverty
- Identify primary and secondary target populations
- Identify characteristics of target populations and knowledge/attitudes they have about the risk issue
- Identify a relationship between target populations and risk issues
- Develop intervention strategies to address risks

Uses for Process, Impact, and Outcome Evaluation

Process, impact, and outcome data from one fire and life safety education program can capture gains from a given program as well as document information and gains for use in other subse-

quent programs. For example, process evaluation data can do the following:

- Help document the steps needed to create a specific risk reduction program
- Document the creation and monitor implementation of risk reduction programs
- Evaluate the performance of staff members as they implement and deliver programs
- Track and document outreach into the community
- Evaluate the overall public opinion of a program or initiative
- Document the allocation of additional funding or positions to address risk reduction

Similarly, impact evaluation data can help with the following:

- Evaluate knowledge gain
- Track behavioral and environmental changes
- Document adoption of codes, standards, and pertinent legislative actions
- Document behaviors leading to institutionalized risk reduction as a core value at both the organizational and community level

Finally, outcome evaluation data can be used to help with the following:

- Monitor and document changes in statistical data that identify leading risks and associated causation behaviors
- Gather and document anecdotal evidence supporting risk reduction initiatives

SUMMARY

Evaluation is a key component of fire and life safety education programs for two reasons. First, evaluation is a technique for making the most effective use of limited fire and life safety education resources. Second, evaluation provides the educator with the feedback needed to know whether fire and life safety education is indeed reducing incidents and preventing incidents. Either reason is a strong argument for the merits of evaluation. Together, the two reasons make a compelling case for undertaking evaluation activities.

ACKNOWLEDGMENT

The first version of this chapter appeared in the eighteenth edition of the *Fire Protection Handbook* and was largely based on the book *Proving Public Fire Education Works* published by TriData Corporation in 1990 under the authorship of Philip Schaenman and Paul Gunther. Many of the tables in this chapter originally appeared in that book.

SECTION 6

Characteristics of Materials and Products

Robert P. Benedetti

6.1 Fire Hazards of Materials
6.2 Combustion Products and Their Effects on Life Safety
6.3 Concepts and Protocols of Fire Testing
6.4 Wood and Wood-Based Products
6.5 Fibers and Textiles
6.6 Upholstered Furniture and Mattresses
6.7 Fire-Retardant and Flame-Resistant Treatment of Cellulosic Materials
6.8 Dusts
6.9 Metals
6.10 Gases
6.11 Medical Gases
6.12 Flammable and Combustible Liquids
6.13 Polymeric Materials
6.14 Pesticides in the Workplace
6.15 Explosives and Blasting Agents
6.16 Manufacture and Storage of Aerosol Products
6.17 Tables and Charts

Section 6 of the *Fire Protection Handbook*® presents detailed information about the fuel portion of the fire tetrahedron. The section includes one new chapter: Chapter 3, "Concepts and Protocols of Fire Testing." For the convenience of the reader, tables and charts formerly included in an appendix are now located at the end of this section.

Chapter 1, "Fire Hazards of Materials," is the most fundamental of the section's 17 chapters. This overview chapter discusses burning of materials, extremes of burning behavior, measuring and controlling hazards, flame resistance treatments and fire performance testing, and hazards of smoke.

Chapter 2, "Combustion Products and Their Effects on Life Safety," describes the toxicity of smoke and fire gases. The chapter provides appropriate background information on the several toxic components of combustion products. It discusses the measurement of the hazards of combustion gases and describes test protocols used to assess the effects of combustion products on life safety.

For the first time, the *Fire Protection Handbook* includes a chapter focusing on concepts and protocols of fire testing. Chapter 3, "Concepts and Protocols of Fire Testing," addresses the use of fire tests that measure the fire performance of materials and products and also the manner in which to select those that are more likely to be usable for fire safety engineering calculations and can assess fire hazard risk. Topics include classification of fire tests, fire resistance tests, and reaction-to-fire tests.

The next several chapters concentrate on individual materials. Chapter 4, "Wood and Wood-Based Products," is an overview of those characteristics of solid wood and of products made from wood and wood-based cellulosic material that influence their ease of ignition and burning behavior. The chemistry of cellulose is described, as is the behavior of wood and wood-based products as structural components under conditions of fire exposure. Chapter 5, "Fibers and Textiles," parallels Chapter 4, covering similar topics for commonly used fibers and textiles. It presents an overview of their manufacture, combustibility, and end use. Also discussed are fire-retardant treatments for textiles and fabrics and the test methods employed in evaluating and creating standards for the use of fibers and textiles. Chapter 6, "Upholstered Furniture and Mattresses," addresses the performance of upholstered furniture and mattresses when exposed to cigarettes and other flaming sources of ignition. Chapter 7, "Fire-Retardant and Flame-Resistant Treatment of Cellulosic Materials," presents a more detailed discussion of the basic principles of treatments that impart various degrees of fire and flame retardancy, as well as their limitations.

Chapter 8, "Dusts," looks at the factors that influence the explosibility of dusts and the various ways in which dust clouds are ignited. The chapter also describes the deflagration characteristics of selected combustible dusts, discusses factors that influence how destructive a dust explosion can be, and describes some test protocols used to quantify dust explosions.

Robert P. Benedetti, P.E., CSP, is principal flammable liquids engineer at NFPA and is responsible for standards development in the area of flammable and combustible liquids.

Chapter 9, "Metals," covers the fire hazard properties of combustible metals and the means to prevent their ignition or explosion.

The goal of Chapter 10, "Gases," is to provide information on the properties of gases, their classification, and the equipment needed to store gases safely, including key safety devices. The chapter also provides information on the properties, storage, and hazards of gases. Chapter 11, "Medical Gases," covers types and hazards of medical gases, including those used for respiratory therapy and anesthesia, and in health care facility laboratories, hyperbaric chambers, and ambulatory care facilities. The safe practices and hazards discussed in Chapter 11 apply to all health care facilities and the home health care environment.

Chapter 12, "Flammable and Combustible Liquids," addresses hazards and classification of flammable and combustible liquids and their physical characteristics. Emphasis is placed on their burning behavior. Fire prevention methods for the use, handling, and storage of liquids complete the chapter.

Among other topics, Chapter 13, "Polymeric Materials," covers major groups of plastics, their uses, additives and blends, fire behavior, fire tests, and appropriate fire- and flame-retardant treatments.

Chapter 14, "Pesticides in the Workplace," provides an overview of the requirements and practices in location, construction, and administration of facilities that handle pesticide products, from manufacturing facilities to local businesses and farms. Emergency plans and security concerns are covered.

Chapter 15, "Explosives and Blasting Agents," describes the nature and types of explosive materials, as well as their manufacture, transportation, and storage. Chapter 16, "Manufacture and Storage of Aerosol Products," discusses the hazards of flammable aerosol products, their classification, and their safe storage.

Chapter 17, "Tables and Charts," was formerly Appendix A.

Chapter 1

Fire Hazards of Materials

Revised by
Robert P. Benedetti

Chapter Contents

Burning of Materials
Extremes of Burning Behavior
Measuring and Controlling Hazards
Flame Resistance Treatments and Fire Performance Testing
Hazards of Smoke

Key Terms

auto-oxidation, cellulosic material, combustion, flame resistance, flame spread, heat of combustion, heat release rate, hydrocarbon-based material, organic materials

This chapter provides an overview of the fire hazards of materials. Specifically, it concentrates on how those fire hazards can be quantified and how they are related to the physical and chemical characteristics of the materials with which they are associated. Subsequent chapters in this section deal in detail with the fire problems of particular classes of materials.

This chapter focuses on materials, by which is meant substances of relatively uniform composition, as distinguished from products, which are assemblies of materials intended for a specific use. For example, upholstered furniture is a product; the wood, cushioning and fabric of which it is made are each materials. The distinction between materials and products is not always a sharp one because many materials are themselves products, but it is an important distinction because the fire performance of a product is often quite different from that of the materials of which it is made. Hence, a laminated composite may show considerably lower flame spread than most or all of its layers would exhibit when tested individually. In other cases, assembling the materials may degrade their fire performance.

Another distinction which is useful (but also sometimes imprecise) is between materials whose contribution to fire hazard is active—that is, they affect the initiation, the growth of the fire, or its effects—and passive—that is, by how they respond to heat. The structural steel elements of a high-rise building, for example, are unlikely to ignite even in the most severe fires, but how well they retain their strength at high temperature can have a profound effect on fire safety. This, of course, was demonstrated by the collapse of the World Trade Center buildings. Most of the discussion that follows, however, addresses materials that burn.

For additional information on this and related topics see the following chapters: Section 3, Chapter 4, "Use of Fire Incident Data and Statistics"; Section 3, Chapter 7, "Fire Hazard Analysis Techniques"; Section 6, Chapter 2, "Combustion Products and Their Effects on Life Safety"; and Section 6, Chapter 17, "Tables and Charts."

BURNING OF MATERIALS

Ordinary burning is combustion, the chemical reaction of a material with atmospheric oxygen accompanied by the release of sensible energy as heat and usually light. The products resulting from combustion are oxides, that is, they contain oxygen as part of their chemical makeup. Once a material is in its fully oxidized form, it is no longer susceptible to combustion. For this reason, many materials suitable for use at high temperatures, such as asbestos and most ceramics, are basically oxides.

One descriptor of hazard is the maximum amount of energy produced as heat per unit weight of material burned. This quantity, commonly called the heat of combustion, is also a measure of the material's value as a fuel. The heat of combustion is determined almost entirely by the chemical

Robert P. Benedetti, P.E., CSP, is principal flammable liquids engineer at NFPA and is responsible for standards development in the area of flammable and combustible liquids.

composition of the material. The speed with which the heat is produced, on the other hand, is determined by the material's physical form. For example, excelsior burns more quickly than a solid block of wood, although equal weights of the two will produce essentially the same amount of heat. In some cases, the physical form of the material is the principal determinant of hazard. Aluminum in its familiar forms, for example, rarely burns even in major fires but aluminum powder or shavings can, under certain conditions, be explosive.

Organic Materials and Energy Production

Any discussion of the fire hazards of materials centers on those materials that are organically derived, that is, based on carbon, because organic materials as a class are ubiquitous. The simplest organic compounds, such as methane and propane, are common gaseous fuels. Organic liquids are fuels, solvents, and chemical intermediates, but the richest variety of materials are organic solids. They include everything from specific compounds, such as aspirin, to common but complex everyday materials, such as wood, paper, textiles, and plastics. These materials have carbon as their principal constituent; almost all contain some hydrogen; and many contain oxygen, nitrogen, and other elements in varying amounts.

The molecules of most common organic structural materials are large, that is, they are "macro" molecules or polymers. They consist of many simple molecules linked together in a regular pattern to form the chains and networks necessary for useful mechanical properties. Some polymers are of natural origin, such as the cellulose in wood or cotton, or the protein-based fibers of wool. Plastics are manufactured polymers. Polyethylene, for example, is made (as the name suggests) by chemically linking, or polymerizing, many molecules of ethylene, a gas, to form a nonvolatile solid with many everyday uses.

Most organic materials burn readily. The common products of combustion of organic materials are water, which is the oxide of hydrogen, and carbon dioxide. A tabulation of the heats of combustion of organic materials is contained in Section 6, Chapter 17, "Tables and Charts." Those figures are based on complete burning. In practice, there may be insufficient oxygen available to convert all of the carbon to carbon dioxide; some carbon monoxide and soot may be formed, so the heats are upper limits of the actual amount expected from combustion under normal conditions.

Examination of the heats of combustion tables in Section 6, Chapter 17 will show that although the heat of combustion is quite different for different organic materials, the heat produced per unit weight of oxygen consumed is the same within about 10 percent. This fact, sometimes called Thornton's Rule,[1] allows one to use oxygen consumption as a reasonable measure of the heat produced by a burning organic material.

Organic materials fall into two broad classes: (1) hydrocarbon based and (2) cellulose based. The former are derivatives of the unoxidized hydrocarbon building blocks: —CH_2—, or —CH—. The latter are based on a partly oxidized carbon unit: —CH(OH)—. In a sense, cellulose-based material is already partly oxidized in its natural state, so that when the two classes are combusted to carbon dioxide and water, cellulose consumes less oxygen and produces less heat. On a weight basis, the difference is greater: hydrocarbons produce over twice the heat per unit of weight as do cellulosics. Hence, from an energy viewpoint, oil and natural gas, both hydrocarbons, are better fuels than wood, which is composed largely of cellulose.

Rate of Burning

The rate at which the fire products are produced is controlled by the rate at which a material burns. Later sections of this chapter address the measurement of this quantity, but it is instructive to examine some of the general physical factors that contribute to the burning rate.

The material that constitutes the fuel may be gaseous, liquid, or solid, but the oxygen in the air is gaseous. For the necessary chemical reactions to occur, the fuel and oxygen must be brought into contact at a molecular level, and this, in turn, means that burning is generally a vapor-phase phenomenon.

The rate of burning is a function of how fast the chemical reaction of oxidation occurs. In premixed flames, that is, those in which mixing has occurred before the combustion is initiated, the burning rate is the inherent rate at which the substances combine. This is generally quite fast; flames propagate under premixed conditions at more than a meter per second. It is for this reason that the contact of air and combustible vapors is so dangerous; the process, once started, is virtually impossible to interrupt, except in closed spaces specifically equipped for that purpose.

Liquids and solids commonly burn in diffusion flames, shown schematically in Figure 6.1.1. Diffusion flames differ from premixed flames in that the fuel vapor and the air mix by diffusion as burning occurs, and so the burning rate is generally controlled by the rate at which the scarcer component, fuel vapor or oxygen, enters the combustion zone.

Energy is required to convert the fuel in the fuel bed from its original liquid or solid form to the vapor state and this has an important influence on the intensity of the fire. Specifically, the rate of heat release of a material is proportional to the ratio of its heat of combustion to its heat of vaporization, a parameter sometimes called the combustibility ratio.[2] A liquid hydrocarbon

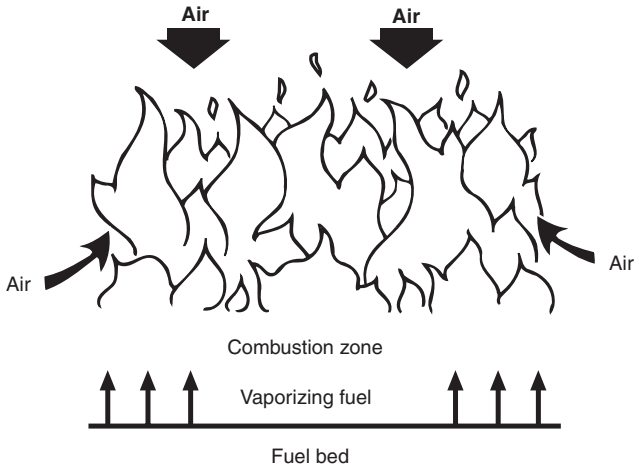

FIGURE 6.1.1 Schematic View of a Burning Surface

such as heptane has a combustibility ratio of about 93, whereas polyethylene, which has roughly the same chemical composition, has a combustibility index near 25.[3] One therefore expects that, to a first approximation, a burning pan of heptane would produce heat almost four times as fast as a pan of the same size containing polyethlylene granules. From a microscopic viewpoint, the difference is that the heptane molecules are readily vaporized and can be transported into the combustion zone without decomposition. For fuel vapor to reach the combustion zone from the polyethylene, however, volatile fragments must actually be broken off the polymer chain; that is, chemical bonds must be ruptured. This process requires considerably more energy than does simple vaporization.

Liquids and solids are more concentrated fuels than are gases. Propane, for example, burns completely according to the following expression:

$$C_3H_8 + 5\ O_2 \rightarrow 3\ CO_2 + 4\ H_2O$$

One volume of propane gas consumes five volumes of oxygen, or about 25 volumes of air. By contrast, liquefied propane is some 300 times denser than propane gas under normal conditions. This means that one volume of the liquid will produce 300 times as much heat, but it will also require 300 times as much air. Thus, the burning of highly volatile liquids and solids is sometimes limited by the rate of delivery of oxygen to the combustion zone, especially under poorly ventilated conditions.

Except for hypergolic combinations of materials (i.e., those that ambient temperatures are sufficient to ignite), the initiation of the combustion reaction requires added heat. This heat must be sufficient to vaporize enough of the fuel to initiate reaction and to accelerate the chemical combustion reaction to a rate where it can sustain itself. The heat required for ignition is greatly dependent upon the physical state of the materials and the heat transfer properties of its environment. Thus, a combustible material present as a dust, that is, with a large surface-to-volume ratio, may burn very readily or explode, whereas the same material in a solid block may be very difficult to ignite at all.

EXTREMES OF BURNING BEHAVIOR

The extremes of burning behavior differ from normal burning principally in the time scale over which burning occurs. At the fast end of the spectrum are explosions and at the slow end are the phenomena of auto-oxidation and smoldering. Explosions are a source of substantial hazard and are discussed in detail in several chapters in this handbook. The slow processes, however, are less well known. Auto-oxidation is the combination of a material with oxygen at a rate too slow to produce the observable heat and light normally associated with fire. Metals are particularly prone to auto-oxidation, demonstrated by the rusting of iron and the tarnishing of silver, as are many organic materials. The deterioration of rubber and plastics over time is often the result of slow oxidative processes. Antioxidants can be added to such materials in order to increase their durability and working life. Such additives operate either by being themselves oxidized in preference to the organic material or by chemically inhibiting the oxidation reaction.

Self-heating and eventual spontaneous ignition can occur if the heat produced by auto-oxidation is not removed. This is especially true in porous solids, such as coal, where air can diffuse into the interior of the material, but the heat produced is effectively contained by the insulating properties of the material.

Smoldering is a distinct burning process, quite different from flaming. Only a small fraction of combustible materials, those that produce a porous char during the course of combustion, will smolder. This char allows air to reach the smoldering region, which is on or below the surface of the fuel. Compared to flaming, smoldering is a slow process. Temperatures in the smolder zone are typically 900 to 1600°F (480 to 870°C), whereas temperatures in a flame typically reach 2700°F (1480°C). When materials smolder, the degree of combustion is usually less complete than when the same materials burn under flame. Most smolderers are organic and all are solids.

MEASURING AND CONTROLLING HAZARDS

The vastly different burning characteristics of gases, liquids, and solids pose different types of hazards. The methods for measuring and controlling them are also different. Table 6.1.1 shows the different kinds of measurement techniques available for different components of hazard. It is most convenient to think of hazard control in terms of first controlling the likelihood of ignition, then controlling or containing the fire spread, and finally managing fire impact if ignition and spread cannot be prevented.

Fire Hazards of Gases and Dusts

Combustible gases and dusts burn rapidly once ignited, so avoidance of ignition is very important. The two steps for doing this are (1) the determination of flammability limits, that is, the concentration range of a particular gas or dust (usually in air) within which ignition will occur, and (2) operating in a manner such that the concentration is maintained outside those limits. It is also possible to reduce the likelihood of ignition of a gas or dust by adding chemical inhibitors to raise the lower flammability limit. In practice, however, this is rarely done, either because of expense or because it alters otherwise desirable properties.

Ignition control is generally effected by stringent storage and handling safeguards; the bulk of the discussion in the chapters of this handbook on flammable gases are concerned with these procedures. It is also possible in closed environments to reduce the amount of oxygen available and thereby to raise the effective flammability limit. Conversely, atmospheres that are enriched with oxygen beyond normal atmospheric concentrations offer special explosion hazards for vapors and dusts. The intensity of a fire resulting from gases, vapors, or dust is a function of the density of gas or the concentration and particle size of the dust. Gases (hydrogen, for example) and very finely divided dust are rapidly dispersed and can lead to the onset of explosive conditions in short periods of time. Fire and explosion control efforts concentrate on containing the products and, under specialized conditions, providing for automatic suppression of an incipient explosion. This is done by rapidly introducing a

TABLE 6.1.1 Means of Measuring and Controlling Fire Hazards of Materials

	Ignition		Spread and Growth		Fire Impact	
Hazard Component Material	*Measurement*	*Ignition Control*	*Measurement*	*Control of Spread and Growth*	*Measurement*	*Control of Fire Impact*
Gases	Flammability limits	1. Storage and handling safeguards 2. Inerting of atmospheres	Flammability limits, density, diffusion coefficient	Tank venting procedures	Placarding, NFPA hazardous materials identifiers	1. Emergency response and evacuation 2. Placarding, NFPA hazardous materials identifiers
Liquids	Flashpoint	1. Handling safeguards 2. Hazard classification systems	Volatility	1. Ventilation and flame arrest 2. Storage and tank separation	Placarding, NFPA hazardous materials identifiers	1. Emergency response and evacuation 2. Placarding, NFPA hazardous materials identifiers
Solids 1. Textiles, cushioning materials	1. Ease of ignition tests and small-scale flame spread tests	1. Flame-resistive materials and treatments 2. Protective layers	1. Supported flame spread 2. Rate-of-heat release	1. Material selection and assembly 2. Detection and suppression	1. Smoke hazard assessment	1. Breathing apparatus for fire fighters 2. Smoke control systems
2. Structural materials, building components and finishes	Same	Same	Flame spread, rate-of-heat release	1. Fire resistivity 2. Low combustibility 3. Fire-resistive coatings 4. Detection and suppression	1. Fire endurance (stability, integrity, insulation) 2. Smoke hazard assessment	Same, plus construction design: compartmentation; separation

suppressant, such as water vapor or a chemical inhibitor, into the exploding cloud. To be effective, automatic suppression must occur in a time scale of a few hundredths of a second.

There has been concern over the possibility of large flammable gas fires in populated areas. With vast quantities of gaseous fuels now being transported either in bulk or by pipeline and the renewed interest in importation of liquefied natural gas by oceangoing tank vessels, the likelihood of such occurrences commands attention. The principal means by which the impact of such accidents is minimized is the use of hazardous material identification systems, for example, placarding and NFPA 704, *Standard System for the Identification of the Hazards of Materials for Emergency Response.* In the absence of a major breakthrough in the prevention or suppression of such fires, the most appropriate means of minimizing fire impact is the advanced planning, preparedness, and response of trained emergency personnel.

Fire Hazards of Liquids

Since burning actually occurs in the vapor phase, the most hazardous combustible liquids are those with a high vapor pressure, or volatility. An empirical measure that combines volatility with the heat-producing capabilities of the vapor is the flashpoint determination. The flashpoint is simply the temperature at which a liquid gives off vapors that can be ignited under specified laboratory conditions. Flashpoint determinations give rise to hazard classification systems, the most severe hazard being afforded by those liquids with the lowest flashpoints. As in the case of gases, however, the principal means of controlling the ignition of combustible liquids is in handling safeguards. Elaborate procedures exist to minimize the escape of flammable vapors in the handling of volatile liquids and to avoid sources of ignition.

If a fire involving such materials is initiated, means are also available to prevent the supply of additional combustible

fuel to the fire. These means include designs for the safe venting from storage tanks of vapors produced by heating due to fire exposure as well as flame arrestors to guard against the travel of the flame into the storage area itself. Storage and separation criteria for bulk storage of flammable liquids are also used to minimize the likelihood that additional supplies of flammable liquids will come in contact with the fire. As described in a previous section, the intensity of the fire once begun is controlled by (1) the fuel's volatility and (2) the amount of heat released when the fuel burns. Thus, heavy oils or tars may be difficult to ignite, but can burn readily once underway.

Some fire-fighting techniques interfere with the passage of fuel from the liquid to the vapor phase. These include cooling the liquid to slow vaporization and the use of foam to cover the liquid surface.

Fire Hazards of Solids

The part of Table 6.1.1 relating to solids concentrates on common materials; it ignores the large group of chemicals that are primarily found in specialized industrial environments. Unless these materials are present as dusts, foams, or in other forms that present high surface areas, their fire hazards are similar to those of liquids.

In Table 6.1.1, solid materials are divided into two major classes: (1) flexible materials, such as textiles and cushioning; and (2) structural materials, which can include everything from steel and concrete to wood and synthetic structural plastic foams. For both of these classes of materials there is a variety of tests to determine their susceptibility to ignition. However, since ignition requires the volatilization of some of the solid fuel, ignition behavior is strongly dependent on the amount of heat applied to the surface. Therefore, different ignition tests often give different results, depending on the size of the ignition source. The same principle applies to tests that attempt to measure flame spread over small samples. In many such tests, a sample receives no radiant heat load except that available from its own burning. The larger the amount of sample burning, the greater the heat transferred to the unburned area ahead of the flame and a large sample will appear to have a higher flame spread rate than a small one.

The fire hazards posed by inorganic structural materials are most likely to be passive. For example, steel can lose its strength, concrete can crack and spall, and glass can break and melt on exposure to high temperature. Such materials are therefore rated on their ability to withstand such high-temperature effects.

FLAME RESISTANCE TREATMENTS AND FIRE PERFORMANCE TESTING

Improvements in ignition control of materials have come about as a result of flame-resistant treatments developed for both natural and synthetic materials. One is the incorporation of flame-inhibition agents, which commonly contain large amounts of chlorine, bromine, or phosphorus, into the material. With natural materials, such as wood or cotton, this is accomplished by topical or pressure treatment. With synthetic materials, such agents are usually added during the polymerization process. Another approach, useful for plastics, is dilution of the material with an inert or energy-absorbing filler, such as calcium carbonate or alumina trihydrate. A third route is the fabrication of materials with very high effective heats of vaporization. An elevated heat of vaporization often accompanies charring, because the formation of char structures can compete with, or inhibit, the release of volatile fuel vapor.

Flame spread tests are probably the best-known fire performance tests. The most widely used of these are the Steiner Tunnel Test, contained in NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials* (ASTM E84), and the radiant panel test, included in ASTM E162, *Standard Test Method for Surface Flammability of Materials Using a Radiant Heat Energy Source.* These tests attempt to simulate spread of fire across a plane surface and, because flame spread under actual conditions often occurs over preheated surfaces, the latter test includes radiant heating of the sample from an imposed external heat flux.

The role of heat release rate in determining fire hazards is characterized by two standard test methods: (1) ASTM E906, *Standard Method of Test for Heat and Visible Smoke Release Rates for Materials and Products Using a Thermopile Method,* and (2) ASTM E1354, *Standard Test Method for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter.* These tests measure the rate at which heat is produced, generally as a function of the imposed radiant energy. Because of the importance of an imposed flux in real fire hazard, these measurements have utility in predicting fire hazards. Ideally, the effects of fire-resistant treatments should be detectable as diminished heat release rate measurements.

It is important to recognize that claims for flame resistance are tied closely to the test method that is used to evaluate fire performance. Materials that resist ignition or behave acceptably in small-scale tests may be wholly inappropriate for use when more severe or substantially different fire conditions are encountered. Figure 6.1.2, for example, shows that the burning rate depends heavily on imposed heat load (external flux). The steepness of this dependence can be estimated from the combustibility ratio. The higher the ratio, the more burning rate will increase with increasing external flux.

The relative performance of materials under a radiant heat load of 1 or 2 W/cm^2 may be different from their performance at 5 W/cm^2, an external flux representative of what might be experienced by an exposed surface in a well-developed room fire. This makes it important that materials be tested under conditions that duplicate those expected in real fires whenever possible.

HAZARDS OF SMOKE

Because smoke* is usually the primary threat to life safety, it receives a great deal of attention. Traditionally, smoke has

*Smoke is defined in most NFPA standards as the total airborne effluent from heating or burning a material. Expressions such as "smoke and toxic gases" are, by this definition, redundant.

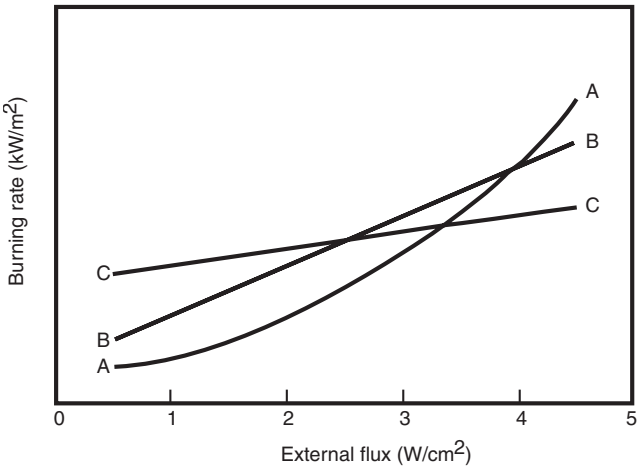

FIGURE 6.1.2 Burning Behavior of Various Materials as a Function of External Flux (W/cm^2)

been characterized simply by its ability to obscure light. As synthetic materials have become common components of building construction and furnishings, however, there has been increasing interest in the identity and effects of combustion products themselves.

Three major effects have been identified: light obscuration, toxicity, and postfire impact. The first two effects are closely related: smoke can reduce visibility, thereby slowing escape and making one more vulnerable to its toxic properties. The third can include any toxic effects encountered by fire fighters during overhaul, but it is more usually interpreted as a property issue in situations where smoke deposition can affect the behavior of sensitive equipment and circuitry.

There are measurement techniques (not necessarily NFPA standards) for all three effects (see in particular NFPA 269, *Standard Test Method for Developing Toxic Potency Data for Use in Fire Hazard Modeling*) but, in each case, the hazard depends as well on the burning rate of the material. The latter in turn is the result of a host of material-related and situational variables. Thus, characterizing the hazards of smoke involves analyzing or assessing the hazards of the fire itself. Indeed, smoke hazard assessment is an important component (often the dominant one) of fire hazard analysis. This important discipline is described in more detail in Section 3, Chapter 4, "Use of Fire Incident Data and Statistics," and Section 3, Chapter 7, "Fire Hazard Analysis Techniques."

SUMMARY

The fire hazards of a given material stem from the material itself (whether hydrocarbon or cellulosic, for example) and on the form of the material: gas, dust, liquid, or solid. Regardless of form, a material can be evaluated in terms of ignition potential, fire spread and growth, and fire impact. Fire performance testing can be used to assess a material's ignition potential and fire spread and growth.

Chapter 2

Combustion Products and Their Effects on Life Safety

Revised by
Richard G. Gann ❑ Nelson P. Bryner

Along with heat, the burning of every combustible material or product* produces smoke—gases and aerosols that, in sufficiently high concentration, present hazards to people in the vicinity. Products near those already burning may also contribute to the smoke as they decompose from exposure to the heat from the fire. Predominant among the hazards, which generally occur simultaneously, are the following:

- Sensory irritation of the upper and/or lower respiratory tract, which can affect speed of movement and the ability to negotiate escape and, at higher exposures, can lead to incapacitation or death
- Central nervous system depression resulting from inhalation of asphyxiant fire gases, which can, in ascending exposures, lead to impaired judgment, disorientation, loss of motor coordination, unconsciousness, and, ultimately, death
- Thermal effects, including hyperthermia and thermal burns of the skin and respiratory tract

Exposure to these hazards is often prolonged by eye irritation and diminished visibility due to smoke obscuration, which can affect the ability of occupants to see and negotiate escape routes efficiently. Survivors from a fire may also experience postexposure complications that can lead to delayed health effects or even death.

The *nature and concentration* of the generated smoke depends on a variety of factors. These include the quantity of the product that is burning, whether the product is flaming or pyrolyzing, the ventilation in the area, and distance from the fire. Thus, smoke toxicity is not a singular property of a product.

The *threat to people* from the heat and smoke depends on additional factors, including the entire ensemble of burning products, the location of people relative to the fire, the locations of exits from the burning enclosure and the paths to those exits, the time (in the fire growth history) at which people are in the vicinity of the fire-generated atmosphere, and individual susceptibility of each person to the components of the smoke. Thus, the hazard and risk to people from exposure to the fire effluent (heat and smoke) from a burning product is also not a singular property of the product.

See also Section 2, Chapter 3, "Flammability Hazard of Materials"; Section 4, Chapter 2, "Calculation Methods for Egress Prediction"; and Section 6, Chapter 3, "Concepts and Protocols of Fire Testing."

*In this chapter, *product* refers to a finished commercial item, and *material* refers to a single substance. Thus, for example, a chair (the product) is composed of several materials (e.g., a wooden frame, polyurethane padding, cotton batting, an aramid fire barrier, and a polyester/cotton cover fabric).

Richard G. Gann, Ph.D., and **Nelson P. Bryner,** M.S., are in the Building and Fire Research Laboratory of the National Institute of Standards and Technology (NIST). Dr. Gann, a senior research scientist, was formerly chief of the NIST Fire Science Division and is currently the chair of ISO TC92 SC3, Fire Threat to People and the Environment. Mr. Bryner is a chemical engineer with experience in fire research including lab- and full-scale experiments. He is head of the Fire Fighting Technology Group at NIST.

This chapter was prepared by federal employees and is not subject to copyright.

Chapter Contents

Fire and Combustible Materials
Generation of Fire Gases
Toxicity of Fire Gases
Quantification of Toxic Potency
Test Methods for Toxicity of Smoke
Estimation of Toxic Hazard in Fires
Development of Toxic Hazards in Full-Scale Fires

Key Terms

asphyxiant, available safe egress time (ASET), carbon dioxide, carbon monoxide, combustion product, cup furnace test, fractional effective dose, hydrogen cyanide, irritant, LC_{50}, mass loss model, N-gas model product of combustion, pyrolysis, radiant panel test, required safe exit time (RSET), smoke, Station Nightclub fire, stoichiometric, supertoxicant, test, toxic gas model, toxicity, University of Pittsburgh (UPITT) device

FIRE AND COMBUSTIBLE MATERIALS

Pyrolysis and Combustion

Almost all polymeric materials, both natural (e.g., wood) and synthetic (e.g., polyurethane or nylon), can undergo pyrolysis and/or combustion. *Pyrolysis* is defined as a "process of simultaneous phase and chemical species change caused by heat," with combustion being defined as "a chemical process of oxidation that occurs at a rate fast enough to produce temperature rise and usually light, either as a glow or flame."[1] The processes of pyrolysis and combustion have both physical and chemical aspects.[2]

Polymeric materials, on exposure to sufficient thermal energy, typically first undergo phase change, such as melting in the case of thermoplastics, followed by chemical decomposition. These are endothermic processes, resulting in the production of volatile low-molecular-weight products, which may or may not then undergo actual combustion.

If pyrolysis produces gases that are themselves combustible, flaming may occur if the following exist in the same volume:

- Sufficient oxidizing agent (air)
- An ignition source of sufficient intensity
- Sufficient gaseous fuel vapors or volatiles

The nature of the gases generated by the pyrolysis can have a significant effect on when and whether ignition takes place. For example, a material that contains a readily volatile fire retardant may not ignite until the fire retardant has been sufficiently depleted. Should the fire retardant and the host polymer continuously volatilize until the polymer is depleted, ignition may be prevented altogether.

For the process of combustion to be self-sustaining, it is necessary for the burning gases to impart sufficient heat energy to the material to continue the production of ignitable volatiles. The process is a continuous feedback loop: heat transferred to the material causes the generation of flammable volatiles, these volatiles react with oxygen in the air to generate heat, and a part of this heat is transferred back to the material to continue the process. The chemical oxidation processes for flaming combustion of organic materials are generally quite exothermic, with more than enough energy being produced to continue the pyrolysis and bond-breaking processes if the heat transfer is efficient and heat losses to the environment are not too great.

Smoldering is a different form of combustion occurring only in certain porous materials. Here, air diffuses into the pores of the material and reacts directly with the interior surfaces of the pores. The combustion products from this slower process are typically quite different from those from flaming combustion. They are, however, a significant cause of fire deaths when a person is close to the smoldering product, as can occur following cigarette ignition of a bed or piece of upholstered furniture.[3]

Flammability Properties of Materials and Products

It is difficult to generalize the flammability properties of materials, since fire performance is influenced by a number of factors, including the chemical composition and structure of the material, the use of additives in formulated systems, and even the conditions of the fire. Highly crosslinked thermoset polymers normally burn less readily than thermoplastics. Cellular plastics (foams) generally burn quite readily due to their large surface area and good thermal insulating properties, which prevent dissipation of heat. Polymer systems containing halogen atoms (e.g., polyvinyl chloride [PVC]) burn with difficulty; however, the addition of plasticizers increases the propensity of these polymer systems to burn. Fire-retardant additives, which include organic halogen and phosphorus-containing compounds and several metal oxides and hydrates, are employed to increase resistance to ignition and/or lower burning rates of polymer systems.[4] However, inherently fire-resistant polymers and polymer systems containing fire-retardant additives will still burn under sufficiently severe thermal conditions.

GENERATION OF FIRE GASES

Smoke is commonly defined as "the airborne solid and liquid particulates and gases evolved when a material undergoes pyrolysis or combustion."[1] The particulates and aerosols produced affect occupants' visibility as they attempt to escape from a fire; this will be addressed in a later portion of this chapter. Consideration will be given first to the formation and toxicity of the gases commonly produced in fires.

Carbon Dioxide

In well-ventilated flaming fires, nearly all the carbon lost from the combustibles is converted to carbon dioxide (CO_2). Even in postflashover fires, the fraction of carbon conversion to CO_2 is fairly high. Thus, the yield* of CO_2 has been used to estimate the burning rate of products when a direct measurement of mass loss is not possible. Carbon dioxide is also generated in smoldering fires, but the generated carbon monoxide is far more hazardous.

Carbon Monoxide

Carbon monoxide (CO) is produced from both smoldering and flaming combustion. The production of CO from smoldering fires is quite slow, but these fires are not accompanied by vigorous mixing and diluting of the combustion products with room air. Thus, lethal concentrations of CO can be generated in the immediate vicinity of the ignition within 10 minutes. Lethal concentrations of CO elsewhere in the room may take 1 to 3 hours. By then, smoldering may have ceased or may have undergone transition to flaming combustion.[5]

The production of CO from flaming combustion is a gas phase process. The fuel vapor or carbon-containing decomposition products react in a complex sequence with the oxygen in the air to form carbon monoxide. Subsequent reaction further oxidizes the CO to CO_2. The completeness of this process is largely dependent on the local supply of oxygen. Oxygen available to

*The yield of a fire-generated gas is defined as the mass of the gas produced divided by the mass of the combustibles consumed in the burning. A parallel definition applies to the overall yield of smoke.

a fire can be limited either by lowering the oxygen concentration in the incoming air supply or by reducing the volume flow of air to a fire. The formation of CO is related to the fuel-to-air equivalence ratio,[6] which is defined as

$$\phi = \frac{(\text{kg fuel/kg air})}{(\text{kg fuel/kg air})_{\text{stoich}}} \quad (1)$$

where "stoich" denotes conditions at which the ratio between fuel and oxygen is that required for complete combustion, with no excess oxygen. Thus, when $\phi = 1$, exact stoichiometric conditions exist between fuel and air. For values of $\phi < 1$, the fire is fuel-lean and well ventilated; for values of $\phi > 1$, the fire is fuel-rich and ventilation controlled. These latter conditions ($\phi > 1$) are ones that favor the formation of CO.

Studies have shown that under well-ventilated conditions ($\phi < 0.5$), yields of CO are very low, typically less than 0.01.[6] Above equivalence ratios of about 0.5, the yield of CO increases rapidly as the value of ϕ increases. For compartments of moderate size and ventilation, this rise in the yield of CO occurs near the point of flashover. Flashover occurs when the thermal environment is sufficiently intense that many or all the combustibles in the compartment burst into flame. The result is a high density of combustible vapors, a decrease in the oxygen within the compartment, and thus a sharp increase in ϕ. This is the same condition that favors generation of CO. According to NFPA 269, *Standard Test Method for Developing Toxic Potency Data for Use in Fire Hazard Modeling,* once ϕ reaches a value greater than about 1.5, the CO yield becomes rather constant at about 0.2 kg CO/kg fuel consumed, with the production rate being dependent principally on the mass burning rate. For a sufficiently large fire whose flame radiative heat flux and mass generation rate of material vapor have approached their asymptotic values, the mass burning rate remains rather constant, and, thus, the CO production rate is also fairly constant (until the fuel supply becomes depleted).[7] These phenomena have been observed with large-scale fire tests involving fully furnished rooms.[8]

The ratio of the concentrations of carbon dioxide to carbon monoxide, often used as a descriptive characteristic of a fire, depends more on the ventilation conditions of the fire than on the nature of the materials being burned.[9] Studies of the dependence of CO_2/CO ratios on the equivalence ratio show that for well-ventilated fires (i.e., $\phi \ll 1$), essentially all the fuel carbon is oxidized to CO_2 and the ratio exceeds 20.[10] Once the equivalence ratio has exceeded that associated with flashover, indicating a fuel-rich or ventilation controlled fire, the CO_2/CO ratio reaches a plateau at about 2 to 10.[6,10] The bases for this range have not been established.

Hydrogen Cyanide

The generation of hydrogen cyanide (HCN) is both material-dependent and temperature-dependent. In smoldering fires and pyrolysis from flaming fires, HCN can be produced by decomposition of some nitrogen-containing polymers. HCN can be generated from nitrogen-containing polymers during flaming combustion as well. In neither case is there evidence of toxicologically significant HCN formation by fixation of the nitrogen in the air. In contrast to CO, there have been insufficient studies on HCN to enable quantitative prediction of its formation in fires. If sufficient oxygen is present, oxides of nitrogen (NO_x) may also be formed from nitrogen-containing materials. Although one study reported NO_x production from nitrogen-containing fuels to be far less than that for HCN, there are conflicting data in the literature.[11] HCN has also been seen to be oxidized to NO_x when flames extended from a flashed-over room and continued to burn outside the doorway.[12]

Halogen Acids

Polymer systems containing halogen atoms (fluorine, chlorine, or bromine) result in the formation of the halogen acids—hydrogen fluoride (HF), hydrogen chloride (HCl), and hydrogen bromide (HBr), the production of which is largely material-dependent as long as thermal decomposition temperatures are reached. The halogen acids are formed in the pyrolysis component of the combustion process and are not oxidized further. Thus, the halogen acids are produced even if flaming combustion does not occur. Since the production efficiencies for the formation of HF, HCl, and HBr are close to being unity, maximum yields might be expected in fires. For example, HCl is readily evolved from polyvinyl chloride (PVC) at temperatures of about 437 to 527°F (225 to 275°C).[2] Since HCl can be released before significant carbon from the material is combusted, the mass yield of HCl can exceed the stoichiometric value early in the material's decomposition. Nonetheless, the maximum possible concentrations of halogen acids are generally not encountered. Far lower yields have been found from PVC that contains a high fraction of calcium carbonate filler.[13] Presumably, this reflects reaction with the chlorine atoms to form (solid) calcium chloride, which is thermally stable under ordinary fire conditions. Furthermore, halogen acid concentrations decay rather quickly in the presence of adsorptive surfaces[14] and water droplets present in most fire effluents at temperatures below 212°F (100°C).

Organic Irritants

Pyrolysis and/or incomplete combustion of organic materials can lead to a wide variety of organic irritant species. Those considered to be the most important toxicologically are formaldehyde, unsaturated aldehydes (especially acrolein), and isocyanates (from nitrogen-containing polymers[15]). The first two result from partial oxidation of the carbon in the material. (Further oxidation leads to the formation of CO and then CO_2.) Acrolein, in particular, has been demonstrated to be present in many fire atmospheres.[16] It is also formed from the smoldering of all cellulosic materials and from the oxidative pyrolysis of polyethylenes.[17]

Other Gases and Aerosols

Depending on the composition of the combusting products, additional toxic components of smoke can be produced in a fire. For example, phosphorus-containing fire retardants can result in phosphoric acid aerosol, and sulfur-containing polymers can generate sulfur oxides. There is yet no predictive capability for the yields of such species.

TOXICITY OF FIRE GASES

Fire gas toxicants are usually considered as belonging to one of three basic classes:

1. Asphyxiants, or narcosis-producing toxicants
2. Sensory/upper respiratory irritants or pulmonary irritants
3. Toxicants exhibiting other or unusual effects; although always a possibility, this class has few documented examples

The toxicological effects of smoke produced from fires usually involve relatively high concentrations of toxicants inhaled over quite short periods of time. Thus, many criteria commonly used in conventional toxicology to describe hazardous conditions, such as threshold limit values (TLVs[18]) and occupational long-term exposure values, are normally of little use in combustion toxicology.

This section addresses the toxicity of the major fire gases in a largely descriptive manner. It also provides guidance on limiting criteria for exposure of humans in fires.

Asphyxiants

In combustion toxicology, the term *narcosis* refers to the effects of asphyxiant toxicants that are capable of resulting in central nervous system depression, with loss of consciousness and ultimately death. Effects of these toxicants depend on the accumulated dose, that is, both concentration and duration of the exposure. The severity of the effects increases with increasing dose.

Carbon Monoxide. The toxic effects of carbon monoxide are those of anemic hypoxia.[19] Hypoxia refers to the condition in which there is an inadequate supply of oxygen (O_2) to body tissue, with anemic hypoxia being characterized by a lowered oxygen-carrying capacity of the blood, even when the arterial partial pressure of O_2 and the rate of blood flow are normal. This is due to competition between O_2 and CO for the heme-binding sites of hemoglobin, with the affinity of hemoglobin for CO being about 250 times greater than that for O_2.[19] Even partial conversion of hemoglobin to carboxyhemoglobin (COHb) significantly reduces the oxygen-transport capability of the blood such that serious toxic signs and symptoms are produced. Additionally, partial conversion of hemoglobin to COHb causes oxygen that is bonded as oxyhemoglobin (HbO_2) to be more tightly held and less available to body tissues. The extent to which blood hemoglobin is converted to COHb can readily be measured in a clinical laboratory and is expressed as percentage of COHb saturation. An ISO standard for these measurements is being processed in ISO TC 92/SC 3.[20]

The signs and symptoms produced by exposure to CO are directly related to the percentage of blood hemoglobin that is converted to COHb.[21] Deaths of humans exposed to CO produced in fires have been associated with COHb saturations ranging from 1 to 99 percent.[22] Although most deaths have been reported to be in the 50 to 70 percent COHb range, both lower and higher values are not unusual.[23,24] Low COHb values in fire victims may be due to preexisting physiological conditions, such as pulmonary insufficiency or cardiovascular disease, which may have already compromised the individual. The high oxygen demand resulting from physical exertion may also cause a person to succumb to low COHb saturation. High COHb values at death may be attributed to the low oxygen demand of a person either at rest or at quite low physical activity. There is no specific COHb saturation below which one would be expected to live and above which death would occur. As with essentially all biological responses, there is a distribution of COHb saturations associated with death.[24] Sometimes, in the case of even a single exposure, permanent harm may result from hypoxic damage to neural structures.[19] The peak incidence of such delayed neurological impairment is with the elderly.[25]

Binding of O_2 and CO with hemoglobin occurs as an equilibrium, with both association and dissociation taking place.[19] Thus, CO and hemoglobin are in equilibrium with COHb, with the concentration of COHb being dependent on the partial pressure (or concentration) of CO in the atmosphere. Each concentration of CO is associated with an equilibrium COHb saturation, or, stated another way, for any given value of COHb saturation there is a minimum concentration of CO that will attain it. At any given O_2 concentration, higher equilibrium COHb saturations can be obtained only by increasing the concentration of CO.

The competition between O_2 and CO for bonding sites on hemoglobin is defined by the Haldane equation:[19]

$$\frac{(\text{COHb})}{(\text{HbO}_2)} = M\frac{(P_{\text{CO}})}{(P_{\text{O}_2})} \tag{2}$$

where

$(\text{COHb})/(\text{HbO}_2)$ = Ratio of carboxyhemoglobin to oxyhemoglobin

$(P_{\text{CO}})/(P_{\text{O}_2})$ = Ratio of the respective partial pressures (or concentrations)

M = A constant that is, to some extent, species dependent

The Haldane equation is commonly used to calculate the CO concentration that would be in equilibrium with any given COHb saturation.

The time required for a human subject to attain a given COHb saturation can be approximated from the Stewart-Peterson equation:[26]

$$\%\ \text{COHb} = (3.32 \times 10^{-5})(\text{CO})^{1.036}(\text{RMV})(t) \tag{3}$$

where

(CO) = CO concentration (μL/L)*

RMV = Respiratory minute volume (L/min)

t = Exposure time (min)

At rest, the RMV for humans averages approximately 8.5 L/min,[23] but may increase during strenuous activity to as much as

*The concentration in μL/L is numerically equal to the frequently used unit of "ppm." The use of the latter unit is discouraged.

100 L/min. Curves showing the relationship between CO concentration and time of exposure for various COHb saturation values for humans have been constructed using the Stewart-Peterson equation.[27]

Studies using rats have shown that elevated temperatures have an exacerbating effect on CO intoxication,[28] possibly through increased rate of respiration. This is likely to occur with humans as well. The obvious treatment for persons exposed to CO is to provide for inhalation of fresh air or even pure oxygen. For example, the half-recovery time in terms of blood COHb levels for resting adults breathing air at 1 atmosphere is 320 minutes.[19] When oxygen is given at 1 atmosphere, the time is reduced to 80 minutes.

Hydrogen Cyanide. Hydrogen cyanide (HCN), whose lethal dose is approximately 25 times smaller than that of carbon monoxide, is a very rapidly acting toxicant.[29] The action of HCN is due to the cyanide ion, which is formed by hydrolysis in the blood. Unlike CO, which remains primarily in the blood, cyanide ions are distributed throughout the body water and make contact with the cells of tissues and organs. Cyanide ions readily react with the enzyme cytochrome oxidase to form a cytochrome oxidase–CN complex and also with methemoglobin to form cyanomethemoglobin. If the concentration of cyanide ions is not sufficiently great to cause death, the ions are slowly released from the complexes with cytochrome oxidase and methemoglobin and converted to thiocyanate ions by the enzyme rhodanese. This detoxification process, along with the fact that cyanide is distributed throughout the body, makes correlation of blood cyanide content with actual exposure to HCN difficult.

Cytochrome oxidase occupies a central role in the utilization of oxygen in practically all cells. Its inhibition rapidly leads to loss of cellular functions (cytotoxic hypoxia) and then to cell death. In contrast to CO, cyanide ions do not decrease the availability of oxygen but rather prevent the utilization of oxygen by cells. The heart and brain are particularly susceptible to this inhibition of cellular respiration, with bradycardia, cardiac arrhythmia, and EEG brain wave activity, indicative of central nervous system depression, having been reported in studies using monkeys.[30] Although cardiac irregularities are often noted in HCN intoxication, the heart tends to outlast respiration, and death is usually due to respiratory arrest of central nervous system origin.

A complication resulting from the inhalation of HCN is one of respiratory stimulation or hyperventilation,[23] presumably due to the body's regulating chemoreceptor cells responding to a need for oxygen. This causes a more rapid uptake of not only HCN but also other toxicants that may be present. The hyperventilatory effect of HCN may also account for its rather steep dose-response relationship.

Data relating symptoms in humans to various concentrations of HCN are very limited. One widely referenced descriptive account of HCN intoxication of humans reports that 50 µL/L may be tolerated for 30 to 60 minutes without difficulty, 100 µL/L for that same period is likely to be fatal, 130 µL/L may be fatal after 30 minutes, and 181 µL/L may be fatal after 10 minutes.[31]

The role of HCN as a causative agent in human fire fatalities is considerably less clear than that of CO. Documented cases are rare in which HCN alone can be shown to be the primary toxicant. Blood can be analyzed for cyanide, but the procedure is more complex than that for CO, and the reliability of the results is dependent on proper blood storage conditions prior to analysis. Analyses should be interpreted with caution, with consideration given to the analytical method used, the blood storage history, and the past performance of the responsible laboratory. It is generally held that blood cyanide concentrations greater than 1.0 µg/ml are indicative of possibly significant toxicological effects due to inhalation of HCN.[22,32] Blood cyanide levels greater than 3.0 µg/ml are generally considered to be lethal. Significant concentrations of blood cyanide are normally found associated with carboxyhemoglobin saturation due to inhalation of CO.[32,33] The contribution of each to death often cannot be determined with confidence. There is no evidence for synergism between HCN and CO, and it is generally agreed that these two toxicants are additive in their effects.[34,35]

Carbon Dioxide. Carbon dioxide (CO_2) is quite low in its own toxicological potency and is not, by itself, normally considered to be significant as a toxicant in fire atmospheres. However, it does stimulate both the rate and depth of breathing, thereby increasing the RMV. The RMV, increasing about 50 percent with only 2 percent CO_2, may be as much as 8 to 10 times normal in the presence of 10 percent CO_2. Such respiratory stimulation causes accelerated inhalation of other toxicants leading, for example, to an increased rate of formation of blood COHb from inhalation of CO. However, the same equilibrium COHb saturation of blood is reached as in the absence of CO_2.[36]

Increased incidence of lethality of rats has also been reported with combinations of CO and CO_2, particularly occurring after the exposure period.[37] This effect may be associated with the combined insult of respiratory acidosis (caused by CO_2) and metabolic acidosis (caused by CO), a condition from which the rodent has difficulty recovering postexposure. Whether or not this latter effect of CO_2 also occurs with people has not been determined.

Oxygen Depletion. Since oxygen is consumed in the combustion process, oxygen depletion or vitiation must also be considered a toxic component of smoke. When oxygen drops from its usual level of nearly 21 percent in air to approximately 17 percent, a person's motor coordination may be impaired. When oxygen drops to the range of 14 to 10 percent, a person can be still conscious but may exercise faulty judgment and will be quickly fatigued. In the range of 10 to 6 percent, a person loses consciousness and must be revived with fresh air or oxygen within a few minutes to prevent death.[38] During periods of exertion, increased oxygen demands may result in oxygen deficiency symptoms at higher oxygen levels.

Irritants

Both inorganic irritants (e.g., halogen acids and those formed from nitrogen oxides) and organic irritants (e.g., aldehydes) can be formed in fires. Irritant effects, produced from exposure

to essentially all fire atmospheres, are normally considered by combustion toxicologists as being of two types:

1. Sensory irritation, including irritation of the eyes and the upper respiratory tract
2. Pulmonary irritation affecting the lungs

Most fire irritants produce signs and symptoms characteristic of both sensory and pulmonary irritation.

Eye irritation, an immediate effect that depends primarily on the concentration of an irritant,[39] may significantly impair a person's escape from a fire. Nerve endings in the cornea are stimulated, causing pain, reflex blinking, and tearing. Severe irritation may also lead to subsequent eye damage. Victims may shut their eyes, partially alleviating these effects; however, this action may also impair their escape from a fire.

Airborne irritants also enter the upper respiratory tract, causing burning sensations in the nose, mouth, and throat, along with the secretion of mucus. These sensory effects are also primarily related to the concentration of the irritant and do not normally increase in severity as the exposure time is increased.[39]

Following signs of initial sensory irritation, significant amounts of inhaled irritants may also be quickly taken into the lungs, with the symptoms of pulmonary or lung irritation being exhibited. Lung irritation is often characterized by coughing, bronchoconstriction, and increased pulmonary flow resistance. Tissue inflammation and damage, pulmonary edema, and subsequent death may follow exposure to high concentrations, usually within 6 to 48 hours. Inhalation of pulmonary irritants also appears to increase susceptibility to postexposure bacterial infection. Unlike sensory irritation, the effects of pulmonary irritation are dependent both on the concentration of the irritant and on the duration of the exposure.

Halogen Acids. The halogen acids have received particular attention, with the most prevalent case being hydrogen chloride (HCl) resulting from the decomposition of polyvinyl chloride (PVC). HCl is both a potent sensory irritant and a strong pulmonary irritant. Volume fractions as low as 75 to 100 µL/L are extremely irritating to the eyes and the upper respiratory tract, suggesting possible impairment of physical activity such as is needed for escape.[40] Although HCl was found not to be physically incapacitating to baboons subjected to volume fractions up to 17,000 µL/L for 5 minutes, postexposure deaths were reported from doses that did not appear to incapacitate.[41] Comparable studies have not been conducted using actual PVC smoke.

Another study, using baboons exposed for 15 minutes to (flaming) PVC smoke containing 5000 µL/L HCl, did not show any smoke-related impairment of pulmonary function when tested at 3, 90, 180, and 360 days postexposure.[42] Lesions to mucosal surfaces of the mouth were observed, however, along with evidence of bronchoconstriction and lowered PaO_2 (arterial oxygen) levels during the exposure.

Considerable controversy has existed as to what concentration of HCl may be hazardous to humans. It is questionable whether data from numerous studies with rodents can be directly extrapolated to humans because of significant anatomical differences between the respiratory tracts of the rodent and the primate which, in turn, result in very different responses to HCl. Rodents exhibit a decrease in respiratory rate and minute volume on exposure to HCl, whereas these values have been shown to increase for primates.[43] Interestingly, exposure doses (concentrations × time) of HCl causing postexposure lethality in rats are in the same range as those that have resulted in postexposure deaths of baboons.[44] However, the data for baboons are very limited, and the comparison made is rather subjective. From studies using exposure of baboons, HCl would not appear to be physically incapacitating, nor would it seem to produce significant chronic respiratory complications after short exposures to volume fractions of 5000 µL/L and below. Although acute symptoms, ranging from severe discomfort to noticeable upper respiratory tissue damage, may be experienced, significant pulmonary function changes would not be expected except at higher concentrations.

It would still be prudent, however, to recognize that HCl is likely to be dangerous to humans at concentrations far below those indicated from studies using baboons. Evidence of bronchoconstriction and markedly lowered PaO_2 levels from inhalation of HCl were observed with baboons,[45] suggesting a potential for adverse effects with humans. Furthermore, persons having preexisting compromised pulmonary function may be more susceptible than healthy individuals.

Fire-retardant additives based on chlorine or bromine are also sources of halogen acids in fires. Fluoropolymers are a major source of HF. Although studies using the halogen acids HF and HBr have been very limited, it would appear that these acid gases exhibit irritant effects similar to those of HCl at comparable concentrations.[23]

The determination of incapacitation threshold criteria for the initial effect of the halogen acids (and for irritant gases in general) has involved considerable controversy, since very few controlled studies have been made that relate to the effects of human exposure. Most information has been only anecdotal. Taking expert cognizance of relevant published information, ISO 13571 suggests the following incapacitating volume fractions:[46] F_{HCl} = 1000 µL/L, F_{HBr} = 1000 µL/L, and F_{HF} = 500 µL/L. These are for use in Equation (7) on p. 6-20.

Nitrogen Oxides. Nitrogen dioxide (NO_2) and nitric oxide (NO) are the major components of a mixture of nitrogen oxides usually referred to as NO_x. Nitric oxide is only about one-fifth as potent as NO_2.[11] Studies on rats exposed to NO_2 under the conditions of smoke toxicity test methods indicate NO_2 to have a lethal toxic potency comparable to HCN.[47] In contrast to HCN, the toxicity of NO_x is primarily due to its properties as a pulmonary irritant, with lethality of rats being postexposure, usually within one day. A consensus (ISO 13571) incapacitating volume fraction is F_{NO_2} = 250 µL/L.

Other Inorganic Irritants. As indicated above, the presence of other atoms in the burning materials can lead to the generation of inorganic oxides and acids, which behave as irritants as well. The toxic effects of these gases are likely to be additive with the irritants discussed above. A consensus value for the incapacitating volume fraction of SO_2 is 150 µL/L. Consensus values for other inorganic irritants have not yet been determined.

Organic Irritants. Although numerous organic irritants may be produced in fires, only acrolein has received significant attention in combustion toxicology. It is deemed to be the most potent of the organic irritants. Volume fractions of acrolein as low as a few μL/L are extremely irritating to the eyes and upper respiratory tract. Interestingly, studies with baboons showed that volume fractions up to 2780 μL/L (5700 g/m^3) for 5 minutes were not physically incapacitating during exposure.[41] Pulmonary complications caused by that and even lower concentrations resulted in death within hours after the exposure, however. Values of incapacitating volume fractions for acrolein and formaldehyde are 30 μL/L and 250 μL/L, respectively.[46] However, given the results of the baboon studies, this figure for acrolein seems conservative.

Supertoxicants

Concern regarding potential "supertoxicants" (materials generating smoke of extremely high potency) in fire atmospheres was prevalent in the 1970s and 1980s. With more experience in the testing of materials, this concern has diminished, since there have been few documented examples. One involved the formation of a neurotoxin from the thermal decomposition of a noncommercial rigid polyurethane foam,[48] whereas another concerned the extreme toxic potency exhibited by polytetrafluoroethylene in some laboratory tests. The latter eventually came to be regarded as largely an artifact of the test methods.[49] For most materials and products it is now widely accepted that smoke toxicity can, to a large extent, be explained both qualitatively and quantitatively on the basis of a small number of common toxic gases.[50,51] A protocol for identifying a supertoxicant is presented below in the section Test Methods for Toxicity of Smoke.

QUANTIFICATION OF TOXIC POTENCY

The LC_{50}

The standard in combustion toxicology for quantifying the toxic potency of individual fire gases or of smoke has mostly been the LC_{50} for 30 minute exposure of rats.[52,53] The LC_{50} is defined as the volume fraction of toxic gas in μL/L or smoke in g/m^3 statistically calculated from concentration-response data to produce lethality in 50 percent of test animals within a specified exposure and postexposure time.* The IC_{50} is similarly defined for incapacitation. It is significant that consensus among experts has been to recognize that the rat is a reasonably acceptable animal model for human exposure to smoke when the principal effects are due to inhalation of asphyxiant toxicants.[27,54] Over the years, LC_{50} values have been experimentally determined for rodent (and less frequently, other laboratory animals) exposure to individual fire gases,[54] as well as for many materials and products.[55]

*"Within a specified exposure" refers to the time interval during which the animals can inhale the gas or smoke. A "specified postexposure time" refers to a length of time after that, when the animals are breathing fresh air.

Lethal Toxic Potency from Chemical Analysis

Although individual fire gas toxicants may exert quite different physiological effects through different mechanisms, when present in a mixture each may result in a certain degree of compromise experienced by an exposed subject. It should not be unexpected that varying degrees of a partially compromised condition may be roughly additive in contributing to death. The extensive bank of rodent lethality data became useful in the development of a strategy for calculating smoke LC_{50} values from combustion analytical data without the need for exposure of animals. As early as 1972, Tsuchiya and Sumi proposed that a toxicity index could be constructed from the sum of terms for all the gases generated by a fire. Each term was the ratio of the actual concentration of the gas divided by the concentration fatal to a person in a 30 minute exposure.[56] Three further developments made this concept tractable for estimating lethal toxic potency.

Additivity Studies

The additive effects of combustion gases were demonstrated in a number of studies using rodents.[34,35] As a result, it is now fairly well agreed that the asphyxiants CO and HCN are additive. Furthermore, analysis of data from experiments exposing rats to mixtures of HCN and CO, and also mixtures of HCl and HCN, suggests that their effects leading to lethality may also be approximately additive.[57,58]

Fractional Effective Dose (FED)

The additive effects of fire gases was advanced to include consideration of variable exposure time. This strategy is commonly referred to as the fractional effective dose (FED) methodology.[34,59,60] The FED is "the ratio of the *Ct* product (concentration × time) for a gaseous toxicant produced in a given test to that *Ct* product of the toxicant that has been statistically determined from independent experimental data to produce lethality in 50 percent of test animals within a specified exposure and postexposure time."[53]

The additivity of FEDs has become a useful tool in combustion toxicology for the calculation of lethal toxic potencies from combustion product analysis data, as well as for the assessment of potential toxic hazards to humans.[51] Mathematically, the principle is expressed as

$$\text{FED} = \sum_{i=1}^{n} \sum_{t_1}^{t_2} \frac{C_i}{(Ct)_i} \Delta t \qquad (4)$$

where

C_i = Concentration of toxic component i

$(Ct)_i$ = Specific dose (concentration × time) required to produce lethality

t = Time increment (min)

When the accumulated FED = 1, it is expected that the mixture of gaseous toxicants would be lethal to 50 percent of exposed animals, that is, the LC_{50}.

N-Gas Model

The combustion of the complex formulations used in commercial products generates hundreds of different gases. The evaluation of the FED values and the nature of the combination of those FED values would have been a daunting, if not insurmountable, task. Researchers at the National Institute of Standards and Technology (NIST) proposed the N-gas model. This concept suggests that the toxic potency of most commercial products could be estimated from the contributions of a small number, N, of the combustion gases.[35,51] The results of rat exposure experiments to single and mixed gases were compared with experiments in which rats were exposed to the gases generated by the combustion of a number of materials. The mean FED value corresponding to the LC_{50} was 1.07, using the "N-gas" calculation, with 95 percent confidence limits of 0.20.[61] This provided substantial support for this concept.

Two equations have been developed to fit rodent data.[52] The first, Equation 5, was developed empirically by Levin and coworkers[9] from exposure of laboratory rats to individual and mixed gases:

$$\text{FED} = \frac{m \cdot f_{CO}}{f_{CO_2} - b} + \frac{21 - f_{O_2}}{(21 - 5.4)} + \frac{f_{HCN}}{150} + \frac{f_{HCl}}{3700} + \frac{f_{HBr}}{3000} \quad (5)$$

where m and b are, respectively, the slope and intercept of the interactive curve of CO and CO_2, which depicts the increasing toxicity of CO as CO_2 concentration increases. The values of m and b depend on the volume fraction of CO_2. If $f_{CO_2} \leq 0.05$, $m = -18$ and $b = 122{,}000$. If $f_{CO_2} > 0.05$, $m = 23$ and $b = -38{,}600$. Confirmatory work using this model has been published by Pauluhn.[61]

The terms f_x are the volume fractions of those species in µL/L, except for O_2 and CO_2, where the volume fractions are in volume percent.

The second, Equation 6, was developed by Purser,[62] fitting the rat LC_{50} data obtained mainly by Levin et al.[61,63] and Kaplan and Hartzell.[27]

$$\text{FED} = \left(\frac{f_{CO}}{LC_{50,CO}} + \frac{f_{CN}}{LC_{50,HCN}} + \frac{f_X}{LC_{50,X}} + \frac{f_Y}{LC_{50,Y}}\right) V_{CO_2} + A + \frac{21 - f_{O_2}}{(21 - 5.4)} \quad (6)$$

where, in addition to the definitions for Equation 5,

f_{CN} = The volume fraction of HCN in µL/L, corrected for the presence of other nitriles and the protective effect of NO_2, and is equal to $f_{HCN} + f_{\text{total organic nitriles}} - f_{NO_2}$

$LC_{50,X}$ = The LC_{50} of each acid gas irritant in µL/L

$LC_{50,Y}$ = The LC_{50} of each organic irritant in µL/L

V_{CO_2} = A multiplication factor for CO_2-driven hyperventilation equal to $1 + e[(0.14 \cdot CO_2\%) - 1]/2$

A = An acidosis factor equal to $f_{CO_2} \times 0.05$

The 30 minute LC_{50} values used in Equation 6 are given in Table 6.2.1.[54]

Between the two equations, there are small numerical differences in the LC_{50} values for HCN, HCl, and HBr. These differences are within the uncertainties of the experiments from which the values were derived.

There are also functional form variations in the way CO, CO_2, and depleted O_2 are included in the two equations. These variations will lead to modest differences in the calculated values of the FED. A reasonable estimate of agreement between the two equation calculations is ±30 percent for FED values ≈ 1.

Sublethal Effects of Fire Smoke

Smoke inhalation can lead to a succession of sublethal effects that each can affect how readily a person can find safety from a fire. For nearly all of these, there are few quantitative data from controlled experiments or actual fire experience for the degree to which these effects alter the ability of laboratory animals or people to escape from a fire. Although tests have been developed for assessment of incapacitation due to sensory irritation,[64] they have not received significant use. This is due, at least in part, to a lack of validation between the tests and actual effects on humans. This has led the experts assigned to ISO TC92 SC3 to affirm that the focus should be on incapacitation.[10] Incapacitation is defined as the inability to take action to accomplish an escape from a fire.

Some measurements have been made of incapacitation on rodents.[27] A literature review of the animal exposure data for CO and HCN showed that the concentrations that caused incapacitation were one-third to one-half those that resulted in death.[27] A subsequent review was performed of the literature of the animal exposure data for exposure of animals to combustion smoke from a wide variety of materials and products.[55] The mean value of the ratios of the IC_{50} to the LC_{50} and the standard deviation were 0.50 and 0.21, respectively.

Although considerable attention was once directed toward incapacitation studies, testing for smoke toxicity ultimately made no such assessment. Incapacitation is simply inferred from lethality data, with combustion toxicologists generally regarding incapacitating exposure doses to be about one-third to one-half of those required for lethality.[27]

TABLE 6.2.1 30 Minute LC_{50} Values for Rats

Combustion Product	*30 min LC_{50} (µL/L)*
CO	5700
HCN	165
HCl	3800
HBr	3800
HF	2900
SO_2	1400
NO_2	170
Acrolein	150
Formaldehyde	750

TEST METHODS FOR TOXICITY OF SMOKE

Evolution of Testing

In the 1970s and 1980s, the dominant philosophy was that smoke toxicity was a property of a material and that control of this property was the proper approach to improving life safety in fires. Accordingly, a number of bench-scale apparatus were developed to measure the toxicity of smoke produced from the burning of materials and, sometimes, products.[65] These tests exposed a sample of a material or a finished product to a thermal exposure that was deemed appropriate to simulate a fire. Multiple rats or, less commonly, mice were exposed to the combustion products. Sufficient experiments were performed to estimate the LC_{50} for a 30 minute exposure and frequently within a postexposure period of up to 14 days. The LC_{50} values were expressed in units of g/m^3, that is, grams of the test specimen that were consumed (and presumed to be present as smoke) per unit exposure chamber volume (for closed box apparatus) or total air flow (for flow-through apparatus). One test method, The University of Pittsburgh (UPITT) device, expresses the LC_{50} only as grams of material subjected to the test protocol, which is not a true expression of concentration. In general, care should be taken in comparing LC_{50} values obtained from different test methods to ensure that the basis for reporting data is the same.

Although this type of testing may have led some manufacturers to not market certain products, regulation on this basis was limited. For a number of years, the state of New York required the testing and filing of test data for certain construction and finish materials using the "LC_{50}" value from the UPITT method. However, when it became widely recognized that the results of such testing were often irrelevant to the toxic hazards of real fires, the regulation was repealed and most of the laboratory testing ceased. At present, there are no laboratories conducting nonproprietary animal tests for smoke toxicity on a routine basis.

In recent decades, there has been growing resistance to the routine use of laboratory animals for testing products, whether this be for skin care or fire safety. This has resulted in a move toward the N-gas concept. Unfortunately, there were, and continue to be, some regulations based on limiting the concentration of one or more gases generated using a particular test apparatus. As noted in the introduction to this chapter, this is not likely to help achieve a desired level of fire safety, since the gas yields are not singular properties of a product.

More recently, there has been enhanced awareness that the proper use of smoke toxic potency data is as input to a fire hazard or risk assessment, rather than stand-alone pass/fail testing of materials or products.[10] The values to be used are the yields of the toxic gases. This is the mass of the gas generated divided by the combusted mass of the test specimen. Less commonly, the calculations use the specimen mass subjected to the test conditions. (These values will be identical if the specimen is completely combusted with no residue.)

Per NFPA 269 and ASTM E1678-02,[53] there is now a protocol that balances the need for accuracy in toxic potency measurement while minimizing the use of laboratory animals. In this method, the measured concentrations of the principal toxicants that are generated when a test specimen is combusted are used to estimate the LC_{50} using the N-gas equation. Rats are then exposed to smoke at concentrations 30 percent below and 30 percent above this value. If the animal mortality agrees with the predicted LC_{50}, then it is presumed that the smoke is "normal" and the estimated value is used. This will generally be the case for a product whose chemistry is similar to other products for which the animal confirmation test was successful. If the smoke is unusually toxic to rats, then additional research or testing is warranted.

The question then arises as to which of the many tests available gives toxic potency values that are "right." ISO 16312-1 describes the characteristics of the ideal fire effluent toxicity test method:[66]

- The combustor (or physical fire model) replicates one or more fire stages (radiative pyrolysis, well-ventilated flaming, etc.).
- The test specimens are representative of as-used products.*
- The apparatus itself does not affect the results.
- The apparatus is straightforward to use.
- The method generates gas/smoke yields and specimen mass loss data.
- The method has demonstrated accuracy relative to real-scale fires.
- The results are repeatable and reproducible.

The standard then provides criteria to evaluate a real method. ISO/TR 16312-2 (not a Standard, but a Technical Report that presents the ISO TC 92/SC 3 assigned experts' appraisal) applies these criteria to twelve test methods in use today.[67]

The following sections present the essential features of some of the tests whose data are most likely to appear in the published literature or which are more commonly used for the regulation of materials and products. For a broader coverage of the many apparatus that have been developed over the years, the reader is referred to more complete compilations.[66,67]

Cup Furnace Test

The cup furnace test,[68] described in Figure 6.2.1, combusts a test specimen in a quartz beaker (the "cup"); the effluent rises and expands to fill an 0.2 m^3 closed box. Data for both nonflaming and flaming combustion are obtained by conducting tests just below and just above the autoignition temperature of the specimen, respectively. In each test, six rats are held in tubular restrainers, with their heads inside the box. They inhale the smoke for 30 minutes and then are observed for the following 14 days. Multiple experiments are conducted, with varying masses of the test specimen placed in the cup furnace, leading

*This may be the most difficult of the characteristics with which to comply. Some test methods can accommodate a specimen prepared to resemble, as much as possible, a product in its form of use as it would be exposed in a fire. Other test methods require, or can only accommodate, a ground or crumpled specimen. The latter is less representative of a product having complex construction (e.g., layers of different materials). These two approaches may yield different results for the toxicity of smoke produced by a product.

to different concentrations of smoke in the box. The number of animal deaths per test is plotted against the smoke concentration (specimen mass in the furnace divided by the box volume). Statistical analysis of the data then generates an estimate of the LC_{50} (30 minute exposure plus 14 day postexposure period). Chemical analysis of the principal toxicants enables a second estimation of the LC_{50} using Equation 5 for FED = 1. The use of rats can be minimized by using the animal check test protocol as noted above under "Evolution of Testing."

Extensive data on individual fire gases, combinations of those gases, materials, and products have been produced using this method. The data can be found in the references to Levin and coworkers in the bibliography of this chapter. This method is no longer in use since the radiant furnace apparatus (discussed next) manifests a more fire-like exposure of the test specimen. However, the data from the cup furnace method are still widely referenced.

Radiant Furnace Test

The radiant furnace test[53] uses the same 0.2 m^3 box as the cup burner test. However, the cup furnace is replaced by an assembly that applies a fixed radiant flux to the test specimen, as shown in Figure 6.2.2.[69] A spark source is used to ignite the fuel vapors. The test is particularly applicable to layered products, such as furniture or wall coverings. In the operation of the method,[9] a test specimen up to 10 cm by 15 cm by 5 cm thick is exposed to a radiative flux of 50 kW/m^2 for 15 minutes. The smoke enters the box through the center hole of a three-slot chimney. Air from the box is recirculated to the combustion zone through the two outer slots. The rat exposures and gas analyses are the same as with the cup furnace test. Successive tests are performed, with the top surface area of the specimen being varied to vary the concentration of smoke in the box.

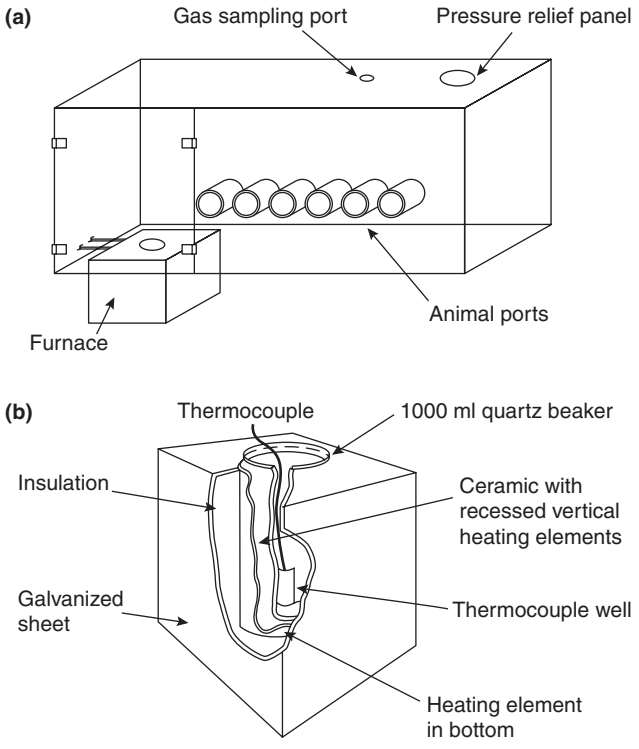

FIGURE 6.2.1 Schematic of the Cup Furnace Apparatus. (a) Orientation of furnace to exposure box. (b) Details of cup furnace. (Source: National Institute of Standards and Technology)

The lethal toxic potency, LC_{50}, of the smoke from the test specimen is predicted from the combustion atmosphere analytical data by first calculating the FED for the test. The 30 minute LC_{50} is then calculated as that specimen mass loss that would yield FED = 1 within a chamber volume of 1 m^3 from the equation:

$$LC_{50} = \frac{\text{Specimen mass loss}}{\text{FED} \times \text{Chamber volume}} \quad (7)$$

where the specimen mass loss is in grams and the chamber volume is 0.2 m^3. The resulting LC_{50} has the units of g/m^3. The predicted LC_{50} is then confirmed in limited tests using rats to ensure that the monitored toxicants account for the observed toxic effects.

The apparatus and procedures have been standardized (identically) as ASTM E1678, *Standard Test Method for Measuring Smoke Toxicity for Use in Fire Hazard Analysis*[53] and NFPA 269, *Standard Test Method for Developing Toxic Potency Data for Use in Fire Hazard Modeling.* Both standards also provide for a mathematical adjustment of experimental LC_{50} values in order to make them appropriate for the toxic hazard assessment of oxygen-vitiated, postflashover fires.

The test results have been compared to results from room-scale postflashover fires.[70] Prior to performing the comparison, an adjustment was made to the CO yield. Following flashover, the oxygen concentration in a room drops precipitously. Were this condition replicated in the current test, the animals would succumb to the reduced oxygen, regardless of the effects of the other gases in the smoke. A literature search indicated that postflashover fires typically generate yields of CO of about 0.2 kg CO per kg fuel consumed. This yield is substituted for the CO yield determined in the tests. For five different criteria, the bench-scale apparatus produced results consistent with the room-scale data. Accuracy to within a factor of three was established as both attainable and practical.

University of Pittsburgh (UPITT) Test

The UPITT test,[71] shown in Figure 6.2.3, exposes four mice per test to fire effluent produced in a flow-through system from the 68°F (20°C) per minute ramped heating of a specimen in a box or muffle furnace. Exposures are for 30 minutes, starting when 1 percent of the sample weight has been lost. The animals are also observed for 10 minutes following the exposure to the combustion gases. Animal measurements include concentration-response for lethality and time-to-death. Although the results are reported as LC_{50} values, the values are actually the weight of test specimen charged to the furnace, rather than actual concentrations of smoke, which varies considerably during a test. Thus, "LC_{50}" values obtained from this test are not directly comparable to those from other methods. Between 1987 and 1998, this

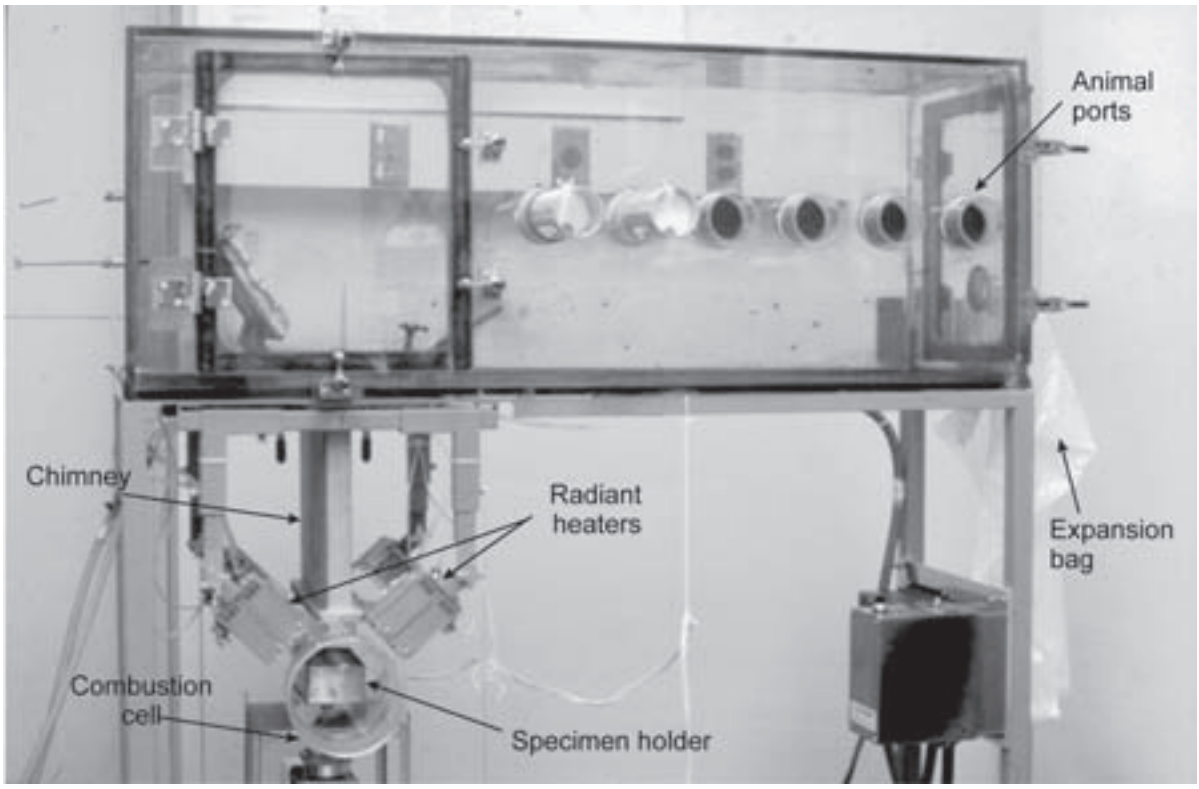

FIGURE 6.2.2 ASTM E1678/NFPA 269 Test Apparatus (Source: National Institute of Standards and Technology)

test was required by the state of New York for certain construction and finish materials. No acceptance levels or criteria for classification of materials were ever set. During the years over which testing was conducted, LC_{50} values were reported and filed with the state of New York for over 15,000 products.[72]

There are a number of differences between real-scale fires and the conditions in this apparatus. There is no ignition source, so the samples autoignite or don't, depending on the mix of gases generated, the point in the temperature ramp, and the sufficiency of the oxygen at that point. Furthermore, it is not clear

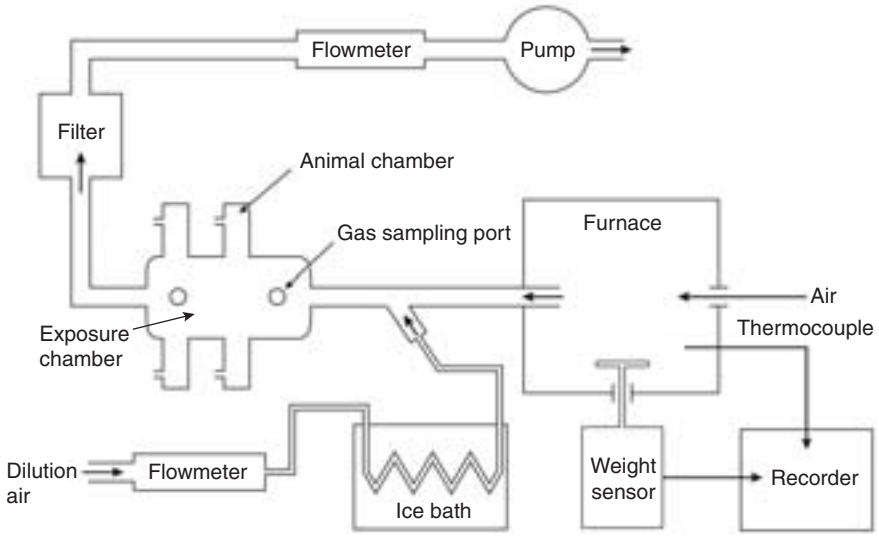

FIGURE 6.2.3 Schematic of the University of Pittsburgh Apparatus (Source: National Institute of Standards and Technology)

when the combustion conditions in the furnace resemble preflashover burning, postflashover burning, or neither. Because the combustion gases flow past the mice, the mice can be exposed to some gases in series, rather than concurrently.

Closed Cabinet Toxicity Test

The closed cabinet toxicity test is illustrated in Figure 6.2.4. This apparatus, standardized in NFPA 270, *Standard Test Method for Measurement of Smoke Obscuration Using a Conical Radiant Source in a Single Closed Chamber,* and ISO 5659-2,[73] was designed for measurement of smoke optical density. However, with the addition of gas concentration measurements, it is used by the International Maritime Organization and the European Union, among others, as an acceptance test based on gas concentrations.

In a test, a planar test specimen, 7.5 cm by 7.5 cm by up to 2.5 cm thick, is exposed to a radiant flux of either 25 kW/m^2 or 50 kW/m^2 for 10 minutes. A pilot flame is standard, but provision is made for testing without the pilot flame. The combustion products accumulate in the 0.5 m^3 chamber. Combustion products are sampled through a probe whose tip is located at the geometric center of the chamber. Should the concentration of any of the specified fires gases exceed a prescribed limit, the material or product fails the test.

During the course of a test, the air in the chamber becomes vitiated, and the generation rates of the combustion products evolve.[74] Thus, it is not clear what stage of a fire is being replicated. It follows that the use of the gas concentration data are of questionable value as an indicator of fire safety. There have been no reported comparisons of data from this apparatus with data from real-scale fire tests of the same materials or products.

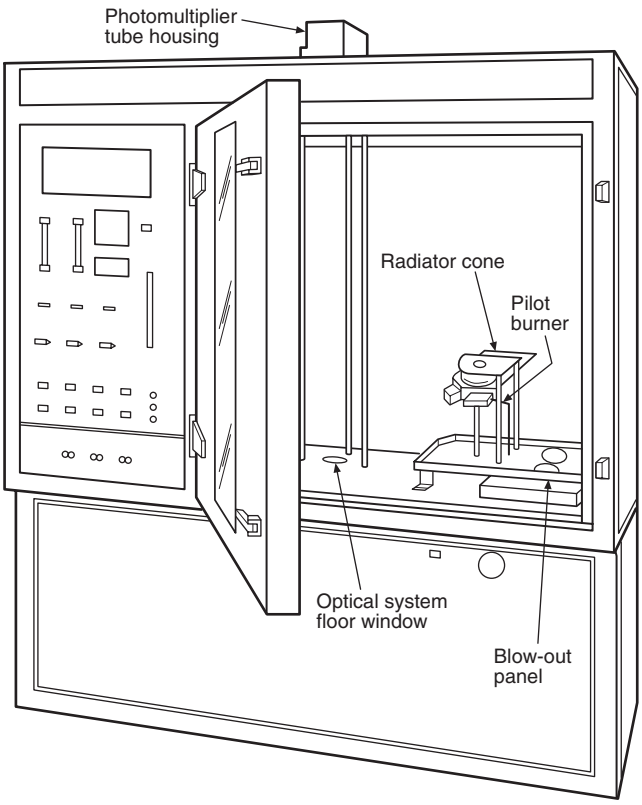

FIGURE 6.2.4 Typical Arrangement of the Closed Cabinet Test Chamber (Source: NFPA 270, *Standard Test Method for Measurement of Smoke Obscuration Using a Conical Radiant Source in a Single Closed Chamber,* 2002 ed., Figure 4.1)

Tube Furnaces

There are a number of designs of these apparatus in use around the world. Two are described here, the first because of the data that have been generated, the second because of its potential as an ISO standard.

The DIN 53436 Test, developed by the German Standards Institution and shown in Figure 6.2.5, is characterized by the use of a moving cylindrical tube furnace operating at a constant temperature in the range of 392 to 1832°F (200 to 1000°C).[75] The furnace is programmed to travel the length of a quartz tube containing the sample, which has a volume of about 40 mL. Decomposition, taking place in an air stream countercurrent to the direction of furnace travel, is intended to result in the continuous flow of fire effluents of constant composition. The standard procedure includes exposure of 10 rats to the effluent and measurement of the gases generated.

This test device, used in six European countries, offers a rather wide range of well-controlled combustion conditions. Ratios of CO_2/CO can be made to vary widely, depending on the air flow used. Thus, both well-ventilated and ventilation-limited fires may be simulated. Specimens may undergo either flaming or nonflaming combustion, depending on the imposed heat flux.

Combustion product analytical data obtained from the DIN 53436 test have been used for the calculation of LC_{50} values using the FED principle, as well as the N-gas method described in connection with the ASTM E1678 test. [76] Comparisons between calculated and experimental LC_{50} values for over 30 materials tested revealed fairly good correlation and predictability, giving additional credibility to the concept that lethal toxic potency can largely be attributed to a small number of major toxic gases.

The tube furnace used in ISO/TS 19700[77] is larger in diameter (4.3 cm) than the DIN furnace. It is described in Figure 6.2.6. The test specimen fills a boat that is at least 0.8 m long. The boat is driven through a tube furnace at a set temperature, 660°F (350°C) for oxidative pyrolysis, 1200°F (650°C) for well-ventilated flaming combustion, and 1520°F (825°C) for postflashover combustion. The fixed sample speed and the variable air flow though the tube allows predetermination of the equivalence ratio. There is a small open box at the exit end of the tube from which the effluent gases are sampled. The box can be adapted for exposing laboratory animals. The apparatus is identical to the tube furnace in BS 7990;[78] there is a less well-defined version that has been adopted by the International Electrotechnical Commission.

Because of the wide variation in tube furnaces, ISO/TS 19700 was developed to encourage broad construction of uni-

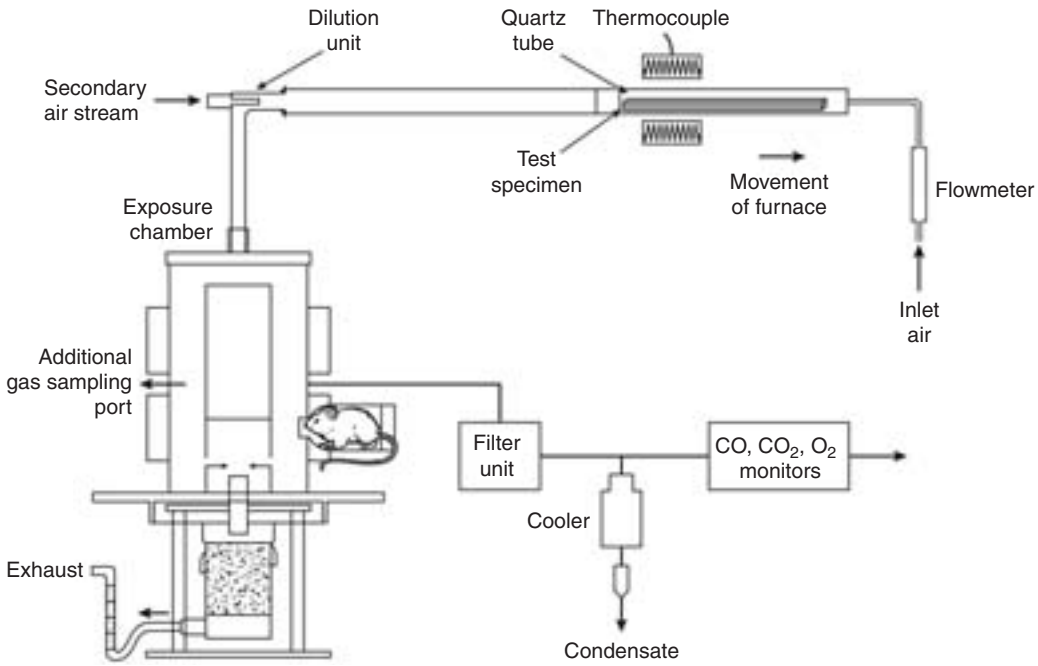

FIGURE 6.2.5 Schematic of the DIN 53436 Tube Furnace (Source: National Institute of Standards and Technology)

form devices. A correlation has been found between CO yields in real-scale fire tests and those from the tube furnace.[79]

ESTIMATION OF TOXIC HAZARD IN FIRES

The fundamental principle in designing for the safety of people in fires is to provide sufficient time for them to escape or find a place of refuge before being overcome by the flames, heat, or smoke. In quantitative terms, the objective is for ASET to be greater than RSET. ASET, the *available safe egress time,* is the interval between the time of ignition of the fire and the time at which an individual is incapacitated. RSET, the *required safe egress time,* is the time it takes that individual to find a safe location. Each person may have a different value for each of these terms, depending on such factors as his/her starting location, physical condition, and susceptibility to smoke. The magnitude of the difference between ASET and RSET is an indicator of the degree of safety being provided.

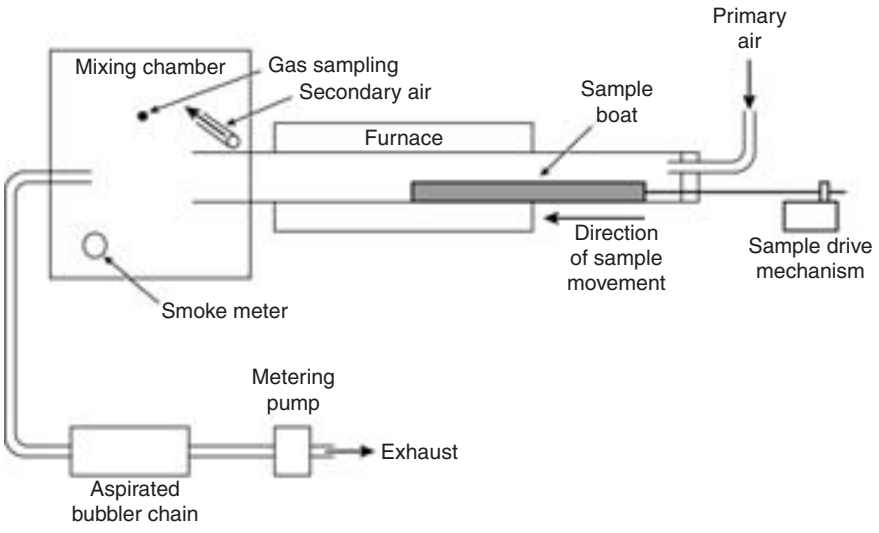

FIGURE 6.2.6 Schematic of the ISO/TS 19700 Tube Furnace (Source: National Institute of Standards and Technology)

A fire simultaneously generates gases, heat, and aerosols. Each of these three can lead to a state in which a person cannot effect his or her own escape, which is the definition of incapacitation. Typically, one estimates an independent ASET value for flames, heat, or smoke.* The limiting hazard is the effluent component that leads to the shortest value of ASET.

The following sections summarize the consensus of the assigned experts to ISO TC 92/SC 3 regarding the best representation of incapacitating levels of these three threats. Additional information may be found in ISO 13571.[46]

Response of People to Fire Gases

The modeling of this component of toxic hazard assessment can take either of two forms, depending on the nature of available input data. [80] In each case, a person moves from a location at the time of ignition to a final location (which may be a site of safety or a site of incapacitation), passing through a time-varying field of combustion products. In some simplified calculations, the person remains in a fixed location. The tenability of various locations is then examined as a function of time following ignition of the fire. There are very few data on exposures of an hour or more. Thus, using the following information for estimation of incapacitation or lethality due to long exposures to very low levels of heat and smoke is not advised.

Toxic Gas Model

The toxic gas model is most useful in considering fires where the time varying concentrations of the individual fire gases can be simulated using a fire growth and effluent spread model, such as the Fire Dynamics Simulator (FDS).[81†] The effects of asphyxiant toxicants and sensory/upper respiratory irritants are considered separately. This is because effects due to asphyxiants are related to their accumulated exposure dose (concentration × time), whereas the initial effects due to sensory/upper respiratory irritants are related largely to their concentration. Thus, the model also requires as input the exposure dose for each asphyxiant and concentration for each irritant that would be expected to cause incapacitation. These latter values are obtained from exposure of laboratory animals, with the results then being extrapolated to people. ISO 13571 contains consensus estimates of the incapacitating values and two equations, one for the effects of asphyxiant gases and one for the effects of irritant gases.

The modeling of the asphyxiant gases involves the same FED concept used to calculate LC_{50} values from analytical data. As before, incremental exposure doses of each gas are accumulated over time, with the incremental time interval being at the discretion of the modeler. However, rather than determining the accumulated FED by integration over 30 minutes, here the exposure doses of the gases are accumulated until the time at which a chosen FED criterion is reached.[46] For example, the time required to reach FED = 1 can be defined as the most frequently expected time for incapacitation to occur. ISO 13571 indicates lower FED criteria could provide safety for a larger fraction of the population at large, as well as for the subpopulations that are more sensitive to fire smoke.[46]

The FED equation for incapacitation due to asphyxiants is

$$\text{FED} = \sum_{t_1}^{t_2} \frac{[\text{CO}]}{35{,}000\ \mu\text{L/L} \cdot \text{min}} \Delta t + \sum_{t_1}^{t_2} \frac{\exp\left([\text{HCN}]/43\right)}{220\ \text{min}} \Delta t \qquad (8)$$

where CO and HCN volume fractions are in µL/L. Equation 8 is derived from actual incapacitation experiments using nonhuman primates.[23,41] It is most applicable when oxygen volume fractions are not lower than 0.13, and CO_2 volume fractions do not exceed 0.02.

The sensory/upper respiratory irritant component of toxic hazard is addressed in a somewhat analogous manner, with the exception that instantaneous concentrations, rather than accumulated doses, are used. For irritants, the time at which the total fractional effective concentration (FEC) becomes equal to 1 is the time at which the average person will become incapacitated.

A generic equation for incapacitation due to sensory/upper respiratory irritants is

$$\text{FEC} = \frac{f_{\text{HCl}}}{F_{\text{HCl}}} + \frac{f_{\text{HBr}}}{F_{\text{HBr}}} + \frac{f_{\text{HF}}}{F_{\text{HF}}} + \frac{f_{\text{SO}_2}}{F_{\text{SO}_2}} + \frac{f_{\text{NO}_2}}{F_{\text{NO}_2}} + \frac{f_{\text{acrolein}}}{F_{\text{acrolein}}} + \frac{f_{\text{formaldehyde}}}{F_{\text{formaldehyde}}} + 3\frac{f_{\text{irritant}}}{F_{\text{irritant}}} \qquad (9)$$

where irritant volume fractions are in µL/L. Consensus values of the denominator constants, *F,* were given in the prior section of this chapter.

Mass Loss Model

For many combustibles, there are no data and no predictive capability for the yields of the toxic gases as a function of time. However, if an LC_{50} or an IC_{50} value has been measured, a simulation of toxic hazard is still possible. Rather than generating individual gases and then distributing them throughout the building, this model distributes a single "gas," the combusted mass from the burning fuels. The basic FED concept is then employed, giving Equation 10.[46]

$$\text{FED} = \sum_{i=1}^{n} \sum_{t_1}^{t_2} \frac{\Delta m}{V(Ct_i)} \Delta t \qquad (10)$$

where

Δm = Average accumulated mass loss (g) over the time increment, Δt

V = Volume (m^3) into which fire effluents are dispersed

Δt = Time increment (min)

(Ct_i) = ½$(LCt)_i$ in $g \cdot m^{-3} \cdot min$ as determined from test methods (e.g., NFPA 269)

*Although it is likely that the three components of the fire effluent act in combination to retard the escape process, there are very few data on which to base the quantification of the interactions. Thus, for example, it is not known whether or how elevated temperature affects a person's ability to find his or her way through dense smoke.

†FDS, as well as all current "fire" models, does not contain the chemistry to predict the generation rates of fire gases or aerosols. The yields of these species are input parameters, and the computational model distributes the species around the building.

As with the toxic gas model, the time required to reach FED = 1 can be defined as the most frequently expected time for incapacitation to occur for the person of median susceptibility to fire smoke. The mass loss model represents a considerable simplification for assessment of the life-threatening effects of combustion atmospheres:

- It combines the effects of irritant and asphyxiant gases. Although there are data to indicate the additive effect of HCl and CO on the lethality for rats, there are no published data to verify this (or any other mode of combination) for people.
- It also presumes that the two types of gases stay in the same proportion to each other as they spread away from the fire. In this sense, the mass loss model is conservative, because the acid gases, for instance, are likely to stick to surfaces. Their concentrations thus diminish relative to those of the narcotic gases as one gets farther from the fire.

Further Simplification

An even further simplification employs a "generic" LCt_{50} value for lethal toxic potency when combustible fuel in a fire consists of a mixture of materials and products that are unidentified as to their nature and relative quantity. Suggested "generic" LCt_{50} values are 900 g/m^3·min for well-ventilated, preflashover fires and 450 g/m^3·min for vitiated, postflashover fires.[46] For incapacitation, values of (Ct_i) in Equation 8 then become 450 g/m^3·min for well-ventilated, preflashover fires and 220 g/m^3·min for vitiated, postflashover fires. It is cautioned that these "generic" LCt_{50} values represent only an approximation and their use should be subject to expert toxicological and engineering judgment.

Whereas compiled data of laboratory determination of LC_{50} values have a mean value of about 30 g/m^3 for well-ventilated combustion, the measured values range from about 5 to 60 g/m^3.[55] Thus, there are some materials whose smoke is over five times as potent as the average material. Fortunately, flaming fires of toxicological importance generally involve a mixture of materials, and it is infrequent that such large fires would be dominated by a single product whose smoke is of very high toxicity. Nonetheless, the person performing the hazard or risk analysis should be aware of the presence of such materials.

Variability of Human Responses to Fire Gases

The variability of the responses of people to the toxicological insults of fires is best represented by a statistical distribution that takes into account their varying susceptibilities. The overall human population contains a number of subpopulations that exhibit a greater than average sensitivity to fire gas toxicants. The largest of such subpopulations are the very young, the elderly, and those who suffer from compromised respiratory systems (e.g., asthmatics). Infants and young children are particularly susceptible to asphyxiant toxicants due to a greater volume of air inhaled per minute relative to their body weight. The elderly, particularly those with compromised cardiovascular systems, are also especially susceptible to asphyxiant toxicants. Asthmatics, along with sufferers of other lung conditions such as chronic bronchitis and reactive airways dysfunction syndrome, are particularly susceptible to bronchoconstriction from even brief exposure to low concentrations of irritants, with collapse and sometimes even death resulting. To provide a degree of protection to these more vulnerable subpopulations, safe levels for exposure of the human population to fire gas toxicants must always be significantly lower than those that might cause incapacitation or other adverse effects with healthy young adults.

According to the methodology described, FED and/or FEC values of 1.0 are associated with sublethal effects that would incapacitate persons of average susceptibility. In the absence of information to the contrary, a log-normal distribution of human responses is a reasonable choice, with FED and/or FEC values of 1.0 corresponding to the median value of the distribution. (Half the population would be more susceptible to an insult and half would be less susceptible.) Statistics then show that at FED and/or FEC criteria of 0.3, 11.4 percent of the population would be susceptible to less severe exposures (lower than 0.3) and, therefore, be statistically subject to incapacitation.[82]

Lower criteria would reduce that portion of the population. These would be appropriate for occupancies in which the people are expected to be more susceptible to heat and smoke or for whom escape is more difficult and thus might take longer. Examples of such occupancies are hospitals and schools for very young children. Note, however, that there is no criterion so low as to be statistically safe for all people. For proper balance between the effects of narcotic and irritant gases, the FEC and FED threshold criteria should be equal.

A consequence of the statistical distribution of human responses resulting from exposure of people to smoke atmospheres is that the distributions for two such responses, such as incapacitation and death, may overlap. This gives rise to a probability that some may die without others even being incapacitated. It is known that this occurs in real fires.

Extrapolation of Rodent Data to Humans

The propensity for smoke to have the same effects on humans in fires can only be inferred to the extent that the rat or mouse can be correlated with humans as a biological system. As a result of comparisons of rodent data with limited human and nonhuman primate data, the use of the rat as an acceptable model for human exposure, at least for the asphyxiant gases, has received general endorsement among smoke toxicologists.[54] The 30 minute exposure time for animals in laboratory smoke toxicity tests is considered by some to be rather long compared to most human exposures to smoke in fires. Traditional extrapolation of toxic potency test data for shorter exposures has presumed that the product of lethal concentration and exposure time is a constant.

A recent publication[83] provides an estimation method for relating the normal rat lethality data to incapacitation values for smoke-sensitive people:

- For materials and products that do not generate strong acid gases, assume that CO (as a surrogate for asphyxiants) is the primary toxicant and use one-fourth the 30 minute rat LC_{50} as the 5 minute human IC_{sens}.
- For materials and products that do generate strong acid gases, narcotic gases still generally account for the majority

of the combined incapacitating effect of narcotic and irritant gases. Based on the relative generation rates of CO and HCl cited above, one could use one-fifth of the 30 minute rat LC_{50} as the 5 minute human IC_{sens}.

- Because the narcotic component dominates the IC_{sens} values, the use of C^2t as a time scaling formula is preferred.

Gann[83] estimates that, for an unknown mixture of combustibles, a generic value for the concentration of smoke that would incapacitate a rat of average sensitivity in 30 minutes would be 30 g/m^3 ± 20 g/m^3 for a well-ventilated flaming fire and 15 g/m^3 ± 3 g/m^3 for a postflashover fire. Incorporating the above guidance leads to corresponding values for the concentration of smoke that would incapacitate smoke-sensitive people in 5 minutes: 6 g/m^3 for a well-ventilated fire and 3 g/m^3 for an underventilated postflashover fire. The user of these values needs to be mindful of three key factors:

1. There is a wide range of smoke toxicity values reported for various materials. Some of these have significantly higher or lower values than these generic values.
2. These generic values are estimated with significant assumptions in their derivations. An estimated uncertainty is about a factor of two.
3. People involved in fires are often excited and physically active. Both of these can increase the intake of the smoke-laden air and increase its toxic potency. At present, there is no quantitative literature on these effects or any way to apply them to the population as a whole.

Response of People to Heat

The burning of most materials is an exothermic chemical oxidation process. Enthalpy from the process is evolved as heat, which possesses both convective (hot gases) and radiative components, each measured as a heat flux (kW/m^2).

Heat produced from a fire presents significant physical danger to humans in three basic ways: burns to the skin, hyperthermia or heat stroke, and respiratory tract burns. Before skin can absorb sufficient heat to raise its surface temperature, the body's heat-dissipating capabilities must be defeated. The body dissipates heat by evaporative cooling (perspiration) and by circulation of blood. If the total heat energy reacting with the body surpasses the capability of the physiological defense processes to compensate, a series of events can occur, ranging from minor injury to death. Up to a critical exposure, one can reasonably tolerate excess heat, but above that exposure, tolerance decreases exponentially.

For radiant heat, there is a threshold radiant flux below which significant heating of the skin is prevented, but above which quite rapid heating occurs. The tenability limit for exposure of skin to radiant heat is approximately 2.5 kW/m^2, below which exposure can be tolerated for 30 minutes or longer without significant consequences.[23,46] Above this threshold, the time to burning of skin decreases very rapidly to about 20 seconds and less. Clothing offers a degree of protection and increases tolerance times.

Skin tissue burns commonly are classified as first-, second-, or third-degree. First-degree burns involve only the outer layer of the skin and are characterized by abnormal redness, pain, and sometimes a small accumulation of fluid underneath the outer layer. Second-degree burns penetrate more deeply into the skin. The burned area is moist and pink, the skin blisters, and there is usually a considerable amount of subcutaneous fluid accumulation. Third-degree burns usually are dry, charred, or pearly white. If a large percentage of the body skin tissue has suffered third-degree burns, postexposure consequences may be extremely critical, often leading to death. A relationship for time (min) to the second-degree burning of skin due to radiant flux, q (kW/m^2), is shown in Equation 11.[84]

$$t_{I,rad} = 6.9q^{-1.56} \tag{11}$$

The effects of exposure to convective heat are also a strong inverse exponential function of temperature. An empirical relationship between temperature and the time to incapacitation is shown in Equation 12.[85]

$$t_{I,conv} = 4.1 \times 10^8\, T^{-3.61} \tag{12}$$

where $t_{I,conv}$ is the time (min) to thermal collapse and T (°C) is the temperature at the skin surface.

Thermal tolerance data for unprotected skin of humans suggest a limit of about 248°F (120°C) for convected heat, above which considerable pain is quickly incurred along with the production of burns within a few minutes or less.[23] Depending on the length of exposure, convective heat below this temperature may still result in hyperthermia. Hyperthermia occurs if the body absorbs heat faster than it can be dissipated by evaporation of surface moisture and outward radiation. The entire body temperature is thereby elevated sufficiently above normal to cause damage to the central nervous system and, possibly, death.

Thermal burns to the respiratory tract from inhalation of air containing less than 10 percent by volume of water vapor do not occur in the absence of burns to the skin or face. Thus, tenability limits with regard to skin burns are normally lower than for burns to the respiratory tract.

Moisture can be present in a fire environment as the result of natural humidity, from the combustion itself, and from the application of water for extinguishment. The effects of exposure to heated air are greatly exacerbated by the presence of moisture. With higher moisture content, transfer of heat energy is more efficient and the body is less able to rid itself of the heat burden. If excessive heat is conducted rapidly to the lungs, a serious decline in blood pressure may result, along with capillary blood vessel collapse leading to circulatory failure. Severe heat may also cause fluid buildup in the lungs.

In fire tests conducted by the National Research Council of Canada, 300°F (149°C) was taken as the maximum survivable breathing air temperature.[86] A temperature this high can be endured for only a short period and not at all in the presence of moisture. The city of Los Angeles selected 150°F (66°C) at 1.5 m above the floor as the design temperature beyond which teachers and children could not be expected to enter a corridor from a relatively cool room.[87] This selection assumed exposure to dry air and only for the brief period of time necessary to reach exits.

Response of People to Visible Smoke

In addition to fire gases, smoke also consists of particulate matter, formed from the burning of most materials under the conditions of incomplete combustion, and suspended liquid droplets known as aerosols. Since the average size of the particulates and aerosols is about the same as the wavelength of visible light, light is scattered and vision through smoke can be obscured. Petroleum-derived materials, especially those from aromatic hydrocarbons, are particularly prone to the formation of dark, sooty smoke. There is, however, no established relationship between the color of the smoke and the toxicity of fire gases that may be present.

Since smoke obscures the passage of light, visibility to exits may be hampered, impairing escape from a fire. The development of quantities of smoke sufficient to impair egress can be very rapid and usually is the first hazard to occur in a fire. As evidenced in nearly every one of the Los Angeles school fire tests, smoke in the corridors arising from fires in the basement reached untenable levels before temperatures attained hazardous condition.[87] Smoke was therefore the principal hazard. Although smoke frequently provides an early warning of fire, it also limits visibility because of its blinding and irritating effects, slowing escape.

Obscuration of vision due to smoke is related to its concentration and is usually expressed as optical density per meter, OD (m^{-1}). Visibility is, then, the reciprocal of the OD. People's response to obscuration of vision and its detrimental effects on the speed of movement and way-finding efficiency is highly variable. Visibility requirements for escape depend to a large extent on the size of an enclosure and occupants' familiarity with escape routes. Suggested OD limits for impairment of egress have ranged from 0.5 m^{-1} (2 m visibility),[88] for occupants of small rooms who are familiar with escape routes, down to about 0.065 m^{-1} (15 m visibility),[89] for large enclosures in which occupants are unfamiliar with their surroundings.

For visible smoke, the equivalent of toxicological incapacitation for fire gases is an inability to orient oneself with one's surroundings. This is the equivalent to not being able to see one's hand in front of one's face. ISO 13571 estimates that this occurs when a person is confronted with a fuel mass loss concentration of 20 g/m^3 for well-ventilated fires and 10 g/m^3 for underventilated fires.[46] This is based on a minimum detectible contrast of 0.02[90] for a distance of 0.5 m, published smoke yields,[91,92] and a generic value of the mass specific extinction coefficient of the smoke[91] of 10 m^2/g. At these high smoke densities, the presence of light-reflecting or light-emitting exit signs does not change the incapacitation criterion significantly. The equivalent smoke optical density is 1.7 m^{-1}.

The analog to people who are sensitive to the inhalation of fire gases is people who require a higher degree of contrast to discern an object against a background. If one intended to provide the same additional degree of protection as with, for example, the FED value of 0.3, the incapacitating concentrations of smoke would be 15 g/m^3 for well-ventilated fires and 7 g/m^3 for underventilated fires. This reflects the logarithmic dependence on the capacity for visual perception.

Smoke particulates and aerosols also can be harmful when inhaled, and long exposure may cause damage to the respiratory system. Also, smoke particulates often are of a sufficiently small size that enable them to be inhaled deeply into the lungs, where adsorbed toxicants may produce damage to the respiratory system. These effects have not been sufficiently studied to enable a full understanding of their consequences.

DEVELOPMENT OF TOXIC HAZARDS IN FULL-SCALE FIRES

Importance of Full-Scale Experiments

While lab-scale tests and fire models can provide valuable insight into ignition and fire growth, full-scale experiments are still necessary to understand and validate critical fire phenomena. Full-scale fire reconstructions can document many important interactions within a fire environment not captured by small-scale tests or fire models. These interactions can include how fuel density can impact fire growth, how the thermal feedback from a hot smoke layer may increase the pyrolysis of the fuel, how specific fuels may generate toxic gases in vitiated smoke layers, or how the lack of ventilation can limit fire development. Full-scale experiments or reconstructions are often used to better understand the development of toxic hazards in specific fire incidents, especially scenarios with unusual conditions. An example of an incident that exhibited some unusual conditions, including rapid fire growth, quick smoke layer development, and multiple toxic gas species, was a fire that occurred on February 20, 2003, in the Station Nightclub in West Warwick, Rhode Island.

Reconstruction of Station Nightclub Fire

Full-scale experiments were conducted at NIST to reconstruct the fire and better understand how the toxic hazard may have developed that night in the Station Nightclub.[93] During a band performance at the nightclub, pyrotechnics ignited polyurethane foam insulation that lined the walls and ceiling of the band platform. The fire spread quickly along the walls and ceiling area over the dance floor. Smoke was visible in the exit doorways in a little more than 1 minute, and flames were observed breaking through a portion of the roof in less than 5 minutes. Egress from the nightclub, which was not equipped with sprinklers, was hampered by crowding at the main entrance to the building. One hundred people lost their lives in the fire.

In order to characterize the fire growth and spread in the early stage of the fire, two real-scale mockup experiments reconstructed approximately 20 percent of the nightclub with polyurethane foam covered walls, a drummer's alcove, a raised platform, carpeting, and wood paneling. Figure 6.2.7 shows the dimensions of the mock-up floor plan and Figure 6.2.8 compares the test compartment to a floor plan of the nightclub. Full-scale data, including gas temperatures, heat fluxes, and gas concentrations, provided insight as to how quickly the toxic hazards, in particular, the generation of CO and HCN, can develop during the early stages of a fire.

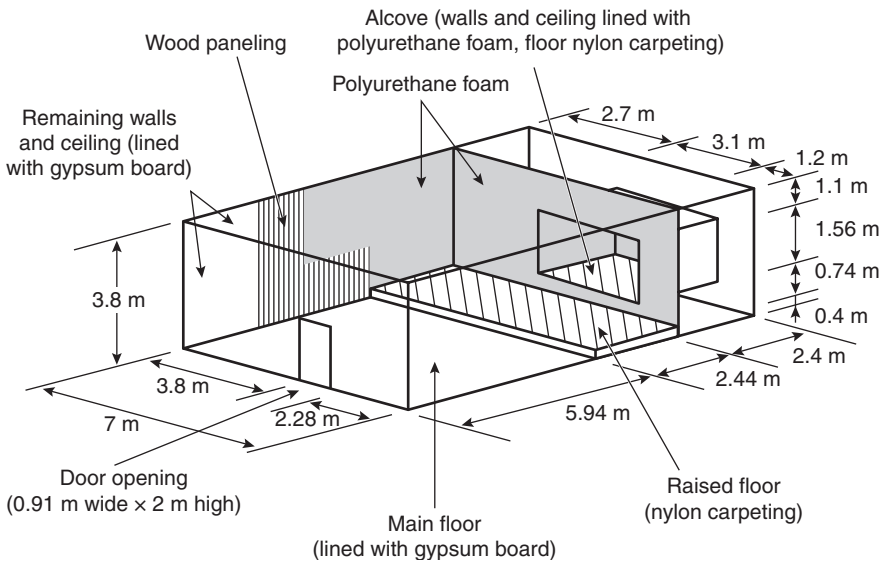

FIGURE 6.2.7 Isometric View of Test Compartment and Fuels (Source: National Institute of Standards and Technology)

A physical mock-up was created at the NIST Large Fire Laboratory with overall floor dimensions of the test room of 10.8 m by 7.0 m, and a ceiling height of 3.8 m. A single opening, 0.91 m wide and 2.0 m high was located in the wall opposite the alcove. The test area was constructed with a structural steel frame, lined with two layers of 12 mm thick calcium silicate board, covered with 12 mm thick gypsum board. The walls of the alcove and the raised floor area had 5.2 mm thick plywood paneling installed over the gypsum board. The paneling had a flame spread index of 200 or less, as tested by ASTM E84, *Stan-*

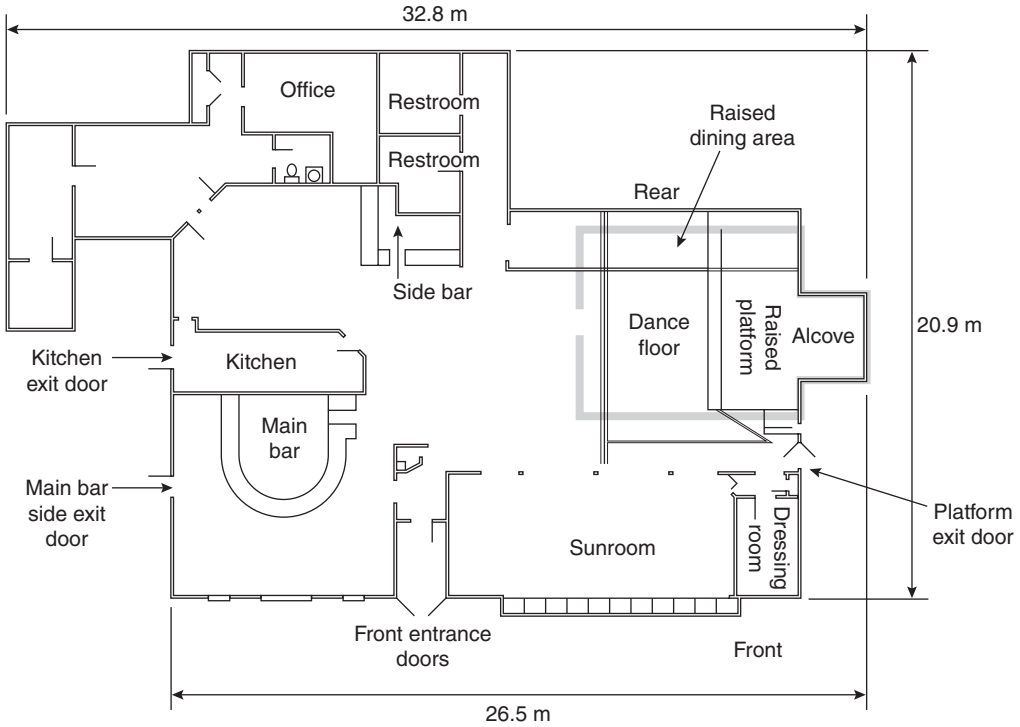

FIGURE 6.2.8 Full-Scale Mock-Up Floor Plan Versus Station Nightclub Floor Plan (Source: National Institute of Standards and Technology)

dard Test Method for Surface Burning Characteristics of Building Materials,[94] according to the manufacturer. The plywood paneling extended 3.6 m from the raised floor along the rear wall of the test area. The rear wall was adjacent to the platform on the right as one stands on the platform facing the audience (stage-right). A non-fire-retardant, ether-based polyurethane foam was glued over the paneling in the alcove and along the walls on both sides of the alcove opening and to the rear wall. The flat side of the foam was mounted next to the plywood and the convoluted side was left exposed. The foam was installed from the top of the wall down to 1.35 m above the floor. It was also applied to the ceiling of the alcove and extended for 2.4 m from the raised floor along the rear wall.

The test room (Figure 6.2.9) was equipped with thermocouples, video cameras, heat flux gauges, bidirectional probes, and gas extraction probes to measure CO, CO_2, O_2, and HCN. In addition, fixed temperature and rate-of-rise heat detectors were installed, as were sprinklers. Data for 194 channels were recorded at 1 second intervals. Ignition of the foam was initiated simultaneously using electric matches at two locations on the outer corners of the alcove, 1.66 m above the raised floor area. The fire gases that emerged from the open door on the end of the test room were captured in the hood of the oxygen depletion calorimeter. The succession of video frames in Figure 6.2.10 show how rapidly the fire spreads during the first 90 seconds.

Data were collected at several locations as indicated in Figure 6.2.9. Selected data (collected at Location D, on the centerline of the doorway and 6 m from the front of the drummer's alcove) including gas concentrations (O_2, CO, CO_2, and HCN), gas temperatures, and heat fluxes, are presented in Figures 6.2.11 and 6.2.12. As can be seen in Figure 6.2.10, the fire was ignited at two locations on either side of the drummer's alcove. The fire spread up the polyurethane foam wall lining on both sides of the alcove and within 60 seconds the alcove was fully involved. The smoke layer continued to descend quickly and, within 90 seconds, the layer was near the floor of the mock-up compartment.

In less than 90 seconds, conditions at Location D and 1.4 m above the floor included gas temperatures exceeding 750°F (400°C), total heat flux in excess of 30 kW/m^2, O_2 volume fractions below 0.05, and HCN and CO volume fractions greater than 0.0015 and 0.03, respectively. The tenability of the compartment deteriorated quickly due to high temperature, high heat flux, O_2 depletion, and toxic concentrations of HCN and CO. Exceeding the tenability limit does not imply that any or all occupants who are present in that environment will succumb due to a particular limit exceeded. The length of time exposed, the rate of change of the environmental conditions, the individual's starting location, his/her breathing rate, and the susceptibility of the individual all play a role. Occupants in this compartment would have likely have had less than 1½ minutes to escape safely from this rapidly growing fire.

A second mock-up experiment was also conducted and was a duplicate of the first except that automatic water sprinklers were installed and charged. Sprinkler heads began to activate in less than 30 seconds and quickly controlled the fire growth. Throughout the second experiment, conditions in the compartment at

Location D remained tenable in terms of temperature, heat flux, O_2 depletion, and concentrations of HCN and CO.

SUMMARY

All combustibles produce heat and smoke that, in sufficiently high concentration, may be hazardous to life safety. Incapacitation can result from exposure to the asphyxiant gases, irritant gases, and heat. Irritant gases and visible smoke can reduce a person's ability to find and negotiate escape routes efficiently. Survivors of the acute effects of exposure during a fire may also experience serious postexposure health effects. Responses of people to the effects of exposure to the combustion products of fire vary considerably. This is due both to the degree of physi-

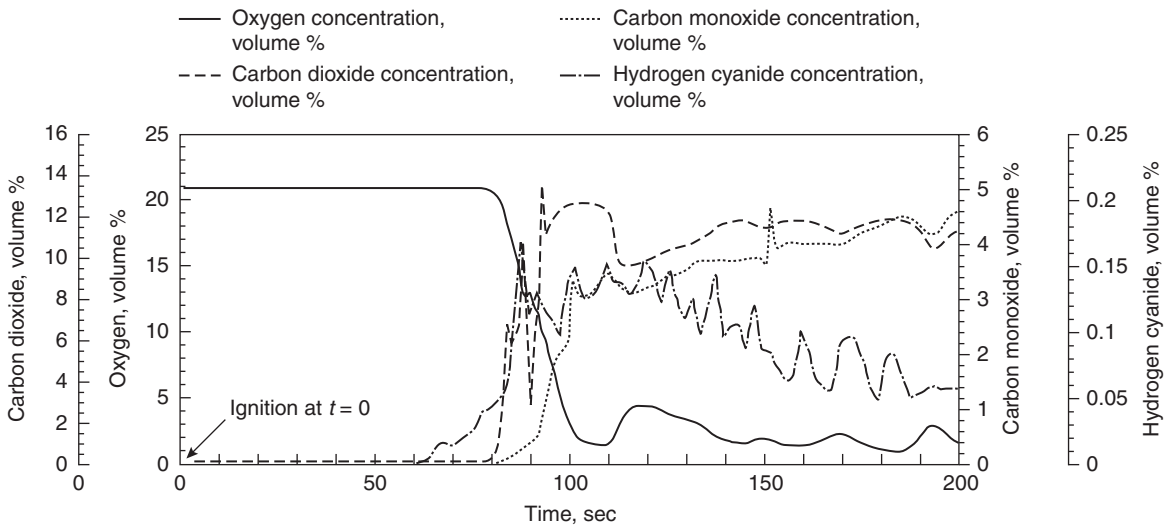

FIGURE 6.2.11 Gas Concentrations Measured at Location D During First 200 Seconds of Unsprinklered Mock-Up Experiment. Gas sampling probe was located 1.4 m above the floor. Ignition occurred at $t = 0$. (Source: National Institute of Standards and Technology)

cal activity during exposure and to the vulnerability of certain subpopulations. Techniques are available for estimating the fire environments that can led to incapacitation of building occupants. The understanding for estimating other sublethal effects and postexposure harm is not yet developed.

The testing of materials and products in the laboratory does not, in itself, address their toxic hazards when involved in fires. Numerous other factors, including their heat release and mass burning rates, contribution of other combustibles present, size and configuration of the enclosure, ventilation, smoke transport, the nature of the occupants, and occupant movement also affect toxic fire hazard. These factors must all be considered in concert.

Chapter 3

Concepts and Protocols of Fire Testing

Marcelo M. Hirschler

Chapter Contents

Background
Classification of Fire Tests
Fire Resistance Tests
Reaction-to-Fire Tests

Key Terms

cone calorimeter, design fire, fire load, fire resistance, fire test, flame spread, fuel load, heat release, ignitability, ignition temperature, lateral ignition and flame spread test (LIFT), oxygen index, room-corner test, smoke release, Steiner tunnel test, time-temperature curve

The traditional approach to fire safety has been the use of prescriptive measures based on fire tests that give pass/fail or categorized results. If someone designs a structure, that person is told to follow certain rules, such as the test criteria a material or product must meet to be considered acceptable and the limitations on physical dimensions and often on chemical composition with which the material or product must comply. Whereas the use of such materials coupled with proper installation is deemed to create a building safe from the effects of fire, there is no explicit requirement to create a design that is safe in case of fire. The type of requirements represented by such prescriptive rules, present either in codes or in specifications, limit material choices to certain applications and work to ensure proper fire safety in most circumstances. There may be extraordinary circumstances, however, in which safety cannot be guaranteed. Such traditional prescriptive requirements involve the implicit assumption that the prescribed design is fire safe, which is often the case. The prescriptive measures, in turn, imply a level of fire safety deemed acceptable by the authority having jurisdiction (AHJ), based on the conclusions of the code writers, which is sometimes, but not always, quantified in numerical terms. There are two alternative ways this can be applied: (1) by using fire tests that produce results that can be used as input for fire modeling and fire hazard assessment and (2) by requiring the use of fire hazard assessment for any fire safety approach, while ensuring that this is done without ignoring other solutions involving active or passive fire protection.

Codes tend to address those construction and material products that (1) have the largest size or (2) have traditionally been shown to represent a specific problem. Thus, a building code will regulate type of construction, exterior walls and roofs, exterior veneer, interior finish, insulation, and glazing. Other codes will regulate hazardous materials and some furnishings and contents, such as upholstered furniture, mattresses, curtains and drapes, and "decorations of an explosive, or highly flammable character" (as stated in NFPA *101®, Life Safety Code®*). This means that there is no guarantee that all products that could have a large impact on fire safety are controlled. One reason for this is that individual code changes rarely involve an effort to consider the overall picture, as this tends to happen only when codes are first designed. Committees reviewing such changes will, however, normally consider how such changes can affect the "bigger picture." Of course, the larger items tend to have the greatest potential contribution to fire safety. However, smaller items may present a severe problem if they represent a large source of effective heat of combustion and thus have the potential to release heat very rapidly. This is the second, and principal, reason that some potentially dangerous products might be ignored: traditional tests cannot assess heat release and cannot produce test results in units that can be used for fire safety engineering assessments. This is a key problem, because heat release is a key property for fire safety when considering individual component and material properties:[1] the peak heat release rate is the intensity of a fire.

Regulations can call for improved fire safety via passive fire protection, through requirements for materials, products, and assemblies that exhibit better results in fire tests; via active fire protection, through requirements for sprinklers and smoke detection systems; or via a combination of the two, through construction modifications wherein differing fire test requirements are allowed when enhanced active fire protection systems are present.

Dr. Marcelo M. Hirschler is a consultant with GBH International in Mill Valley, California.

This chapter addresses the use of fire tests for assessing the fire performance of materials and products and also how to choose those that are more likely to be usable for fire safety engineering calculations and assessments of fire hazard and fire risk.

For related topics, see Section 2, Chapter 3, "Flammability Hazard of Materials"; Section 2, Chapter 4, "Dynamics of Compartment Fire Growth"; Section 2, Chapter 5, "Basics of Fire Containment"; Section 6, Chapter 1, "Fire Hazards of Materials"; Section 6, Chapter 2, "Combustion Products and Their Effects on Life Safety"; and Section 18, Chapter 2, "Interior Finish."

BACKGROUND

Changes in fire safety requirements often follow large fires. The Great Fire of London in 1666, the 1871 Chicago fire, and the 1906 San Francisco earthquake and fire destroyed large parts of great cities where wood construction was prevalent and societal fire protection was nonexistent. By the time of the Chicago fire, insurance companies started to see the potential for minimizing huge losses by means of prevention. Thus, organizations like the National Fire Protection Association (NFPA), the American Society for Testing and Materials (ASTM), and Underwriters Laboratories (UL) started, around the transition of the nineteenth century to the twentieth century, to develop recommendations for obtaining public fire safety, including standard fire tests. The most frequent way to change fire safety requirements has always been, and continues to be, public demand following fire incidents that result in numerous fire deaths or injuries and severe property damage. Thus, multiple fire fatalities occurring in a single large fire—for example, a hospital, hotel, school, or nursing home—can be expected to trigger some major changes in code requirements that will address the specific cause of that particular tragedy. However, such solutions often do not fully take into account the probability of such a fire occurring. Some of the changes to the codes, however, may address the specific event, but may also be equally effective in other fire events that may occur.

Not surprisingly, many advances in fire safety tend to be reactive rather than proactive and, in some cases, address a narrow rather than a comprehensive issue. Also, they tend to be prescriptive rather than flexible. All of this is important in setting the context for fire testing, a context that shapes the concepts and protocols, which in turn shape the specifics of test design and of the interpretation and usage of test results.

These tragedies usually represent a small fraction of overall structure fire fatalities but do, however, represent a significant portion of the fatalities for a specific occupancy. Even when the relatively inclusive NFPA definition of catastrophic fire (one that kills three or more people, or five or more people in a residential property) is used, such incidents almost invariably represent less than 10 percent of the overall structure fire fatalities (Table 6.3.1). This means over 90 percent of all fire deaths occur in fires that rarely merit headlines and may not even receive press coverage outside the area where they occur. For example, fires where at least 25 people die—fires serious enough to merit headlines across the country—are extremely rare. There were only five such incidents from 1991 to 2005, and they represented only 5 percent of overall structure fire fatali-

TABLE 6.3.1 Structure Fire Fatalities in the United States, Overall and in Catastrophic Fires

Year	*Total Civilian Fire Deaths in Structure Fires*	*Civilian Fire Deaths in Catastrophic Fires**	*Deaths in the Deadliest Fire*	*Percentage Civilian Structure Fire Deaths in Catastrophic Fires (%)*
1991	3765	252	25	6.7
1992	3940	145	11	3.7
1993	3980	269	47	6.8
1994	3590	235	9	6.5
1995	3985	320	168	8.0
1996	4220	159	9	3.8
1997	3510	181	10	5.2
1998	3420	171	11	5.0
1999	3040	172	7	5.7
2000	3535	118	8	3.3
2001	5671	2943	2451	51.9
2002	2775	111	8	4.0
2003	3385	254	100	7.5
2004	3305	115	10	3.5
2005	3105	98	15	3.2

*Catastrophic fires are residential structure fires in which five or more people die and other fires in which three or more people die. The following are the 1991–2005 structure fires in which at least 25 civilians died:
World Trade Center (2326), New York, NY, attack; Pentagon (125), Arlington, VA, attack, 2001
Murrah Federal Building (168), Oklahoma City, OK, 1995
Station Nightclub (100), West Warwick, RI, 2003
Branch Davidian dormitory (47), Waco, TX, 1993
Poultry processing plant (25), Hamlet, NC, 1991

Source: NFPA Fire Experience Survey and Fire Incident Data Organization.

ties, with most of those occurring in the September 11, 2001, terrorist attacks.

This way of defining fire safety priorities primarily by reacting to major incidents is not unique to the United States but can be seen in many (if not most) countries. In fact, the vast majority of fire fatalities in the United States and other countries occur in private homes and private vehicles, where the public tends to feel safest, the clamor for more fire safety is weakest, and fire safety requirements are minimal.

CLASSIFICATION OF FIRE TESTS

Fire tests have been developed to address almost every fire property, and those developed by NFPA, UL, ASTM International, and the International Organization for Standardization (ISO) are shown in the references at the back of the chapter. Fire tests typically relate to two types of fire properties: fire resistance and reaction to fire.

Fire resistance is associated with construction assemblies, such as structural members and fire barriers (walls, floors, columns, doors, windows) and with the protection of openings. Thus, fire resistance tests on these assemblies are concerned with preventing fire from penetrating from the compartment of fire origin through the assembly and into adjacent compartments.

Reaction-to-fire tests are concerned with the measurement of the fire properties of the material or product being tested that might cause damage. Materials in this type of test are developed to minimize or eliminate the release of heat, smoke, and combustion products, or minimize or prevent the spread of flame. Reaction-to-fire tests are thus usually associated with interior finish furnishings, contents, and consumer products. Fire safety engineering calculations concerned with the intensity of fires and the ease of escape from fires often use results of reaction-to-fire tests. Table 6.3.2 shows the test designations from NFPA and other fire test development organizations.

FIRE RESISTANCE TESTS

Fire resistance tests are based on the concept that structures are required to meet the protection and separation requirements of a code that describes the fire resistance ratings applicable to each construction element for each type of building. The fire resistance performance of construction members under fire exposure conditions is an issue of major importance in ensuring construction that is safe. The analysis of the code requirements is done on the basis of an assessment of the potential fire exposure as a function of the use of the structure, its contents, ease of escape, and other such factors.

Standard Time-Temperature Curve

The fire test most often used to assess fire resistance ratings in the United States is NFPA 251, *Standard Methods of Tests of Fire Resistance of Building Construction and Materials,* or its corresponding equivalent procedures, ASTM E119, *Standard Test Methods for Fire Tests of Building Construction and Materials,* or UL 263, *Standard for Fire Tests of Building Construction and Materials.* Performance in these tests is the time, designated as the "fire resistance rating," during which the assembly "resists" the standard exposure before the first critical end point is observed. If a safety factor greater than that inherent in the test conditions is desired, a relevant increase needs to be made in the specified fire resistance rating. In the test, the construction element is exposed to a fire that becomes more severe with time, following a standard time-temperature curve (Figure 6.3.1).

It is important to note that a fire resistance rating applies to the entire assembly as tested and not to its individual components. For walls and partitions, the failure criterion is a temperature rise of 250°F (140°C) above the test specimen's initial temperature on the unexposed side, with a specified maximum temperature rise allowed for each individual thermocouple on the unexposed side. The time until the first occurrence of the critical temperature rise is measured on the unexposed side is the fire resistance rating. Figure 6.3.2 shows a wall assembly undergoing a fire resistance test. The assembly has just failed the test.

Note: This table contains NFPA and ASTM fire test standards that are technically equivalent and those fire test standards from UL and ISO that are similar, even if not technically equivalent.
[a]Tests are not technically equivalent to the NFPA or ASTM tests in columns 2 or 3.
[b]NFPA 289 is still under development.

For load-bearing structural elements, fire resistance tests also monitor the load-carrying capability of the test specimen during the test exposure. When required, the fire exposure is followed by application of a specified standard fire hose water stream. It is also critical to point out that these fire resistance ratings are somewhat arbitrary and the fact that an assembly has been tested to give a certain fire resistance rating does not mean that it will fail in a fire after that amount of time; rather, the fire resistance rating represents a relative representation of expected fire resistance performance of the rated assembly. In other words, fire exposure intensity that is less than the prescribed test will provide a longer fire resistance duration. Conversely, a fire intensity greater than that called for in the test may result in lower fire resistance duration.

If penetrations in a building element assembly, such as those through which pipes, wires, or cables pass from one compartment to another, are unprotected, they will generally negate the barrier qualities of the assembly and will lead to rapid spread of fire to the other compartment. This can be solved, however, if the penetrations are protected by filling the voids with fire-rated materials, typically known as firestop materials. In order to ensure that the firestop material is adequate, it will have to be tested to the same time-temperature curve as the building element it is protecting and that is done by testing to ASTM E814, *Test Method for Fire Tests of Through-Penetration Fire Stops*. Fire resistance tests using the same time-temperature curve are used for testing doors (NFPA 252, *Standard Methods of Fire Tests of Door Assemblies*), windows (NFPA 257, *Standard on Fire Test for Window and Glass Block Assemblies*), floor doors (NFPA 288, *Standard Methods of Fire Tests of Floor Fire Door Assemblies Installed Horizontally in Fire Resistance–Rated Floor Systems*), and joints (ASTM E1966, *Test Method for Fire-Resistive Joint Systems*).

The standard time-temperature curve used in NFPA 251 and ASTM E119 is considered to represent a severe building fire.[2] The curve was adopted in 1918 as a result of several conferences by eleven technical organizations, including testing laboratories, insurance underwriters, fire protection associations, and technical societies.[3,4]

Other Time-Temperature Curves

Internationally, a different time-temperature curve was initially developed in the United Kingdom and was eventually adopted by the ISO Technical Committee on Building Products, ISO TC92, as the fire resistance standard ISO 834, *Fire Resistance Tests*. The ISO 834 time-temperature curve is very similar to that in NFPA 251/ASTM E119, albeit not identical. Two other standard time-temperature curves exist that are significantly more severe than the one in NFPA 251/ASTM E119—namely, the curves in ASTM E1529, *Test Methods for Determining Effects of Large Hydrocarbon Pool Fires on Structural Members and Assemblies,* and UL 1709, *Standard for Rapid Rise Fire Tests of Protection Materials for Structural Steel,* which are similar to one another and intended for structures that must withstand the assault of a hydrocarbon fuel fire (e.g., overhead piping supports in petrochemical facilities).

A key consideration is that very few, if any, studies have been conducted on the precision of fire resistance testing, principally due to the complex and costly nature of conducting the tests. There is, thus, an inconsistency between what the codes require (where, for example, a 1-hour fire resistance rating may be called for and a material or assembly that fails the test after 59 minutes is not permitted to be used) and actual test results (where differences of a few minutes are to be expected).

Differences in test results can be due to variability in the fire test (precision), variability in the execution of the test instructions by the laboratory (part of the uncertainty), and variability in the test specimen (typical manufacturing variability). This actually means that materials that were tested many years ago using the test methods of that time, and for which compliance with certain test requirements has become accepted, do not need to perform as well as new materials, which must pass the current requirements of updated (and usually improved) editions of the same tests. This also means that "shopping" for the best test results can occur, as manufacturers can conduct the test several times (perhaps even in different laboratories) until the desired outcome is obtained and no further testing is needed. Efforts to address reproducibility and consistency in test outcomes within and between testing laboratories is an ongoing theme and topic of debate.

Concepts for Predicting Fire Resistance Rating of Construction Elements

Of course, the time temperature relationship represented by any standard curve cannot represent more than a single fire scenario. Data have been developed to evaluate the fire resistance performance of assemblies under other fire exposure conditions, ones that may be more representative of particular fire situations, that is, using different time-temperature curves to simulate a different fire scenarios.[3,5–13] Also, Harmathy[14] developed a series of 10 rules that can be used as concepts for predicting the fire resistance rating of construction elements, thereby extending the usefulness of test results. The rules can be paraphrased as follows (replacing the term "fire endurance" used by Harmathy by the current terminology, namely, "fire resistance"):

1. The "thermal" fire resistance of a construction consisting of a number of parallel layers is greater than the sum of the "thermal" fire resistance characteristics of the individual layers when exposed separately to fire.
2. The fire resistance of a construction does not decrease with the addition of further layers.
3. The fire resistance of constructions containing continuous air gaps or cavities is greater than the fire resistance of similar constructions of the same weight, but containing no air gaps or cavities.
4. The further an air gap or cavity is located from the exposed surface, the more beneficial is its effect on the fire resistance.
5. The fire resistance of a construction cannot be increased by increasing the thickness of a completely enclosed air layer.
6. Layers of materials of low thermal conductivity are better utilized on that side of the construction on which fire is more likely to happen.

7. The fire resistance of asymmetrical construction depends on which side is exposed to the test fire.
8. The presence of moisture, if it does not result in explosive spalling, is beneficial to fire resistance.
9. Load-supporting elements, such as beams, girders, and joists, yield higher fire resistance when subjected to fire resistance tests as parts of floor, roof, or ceiling assemblies than they would when tested separately.
10. The load-supporting elements (beams, girders, joists, etc.) of a floor, roof, or ceiling assembly can be replaced by such other load-supporting elements which, when tested separately, yield fire resistance not less than that of the assembly.

More important, however, is the concept that time-temperature curves should be based on design fires applicable to the fire scenario being investigated. Therefore, there is a tendency to move away from "one size fits all" fire resistance testing and toward specific fire resistance testing that takes into account the fire load (or the potential for release of heat due to the building products, furnishings, and contents present) and other issues representative of the fire scenario in question.

Developing Standardized Methodology

Two complementary activities are under way to develop standardized means of generating appropriate design fires. The Society of Fire Protection Engineers (SFPE) Task Group on Fire Exposures to Structural Elements has produced a guide, the *SFPE Engineering Guide to Fire Exposures to Structural Elements,*[15] intended to develop guidance on estimating fully developed fire heat transfer exposures for the purpose of performance-based analysis and design. This guide is intended to be developed into a standard by an SFPE committee so as to provide a standard methodology to predict thermal boundary conditions for fully-developed fires to a structure over time. The NFPA Technical Committee on Hazard and Risk of Contents and Furnishings is working on NFPA 557, *Standard Fire Loads for Structural Fire Protection Design,* which is intended to standardize the fire load portion of this issue.

Fuel Load and Fire Load Concepts

The original fuel load concept (at that time called "fire load") incorporated the premise that the duration of a fire is proportional to the mass of combustible material per unit floor area. It has long been believed that there is a relationship between the mass of combustible material and the duration of a fire; this was done on the basis of fire tests in structures incorporating a variety of materials. In its simplest terms, the fuel load theory states that 50 kg of combustible material per m^2 of floor area (roughly 10 lb per ft^2) will produce a fire of 1 hour duration.[16] That concept has now been superseded with increased understanding of material fire performance and overall fire testing and it is now clear that a greater number of factors are important, including the type of combustible materials, the distribution of the fuel load, fire scenario characteristics, such as geometry and ventilation in the fire compartment, and characteristics of the compartment walls, floors, and ceilings.

With that in mind, more modern concepts address fire load instead of fuel load. Although these terms are sometimes used interchangeably, the concepts used here are that fire load will refer to the energy density per unit area and fuel load will refer simply to the total mass of combustibles. With that in mind, it is possible to define *fire load* as "The heat energy of all combustibles available from the constituent materials of a certain fuel package, expressed in energy units (e.g., MJ)." For comparison, *fuel load* would then be defined as "the quantity of combustible contents of a building, space, or fire area, including interior finish and trim, expressed in mass units (e.g., kg)." The key difference between the two is that fire load takes into account the twin concepts that different combustible materials will have different heats of combustion (MJ/kg) and that the heat released in fires is usually not the total heat content of the materials burning. In other words, there is a difference between the theoretical (or gross) heat of combustion and the effective heat of combustion. It is the latter that should be considered in fire hazard analyses.

The analysis conducted by the National Institute of Standards and Technology (NIST) on the World Trade Center disaster of September 11, 2001, indicated that it is critical to use proper design fires for the assessment of appropriate structural fire protection, rather than rely exclusively on standardized fire tests.[17] NIST considered future research in areas of high priority, such as prevention of progressive collapse, fire resistance design and retrofit of structures, and fire-resistive coatings for structural steel. The recommendations stemming from the investigation may result in changes in the area of fire resistance testing and in code requirements for structural fire protection.

REACTION-TO-FIRE TESTS

The bulk of the fire testing currently being conducted addresses reaction-to-fire properties. The typical fire properties being assessed are ignitability, ease of extinction, flame spread, smoke release, heat release, and toxic gas release. Plastic materials are often assessed by a specific flammability test, which assesses a combination of ignitability, ease of extinction, and flame spread, and is addressed separately.

Ignitability

Unless a material ignites, there is no fire. Therefore, low ignitability is the first line of defense in a fire. All combustible materials do ignite, but the higher the temperature a material has to reach before it ignites, the safer it is. Therefore, measures of ignition are of three types, as follows:

1. Minimum temperature for ignition (in the absence or presence of a pilot source of ignition)
2. Time to ignition under a certain applied thermal insult (typically an incident heat flux or a flame of a particular size)
3. Minimum (or critical) heat flux required to reach ignition (because temperature and heat flux can be correlated with the Stefan-Boltzman constant and black-body radiation)

Traditional Method of Assessing Ignition Temperatures. The traditional method of assessing ignition temperatures is done

with a test such as the Setchkin chamber, ASTM D1929, *Test Method for Determining Ignition Temperature of Plastics,* which has been used for many years to determine self-ignition temperatures and flash ignition temperatures (i.e., with an applied pilot flame). ASTM D1929 specimens are small pieces (typically pellets) exposed inside a vertical furnace tube. Specimens are electrically heated under a slow air flow. ASTM D1929 test results are no longer considered truly indicative of fire hazard because the exposure is not fully representative of real fires. However, results from this test are frequently required in specifications and quoted in data sheets. The test is referenced in building codes to determine the suitability of some plastics for use in construction because test results are reported as an easily understandable single number.

On the other hand, the time to ignition at a certain incident heat flux is an excellent way of comparing material properties. Unfortunately, such a measurement will yield a numerical result only if the heat flux is high enough to cause ignition. The advantage of the critical heat flux for ignition is that it can always be assessed. It results from extrapolation after measurements made at a variety of incident heat fluxes. As such, it is a measure that has value for fire safety engineering calculations or fire modeling.

This parameter is typically obtained from tests that also measure heat and smoke release, such as the cone calorimeter (NFPA 271, *Standard Method of Test for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter*/ASTM E1354, *Test Method for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter*/ISO 5660, *Reaction to Fire Tests—Heat Release, Smoke Production, and Mass Loss Rate*), the Ohio State University calorimeter (ASTM E906, *Test Method for Heat and Visible Smoke Release Rates for Materials and Products*), and the FM Fire Propagation Apparatus (NFPA 287, *Standard Test Methods for Measurement of Flammability of Materials in Cleanrooms Using a Fire Propagation Apparatus (FPA)*/ASTM E2058, *Test Methods for Measurement of Synthetic Polymer Material Flammability Using a Fire Propagation Apparatus (FPA)*), or by the Lateral Ignition and Flame Spread Test (LIFT, ASTM E1321, *Test Method for Determining Material Ignition and Flame Spread Properties*), the primary purpose of which is to assess flame spread.

Whereas a longer time to ignition represents better performance in terms of ignitability, the higher a critical ignition flux is, the better fire performance it represents. A caveat is needed here: extrapolated critical fluxes for ignition are not reliable if such heat fluxes are lower than 15 kW/m^2 and it is recommended that all such data be shown as "≤ 15 kW/m^2."[18]

Other Traditional Ignition Test Methods. There are other traditional ignition test methods: a radiant cone heater with an intermittent gas flame igniter (ISO 5657, *Reaction-to-Fire Tests—Ignitability of Building Products Using a Radiant Heat Source*) and tests for materials coated onto wires, such as those issued by the International Electrotechnical Commission (IEC) and by ASTM, including IEC 60695-2-2, IEC 60695-2-10, ASTM D3874, *Test Method for Ignition of Materials by Hot Wire Sources,* and ASTM D6194, *Test Method for Glow-Wire Ignition of Materials.* The glow wire test (IEC 60695-2-10 and ASTM D6194) involves bringing an electrically heated wire in contact with the material; it simulates the thermal stresses resulting from faults or overload conditions during cable use. Just like ASTM D1929, these tests are also of minor use in performing an engineering assessment of hazard in fire scenarios.

Flammability of Plastic Materials

Plastic materials, as stated above, are often assessed by a test that does not fit as a test for ignitability, ease of extinction, or flame spread, but addresses some of these characteristics. That test, one of the most widely used tests for evaluating the flammability of plastic materials, is UL 94, *Standard for Tests for Flammability of Plastic Materials for Parts in Devices and Appliances.* The test has several component parts:

- 50 W (20 mm gas burner flame) Horizontal Burning Test (ASTM D635, *Test Method for Rate of Burning and/or Extent and Time of Burning of Self-Supporting Plastics in a Horizontal Position;* IEC 60695-11-10, *Fire Hazard Testing Part 11-10: Test Flames 50W Horizontal and Vertical Flame Test Methods*); classification: UL 94 HB.
- 50 W (20 mm gas burner flame) Vertical Burning Test (ASTM D3801, *Test Method for Measuring the Comparative Burning Characteristics of Solid Plastics in a Vertical Position;* IEC 60695-11-10); classifications: UL 94 V-0, V-1, or V-2.
- 500 W (125 mm gas burner flame) Vertical Burning Test (ASTM D5048, *Test Method for Measuring the Comparative Burning Characteristics and Resistance to Burn-Through of Solid Plastics Using a 125-mm Flame;* IEC 60695-11-20, *Fire Hazard Testing Part 11-20: Test Flames 500W Flame Test Methods;* ISO 9772, *Cellular Plastics—Determination of Horizontal Burning Characteristics*); classifications: UL 94 5VA or 5VB.
- 50 W (20 mm gas burner flame) Thin Material Vertical Burning Test (ASTM D4804, *Test Method for Determining the Flammability Characteristics of Nonrigid Solid Plastics;* ISO 9773, *Plastics—Determination of Burning Behaviour of Thin Flexible Vertical Specimens in Contact with a Small-Flame Ignition Source*); classifications: UL 94 VTM-0, VTM-1 or VTM-2.
- 50 W (20 mm gas burner flame) Horizontal Burning Foamed Material Test (ASTM D4986, *Test Method for Horizontal Burning Characteristics of Cellular Polymeric Materials;* ISO 9772); classifications: UL 94 HF-1, HF-2, or HBF

The 50 W/20 mm flame versions of the test, as applied to solid plastics to yield UL 94 classifications of V-0, V-1, V-2, or HB (in decreasing order of fire performance), are the most frequently specified and can be applied to test specimens 125 mm long and 13 mm wide, with thicknesses up to 3 mm. This test is most often used when materials are being characterized in terms of their probability of being ignited by the heat generated from electrical sources contained within an electrical appliance. The test provides an adequate representation of the way materials used for plastics parts perform in such scenarios. By extension, the test is being adequately used as a simple way to compare

the fire performance of plastic materials when subjected to a low-intensity heat source, as a comparative indication of material fire safety in specifications and plastic material information sheets, and as a quality control and material development tool. However, the test is also used with less justification for code compliance as an approval tool for light-transmitting plastics in building construction. It is unsuitable for fire safety engineering calculations.

Ease of Extinction

Ease of extinction is a fire property of interest once a material has ignited. Under those conditions, the easier it is to extinguish the material, the lower is the fire hazard of a product made from the material. ASTM D2863, *Test Method for Measuring the Minimum Oxygen Concentration to Support Candle-Like Combustion of Plastics (Oxygen Index),* is used to determine the oxygen index (or limiting oxygen index, LOI), which is the minimum oxygen concentration in a flowing mixture of oxygen and nitrogen required to support candlelike downward flaming combustion. Thus, in principle, as a normal atmosphere is composed of about 20.9 percent oxygen, a material with limiting oxygen index values above 25 percent should only burn under extreme conditions. In reality the test serves merely as a measure of how easy it is to extinguish the material if it is already burning.

The small specimen is placed vertically inside a glass column and ignited at the top with a small gas flame (Figure 6.3.3). This test method has excellent repeatability and reproducibility and can generate numerical data covering a very broad range of fire performance. However, the test method is inappropriate as a predictor of real-scale fire performance, mainly because of the low heat input and the artificiality of the high oxygen environments used. It is also unsuitable for fire safety engineering calculations. Nevertheless, the test is widely required in specifications for plastic materials. It is, therefore, often quoted in data sheets. The oxygen index test method is also suitable as a quantitative quality control tool during manufacturing. Another use is as a semiqualitative indicator of the effectiveness of additives, during research and development, but in this case its results are primarily applicable to low incident energy situations (e.g., heat fluxes not exceeding 20–25 kW/m^2).

FIGURE 6.3.3 Oxygen Index Apparatus

Flame Spread

A critical aspect of fire performance is the assessment of the tendency of a material to spread and propagate a flame away from the fire source. It has always been understood that this knowledge is a key component in understanding the potential fire hazard. Flame spread tests may refer to materials, to components in diverse applications, or to products and structures.

Classification of Flame Spread Tests. Flame spread tests can be classified in terms of the angle between the exposed surface of the specimen and the horizontal. This angle may vary between 0° (a horizontal material burning on its upper surface), through 180° (a horizontal material burning on its lower surface), 240° (a material burning on its lower surface but rotated a further 60° from the horizontal), up to 270° (for a material burning vertically downwards).[19] This surface angle is closely related both to the extent to which the gaseous products of combustion heat the surface before the flame front reaches it and to the extent to which the hot gases penetrate into the tested material. Sample sizes range widely, from the size of a candle to quite large—24 ft × 22 in. (7.3 m × 0.56 m) in NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials*/ASTM E84, *Test Method for Surface Burning Characteristics of Building Materials,* otherwise known as the Steiner tunnel test.

Steiner Tunnel Test. The Steiner tunnel test is widely used for specifications and building code requirements. The test is unsuitable for fire safety engineering calculations, primarily because it produces a nondimensional numerical flame spread index (FSI) and does not produce results in proper engineering units. The Steiner tunnel test was developed for building materials,[20] such as "fireproof paint" coatings, wood, or gypsum board. It is perhaps the most widely accepted test for surface flammability (but only in North America) and there are a large number of applica-

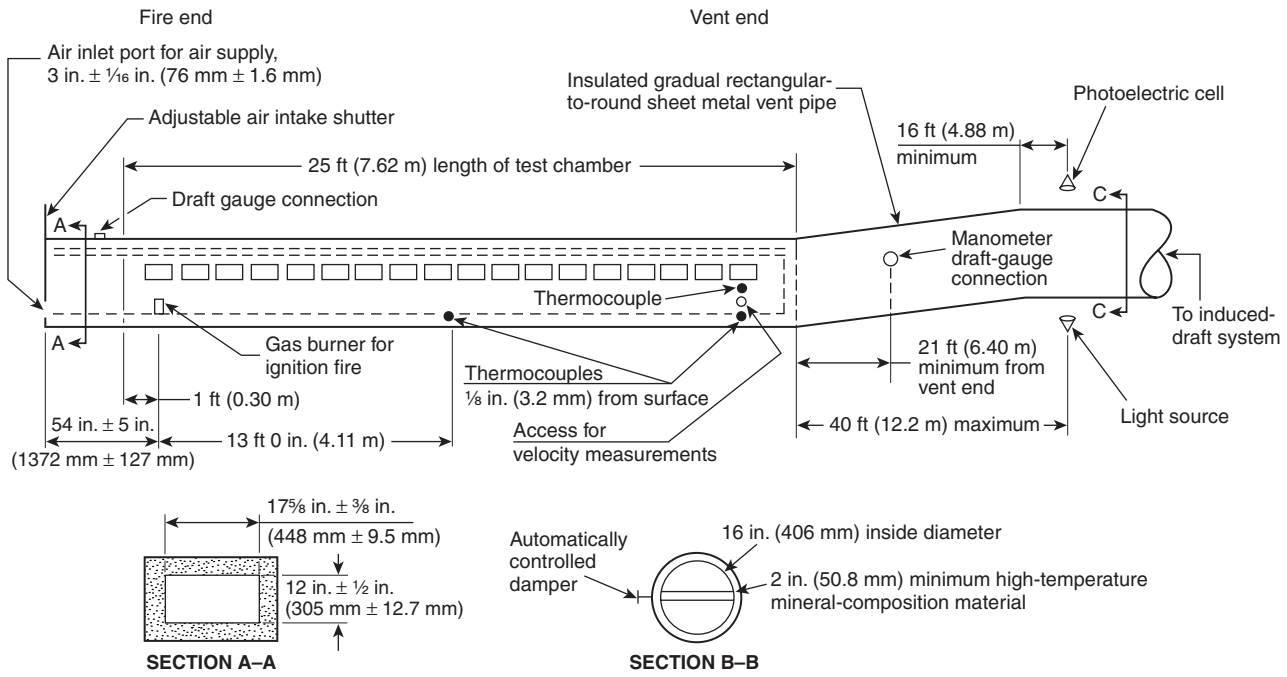

FIGURE 6.3.4 Schematic of the Steiner Tunnel Used in NFPA 255 (Source: NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials,* 2006 ed., Figure 4.1.1(a).)

tions tests developed from it. One such test is used for electrical cables intended for installation in plenums, NFPA 262, *Standard Method of Test for Flame Travel and Smoke of Wires and Cables for Use in Air-Handling Spaces.* Other application tests exist for pneumatic tubing (UL 1887, *Standard for Fire Test of Plastic Sprinkler Pipe for Visible Flame and Smoke Characteristics*), fire sprinkler piping (UL 1820, *Standard for Fire Test of Pneumatic Tubing for Flame and Smoke Characteristics*), optical fiber raceways (UL 2024, *Standard for Optical Fiber and Communication Cable Raceway*), and other products.

The specimen is a building material (normally up to 0.15 m thick), either in one unbroken length or in separate sections joined end to end, mounted face downwards so as to form the roof of a horizontal tunnel 305 mm high. Figure 6.3.4 shows a schematic of the test method. The fire source, two gas burners, ignites the sample from below with an 88 kW fire source. Figure 6.3.5 shows the gas burners as seen from the air inlet end of the tunnel.

FIGURE 6.3.5 Gas Burners at Inlet End of the Steiner Tunnel

Flame Spread Index (FSI). The normal output of the NFPA 255/ASTM E84 test is a flame spread index (FSI). This is a relative number based on the area under the flame spread distance versus time curve of the test, with an FSI of 0 assigned to cement board and an FSI of 100 (approximately) assigned to red oak flooring. Building codes use the test results as "classes," each class representing a range of flame spread indices, as shown in Table 6.3.3. The test method also assesses smoke obscuration and assigns a smoke developed index (SDI) based on a similar concept to the FSI, except that in this case the area assigned to red oak flooring is exactly 100 by definition. To be classified as Class A, B, or C, a material must have an SDI not exceeding 450, as shown in Table 6.3.3.

When plastics were initially used in construction, they were tested in the Steiner tunnel, in spite of the fact that the tunnel was not always appropriate. For example, samples that cannot be retained in place above the tunnel floor or which melt and continue burning on the tunnel floor (typical behavior for thermoplastic materials) are still being tested with this equipment, even though results are often misleading. The Steiner tunnel test can also produce wrong results for thin materials,[21] particularly when they are tested using "poultry

TABLE 6.3.3 Flame Spread Index and Smoke Developed Classes for Use in Building, Fire, and Life Safety Codes

Class	*Flame Spread Index*	*Smoke Developed Index*
Class A	FSI ≤ 25	SDI ≤ 450
Class B	26 ≤ FSI ≤ 75	SDI ≤ 450
Class C	76 ≤ FSI ≤ 200	SDI ≤ 450
Plenum materials	FSI ≤ 25	SDI ≤ 50

netting" support, which absorbs much of the heat generated by the test specimen (see examples in Table 6.3.4). Single-layer membranes or thin laminates consisting of a limited number of similar or dissimilar layers not intended for adherence to another surface are often supported on poultry netting placed on steel rods in the Steiner tunnel. The metal dissipates much of the heat generated by the burning material, thus decreasing the flame spread artificially.

The ASTM technical committee on fire standards, ASTM E05, has developed standard practices for specimen preparation and mounting methods associated with the Steiner tunnel. Three practices have been issued: one for pipe and duct insulation materials (ASTM E2231, *Standard Practice for Specimen Preparation and Mounting of Pipe and Duct Insulation Materials to Assess Surface Burning Characteristics*), one for paper and vinyl wall and ceiling coverings (ASTM E2404, *Standard Practice for Specimen Preparation and Mounting of Paper or Vinyl Wall or Ceiling Coverings to Assess Surface Burning Characteristics*), and one for site-fabricated stretch systems (using fabric or vinyl) (ASTM E2573, *Standard Practice for Specimen Preparation and Mounting of Site-Fabricated Stretch Systems to Assess Surface Burning Characteristics*).

Radiant Panel Index (I_s). ASTM E162, *Test Method for Surface Flammability of Materials Using a Radiant Heat Energy Source,* is another test method used to assess flame spread (Figure 6.3.6). The results obtained from this radiant panel test are expressed in terms of an index; however, this index, now known as the radiant panel index (I_s), is different from the more familiar one produced by the Steiner tunnel, known as the flame spread index (FSI). The radiant panel index is calculated as the product of a "flame spread factor" and a "heat evolution factor," using techniques described in the standard.

TABLE 6.3.4 Effect of Poultry Netting on Steiner Tunnel Test Flame Spread Index

Sample 4	15	45

FIGURE 6.3.6 Radiant Panel Test Apparatus

The test equipment consists of a gas-fed radiant panel that exposes test specimens to a radiant flux equivalent to a blackbody temperature of 670°C (943 K) (approximately 45 kW/m^2) in the presence of a small gas pilot flame. The test specimen (150 × 460 mm, with a normal maximum thickness of 25 mm) is inclined at a 30° angle. Alternate specimen holders can accommodate thicker specimens. The ignition is forced near the upper edge of the specimen and the flame front progresses downward.

The flame spread factor results from the measurements of flame front position and time. The heat evolution factor is proportional to the maximum temperature measured in the exhaust stack. This test has also been shown not to be an adequate predictor of real-scale fire performance and not to be suitable for fire safety engineering calculations. Once more, if the specimen melts or causes flaming drips, such behavior is likely to affect the flame spread in a way that is uneven. The standard simply requires that such events be reported. Moreover, if flame spread

is very rapid, flame spread information is potentially lost unless recording is continuous, which is also not a requirement.

This apparatus is often referred to as the radiant panel test; a variant has been developed for testing foamed materials, ASTM D3675, *Test Method for Surface Flammability of Flexible Cellular Materials Using a Radiant Heat Energy Source.* Results from the relevant test are frequently required in regulations, particularly for transportation environments (both foamed and rigid materials) and in specifications for detention environments (foamed materials).

LIFT Test. Another test apparatus suitable for assessing flame spread of materials is the Lateral Ignition and Flame Spread Test, or LIFT (ASTM E1321). The LIFT apparatus was developed as an improvement on the radiant panel apparatus used by ASTM E162,[22] because it can produce data in engineering units and its results can be used successfully for predictions of full-scale flame spread performance.[23] The specimen size for flame spread studies is 155 mm × 800 mm by a maximum thickness of 50 mm (a smaller specimen is used for ignition studies).

The test method determines the critical flux for flame spread, the surface temperature needed for flame spread, and the thermal inertia or thermal heating property (product of the thermal conductivity, the density, and the specific heat) of the material under test. These properties are mainly used for assessment of fire hazard and for input into fire models. A flame spread parameter, Φ, is also determined and this can be used as a direct way of comparing the responses of the specimens. This test method appears well-suited for materials or composites of materials that are nonmelting and can be ignited without raising the incident flux to potentially dangerous limits. A slight variation on the LIFT test is one used by the marine industry to assess flammability of surface finishes: ASTM E1317, *Test Method for Flammability of Marine Surface Finishes,* also known by its International Maritime Organization (IMO) designation as "Part 5 of the IMO Fire Test Procedures Code." This test is required extensively for marine deck finishes and overlays.

In the area of electric cables, low flame spread is a frequent requirement. NFPA 70, *National Electrical Code®,* contains requirements in terms of flame spread for both electrical and optical fiber cables and subdivides them into 4 categories:

1. Cables that are listed as "being suitable for use in dwellings and for use in raceway" and as "being resistant to flame spread." This category represents minimal improved fire performance. A cable is tested individually in a vertical configuration using the VW-1 (vertical wire) flame test in UL 1581, *Reference Standard for Electrical Wires, Cables and Flexible Cords.*

2. Cables that are listed as "suitable for general-purpose use, with the exception of risers, ducts, plenums, and other space used for environmental air," and as "being resistant to the spread of fire." This represents somewhat better fire performance. Cables are tested in a grouped configuration using the vertical cable tray flame test (20 kW) of UL 1581. Cables are not allowed to spread fire to the top of the 2.4 m tray. An alternate, more severe, test for the same application is the Canadian Standards Association (CSA) vertical flame test for cables in cable trays, CSA C22.2 No. 0.3, *Test Methods for Electrical Wires and Cables.* In this procedure, the cables are also tested in a grouped configuration using a 20 kW flame, but with a more severe application. Cables are not permitted to exhibit char length (basically equivalent to flame spread in concept) larger than 1.5 m up the tray.

3. Cables that are listed as "suitable for use in a vertical run in a shaft or from floor to floor" (risers) and "having fire-resistant characteristics capable of preventing the carrying of fire from floor to floor." This category is the next level up in fire performance. Such cables must pass the requirements of UL 1666, *Standard Test for Flame Propagation Height of Electrical and Optical-Fiber Cable Installed Vertically in Shafts,* whereby cables in a grouped configuration are exposed vertically, in a two-story facility, to a 145 kW flame.

4. Cables that are listed as "suitable for use in ducts, plenums, and other space for environmental air" and as "having adequate fire-resistant and low smoke-producing characteristics." This is the highest level of flame spread fire performance required for cables. Such cables must pass the requirements of NFPA 262 (an application of the Steiner tunnel test, as discussed previously) by exhibiting a maximum flame travel distance of 1.52 m, a maximum peak optical density of 0.5, and a maximum average optical density of 0.15, when tested, in a grouped configuration, horizontally to an 88 kW flame.

In Europe, the fire performance of cables is being assessed by an alternate vertical cable tray flame spread test, IEC 60332-3, which is similar to the North American vertical cable tray tests (same ignition source but a longer cable tray, 3 m high) but slightly less severe. There exists also a European version of the UL 1581 VW-1 test, namely IEC 60332-1. In the late 1990s, a European project developed a first attempt at a classification method for fire performance of cables, the FIPEC project.[24] This is an important development, as the test method, a variation of the IEC 60332-1 vertical cable tray test, also incorporates heat and smoke release and will probably be used for the European classification of cables in terms of reaction to fire, as EN 50399. This will be discussed in greater detail later.

Smoke Release

In a fire, smoke causes impairment of visibility, which results in greater difficulty for exposed people to escape or be rescued. Therefore, many regulations and specifications require that materials or products exhibit reduced smoke emission. The most traditional test used for assessing smoke released by materials is the static smoke chamber developed by the National Bureau of Standards (now National Institute of Standards and Technology, NIST), and standardized as ASTM E662, *Test Method for Specific Optical Density of Smoke Generated by Solid Materials.*

In this fire test, a vertical specimen, 7.5 mm × 7.5 mm by up to 50 mm thick, is exposed to a 25 kW/m^2 radiant heat source, with or without a pilot igniter, inside a 0.5 m^3 closed chamber (i.e., this is a static test, as opposed to tests such as the Steiner tunnel or the cone calorimeter, which have air and smoke circulation and are dynamic tests). In the test, the reduction in visibility within the chamber is assessed by measuring the light transmitted.

This test has been severely criticized for its various deficiencies,[25–29] but is very widely used throughout the world. Results from this test are included as parts of many specifications and requirements, typically for transportation vehicles and for carpets and other floor coverings. The test is also a common tool in material development.

Some of the deficiencies, especially the problem of test specimen dripping, have been addressed by the development of ASTM E1995, *Test Method for Measurement of Smoke Obscuration Using a Conical Radiant Source in a Single Closed Chamber, with the Test Specimen Oriented Horizontally,* NFPA 270, *Standard Test Method for Measurement of Smoke Obscuration Using a Conical Radiant Source in a Single Closed Chamber,* and ISO 5659-2, *Plastics—Smoke Generation, Part 2—Determination of Optical Density by a Single-Chamber Test,* which employ a horizontal test specimen and a conical radiant heater in the same chamber. This chamber is used extensively in the marine environment. An earlier type of smoke chamber was developed for testing light-transmitting plastics, ASTM D2843, *Test Method for Density of Smoke from the Burning or Decomposition of Plastics,* and it is still included in codes as one of the qualifying tests for such materials. One serious problem with all of these small-scale smoke tests is that they normally cause complete destruction of the test specimen, even for materials with excellent fire performance in real fires. Consequently, a material that would not burn up completely in an actual fire (and would thus yield less total overall smoke obscuration than would appear from total material consumption) can appear to have poor smoke performance in these tests due to the characteristics of the test itself.

For electric cables, European requirements call for the 3 m cube test (IEC 61034), which is a large static smoke chamber. Its fire model is a very intense liquid hydrocarbon pool which is sufficient, often, to consume completely the combustible portion of the cables, due to the geometrical arrangement. Thus, the test suffers from most of the same defects that plague small-scale static smoke chamber tests.

The ultimate measure of fire performance of a material or product is, of course, the way the actual product reacts in a real fire, as opposed to testing the component materials individually. Fires typically involve finished products and not individual materials. Thus, the best approximation to fire performance and to the associated smoke release will be found with room-size fire tests, where products can be tested in end-use configurations or as close to them as possible. As the single most important fire property is the heat release rate, since its peak value will determine the peak intensity of the fire, tests that assess smoke release together with heat release will tend to give more realistic smoke results. The fire science community has understood this concept only relatively recently, but the result has been the development of several such tests, which measure smoke obscuration together with heat release. They are discussed as part of heat release test methodology.

Heat Release

As stated earlier, heat release is the most important property in a fire, as the peak heat release rate is the answer to the key fire question: How big is the fire? When a product burns, it will spread the fire to nearby products only if it gives off enough heat to ignite them. Moreover, it has to give off that heat fast enough that it is not "lost" while traveling through the colder air that surrounds a product that is not burning. Therefore, fire hazard is dominated by the rate of heat release.[30–32] In fact, heat release rate has been shown to be much more important than either ease of ignition, smoke toxicity, or flame spread in controlling the time available for potential victims of a fire to escape.[1]

OSU Heat Release Rate (HRR) Calorimeter. In the late 1960s, Professor Edwin Smith at Ohio State University (OSU) developed the first bench-scale (or small-scale) heat release test instrument, the OSU heat release rate (HRR) calorimeter, ASTM E906, to measure heat release rates from small-scale specimens.[33] The OSU calorimeter exposes a 150 mm × 150 mm test specimen vertically and assesses heat release by measuring temperature increases with a thermopile. The test was the first heat release test method to be widely used for regulatory purposes, once the Federal Aviation Administration (FAA) completed a series of full-scale tests that demonstrated that good performance (i.e., low heat release) in the calorimeter test correlated to more time available for escape in an aircraft.[34]

Since the late 1980s, the FAA has based requirements on this equipment (actually, the version of the test apparatus contained in the *FAA Aircraft Material Fire Test Handbook,* Chapter 5). The requirements, which apply to most large surfaces inside an aircraft cabin (such as wall panels and baggage stowage bins), are that the average maximum heat release rate during a 5 minute test not exceed 65 kW/m^2 and that the average total heat released during the first 2 minutes of test not exceed 65 kW min/m^2, with an incident heat flux of 35 kW/ m^2, for all commercial passenger airplanes manufactured after August 20, 1990, and that use United States airports.

The pass/fail criteria were calculated based on requiring a 5 minute escape time from an airplane that has suffered a survivable collision followed by a fuel tank rupture and fire. The success of this regulatory strategy can be seen in the excellent fire safety record of airplanes. For example, most recently on August 2, 2005, a commercial airliner was consumed by fire at the Toronto, Canada, airport with a full complement of passengers and crew, and yet neither fire fatalities nor severe fire injuries occurred. In contrast, hundreds of fire fatalities occur each year in passenger road vehicles, mainly private cars and vans, in the United States alone; there are no heat release requirements for the materials used in passenger road vehicles.[35–37]

FM Fire Propagation Apparatus. In parallel with the OSU calorimeter development, Archibald Tewarson (from FM Global) created the Factory Mutual fire propagation apparatus (FM FPA) (ASTM E2058, *Standard Test Methods for Measurement of Synthetic Polymer Material Flammability Using a Fire Propagation Apparatus (FPA)*).[38] One specific application of this apparatus is the testing of materials for use in cleanrooms (NFPA 287, *Standard Test Methods for Measurement of Flammability of Materials in Cleanrooms Using a Fire Propagation Apparatus (FPA)*). This instrument is used for assessing heat release and fire propagation.

Heat release is assessed by measuring carbon dioxide generation instead of temperature increases with a thermopile. The protocol utilizes three small-scale tests (designated as ignition, combustion, and fire propagation). Ignition and combustion tests are conducted with horizontal test specimens (normally about 100 mm^2) and fire propagation tests are conducted with vertical test specimens (300 mm high by 100 mm wide by no more than 13 mm thick). Ignition tests assess time to ignition and critical ignition flux. Combustion tests are the ones that assess chemical and convective heat release and they are conducted at an incident heat flux of 50 kW/m^2. Fire propagation tests are also conducted at an incident heat flux of 50 kW/m^2, but at an oxygen level of 40 percent, in order to differentiate among the flame heat transfer characteristics of burning materials, in the absence of any imposed, high-intensity radiant flux.[39]

The use of this high oxygen concentration is somewhat controversial, with some researchers questioning its direct relevance to normal oxygen content (20.9%) and vitiated atmosphere fires. However, based on the results of these tests, a fire propagation index (FPI) can be determined for each material tested. The FPI is intended to represent the ease or difficulty of fire propagation on the surface of the material beyond the ignition zone, under simulated flame heating conditions expected in large-scale fires. Experience indicates that nonpropagating materials have FPI values at or below 6.0. Materials that meet the flammability protocol criteria require high heat fluxes to be ignited; once ignited, these materials can burn locally in the ignition area, but they are likely not to propagate a fire beyond the ignition zone.

Research at FM Global has shown that materials with a low fire propagation index determined by ASTM E2058/NFPA 287 are likely to perform well in a larger-scale FM flammability test known as the parallel panel test. FM Global developed three approvals standards that use this apparatus: FM 3972, *Cable Fire Propagation Specification Test Standard,* for electric cables; FM 4910, *American National Standard for Cleanroom Materials Flammability Test Protocol,* for cleanroom materials; and FM 4998, *Class 1 Conveyor Belting,* for coal mine conveyor belts.

Cone Calorimeter. In the early 1980s, Vytenis Babrauskas, at the National Institute of Standards and Technology, developed a new fire test method to measure heat release rate, the cone calorimeter (ASTM E1354/NFPA 271/ISO 5660)[40–41] (Figure 6.3.7), based on the principle of oxygen consumption.[42] This fire test instrument can also be used to assess a number of other fire properties, the most important of which are ignitability (as discussed above), mass loss, and smoke release. Fire test results from this instrument correlate with those from full-scale fires for a variety of products, including interior finish, upholstered furniture, mattresses, and electric cables.[43–45] In order to obtain the best overall understanding of the fire performance of materials, it is important to test the materials under a variety of conditions. Therefore, tests are often conducted at a variety of incident heat fluxes.[18]

Heat release test results from the cone calorimeter are now used for various purposes, beyond just research and development. Such test results are mainly used as primary inputs into models for assessing the fire hazard (and perhaps fire risk) of a fire scenario before a material, product, or system is incorporated into a design. In order to aid in this analysis, several cone calorimeter applications standards have been issued by ASTM: ASTM E1474, *Standard Test Method for Determining the Heat Release Rate of Upholstered Furniture and Mattress Components or Composites Using a Bench Scale Oxygen Consumption Calorimeter* (equivalent to NFPA 272, *Standard Method of Test for Heat and Visible Smoke Release Rates for Upholstered Furniture Components or Composites and Mattresses Using an Oxygen Consumption Calorimeter*); ASTM F1550, *Standard Test Method for Determination of Fire-Test-Response Characteristics of Components or Composites of Mattresses or Furniture for Use in Correctional Facilities after Exposure to Vandalism, by Employing a Bench Scale Oxygen Consumption Calorimeter* (same as ASTM E1474 but intended to apply especially to vandalized mattress specimens, particularly for detention occupancy applications); ASTM E1740, *Standard Test Method for Determining the Heat Release Rate and Other Fire-Test-Response Characteristics of Wallcovering Composites Using a Cone Calorimeter* (for textile and other wall coverings); ASTM D6113, *Standard Test Method for Using a Cone Calorimeter to Determine Fire-Test-Response Characteristics of Insulating Materials Contained in Electrical or Optical Fiber Cables* (for both electric cables and cable insulating materials); ASTM D5485, *Standard Test Method for Determining the Corrosive Effect of Combustion Products Using the Cone Corrosimeter;* and ASTM E2102,

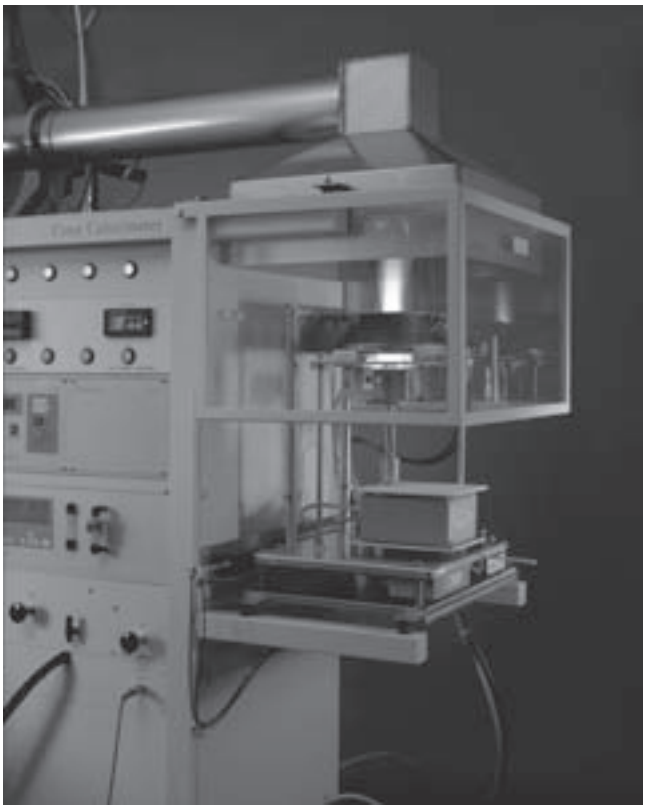

FIGURE 6.3.7 Cone Calorimeter Test Apparatus

Standard Test Method for Measurement of Mass Loss and Ignitability for Screening Purposes Using a Conical Radiant Heater (known as the mass loss cone, which is a screening test for mass loss and ignitability).

The cone calorimeter is also used as part of specifications and regulations, including its use for materials of construction of large garbage cans in health care occupancies (in NFPA 1, *Uniform Fire Code*™), for alternative design of materials in passenger rail applications, and for qualification of materials in the cleanrooms used in semiconductor fabrication facilities ("fabs"). The latter are approved based on testing in accordance with either UL 2360, *Standard for Test Methods for Determining the Combustibility Characteristics of Plastics Used in Semi-Conductor Tool Construction* (an application of the cone calorimeter) or NFPA 287 with the criteria contained in FM 4910, *Clean Room Materials Flammability Test Protocol.*

In all of the above tests, smoke release can be assessed on the same test specimen as heat release, resulting in more realistic smoke results. They are the tests that comply with the following four basic criteria that have been suggested[29] for small-scale smoke obscuration tests, as follows:

1. Tests must measure fire properties so that they can be used for purposes other than simple rankings or pass/fail criteria.
2. Tests should measure fire properties of considerable fire hazard interest, principally the rate of heat release.
3. Tests must have been proven to give results that are representative of the corresponding property in a full-scale scenario.
4. Tests must allow calculations to compensate for complete sample consumption, characteristic of small-scale tests.

In order to compensate for the complete consumption of the sample in small-scale smoke and heat release tests, it is possible to calculate derived combined heat/smoke magnitudes of smoke obscuration, such as the smoke factor, a product of total smoke released and peak heat release rate.[29] An attempt has been made to compare smoke chamber test results with those of full-scale tests and small-scale heat release test smoke obscuration results (cone calorimeter and OSU calorimeter).[46] The results indicate a lack of correlation between the smoke chamber test results and those of any of the other three tests. Moreover, the results also show a fair predictability of the combined heat/smoke parameters from the cone calorimeter and the OSU apparatus and the full-scale results for a variety of plastics.

Moreover, work also showed reasonable correlation between such cone calorimeter parameters and smoke measured in full-scale fire tests of cables in vertical trays.[45] In the same work,[47] the materials used to make the cables were burnt in the cone and in the OSU apparatus; heat release results from both instruments correlated well with one another, as did combined smoke factors in each instrument at different incident fluxes. All this suggests that, probably, the best way of measuring smoke obscuration in a meaningful way for full-scale fires, without conducting full-scale tests, is by using a small-scale heat release test, such as the cone calorimeter and compensating for incomplete burning of fire retardant materials by using the combined heat/smoke magnitude concept.

Intermediate Scale Calorimeter (ICAL) Test. However desirable and predictive small-scale tests are, they are often unable to deal with physical phenomena such as joints, multiple layers, and product irregularities. Intermediate-scale calorimeter tests have been developed to generate data similar to those from small-scale heat release tests, but in a scale that is more likely to allow the use of test specimens that are representative of real-scale products. The intermediate scale calorimeter ASTM E1623, *Test Method for Determination of Fire and Thermal Parameters of Materials, Products, and Systems Using an Intermediate Scale Calorimeter (ICAL),* and the single burning item fire test (SBI, EN 13823) are versions, developed in North America and Europe, respectively, of this concept. In the ICAL test a flat specimen (1 m × 1 m vertically) is exposed to a radiant heat source (a vertical gas-fired panel; Figure 6.3.8) at an incident heat flux ranging up to 50 kW/m^2. The results obtained include heat and smoke release, ignitability, and flame spread across the specimen surface. In North America, the ICAL test is extensively used as a predictor of full-scale fire performance, but not for regulatory purposes (or at least not yet).

Single Burning Item (SBI) Test. In the European Union, the SBI test, shown in Figure 6.3.9, was developed with the objective of using it to regulate building products. In the test, two test specimens, both 1.5 m high, with one 0.5 m wide and the other one 1 m wide, are placed in a corner and exposed to a 30 kW propane gas burner. Determinations are made of ignitability, flame spread, heat release, smoke release, and flaming droplets.

FIGURE 6.3.8 Radiant Panel of ICAL Apparatus

FIGURE 6.3.9 SBI Apparatus

Key new parameters that are calculated from SBI measurements are parameters that are intended to address fire growth rate (FIGRA) and smoke growth rate (SMOGRA); they are required to be reported by the European Commission for product regulation. FIGRA is "the maximum of the function of heat release rate versus time," starting at the time to ignition and it describes the fire growth rate. SMOGRA is "the maximum of the function of smoke production rate versus time," also starting at the time to ignition, and would describe the growth rate of smoke production. These parameters include the concepts of heat or smoke release and time to effect, so that a material or product that takes a long time to generate very high heat or smoke release will be assessed to have better fire performance than one that gets to the same heat or smoke value rapidly.

The SBI test is one of a battery of regulatory tests the European commission uses for building product regulation (mainly interior wall and ceiling finish and insulation). Excluded from this regulation are "linear products," such as electric cables, pipes and pipe insulation, and floor coverings. The other tests for construction products, excluding floorings, are not based on heat release. They are ISO 1182, *Reaction to Fire Tests for Building Products—Noncombustibility Test,* and ISO 1716, *Reaction to Fire Tests for Building Products—Determination of the Heat of Combustion,* both of which require better fire performance than that provided by typical SBI test results, and the small flame test, ISO 11925-2, *Reaction to Fire Tests—Ignitability of Building Products Subjected to Direct Impingement of Flame—Part 2: Single-Flame Source Test,* used for materials with minimal improved fire performance. Everything is then incorporated into EN 13501-1, *Fire Classification of Construction Products and Building Elements.* The SBI test is also used for the European classification/regulation of pipe insulation, but not for electric cables or floorings.

The ultimate way of assessing fire performance is by conducting full-scale tests; fire hazard or fire risk can only be assessed as a result of determining heat release. A number of modern full-scale fire test methods have been developed for products, relying on rate of heat release measurements, such as those involving testing of upholstered furniture (ASTM E1537, *Standard Test Method for Fire Testing of Upholstered Furniture*), mattresses (ASTM E1590, *Standard Test Method for Fire Testing of Mattresses*), stacking chairs (ASTM E1822, *Standard Test Method for Fire Testing of Stacked Chairs*), electric cables (ASTM D5424, *Standard Test Method for Smoke Obscuration of Insulating Materials Contained in Electrical or Optical Fiber Cables When Burning in a Vertical Cable Tray Configuration;* ASTM D5537, *Standard Test Method for Heat Release, Flame Spread, Smoke Obscuration, and Mass Loss Testing of Insulating Materials Contained in Electrical or Optical Fiber Cables When Burning in a Vertical Cable Tray Configuration;* and EN 50399), plastic display stands (UL 1975, *Standard for Fire Tests for Foamed Plastics Used for Decorative Purposes*), or wall lining products (NFPA 265, *Standard Methods of Fire Tests for Evaluating Room Fire Growth Contribution of Textile Coverings on Full Height Panels and Walls;* NFPA 286, *Standard Methods of Fire Tests for Evaluating Contribution of Wall and Ceiling Interior Finish to Room Fire Growth;* ASTM E2257, *Standard Test Method for Room Fire Test of Wall and Ceiling Materials and Assemblies;* and ISO 9705, *Fire Tests—Full-Scale Room Test for Surface Products*).

Room-Corner Tests. In fact, room-corner tests are being used in the newest editions of all codes, as alternatives to replace the NFPA 255/ASTM E84 (Steiner tunnel test), thus generating more useful results. Figure 6.3.10 shows a room-corner test layout. The standard room used for all these tests, except for the cable tray tests, is the same size: 2.4 m × 3.7 m × 2.4 m high, with a door in the center of one of the shorter walls and a hood/vent and outlet outside the door. Wall lining material tests, also known as room-corner tests, such as NFPA 265, NFPA 286, ASTM E2257, and ISO 9705, require that the tested material be lined on three walls (all except the wall with the door) or on three walls and the ceiling or on the ceiling only. A variety of burners and ignition source intensities are used and the details are indicated in each standard.

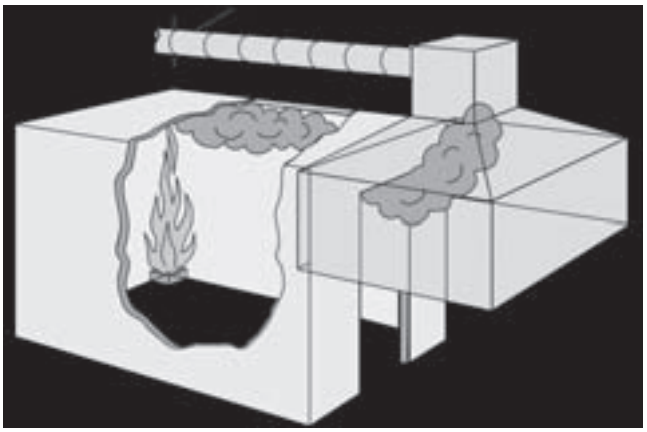

FIGURE 6.3.10 Room-Corner Fire Test Layout

In the case of ASTM cable tray tests, the standard room is 2.4 m × 2.4 m × 3.4 m high, with a door in the center of one wall and a hood/vent and outlet in the middle of the room; the IEC 60332 and FIPEC cable tray tests have a different size room. In all of these cases, other size rooms are permitted, within certain limits. Cable tray tests require that a vertical cable tray be placed in the middle of the test room, as shown in Figure 6.3.11.

Furniture standard tests (ASTM E1537, ASTM E1590, and ASTM E1822) require the item for test to be placed on a load cell near one of the corners and away from the door; again each standard test has different burners and ignition source intensities.

Furniture calorimeter tests are an added way of assessing heat release of full-scale items, where the product to be tested is placed on a load cell under a hood/vent and outlet. UL 1975 is a standard version of a furniture calorimeter and it is applicable to foam plastic displays and uses a 340 g wood crib as the ignition source. The NFPA Technical Committee on Fire Tests is developing another standard furniture calorimeter test, designated NFPA 289, which is intended to apply to all sorts of individual fuel packages and to use a variety of gas ignition sources, depending on the application. When testing does not have to follow standard protocols, ASTM E603, *Standard Guide for Room Fire Experiments,* and ASTM E2061, *Standard Practice for Full-Scale Oxygen Consumption Calorimetry Fire Tests,* offer adequate guidance.

FIGURE 6.3.11 Cable Tray Test Burn

Toxic Gas Release

All of the comments made for smoke release (i.e., smoke obscuration) are equally valid for the release of all combustion products, especially since it has now been demonstrated that smoke toxicity does not represent the most significant aspect of the fire hazard.[1] In fact, fire statistics and studies of fire fatalities have shown that (1) most fire victims die when fires have become large and have grown beyond the room of fire origin and (2) fire fatalities can be correlated to the amount of carbon monoxide generated in fires.[48–50] This is very important as carbon monoxide is generated by all combustibles and, in fires that extend beyond the room of fire origin, its yield is 20 percent of the burnt mass, irrespective of what is burning.[51–54] Thus, fires resulting from materials with better fire performance tend to generate less fire hazard, even if they generate more toxic gases or more smoke per unit mass burnt.[55] In other words, addressing purely the toxic potency of the smoke of a particular material can be very misleading. For example, materials associated with low heat release usually represent a much lower level of fire hazard, almost irrespective of the toxic potency of their smoke. It has been shown that, although redesigning an upholstered furniture item so that its heat release rate is doubled will lead to a 70 percent decrease in time to lethality in a small room, redesigning it so that the toxic potency is twice as high will have a negligible effect on the time to lethality.[1]

Reaction-to-Fire Tests and Fire Hazard

The key issue in terms of fire hazard is to ensure that a fire does not become self-propagating and remains small. At the very least, it is critical to ensure that flashover does not occur. Flashover is a stage in the development of a contained fire in which all exposed surfaces reach ignition temperatures more or less simultaneously and fire spreads rapidly throughout the space. Thus, an initial strategy for minimizing fire hazard is to prevent flashover; that requires a good measure of heat release or of the potential for materials and products releasing heat in a compartment.

NFPA 555, *Guide on Methods for Evaluating Potential for Room Flashover,* gives adequate guidance on how to assess or predict heat release in actual fires. Since estimates of heat release rate are critical in predicting whether or not flashover is likely to occur in a compartment, NFPA 555 provides techniques for measuring or estimating the heat release rate for various individual items or products in a compartment. NFPA 555 gives the following hierarchical order for preferred techniques for measuring/assessing heat release:

1. A full compartment fire test, including all items expected to be contained within the compartment
2. Full-scale fire tests on individual items
3. Tests on large-scale mock-ups of individual items
4. Small-scale tests, using composite samples representative of the end-use composite assemblies

5. Small-scale tests using individual materials rather than composites as samples
6. Use of estimation techniques for calculating heat release rate in the compartment as determined from the results of tests. This might be done by one of the following:
   - Quantitative estimation techniques
   - Relative estimation techniques

ASTM has also developed two guides that can assist those considering methods for evaluating potential for flashover: ASTM E2061, *Guide for Fire Hazard Assessment of Rail Transportation Vehicles,* and ASTM E2280, *Standard Guide for the Fire Hazard Assessment of the Effect of Upholstered Seating Furniture Within Patient Rooms of Health Care Facilities.*

It has been shown that heat release techniques can be used to adequately predict the fire performance of at least several types of products in actual full-scale fires: aircraft panels, upholstered furniture, mattresses, wall linings (interior finish), and electric cables.[24,34,56–63] Although the use of full-scale fire tests is the best "insurance" that the test results will be fully indicative of fire performance, it is clear that predictive tests will be used with increasing frequency, as they are much more cost effective and practicable to conduct.

The most common models to predict full-scale fire test results are correlative ones, which are based on comparing test results in both sets of tests and interpolating the expected test results from the material or product being investigated (and which has not been tested in full scale). Such predictions are often excellent when they are based on using variations of a set of materials or products (such as the same material with different sets of additives). They are less successful when they compare materials with different types of chemical composition or try to extrapolate results based on data that are not bracketed by full scale tests already conducted. Other models can be used that consider physical/theoretical aspects of the fire issue and yield results that are not (at least in concept) material dependent. This approach is much more complex but has been very successful for simple geometries, such as wall linings/interior finish.

One common problem encountered in regulatory and research studies of fire test results is that most manufacturers are responsible for developing a certain material, which will then become a component of a more complex or composite product or assembly. Such manufacturers often have limited control over the ultimate use of their material. However, it has by now been shown extensively that "the sum of the parts" does not give, in this case, an adequate picture of the "whole." Occasionally, an assembly or a composite system will have better fire performance than expected from individual test results on the component materials. However, very often, when testing individual materials, each may produce adequate test results, which meet the specifications or regulatory requirements, but the combination of materials may generate results indicating that the product would "fail" the required criteria. In such case, the testing of specimens simulating the final product, as intended to be used in the field, is essential.

Very often, it is not immediately apparent how to generate the most suitable test results in a fashion fully representative of the end use. Committees developing test methods have, in recent years, developed mounting practices and application standards that address these issues. As discussed above, such standards have been developed for the NFPA 255/ASTM E84 Steiner tunnel test, for the cone calorimeter, and for the

TABLE 6.3.5 European Community Concept for Fire Classes

Fire Class	*Test Simulations*		*Time to Flashover*	*Contribution to Fire Growth*
A1	Fully developed fire in a room	Single burning item in a room	No flashover	None
A2	Fully developed fire in a room	Single burning item in a room	No flashover	None
B	Small fire attack on limited area	Single burning item in a room	No flashover	Extra small
C	Small fire attack on limited area	Single burning item in a room	After 10 minutes	Small
D	Small fire attack on limited area	Single burning item in a room	2–10 minutes	Medium
E	Small fire attack on limited area		Before 2 minutes	Large
F	No A1 through E			

Essential definitions for European Community regulations:

Material: a single basic substance or uniformly dispersed mixture of substances, for example, metal, stone, timber, concrete, mineral wool with uniformly dispersed binder, polymers.

Homogeneous product: a product consisting of a single material, having uniform density and composition throughout the product.

Nonhomogeneous product: a product that does not satisfy the requirements of a homogeneous product. It is a product composed of one or more components, substantial and/or nonsubstantial.

Substantial component: a material that constitutes a significant part of a nonhomogeneous product. A layer with a mass per unit area ≥ 1.0 kg/m^2 or a thickness ≥ 1.0 mm is considered to be a substantial component.

Nonsubstantial component: a material that does not constitute a significant part of a nonhomogeneous product. A layer with a mass per unit area < 1.0 kg/m^2 and a thickness < 1.0 mm is considered to be a nonsubstantial component. Two or more nonsubstantial layers that are adjacent to each other (i.e., with no substantial component(s) in between the layers) are regarded as one nonsubstantial component and, therefore, must altogether comply with the requirements for a layer being a nonsubstantial component.

For nonsubstantial components, distinction is made between internal nonsubstantial components and external nonsubstantial components, as follows:

Internal nonsubstantial component: a nonsubstantial component that is covered on both sides by at least one substantial component.

External nonsubstantial component: a nonsubstantial component that is not covered on one side by a substantial component.

Class	*Test Method(s)*	*Classification Criteria*	*Additional Classification*
A1	EN ISO 1182[a] and	$\Delta T \le 30°C$ and $\Delta m \le 50\%$ and $t_f = 0$ (i.e., no sustained flaming)	—
	EN ISO 1716	PCS ≤ 2.0 MJ/kg[a] and PCS ≤ 2.0 MJ/kg[b,c] and PCS ≤ 1.4 MJ/m^2[d] and PCS ≤ 2.0 MJ/kg[e]	—
A2	EN ISO 1182[a] or	$\Delta T \le 50°C$ and $\Delta m \le 50\%$ and $t_f \le 20$ sec	—
	EN ISO 1716 and	PCS ≤ 3.0 MJ/kg[a] and PCS ≤ 4.0 MJ/kg[b] and PCS ≤ 4.0 MJ/m^2[d] and PCS ≤ 3.0 MJ/kg[e]	—
	EN 13823 (SBI)	FIGRA ≤ 120 W/sec and LFS < edge of specimen and $THR_{600sec} \le 7.5$ MJ	Smoke production[f] and flaming droplets/particles[g]
B	EN 13823 (SBI) and	FIGRA ≤ 120 W/sec and LFS < edge of specimen and $THR_{600sec} \le 7.5$ MJ	Smoke production[f] and flaming droplets/particles[g]
	EN ISO 11925-2[i] Exposure = 30 sec	$F_s \le 150$ mm within 60 sec	
C	EN 13823 (SBI) and	FIGRA ≤ 250 W/sec and LFS < edge of specimen and $THR_{600sec} \le 15$ MJ	Smoke production[f] and flaming droplets/particles[g]
	EN ISO 11925-2[i] Exposure = 30 sec	$F_s \le 150$ mm within 60 sec	
D	EN 13823 (SBI) and EN ISO 11925-2[i] Exposure = 30 sec	FIGRA ≤ 750 W/sec and $F_s \le 150$ mm within 60 sec	Smoke production[f] and flaming droplets/particles[g]
E	EN ISO 11925-2[i] Exposure = 15 sec	$F_s \le 150$ mm within 20 sec	Flaming droplets/particles[h]
F		No performance determined	

[a]For homogeneous products and substantial components of nonhomogeneous products.
[b]For any external nonsubstantial component of nonhomogeneous products.
[c]Alternatively, any external nonsubstantial component having a PCS ≤ 2.0 MJ/m^2, provided that the product satisfies the following criteria of EN 13823 (SBI): FIGRA ≤ 20 W/sec; and LFS < edge of specimen, and $THR_{600sec} \le 4.0$ MJ and s1 and d0.
[d]For any internal nonsubstantial component of nonhomogeneous products.
[e]For the product as a whole.
[f]In the last phase of the development of the test procedure, modifications of the smoke measurement system have been introduced, the effect of which needs further investigation. This may result in a modification of the limit values and/or parameters for the evaluation of smoke production.
s1 = SMOGRA ≤ 30m^2/sec^2 and $TSP_{600sec} \le 50$ m^2; s2 = SMOGRA ≤ 180 m^2/sec^2 and $TSP_{600sec} \le 200$ m^2; s3 = not s1 or s2.
[g]d0 = No flaming droplets/particles in EN 13283 (SBI) within 600 sec; d1 = No flaming droplets/particles persisting longer than 10 sec in EN 13823 (SBI) within 600 sec; d2 = not d0 or d1. Ignition of the paper in EN ISO 11925-2 results in a d2 classification.
[h]Pass = no ignition of the paper (no classification). Fail = ignition of the paper (d2 classification).
[i]Under conditions of surface flame attack and, if appropriate to the end-use application of the product, edge flame attack.

ΔT = temperature rise
Δm = mass loss
t_f = duration of flaming
PCS = gross calorific potential
FIGRA = fire growth rate
THR_{600sec} = total heat release
LFS = lateral flame spread
SMOGRA = smoke growth rate
TSP_{600sec} = total smoke production
F_s = flame spread

[a]For homogeneous products and substantial components of nonhomogeneous products.
[b]For any external nonsubstantial component of nonhomogeneous products.
[c]For any internal nonsubstantial component of nonhomogeneous products.
[d]For the product as a whole.
[e]Test duration = 30 minutes.
[f]Critical flux is defined as the radiant flux at which the flame extinguishes or the radiant flux after a test period of 30 minutes, whichever is the lower (i.e., the flux corresponding with the furthest extent of spread of flame).
[g]s1 = Smoke ≤ 750%·min; s2 = not s1.
[h]Under conditions of surface flame attack and, if appropriate to the end-use application of the product, edge flame attack.

ΔT = temperature rise
Δm = mass loss
t_f = duration of flaming
PCS = gross calorific potential
F_s = flame spread

radiant panel test. In North America such application tests or mounting practices have been incorporated into a variety of codes. One example is the use of ASTM E2231 as the standard mounting method for using ASTM E84 when testing pipe and duct insulation materials, which is now in widespread use. It is important to note that simple statements such as "testing in the composite form is required," without further detailed explanations, are of little use and are likely to lead to misinterpretations.

In North America, testing using small- or medium-scale fire tests is infrequently used, although a key exception is OSU testing by the Federal Aviation Administration. In contrast, the European Community has developed a "reference scenario" fire test, namely the ISO 9705 room-corner test, and uses other tests as surrogates. Table 6.3.5 shows the concept of what each class is intended to represent in the European Community standard testing approach. The specific classification schemes for construction products, for floorings, for linear pipe thermal insulation products, and for electric cables are shown in Tables 6.3.6 through 6.3.9, respectively. The information on these requirements can be found as part of the European Union directives.

TABLE 6.3.8 European Community Classes of Reaction-to-Fire Performance for Linear Pipe Thermal Insulation Products

Class	*Test Method(s)*	*Classification Criteria*	*Additional Classification*

LFS = lateral flame spread
SMOGRA = smoke growth rate
TSP_{600sec} = total smoke production
F_s = flame spread
FIPEC = "Fire Performance of Electrical Cables"[24]

SUMMARY

Fire testing has undergone a significant change between the 1980s and the start of the twenty-first century. Before the 1980s, it was normal to use old-fashioned tests that generate a simple test result, often with little correlation to the fire scenario being investigated. In modern fire testing, products are tested in ways that are as representative as possible of the end use in the field. That has led to the development of modern tests, often assessing heat release parameters and usually employing test specimens that are indicative of the assemblies the public uses.

Chapter 4

Wood and Wood-Based Products

John M. Cholin

Chapter Contents

Nature of Wood and Wood-Based Products
Physical Nature of Wood
Variables Influencing Combustibility
Ignition of Wood and Wood Products
Combustion of Wood and Wood-Based Materials

Key Terms

bound water, cellulose, fire resistance, flame propagation, flame spread, forest product, free water, heat release rate (HRR), spontaneous heating, thermal conductivity, water of constitution, wood, wood-based products, wood by-products, wood composite products

Wood, arguably the first structural material to be used by prehistoric man, is still arguably the single most versatile structural material in use today. It is light in weight, strong, durable, flexible, and resilient, yet it possesses an intrinsic beauty. These characteristics have made it a persistent first choice construction material. Furthermore, once dwelling spaces are constructed, those spaces are filled with furnishings that are often constructed of wood and wood products. The fact that this material is truly ubiquitous in modern society necessitates a thorough understanding of both its nature as a fuel and its behavior as a structural material under conditions of fire exposure.

One reason wood and wood products have been so universally adopted as a structural material is the fact that they can be processed into so many different forms that take specific advantage of the unique chemical and physical characteristics of wood as a raw material. The wood from a wide variety of trees can be transformed into structural timbers, dimension lumber, shingles, and veneers. These are called *primary forest products,* as only cutting and drying are required to derive these products from the log.

Raw wood can be used to make a variety of wood-based building products, including multiple-ply glue-laminations, fiberboard, insulation board, ceiling tile, plywood, flakeboard, strandboard, and particleboard. Each of these forms of wood has specific structural characteristics that makes it the material of choice for specific applications. These products are often referred to as *secondary forest products,* since secondary processes are necessary over and above cutting and drying to result in the product.

Primary and secondary forest products are usually not consumed directly. They are the material from which directly consumed products are constructed. The primary examples of these are housing and furnishings. Lumber, a primary forest product, is cut and shaped and assembled with other components to ultimately become a finished piece of furniture. Occasionally these are referred to as *tertiary forest products.*

The unique chemical composition of wood makes it possible to process it into materials that have no resemblance to the log from which they came. Wood is the major raw material source for paper and paper-based products, such as cardboard, box board, and corrugated board used in containers. Paper, used alone or combined with metal foils and plastics, is employed in the manufacture of many hundreds of products, including writing and wrapping papers, magazines, books, bags, wall coverings, and labels. Furthermore, when exposed to the appropriate chemical treatment, wood yields a material called cellulose, which is the fundamental raw material for a wide variety of products, including transparent films (e.g., Saran Wrap®), motion picture film, textile fibers, explosives and propellants, coatings, plastics, and foodstuffs.

Because wood and its cellulose derivatives are found in such a wide range of forms, it should come as no surprise that they are frequently involved in fires. The discussion of wood in this chapter is limited to solid wood and wood-based materials, including paper and paper derivatives. This chapter will address the chemistry of cellulose, the process of ignition of wood and cellulosic materials, and the behavior as a structural component under conditions of fire exposure. Those

John M. Cholin, P.E., is an independent fire protection consultant and engineer with J. M. Cholin Consultants, Inc., Oakland, New Jersey.

interested in a more detailed treatment on the subject should consult the list of references at the end of this chapter.

See the following chapters for related topics: In Section 6 see Chapter 2, "Combustion Products and Their Effects on Life Safety"; Chapter 5, "Fibers and Textiles"; Chapter 7, "Fire-Retardant and Flame-Resistant Treatment of Cellulosic Materials"; Chapter 8, "Dusts"; Chapter 13, "Polymeric Materials"; Chapter 15, "Explosives and Blasting Agents." See also Section 7, Chapter 1, "Storage and Handling of Solid Fuels"; Section 9, Chapter 1, "Woodworking Facilities and Processes"; Section 9, Chapter 2, "Spray Finishing and Powder Coating"; and Section 13, Chapter 5, "Wildland Fire Management."

NATURE OF WOOD AND WOOD-BASED PRODUCTS

To understand the behavior of forest products, both as fuel and as structural material under exposure to fire, one must start with an understanding of the material called "wood." This understanding starts with the chemistry of its principal component, cellulose.

Chemical Composition of Wood

Cellulose is a naturally occurring polymer constructed from the simple sugar, glucose. Its chemical structure is shown in Figure 6.4.1.[1]

The individual molecules of glucose are chemically linked together during the growth process of the living cell to produce a long-chain polymer, cellulose. In most cases, the average cellulose molecule is between 300 and 3000 glucose units long.[2] The long-chain polymer cellulose molecules are organized in bundles of parallel chains called fibrils. The fibrils are linked together via hydrogen bonding through a water molecule (Figure 6.4.2).

Adjacent fibrils are cemented together by the living cell with special linking polymeric molecules consisting of hemicelluloses and pectins, also called lignin. These polymeric chemicals bind adjacent fibrils together into a mat or sheet that forms the cell wall of the plant cell. The cells of the living plant are organized into long strands, like a string of pearls, and this gives rise to the cellulose fiber.

A collection of complex polymeric aromatic alcohols, called lignin, binds adjacent cellulose fibers together, forming a matrix around and between adjacent cellulose fibers. This matrix can be imagined as being similar to a microscopic plate of spaghetti, where the noodles are the cellulose fibers and the sauce is the lignin polymers, binding the fibers together. It is a structure that is not unlike glass fiber–reinforced plastic (fiberglass), and results in the wood fiber.

The cellulose molecule also has numerous hydrogen bonding sites along its length.[2] Wherever an –OH group exists along the length of the cellulose molecule, there exists a site where hydrogen bonding via an adsorbed water molecule can serve to bind adjacent cellulose fibers together. The combined effect of the hydrogen bonding via adsorbed water molecules and the chemical linkage formed by the lignin polymers binds adjacent wood fibers together into the material known as wood.

Obviously, wood is a complex structure with tremendous strength for its weight. It consists of bundles of hollow fibers, cemented together along their length, forming a rigid, yet flexible, structure (Figure 6.4.3).

Although wood is a complex of many substances, cellulose [chemical formula $(C_6H_{10}O_5)_x$] represents its major component. Hemicellulose is a five-carbon sugar consisting of carbon, oxygen, and hydrogen. Lignins are aromatic alcohols, also consisting of carbon, oxygen, and hydrogen. Consequently, the majority of the mass of any sample of dry wood consists primarily of carbon, hydrogen, and oxygen, with a small percentage of nitrogen from cellular proteins. There are small quantities of other elements that remain as an ash when wood is burned. It is interesting to note that untreated wood contains virtually no sulfur, distinguishing it from most other solid fuels (Table 6.4.1).

A sample of wood minus all water contains, on average, 50 percent cellulose by weight. Soft woods contain between 23 and

Douglas fir	52.30	6.30	40.50	0.10	0.80

33 percent lignin, by weight, whereas hardwoods contain between 16 and 25 percent.[3] Lignin is a three-dimensional phenylpropane that is critical in binding cellulose polymers together. Another 10 to 25 percent, depending on species, is hemicellulose. Different tree species yield slightly different percentages, but these values can be thought of as the average. In addition to the components noted, there are the *extractives.* These constituents include a wide range of organic compounds that vary widely with tree species and give the wood its characteristic color, aroma, rot resistance, and other characteristics. Finally, there is the inorganic constituent that generally comprises between 0.2 and 1.0 percent by weight. This takes the form of calcium, potassium, and magnesium salts, as well as trace quantities of phosphorous, sodium, iron, silicon, manganese, copper, zinc, and perhaps a few other elements derived from the soil.[3] The ash left over from burning wood is the mineral component and is primarily potash, potassium carbonate, with the remainder being the trace elements already mentioned.

Some woods, especially the soft woods (pines, spruces, and true firs), are quite resinous, with commensurately higher levels of the extractives and lower levels of hemicellulose and lignin. In these woods, the resins can become quite volatile, especially at elevated temperatures. In contrast, most hardwoods contain such small quantities of extractives that they are of little, if any, consequence to the fire protection specialist.

The major difference between various woods depends largely on the density (specific gravity) of the wood produced by a particular species of tree. This variation in density is related to cell wall thickness and translates into the dimensional stability and strength of that particular species of wood. The other species-dependent differences are the quantity and chemical composition of the extractives. In some species, these extractives are resinous materials, which produce combustible vapors. These vapors can produce hazardous atmospheres under the right conditions of temperature and confinement. Furthermore, some resins undergo an exothermic condensation reaction, which has been suspected to be the cause of spontaneous ignition in certain wood products, for example, piled chips of southern pine used in making paper.

Moisture Content

Wood exhibits a natural affinity for water and always contains significant quantities of moisture. Water plays an important part in the physical properties of wood through its contribution to the bonding between adjacent cellulose molecules. When the tree is alive, much of the space within the cells is occupied by water. However, when the log is cut, this moisture begins leaving the wood. The water in the cell interiors is slowly replaced by air. The moisture content varies with species and the degree that the sample has been dried. Regardless of prior processing, wood will always come to equilibrium with its environment. The energy liberated during the combustion of a wood sample is a net heat release, being the remainder after the energy expenditure of driving off the water component of the sample.

The water in a wood sample is generally categorized as *free water, bound water,* and *water of constitution.*[4] *Free water* is liquid water in the living tree (green wood) that is absorbed within the cellular structure of the wood and is free to flow through the cellular spaces and within the tubular veins that convey nutrients along the length of the sample, from the roots to the leaves. This water is readily able to flow from the wood sample and is in excess of the fiber saturation water that is chemically bound to the cellulose that comprises the wood. Free water readily leaves the log through air-drying. As the log dries, air replaces the free water within the veins and cells of the sample.

Bound water is water that exists in the form of adsorbed vapor, found in the veins and cell cavities, as well as adsorbed by the cell walls. The maximum amount of bound water in a sample is called the fiber saturation point (FSP) and represents that moisture content at which water begins to accumulate as liquid in the cellular spaces of the wood sample. The fiber saturation point is a characteristic of the species of tree from which the wood was obtained. At FSP a sample may still contain between 25 and 30 percent water, by weight. This moisture is called bound water since it is hygroscopically bound to the cellulose molecules by relatively weak hydrogen bonds. Bound water will slowly leave the log or board at a rate determined by the temperature, relative humidity and sample thickness. In temperate climates, air drying, given enough time, can achieve moisture contents as low as 10 percent, by weight, for most species. A kiln is usually used to accelerate the drying process.

As the moisture content approaches approximately 7 percent, by weight, very little additional moisture is lost with increases in temperature or duration of heating. The moisture content below the range of 5 to 7 percent is called the *water of constitution.* This water forms bonds between adjacent cellulose molecules and contributes to the structural strength of the wood fiber. This water cannot be removed without the physical destruction of the wood. Consequently, even "dry" wood always contains some moisture.

Construction lumber is considered to be dry at 19 percent moisture content (MC), but wood used for furniture is dried to 7 percent moisture content or less. Moisture content in wood is usually calculated as a percentage of the oven dry weight by the formula:

$$\text{MC} = \left(\frac{\text{Original weight} - \text{Dry weight}}{\text{Dry weight}}\right)100\%$$

Thus the moisture content is expressed as a percentage "dry basis," signifying that the basis for the percentage is the dry weight at which all of the bound water has been driven off.

Wood reaches an equilibrium moisture content (EMC) with its surroundings at a given temperature and relative humidity. In a heated building, the EMC of structural wood members is usually slightly less than 10 percent moisture content in the winter months and about 12 percent moisture content in the summer. The lumber in a newly constructed building is generally wetter than that in a building that has existed for some time. The moisture in wood is not uniformly distributed, and wood is often drier or wetter at the surface than in its interior. Surface layers, which control ignition and flame spread, respond much faster to changes in atmospheric conditions than the interior; thus, bulk moisture content measurement must be considered with this fact in mind. Figure 6.4.4 illustrates conditions under which equilibrium will be established at three different temperatures.

Air-dried wood usually attains a moisture content of approximately 10 percent water by weight. If wood is dried to a moisture content below this nominal 10 percent, in a kiln, for example, it will immediately begin absorbing moisture from the air when it is removed from the kiln. The overwhelming majority of the wood found in structures, either as part of the structure or contents, will be dried, usually kiln dried, and can be assumed to be at a nominal 8 to 10 percent (by weight) moisture content. A small variation about the nominal 10 percent moisture content has very little influence on the ignitability and heat release of wood. It does, however, affect the dimensions and strength of a given piece of wood substantially. This creates the incentive to dry wood to a minimum moisture content and maintain that level, especially with woods used for interior furnishings.

The level of moisture in a wood sample can have an impact on the ignition and combustion of that sample. "Green" wood, that which has not been dried, often contains as much as 50 percent water by weight. This free water boils off as the sample burns, absorbing a significant portion of the heat generated by the combustion of the cellulosic content. Dry wood is devoid of the free water and much of the bound water. Furthermore, the bound water effectively exists as vapor, not liquid, and does not have the ability to absorb heat through vaporization. This results in a combustible material with a significantly greater heat output during a fire.

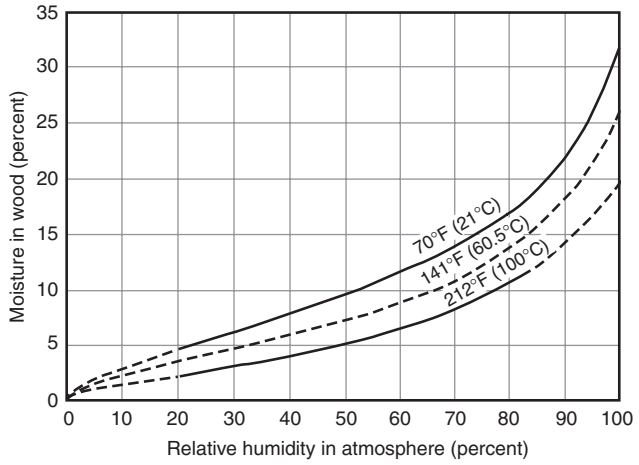

FIGURE 6.4.4 Equilibrium Moisture Content of Wood

Moisture content has an important bearing on the electrical properties of wood. Dry wood is a good insulator, but wet wood is a conductor. The electrical resistance of wood increases in approximate proportion to decreasing moisture content, from 25 percent down to about 6 percent moisture content, where it becomes too high to measure with a resistance moisture meter.

The rate of moisture loss or gain depends a great deal on the size and shape of the wood product. Some finely divided cellulosic materials absorb or lose moisture very rapidly, and their combustibility can vary from low to high within just a few hours. Examples are shredded newspaper, tissues, and loose forest litter (duff). Dense and compact combustibles, such as books or large timbers, change moisture content much more slowly. Rate of moisture loss depends on the relative humidity, the temperature, and the air velocity. Moisture loss is quite slow in air drying where there is no control over air velocity, temperature, or relative humidity; lumber may require 30 days or more to dry in such an environment. But in a kiln, where humidity, temperature, and air velocity can be adjusted, lumber can be dried in less than 24 hours. As a general rule of thumb, the amount of time required to dry lumber varies with the square of the thickness. Thus, a 1-in. (25.4-mm) thick board can be air dried in a few weeks, but a railroad crosstie or large timber requires 24 to 30 months. If wood is dried below the EMC it will reach in service, it will regain moisture slowly until it reaches that EMC.

Wood Derivatives

The chemical nature of wood and its cellulose is the basis for the diverse range of materials that are directly derived from wood. Most papers are made by a chemical process that removes the lignin and hemicellulose from the wood, yet leaves the cellulose fibers intact. This delignined cellulose is called "alpha-cellulose." These fibers are suspended in water and spread out in a thin layer. The layer is passed through sets of rollers that squeeze out the free water, and then through a dryer that drives off much of the remaining interstitial water, resulting in a sheet of paper. The cellulose fibers are held together, forming the sheet of paper, by the hydrogen bonds and the water bound to the cellulose. Newsprint is made by a process in which the fibers are separated by a mechanical or grinding process, that is, no chemicals are used. Some papers are made without any performance-modifying additives, for example, absorbent papers. However, most paper products contain performance-modifying additives, such as binders (wet-strength resins), fillers (clay), pigments (titanium dioxide), colorants (dyes), sizes (rosin, starch), and coatings (paraffins or plastics).

Wood is used as the primary feedstock for the production of purified cellulose. Purified wood cellulose fiber is used in dis-

posable sanitary applications, such as baby diapers and feminine protection products. Purified cellulose is a common ingredient of many food products where it is used to thicken liquids and to improve the texture of foods. It is commonly found in diet aids where it serves as a bulking agent and a source of dietary fiber. Many cellulose-based products are not discernible as being made from wood or paper. Chemically modified cellulose gives rise to such materials as nitrocellulose lacquers; cellulose acetate films; textiles and plastics; rayon textiles; cellophane; and smokeless powder used in small-arms cartridges.

Wood cellulose can be broken down to glucose, using appropriate chemical techniques, to make molasses suitable for cattle feed supplements, or fermented to make ethyl alcohol (grain alcohol). The hemicellulose portion of wood (composed of five-carbon sugars, such as xylose) can be fermented to make methylethylketone (MEK) or butyl alcohol (butanol), which are used as solvents.

Destructive distillation of wood releases the extractives and other products of the pyrolytic decomposition of wood. This process produces charcoal, methanol (wood alcohol), acetic acid, formic acid, and wood creosote, as well as a low-heat-output fuel that could be used to power internal combustion engines. Other processes are used to produce turpentine and rosin, known as naval stores, from standing pine trees, old stumps, or from the by-products of the manufacture of kraft paper by the sulfate process.

Wood-based products, paper, and paper-based products generally contain much less moisture than the wood from which they are derived, making them easier to ignite and more combustible than solid wood.

Wood By-Products

Bark is often encountered in the context of wood-waste utilization and specialty construction materials. Bark is an important by-product of forest products processing. It is often used for fuel in forest products facilities. Bark differs both structurally and chemically from wood. It consists of a cellulosic material called suberin, which finds use in the form of cork. Commercial cork, obtained from the bark of the cork oak, is resistant to high temperatures and ignition and burns with difficulty. Cork contains a natural adhesive that allows small particles to be bonded under heat and pressure to make composition cork. Bark and cork generally have lower moisture contents than wood. Bark is of commercial significance in that it contains tannin, which is extracted and used in the curing of leather.

Many other fibrous cellulosic materials behave in a manner similar to that of wood, and consequently can be included in this chapter. These materials include bagasse (spent sugar cane stalks), jute, hemp, and sisal. These materials have burning characteristics similar to wood-based materials. These and other similar products are often used as a source of fiber for construction materials, papers, and insulating materials. As with more traditional wood-derived materials, these fibers may be impregnated, pressure treated, or coated with a variety of chemicals, potentially altering the ignition and burning characteristics of such materials.

PHYSICAL NATURE OF WOOD

The cellular structure of wood provides a material that is light and strong. It appears to be an ideal structural material. However, it is not without its shortcomings, and it is these shortcomings that have precipitated the development of engineered wood-based materials.

Mechanical Properties

Although wood is strong, its strength is very dependent on the orientation of the stress relative to the grain of the piece under consideration.[5] The modulus of compressibility is good along the grain, but poor across the grain. The structural strength characteristics of wood are dependent on the moisture content. If the moisture content of a sample is allowed to stay above the fiber saturation point, removal of moisture has little effect on wood, other than to reduce its weight. However, once the moisture content is brought below the fiber saturation point, the strength properties improve considerably.

Solid wood is preferred where the nature of wood is consistent with the use. These are applications where strength versus weight, ease of fastening, and environmental endurance make it the most economical approach. Wood products made from solid wood include lumber, timbers, mine timbers, railroad ties, poles, and pilings. Other applications are driven by aesthetic concerns, such as upscale furnishings. Other solid-wood products are barrels, boxes, crates, and similar containers. Each of these uses takes advantage of specific and often unique characteristics of wood or a species of wood and the economies gained from those characteristics. Hardwoods are used primarily for selected interior finish applications, furniture, and as feedstock for cellulose fiber for engineered wood products and specialty papers. Softwoods are more commonly used for structural building components, such as timbers, beams, joists, and studs. They are also the wood of choice for mine timbers, railroad ties, pilings, and other uses where large dimensions are required.

Secondary wood products are designed to address one or more of the shortcomings of primary stock. Lumber dimensions vary with moisture content and the dimensional variation is dependent upon the orientation of the grain. This dimensional instability can be addressed by using wood products made from thin sheets of wood (veneer) bonded together with adhesives. These materials are termed *plywood* and *laminated veneer lumber* (LVL). Present-day large structural wood beams are often made from laminations of smaller dimension lumber.

The percentage utilization of a log is increased when it is converted to smaller particles that are bonded together with an adhesive resin. This yields an engineered wood composite material. Consequently, both the cost and dimensional properties of primary wood can be improved by conversion to a wood composite material. These materials are produced from wood that has been mechanically reduced in size to form flakes, strands, splinters, fibers, or particles. They are then mixed with thermoset plastic resins and processed to form a wood composite material with specific mechanical properties. This category includes a wide range of materials, such as flakeboard, oriented strand

board (OSB), medium-density fiberboard (MDF), particleboard, fiberboard, and hardboard.

Thermal (Heat) Conductivity

Thermal conductivity (*K* factor—the inverse of insulating value, *R* factor) of a particular material greatly influences how a material will burn. Thermal conductivity is a measure of the rate at which absorbed heat flows through the mass of material. Wood is a poor conductor of heat and thus has a high insulating value. The thermal conductivity of wood differs depending on whether the heat flow is across the grain or along the grain. It is also affected by density and moisture content. For most species the across-grain thermal conductivity can be computed from:

$$\lambda = \frac{(0.195\rho + 25.5)}{1000}$$

where

λ = Thermal conductivity, measured in W/m°K

ρ = Density, measured in kg/m^3

This relation provides a reasonably good fit to published experimental data.[6] The thermal conductivity along the grain is usually taken to be approximately 1.8 times that across the grain. Once the wood has charred, its thermal conductivity changes and can be quantified with the following relation:[6]

$$\lambda = 0.67S - 0.71$$

where

λ = Thermal conductivity, measured in W/m°K

S = Specific gravity of the char, roughly $\rho/1000$, when ρ is measured in kg/m^3

Thermal conductivity of wood in any direction is about one-third greater for moisture content above 30 percent than for drier wood.

The poor thermal conductivity of wood is a significant factor in the notably good performance heavy timber construction provides during a fire. When the exterior surface of a timber is exposed to the heat of a fire, the insulating nature of the wood slows the temperature rise of the core of the timber. Furthermore, the surface of the timber forms a char layer, which improves the *R*-factor of the timber and prevents atmospheric oxygen from penetrating into the timber, where it can support combustion.

The heat capacity of wood is predicted from the following relation:[6]

$$C = \frac{0.1031 + 0.003867T + 4.19M}{1 + M} + (0.02355T - 1.32M - 6.191)M$$

where

C = Heat capacity, measured in kJ/kg°K

M = Moisture content expressed as a fraction of dry weight

T = Temperature measured in °K

Once the wood becomes charred, the heat capacity, *C,* is usually taken to be 1.0, although there is a more precise relationship that expresses the heat capacity as a function of sample temperature:[6]

$$C = 1.39 + 0.00036T$$

where

C = Heat capacity, expressed in units of kJ/kg°K

T = Temperature in °K

Effect of Fire Retardants

Fire-retardant chemicals can be, and frequently are, added or applied to wood and wood-based products. (See Section 6, Chapter 7, "Fire-Retardant and Flame-Resistant Treatment of Cellulosic Materials.") When properly formulated and used, fire-retardant chemicals reduce the combustibility of these products. Depending on the formulations used, flame and surface combustion can be reduced once the outside source of heat is removed. Some fire-retardant treatments (FRTs) may adversely affect the strength of plywood sheathing and structural lumber, causing them to become brittle and to fail prematurely or under loads that one would normally expect them to bear without difficulty. There are a number of theories regarding the mechanism of this loss of strength, including chemical attack on the cellulose fibers in the wood by the fire-retardant chemicals and the high temperatures used to redry FRT plywood and lumber after treatment. Regardless, the impact of the use of fire retardants on the strength of wood members must be addressed when using these materials. Current building codes rightfully recognize the contribution these materials make in improving the fire safety of the structures where they are used and provide for derating to accommodate the possible loss of strength.

Effect of Preservatives

To resist rot and insect damage, many wood products are treated chemically with biocidal materials. These include railroad crossties, utility poles, pilings, landscaping timbers, and exterior dimension stock for decks and other wood structures. These wood products are usually pressure treated with various wood preservatives containing creosote (a mixture of single and conjugated ring aromatic compounds made from coal tar) or pentachlorophenol in solutions of oil similar to diesel or fuel oil, or with water-soluble salt solutions containing arsenic, chromium, copper, or phenol. All of these materials are toxic to humans in varying degrees if ingested or applied directly to the skin. Waterborne salts are usually used to treat dimension decking lumber and plywood, whereas the oil-based preservatives are more commonly used for treating utility poles, railroad ties, and pilings.

These treatments introduce two concerns for the fire protection specialist. First, they can affect the ignitability and burning rates of the treated wood products. Wood products freshly treated with creosote or pentachlorophenol in oil solutions can be more easily ignited because of the presence of the oil vehicle and can be expected to burn with a greater heat output. Second, these treatments introduce toxic chemicals into the wood that

will be released if involved in a fire. These materials can add to the toxicity of the smoke produced from such a fire.

Building Fashions

The prevailing trends in housing design have a significant impact on the types of wood products used in a particular structure. This affects the fire safety considerations for that structure, because the selection of construction materials affects the behavior of the structure in the event of a fire. During the 1970s, due primarily to a desire for a more "natural" appearance in homes and enactment of new legislation designed to encourage conservation and save energy, more external wood materials (wood shingles or siding) were used. In many parts of the country, a return to wood as a primary fuel (burned in fireplaces and stoves) and to log homes with wood shingle roofs created new and often unfamiliar fire risks. The 1980s saw increased use of vinyl-clad fiberboards used for building sidings, and substitution of oriented strandboards (OSBs) or flakeboards for plywood in construction. Use of wood shingles declined with a return to fiberglass and asphalt-derived materials. There has also been a marked increase in the manufacture and use of treated lumber and plywood in construction. More insulation products made from various organic and inorganic materials are now being used, whereas asbestos has been virtually eliminated in sidings and flooring materials. All of these factors have important bearing on the ignitability, fire growth rate, heat output, and structural performance of the building during a fire. However, for each period, there remain today millions of existing buildings reflecting the popular choices of that time.

VARIABLES INFLUENCING COMBUSTIBILITY

Whether one is primarily concerned with mere ignition or with the energies obtained from sustained combustion, there are several factors that consistently enter into the analysis.These include the physical form of the fuel wood, the thermal conductivity of the fuel wood (as discussed earlier), and the moisture content of the wood.

Physical Form

The influence of physical form on the ignition and burning characteristics of wood and wood-based products is illustrated by the fact that wood kindling will flame and burn from relatively small heat sources while heavier wood logs will resist ignition to a considerable degree. Paper is easier to ignite than small pieces of wood. The reason for this is that, as the size of the particle diminishes, the ratio of surface area to volume (mass) increases. Thus there is both greater exposure of fuel to air and less mass to conduct heat away from the particle; consequently, heat does not readily dissipate within the material.

It follows that small, thin forms of wood (such as excelsior), or other combustible solids (such as paper), will burn more readily than larger objects of the same material. This fact is most important when dealing with wood-derived combustible particulate solids. Wood dusts, chips, and shavings represent a serious fire risk, especially when pneumatically conveyed. Very finely divided wood particles, such as sander dust or wood flour (often made from nut shells), are prone to deflagration similar to other carbonaceous dusts. These materials create a serious threat of explosion in the pneumatic conveying and dust collection systems commonly used to handle them. Sawdust, router chips, shavings, and other wood waste are often thought of as less hazardous due to the much larger particle sizes. However, the pneumatic conveying of these particulates causes attrition of the particles, which results in fine dusts capable of undergoing a deflagration. Fires in pneumatic conveying and dust-control systems are a hazard in most wood manufacturing operations due to ignitability and pervasive presence of finely divided wood particulates.

Although paper is considered to be easy to ignite, large compact masses of paper, such as books or cut and packaged stacks of paper, do not burn readily due to charring and limited availability of combustion air in the interior of the mass. Additives such as binders, colorants, and sizes in the paper also serve to inhibit combustion. However, large rolls of paper or paper-based products stacked on end may unwind (exfoliate) during a fire, exposing long, single sheets of paper which are easily ignited and burn readily.

Moisture Content

Ignition and burning tests in the laboratory show that the behavior of combustible solids of the same size, shape, and chemical composition varies markedly depending on the moisture content. In research conducted by the British Department of Scientific and Industrial Research (now the Ministry of Technology), the influence of the moisture content of oak and western red cedar on the time necessary for these woods to ignite was studied; the results are shown in Figure 6.4.5.[7] Radiation intensity in this figure is expressed in terms of the number of calories falling on one square centimeter of the exposed wood in one second, using a test apparatus developed by the ministry.

Once a fire is well under way, the significance of the moisture factor decreases, because the heat radiation and therefore

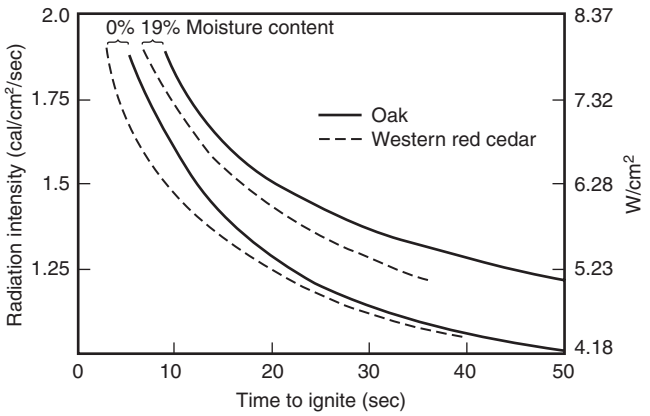

FIGURE 6.4.5 Effect of Moisture Content on the Ignition of Wood

the rate of pyrolysis increases. Under such conditions, even wood with a moisture content of 50 percent or more will burn.[8]

There is a time lag between changes in the fuel moisture content of cellulosic materials and changes in atmospheric humidity. Most solid cellulosic combustibles are not immediately absorptive of airborne water vapor; conversely, the moisture content of most solids will be retained for a longer period of time than air retains its moisture in suspension. Thus, the humidity in the ambient air is not always a reliable index of the moisture content of ordinary combustibles.

IGNITION OF WOOD AND WOOD PRODUCTS

Ignition of Wood

The ignition of a piece of wood is not a simple process; it is quite complex and subject to a number of variables. Furthermore, the process of ignition varies with the heat flux and rate of temperature increase to which the wood is exposed. In the past, different researchers have tried to establish a definitive ignition temperature of wood, each arriving at a different ignition temperature due to the different experimental methods employed. Consequently, no single model or scenario addresses the behavior of wood fuel components in all possible situations.

Babrauskas has performed the most recent review of the literature on ignition temperature and has concluded that, under short-term heating conditions, one should use the figure of 482ºF (250ºC) for the ignition temperature.[9] As the time over which the heat is applied increases, the temperature sufficient to attain eventual ignition decreases. There is one documented case where a steam pipe operating intermittently but repetitively at a temperature of 170ºF (77ºC) over many years eventually led to the ignition of the wooden structural members in contact with the pipe.[10] Indeed, this value is explicitly stipulated in the Building Code of the City of New York.[11] Consequently, one must exercise considerable care when wooden objects are placed in close proximity to heat sources.

The wide range of ignition conditions for wood can be understood when one considers its chemistry. Wood is not a homogeneous material, but a mixture of cellulose, hemicellulose, lignin, various extractives (alcohols, esters, and resins), bound water, and air in a complex cellular structure. As heat is applied to this complex mixture, these constituents undergo reactions that change the chemical makeup of the sample. This process is usually called *pyrolysis.* When one considers the effect of the pyrolysis on the chemical composition of the wood sample, the variability of ignition temperature as a function of heat flux and time is understandable.

Ignition begins with the application of heat of sufficient intensity and power to raise the fuel to a temperature at which pyrolysis begins. It is doubtful that a single temperature for the onset of pyrolysis, irrespective of a time variable, will ever be definitively determined. In all likelihood it will also vary with wood species, just as density varies with species. Numerous studies have been conducted in an effort to determine the conditions required for the onset of combustion reactions and Babrauskas suggests that an activation energy of approximately 125 kJ/mole is appropriate for whole wood such as dimension lumber stock.

The onset and rate of pyrolysis depends on both the temperature and the time frame over which heat is applied. Most studies have been conducted over relatively short time frames. In these short-term tests, as the temperature is raised, the bound water is driven off as water vapor. Evolution of carbon dioxide can also be observed at these temperatures. These products are noncombustible. There are some combustible materials evolved, including the low-molecular-weight extractives, if present, formic acid and acetic acid, that also vaporize and leave the sample as gases at this temperature. However, the heat necessary to drive them off from the sample is greater than the heat that can be derived from their combustion. Consequently, this phase is an energy-consuming (endothermic) phase. The loss of water from the sample is largely reversible if the sample is allowed to cool. But the loss of the low-molecular-weight alcohols, esters, and resins is not. The sample is permanently altered and subsequent heating will advance the reactions further. The outward manifestation of these changes is a gradual change in color from light to brown to black. These changes can occur from exposures to temperature ranging upward from 199°F (93°C).[12] One study showed that higher humidity during heating increased the extent of the charring.[12]

The studies of the behavior of wood between 212°F (100°C) and 424°F (200°C) show the development of a char with lower temperatures being sufficient if applied for longer periods of time and higher temperatures producing char layers in shorter exposure times. If a wood sample is raised to a temperature of 572°F (300°C) it will be charred regardless of the time frame.[12] By the time the sample has reached this temperature, the majority of the water has been driven off. The principal pyrolytic product is carbon monoxide. Whether the wood sample ignites in flaming mode combustion or burns as a glowing ember is determined largely by the rate at which the flammable carbon monoxide, alcohols, esters, and resins are driven off from the sample. If the sample is heated slowly, the concentration of flammable gases might never achieve sufficient concentration in the air surrounding the sample to support a flame. The sample will burn as a char as the pyrolysis reactions are exothermic once this temperature region has been attained. If the sample is brought to this temperature more quickly, the volatile component will be of sufficient concentration to produce a flame. As the temperature exceeds 572°F (300°C), the chemical reactions yield sufficient volatilized combustible chemical species to support flaming combustion.

When the heating is provided by an existing flame, it is called *piloted ignition.* Piloted ignition brings the wood sample up to the combustion temperature of the flame source very rapidly and yields fairly consistent ignition temperatures. For most tests, the range from 572°F (300°C) to 662°F (350°C) encompasses the piloted ignition temperature.[12] One research source concludes the piloted ignition temperature ranges from 572 to 592°F (300 to 311°C) for hardwoods and 660 to 687°F (349 to 364°C) for softwoods.[12]

Ease of ignition is related to the ignition temperature and the radiant power necessary to raise the temperature of a sample

to that temperature. It would take far more energy to reach the ignition temperature if wood were a better conductor of heat. The insulating qualities of wood are critical, allowing attainment of ignition temperatures with relatively small quantities of ignition energy. This is especially important in cases where spontaneous ignition is suspected.

Ignition from radiant flux has been studied. The flux sufficient to cause ignition varies not only with the species, moisture content, and time of exposure, but also grain orientation. A value of 12.5 kW/m^2 has been used for the minimum radiant flux sufficient to cause ignition.[13] But after surveying the published research, Babrauskas suggests using 20 kW/m^2 for short-term exposures and 4.3 kW/m^2 for long-term exposures.[12]

Spontaneous Heating and Ignition

Although coal and other organic materials have a reputation for "self-heating" and "self-igniting," there is little evidence to support the claims of self-ignition of wood products where those products have been stored at normal room temperatures. In general, wood, wood-based products, and cellulosic materials that are clean and dry will not self-heat and spontaneously ignite unless the temperature of the pile or mass of wood particulate has been raised by some external heat source. Normally a spark, open flame, contact with hot surfaces, or exposure to some other thermal radiator is necessary in order to raise the temperature of the wood to the point where pyrolysis begins. Once pyrolysis has begun, the chemical reactivity of the pyrolized wood can lead to self-heating. If this heat cannot escape it is possible to attain the ignition temperatures of wood-based fuels. In those episodes where it has appeared that wood products did ignite spontaneously, there were polymerizing resins involved that provided the exothermic reaction necessary to heat the wood to the temperature at which pyrolysis begins. Babrauskas has studied the phenomenon of self-heating and spontaneous ignition extensively and those cases where the process did occur the temperature of the material was always above 122°F (50°C).[12]

It has been shown that cellulosic materials contaminated with certain drying oils (e.g., linseed oil, tung oil, and turpentine) can self-heat when stored in unventilated spaces. The actual source of the heat is the exothermic chemical reactions involving the oils. In such cases if self-heating is allowed to continue, exothermic pyrolysis can be achieved and ignition can result.

Similarly, external heating can raise certain wood-based materials to a temperature where the exothermic pyrolytic reactions begin. Once this temperature is achieved, the material can then self-heat as long as the conditions are conducive to the retention of the heat generated by the pyrolysis. For example, if wood fiberboards are not subjected to a direct, artificial heat source either during manufacture or when installed in structures, they will not heat spontaneously. On the other hand, heating such fiberboards at relatively moderate temperatures can initiate an exothermic reaction leading to their ignition.

Wood and wood-based products are generally not susceptible to the same type of self-heating from microbiological action that is prevalent in certain agricultural products.

COMBUSTION OF WOOD AND WOOD-BASED MATERIALS

The factors that affect the ignitability of wood are also important factors governing the combustion of wood. The moisture content is an important factor in determining the heat output of a given sample and, hence, the heat available to perpetuate the fire. Likewise, the chemical composition is an important determinant of the combustion of a sample. Some chemical additives will reduce the heat output and yield a less violent flame, whereas other additives may actually increase the heat content of the fuel. Finally, the resin content of the fuel is important.

Wood smoke has a characteristic odor. It is bluish or dark when the wood is green or wet and low temperature or insufficient air is present, but with high temperature and excess air, the smoke is often almost invisible. This can be used to infer the range of size for the particulates that make up the smoke. Since particulates diffract light that is of a wavelength shorter than the particle diameter, the bluish smoke implies smoke particulates with an average diameter of approximately 0.4 microns, the wavelength of blue light. As the efficiency of combustion is improved, the particle diameters become even smaller resulting in "invisible" smoke. Burning wood produces smoke containing glowing particles and large amounts of gray ash. Wood burned under conditions of incomplete combustion in which little or no air is present produces charcoal, carbon monoxide, and a number of condensible yet combustible vapors which are called, in the aggregate, *creosote.*

Availability of Air

An adequate amount of air (oxygen) is essential for the complete combustion of celluslosic materials, regardless of physical form. It is generally accepted that 13,100 kJ of heat is released for each kilogram of oxygen consumed (5.6 Btu per pound of oxygen).[13] Since air is approximately 23 percent oxygen by weight, a heat release of approximately 3030 kJ is produced for each kilogram of air consumed by the fire (i.e., 1.3 Btu per pound of air). These values form the basis for oxygen consumption calorimetry that is used to measure the heat release of a wide variety of fuels.[14] The nominal heat of combustion for wood is about 18,600 kJ per kg (8000 Btu per lb).[13] Using a value of 1.19 kg/m^3 (0.07 lb/ft^3) for the density of air at 20°C (68°F), it can be shown that about 5.2 m^3 (83.5 ft^3) of air is required for the complete combustion of each kilogram (pound) of cellulosic fuel.[15]

When the fire is underventilated, destructive distillates are formed as the cellulose molecule decomposes due to the heat of the fire. These include carbon monoxide, formic acid, formaldehyde and other aldehydes, ketones, and carboxylic acids. All of these compounds are combustible and can deflagrate when exposed to a source of fresh air. This is a serious concern for firefighters that should not be overlooked.

The residue remaining after a fire can provide some insight into the combustion processes of that fire. The products of combustion and the residues remaining after combustion vary according to the degree of ventilation. When excess is available to a wood fire, the solid residue remaining after combustion is a light gray ash. When the residue is a black charcoal, it suggests

that the fire was underventilated or that it was extinguished before combustion was completed.

Rate of Combustion

Because the combustion of wood and wood products is a surface phenomenon, the rate of combustion can be influenced by the physical state and orientation of the fuel and any factor affecting the availability of combustion air. Increasing the volume of air available to the fire, regardless of the means used, accelerates the rate of combustion until the air velocity reaches a point where it begins diluting the pyrolysis gas concentration in air to levels below that necessary for optimum combustion efficiency. Then airflow becomes excessive and the air begins acting as a heat transfer fluid, robbing the fire of the heat needed to continue the pyrolysis necessary to maintain the supply of gaseous distillates that fuel the flame. If the air supply velocity is further increased, the volume of air may exceed the ability of the fuel mass to supply sufficient gaseous distillates, and the flame ceases. The combustion will continue but in a solid phase, evidenced by the glowing surface of the fuel, rather than the gaseous phase evidenced by the flame.

In most freely ventilated fires involving combustible solids, once ignition is achieved, the fire follows the t^2 growth curve until the entire surface of the fuel is involved. Once there is total surface involvement, the rate of combustion remains essentially constant until a limitation in fuel or combustion air is encountered. The rate of combustion is significantly influenced by the physical form of the combustible, the air supply present, the moisture content, and allied factors; but there is the fundamental need for progressive vaporization of the solid by heat exposure for combustion to proceed.

Speed of Flame Propagation

Speed of flame propagation over the surface of a combustible critically affects the severity of a fire in many cases. The 1959 Los Angeles School Fire Tests[16] showed that, under controlled test conditions, flames spread over combustible surfaces with such speed that observers had to flee the sudden release of heat and flame. In 1949, the British Department of Scientific and Industrial Research conducted full-scale dwelling fire tests on the influence of combustible wallboard versus the use of plaster finish.[17] The record of the British tests graphically illustrates the observed time-temperature curves in the living rooms of the two houses tested. Originating in an easy chair in the living room, the fires in their initial stages were identical in both dwellings. The loading of combustible materials was roughly proportional to the loadings observed in occupied dwellings in England. It should be noted that, in the United States and Canada, earlier ignition and faster flame spread on the combustible surfaces could be expected, since winter heating in these countries results in lower relative humidities and, thus, lower moisture content of the combustibles.

Currently, the comparative assessment of flame spread characteristics of building materials is performed per ASTM E84 (NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Burning Materials*) using the Steiner Test Tunnel.[18] Red oak was originally used as a reference standard to establish the performance rating equal to 100. Today the test method is referenced to specific performance parameters on a noncombustible surface. Nevertheless, red oak still achieves a rating of approximately 100, and most other wood species fall into the range between 90 and 160. Flame spread indexes for selected wood species are listed in Table 6.4.2.

Fire Resistance

The fire resistance behavior of wood panels has been reviewed using the ASTM E119 (NFPA 251, *Standard Methods of Tests of Fire Resistance of Building Construction and Materials*) test apparatus and procedure.[19] When wood panels are exposed to this test, surface ignition occurs in approximately 2 minutes.[20] Charring proceeds at a rate dependent upon the species and moisture content. However, the average char rate is approximately 1/30 in. (0.85 mm) per minute for the next 8 minutes. The insulating effect of the char layer slows the subsequent char rate to approximately 1/40 in. (0.63 mm) per minute. ASTM E119[19] test data has yielded a set of empirical relationships for predicting the rate of char in the direction transverse to the grain of the wood.[20]

TABLE 6.4.2 Flame Spread Indexes for Selected Wood Species, 1 in. (25.4 mm) Nominal Solid Dimension Lumber[20]

Species	*Flame Spread Index*	*Source*
Bald cypress	145–150	UL
Eastern red cedar	110	HUD/FHA
Alaska yellow cedar	78	CWC
Western red cedar	70	HPMA
Douglas fir	70–100	UL
Western hemlock	60–75	UL
Western white pine	75, 72	UL, HPMA
Eastern white pine	120–215, 85	UL, CWC
Lodgepole pine	65–110	CWC
Ponderosa pine	105–230	UL
Red pine	142	CWC
Southern yellow pine	130–195	UL
Redwood	70	UL
Eastern white spruce	65	CWC, UL
Sitka spruce	100	UL
Yellow birch	105–110	UL
Cottonwood	115	UL
White (sugar) maple	104	CWC
Red oak	100	UL
White oak	100	UL
Sweetgum	140–155	UL
Walnut	130–140	UL
Yellow poplar	170–185	UL

Note: Flame spread ratings developed for virtually all wood-based panel products are based upon ASTM E84, UL 723, or NFPA 255 flame spread rating tests, using the Steiner Test Tunnel.
CWC = Canadian Wood Council.
HPMA = Hardwood Plywood Manufacturers Association.
HUD/FHA = U.S. Dept. of Housing and Urban Development.
UL = Underwriters Laboratories Inc.

For Douglas fir, $R = 1/(57.4 + 1.16M)\rho + 8.4]$

For southern yellow pine, $R = 1/[(11.7 + 0.24M)\rho + 25.7]$

For white oak, $R = 1/[(40.1 + 0.81M)\rho + 15.0]$

where

R = Rate of char (in./min)

M = Moisture content in percent

ρ = Dry specific gravity

(For SI units: 1 in. = 25.4 mm)

Table 6.4.3 lists the burn-through rates for vertically fire-exposed wood panels of 1.0-in. (25.4-mm) thickness, under the ASTM E119[19] (NFPA 251) fire exposure test method. The specific gravity and rate are for samples at moisture content of 6.0 percent.

The temperature at the base of the char layer is usually in the neighborhood of 550°F (287°C), whereas ¼ in (6.3 mm) beneath the char the temperature is approximately 360°F (182°C).[20] This steep temperature gradient is typical of most wood species and demonstrates the insulating effect of the char layer. This allows wood structural members to retain their load-bearing capacity during a fire until the charring has reduced the residual cross-section of the member below the minimum necessary for the design load.

Heat Release and Heat Release Rate

The heat release rate of wood and wood-based fuels becomes an important consideration when analyzing the behavior of a space under fire conditions. The heat release per unit of mass and the quantity of material present predict the total heat release rate attainable and, hence, the potential for flashover.[21]

The heat of combustion of most species of wood falls within the range of 8000 to 12,000 Btu per lb (18,600 to 27,900 kJ/kg).[20] Under fire conditions, the heat release rate of the wood component of the fuel load depends on the incident radiant flux, moisture content, thickness, orientation, boundary conditions at the rear face, and the oxygen concentration of the ambient air. It is also a function of time, characterized by an early peak followed by a slow decay until flaming ceases. A second peak will also occur if the rear face of the specimen is insulated.

Heat release rates are determined with the ASTM E906 test method, which defines the conditions precisely.[22] For an oven-dry vertical pine board of nominal 1 in. (25.4 mm) thickness exposed to a thermal radiation level of 60 kW/m^2 in normal air with the rear face exposed to a water-cooled plate, a peak heat release rate of 250 kW/m^2 in 19 minutes was reached when the flame went out.[23] A series of wood products with moisture contents of about 8 percent exhibited peak heat release rates between 90 and 170 kW/m^2 under the same conditions. The heat release rate of wood products increases linearly with the density.[24] The total heat release rate of the materials of construction and furnishings is an important factor in determining whether a room will reach flashover conditions.[25]

Table 6.4.4 shows some figures for the heats released by various wood products and also gives comparative figures for some other materials. It should be noted that the heat of combustion of most dry wood products is less per pound (kg) than that of the other fuels listed. The trend of replacing wood furnishings with furnishings made of plastics actually increases the fire load per unit weight. This is an important factor when estimating the quantity of combustible materials exposed to a fire scenario. Such estimates must be adjusted for the nature of the combustibles when determining the needed fire resistance of structural elements or the optimum quantity of water required per unit of floor area for sprinkler discharge.

TABLE 6.4.3 ASTM E119 Fire Resistance Data for Selected Woods

Species	*Specific Gravity*	Rate *(in./hr)*	Rate *mm/hr*
Bald cypress	0.44	1.7	43.2
Basswood	0.42	2.4	61.0
Yellow birch	0.63	2.0	50.8
Chestnut	0.45	1.7	43.2
Douglas fir	0.45	1.6	40.6
Eastern hemlock	0.40	1.6	40.6
White (sugar) maple	0.64	2.1	53.3
Northern red oak	0.61	1.8	45.7
White oak	0.67	1.5	38.1
Eastern white pine	0.39	1.6	40.6
Ponderosa pine	0.42	2.1	53.3
Southern yellow pine	0.55	2.2	55.9
Sugar pine	0.32	2.0	50.8
Redwood	0.38	1.6	40.6
Sitka spruce	0.43	1.7	43.2
Sweetgum-sapwood	0.55	2.4	61.0
Sweetgum-heartwood	0.52	1.6	40.6
Yellow poplar	0.44	2.1	53.3

TABLE 6.4.4 Heat of Combustion of Various Wood and Wood-Based Products and Comparative Substances

Substance	Heating Value *Btu per lb*	Heating Value *kJ/kg*
Wood sawdust (oak)	8,493*	19,755
Wood sawdust (pine)	9,676*	22,506
Wood shavings	8,248*	19,185
Wood bark (fir)	9,496*	51,376
Corrugated fiber carton	5,970*	13,866
Newspaper	7,883*	18,336
Wrapping paper	7,106*	16,529
Petroleum coke	15,800	36,751
Asphalt	17,158	39,910
Oil (cottonseed)	17,100	39,775
Oil (paraffin)	17,640	41,031

*Dry.

The amount of fuel contributed by one combustible versus another, or different forms of the same combustible, can also be used to evaluate the desirability of utilizing the material in a given situation. This is particularly true for measuring the fuel contributed by certain forms of building materials.

Engineered Wood-Composite Products

Engineered wood-composite products include laminated veneer lumber, glu-lam beams, composite/wood joists and beams, and other wood-composite materials, such as oriented strandboard (OSB), flakeboard, medium density fiberboard (MDF), and particleboard. The use of engineered wood-composite materials facilitates the production of lightweight structural components, such as composite/wood joists and beams, with substantially reduced mass and cross-sectional area. For example, composite/wood joists and beams provide superior structural strength with reduced mass, allowing greater design flexibility and economy. There may be occasions where these engineered wood-composite products behave very differently than their primary wood precursers (Figure 6.4.6).

The introduction of glues and resins into the structural materials changes the chemistry of those materials. The relatively simple combustion chemistry of cellulose is complicated by the presence of petroleum-derived plastic resins, some of which may contain aromatic rings, halogens, epoxies, and other unsaturated hydrocarbon constituents. This affects heat output, flame spread rate, smoke composition, and smoke density during a fire involving these materials.

The more serious concern is the structural performance of engineered wood products, especially composite/wood joists and beams, under exposure to a fire. The reduced cross-sectional area of a composite/wood joist or beam provides a larger surface area for a given mass (weight) of material. Since both pyrolysis and combustion are surface phenomena, the increased surface area provides for a more rapid consumption of the fuel. As a result, the engineered wood-composite components burn faster than their solid, sawn lumber equivalents[26] (Figure 6.4.7).

The elevated rate of combustion on a mass consumed per unit time basis would predict earlier structural failure of a building supported by composite/wood components than one constructed of equivalent solid sawn lumber. However, there is the additional factor of the engineered distribution of mass in the composite/wood component. The mass of the composite/wood beam is concentrated in those areas where it is structurally significant, resulting in a cross section similar to an I-beam. This places the web and top flange in compression, and the bottom flange in tension (Figure 6.4.8). As the wood-composite material begins to char, the pyrolysis of the wood fibers leads to a more rapid deterioration of the structural properties than one encounters with dimension sawn lumber of equivalent design capacity. This effect combined with the greater rate of combustion due to the increased surface area and the greater heat release rate due to the petroleum-derived resins can create an expectation of earlier-than-expected failure of structures during fires.

When engineered wood-composite components were first introduced, there were also concerns that the heat of a fire might cause the adhesives to soften, allowing the component to fail. This notion might have come from anecdotal experience with casein adhesives. This does not seem to be the case with current wood-composite components using modern phenolic thermoset resins. The available research has not identified structural failures that are attributable to adhesive/resin failure.[26]

The Fire Protection Research Foundation has been instrumental in the investigation of these questions.[26] As the use of

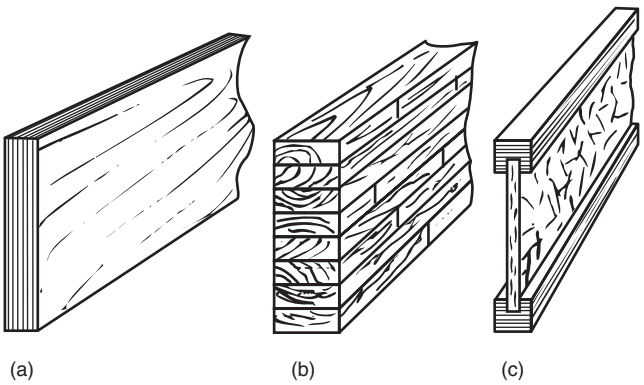

FIGURE 6.4.6 (a) Laminated Veneer Lumber; (b) Glu-Lam Beam; and (c) Composite Wood Joist

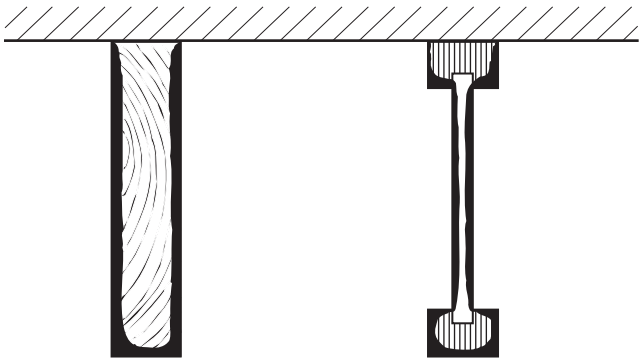

FIGURE 6.4.7 Charring of a Composite/Wood Joist (Right) Compared with a Sawn Joist (Left) After the Same Fire Exposure

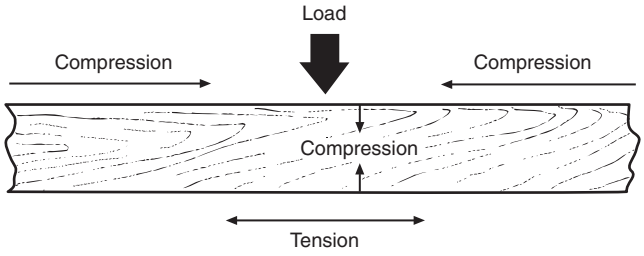

FIGURE 6.4.8 Orientation of Load Forces on a Beam or Joist

composite/wood beams and joists continues, the fire service will probably find it necessary to rethink the length of time a structure can be involved before it is deemed structurally unsafe for interior fire fighting.

The implications of the use of engineered lightweight construction components on the fire safety and fire endurance of structures continues to be an area of research. As wood has become more expensive and as structural engineers continue to make structures more efficient and lighter in weight, lightweight wood trusses may become more common. This demands that their behavior in a fire be better understood.

A solid sawn lumber joist or beam endures both compression and tension stresses under design loads, as shown in Figure 6.4.8. Since the mechanical properties of wood vary with the orientation of the stress to the grain of the wood fibers, greater stresses can be supported by an engineered wood assembly of less weight if the orientation of the grain of the wood fibers is "adjusted" to employ the wood in an orientation relative to the applied stress, which takes maximum advantage of its mechanical properties. This approach yields a structure shown in Figure 6.4.9.

These lightweight assemblies have two features that are considered important. First, the surface area-to-mass ratio of the lightweight truss assembly is much greater than that of the solid sawn plank. Since burning rate is proportional to the surface area, this could mean that the lightweight truss assembly will fail sooner under fire conditions. Second, lightweight truss assemblies are assembled from individual members that are attached to each other with steel gusset plates. There is currently some concern that the transmission of heat through the steel gusset plate will accelerate charring beneath the plate, leading to early failure of the attachment. Since the loss of an attachment threatens the load-bearing capacity of the entire truss, this could provide a mechanism for premature failure of a roof supported by lightweight truss assemblies.[27]

The Fire Protection Research Foundation has been the coordinator of research into these questions. There is considerable research yet to be conducted to develop the answers addressing the above concerns.[27]

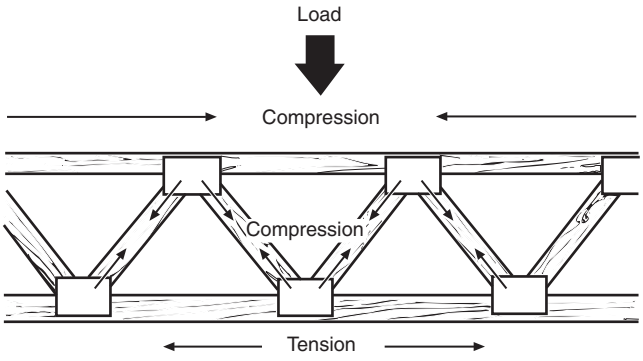

FIGURE 6.4.9 Stresses in the Lightweight Wood Truss Assembly, with Both Compression and Tension Stresses Oriented Along the Wood Grain

SUMMARY

Wood is, by its very nature, a nonuniform and variable material. Its chemistry and internal structure give it mechanical properties that we rely on to produce a wide range of products and structures. However, that same chemistry demands that water play an important role in the behavior of wood, both from a structural point of view and from the point of view of the fire protection engineer.

Unless green wood is involved, moisture content will have limited effect on the ignition temperature and heat release from combustion. Again, unless green wood is involved, the ignition of wood can be modeled as a four-phase process, beginning with drying, progressing to endothermic pyrolysis, then to exothermic pyrolysis, and culminating in flaming combustion. There is some concern, however, that this simple progressive model might not be appropriate when heating occurs at lower temperatures over very long time frames.

The fire protection engineer must be mindful of the effect a working fire can have on wooden structural components. Although it is well known that heavy timber construction provides considerable fire endurance due to char formation, the recent trends in construction, including the use of lightweight wood trusses and light-weight engineered wood beams, necessitates a reassessment of the fire endurance of structures where lightweight components are used. The surface combustion behavior of wood components predicts a loss of structural strength in earlier stages of a fire than would be expected if traditional sawn beams were used. How much earlier has not yet been quantified.

Consequently, despite the fact that wood has been humanity's first choice in structural materials for shelter and implements, there remains much to be learned from this most wonderful of materials.

Chapter 5

Fibers and Textiles

Jeffrey O. Stull ■ Salvatore A. Chines

Chapter Contents

Fibers
Textile Manufacturing
Textile Combustibility
Flame-Retardant Treatments
Relationship of Flammability and End Use
Textile Flammability Tests
Textiles in Special Environments

Key Terms

cellulosic fiber, combustible fiber, flame-retardant fibers, flammable fabric, Flammable Fabrics Act, limiting oxygen index, manufactured fiber, oxygen-enriched atmosphere, protective clothing

Fibers and textiles are an integral part of daily life. Clothing, furniture, carpets, and curtains are examples of textile materials produced with fibers. Almost all fibers are combustible. This characteristic results in problems when the fibers are manufactured, while they are stored, while they are made into fabrics, while they are collected as waste, and while they are worn as apparel or used as furnishings. Fiber combustibility combined with the prevalence of textile products explains the frequency of textile-related fires and the many deaths and injuries that result.

This chapter discusses commonly used fibers and textiles, their manufacturing, combustibility, end use, and fire-retardant treatments. Also detailed in this chapter are special environments where textiles are used and the testing methods employed in evaluating and creating standards for the use of fibers and textiles.

More information can be found elsewhere in this handbook, especially in the following chapters: Section 6, Chapter 6, "Upholstered Furniture and Mattresses"; Section 6, Chapter 11, "Medical Gases"; Section 9, Chapter 17, "Oxygen-Enriched Atmospheres"; Section 12, Chapter 9, "Fire and Emergency Services Protective Clothing and Protective Equipment"; and Section 18, Chapter 2, "Interior Finish."

FIBERS

Role of Fibers in Fires

Studies of fatal fires continue to show that textiles provide the initial fuel for the largest share of fatal structure fires, typically 40 percent or more (Table 6.5.1). These fires also typically accounted for one-sixth of structure fire incidents. There has been no clear trend in shares of fires and deaths, but the trends for the totals have been clearly and significantly down. Many fires start with the ignition of textile products then rapidly involve other combustibles, such as foam plastics used as filling materials in textile-covered upholstered furniture.

Table 6.5.2 shows the types of *fabric or textile* ranked by number of fires, number of civilian deaths, and dollars of direct property damage occurring in structure fires, where the fabric or textile was the material first ignited; the data are for 1994 through 1998. Table 6.5.3 presents data for 1999 through 2003 and includes civilian injuries. The differences between the tables are the result of different data definitions in Versions 4.1 and 5.0 of the National Fire Incident Reporting System (NFIRS). Chapters 3 and 4 of Section 3 contain additional information about NFIRS.

Table 6.5.4 shows the types of *product* (composed wholly or partly of fabric or textile) ranked by number of fires, number of civilian deaths, and dollars of direct property damage for structure fires, where the product was the first item ignited, for the years 1994 through 1998. Table 6.5.5 shows basically the same information for the years 1999 through 2003, but also includes civilian injuries. Again, the differences between the presentations of the two sets of data have to do with different data definitions between Versions 4.1 and 5.0 of NFIRS.

Fibers are the basic components of all textiles and may be either natural or manufactured. Natural fiber sources include cellulosic, protein, and mineral fibers. Cellulosic fibers come from a

Jeffrey O. Stull is president of International Personnel Protection, Inc., in Austin, Texas.

Salvatore A. Chines, P.E., is textile engineer, research consultant with Industrial Risk Insurers, a GE company in Hartford, Connecticut.

TABLE 6.5.1 Structure Fires with Fabrics or Textiles as the Type of Material First Ignited, by Year Based on Data Collected in NFIRS Version 5.0 Only

Year	Fires	Percentage of All Fires	Percentage of All Nonconfined Fires	Civilian Deaths	Percentage of All Deaths	Civilian Injuries	Percentage of All Injuries	Direct Property Damage (in Millions of Dollars)		Percentage of All Damage
								As Reported	In 2003 Dollars	
1980	186,100	(17%)		2670	(47%)	8090	(33%)	831	1855	(15%)
1981	173,800	(17%)		2830	(49%)	8220	(32%)	795	1604	(13%)
1982	148,900	(16%)		2350	(45%)	7980	(31%)	634	1207	(11%)
1983	132,500	(15%)		1980	(39%)	7990	(31%)	765	1410	(13%)
1984	130,100	(15%)		2020	(45%)	6960	(30%)	777	1373	(13%)
1985	129,200	(15%)		2220	(42%)	7030	(30%)	830	1416	(13%)
1986	123,200	(15%)		2060	(41%)	6720	(30%)	837	1404	(14%)
1987	116,300	(15%)		1970	(40%)	7070	(30%)	776	1255	(12%)
1988	112,600	(15%)		2320	(44%)	7920	(30%)	911	1417	(13%)
1989	104,100	(15%)		1950	(42%)	7430	(31%)	842	1248	(11%)
1990	97,000	(16%)		1740	(40%)	7010	(29%)	917	1291	(14%)
1991	99,200	(15%)		1550	(41%)	7560	(30%)	1157	1561	(14%)
1992	98,100	(15%)		1670	(42%)	7490	(31%)	891	1168	(13%)
1993	96,400	(16%)		1580	(40%)	8010	(30%)	1050	1336	(14%)
1994	94,400	(15%)		1510	(42%)	7280	(31%)	987	1225	(14%)
1995	89,300	(16%)		1650	(41%)	6500	(30%)	1076	1297	(14%)
1996	90,700	(16%)		1760	(42%)	6640	(30%)	1074	1259	(14%)
1997	85,600	(16%)		1550	(44%)	6170	(30%)	1063	1217	(15%)
1998	82,800	(16%)		1360	(40%)	5840	(30%)	1019	1150	(15%)
1999	94,300	(18%)	*(18%)*	1370	(45%)	6440	(35%)	1375	1517	(16%)
2000	89,500	(18%)	*(19%)*	1740	(49%)	5910	(30%)	1483	1584	(17%)
2001	82,100	(16%)	*(19%)*	1620	(50%)	5340	(31%)	1431	1486	(16%)
2002	72,600	(14%)	*(19%)*	1290	(47%)	4410	(28%)	1468	1501	(17%)
2003	63,100	(12%)	*(18%)*	1660	(49%)	4650	(30%)	1463	1463	(17%)

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest hundred, civilian deaths and injuries to the nearest ten, and direct property damage is rounded to the nearest million. Sums may not equal totals due to rounding errors. This table includes a proportional share of structure fires in which the type of material first ignited was unknown or not reported when it should have been. Estimates for 1999–2003 are based on nonconfined structure fires collected originally in NFIRS Version 5.0 only. Italicized figures show percents of nonconfined structure fires these years; nonitalicized percents are based on total structure fires and losses.

"Nonconfined" means the fire is *not* one of several categories (e.g., cooking, chimney, heating appliance, or trash) that are considered "confined" and for which causal information is not routinely collected.

variety of plants, the most common being cotton. Protein fibers come from a variety of animal hairs. Mineral fibers include mineral wool and fiberglass. Manufactured fibers are produced by chemical processes. All fibers come in a variety of lengths. Although natural fiber length can be slightly manipulated genetically, manufactured fiber can be produced in any length desired.

Natural Fibers

The most common cellulosic fiber used in textile manufacture is cotton, which consists of more than 90 percent cellulose $(C_6H_{10}O_5)_x$. Other plant fibers, such as jute, flax (linen), hemp, and sisal, are primarily cellulosic in composition. Cellulosic fibers are combustible; the ignition temperature of cotton fiber is 752°F (400°C). When ignited, these fibers produce heat, smoke, carbon dioxide, carbon monoxide, water, and numerous other organic compounds. Plant fibers char but do not melt. Many cellulosic fibers are hollow; thus, each fiber has its own air supply. This allows fire to burrow deeply into bales.

Protein fibers, such as silk, wool, and other hair fibers derived from animals, are chemically different from cellulosics because they consist of complex protein molecules containing high percentages of nitrogen as well as carbon, hydrogen, oxygen, and small amounts of sulfur. Wool, for example, supports combustion only with difficulty and, other factors being equal, is more difficult to ignite, burns more slowly, and is easier to extinguish than cotton. This is seen in wool's small share of the

fire problem, as evidenced in Table 6.5.2, although the data may also reflect a smaller share of total fabric in use for wool versus cotton and manufactured fibers.

Manufactured Fibers

Manufactured fibers are produced by processing liquids through small holes (spinnerets) and allowing the emerging filaments to be immersed in a coagulating medium. Spinneret orifices generally range from 0.002 to 0.005 in. (0.05 to 0.13 mm) in diameter. Most spinnerets are made of iridium and platinum. The resulting fibers can be used as "filament yarns" or can be cut into shorter lengths and spun into "staple yarns." Staple yarns can contain more than one type of fiber, for example, blends of polyester and cotton. In this way, different textile properties can be attained by blending different fibers.

Manufactured fibers can be divided into two groups: (1) "regenerated" or "reconstituted" fibers and (2) fully synthetic fibers. The major regenerated fiber in use today is viscose rayon. Rayon is made from dissolved cellulose and is similar to cotton in its charring and burning properties. Acetate is made by the reaction of cellulose and acetic acid; it melts before burning. Its burning characteristics are more like thermoplastic fibers (nylon, olefin, and polyester) than cellulose.

The major fully synthetic fibers are acrylics (which char, intumesce, and burn when exposed to heat) and the thermoplastic fibers, such as nylon, olefin (including polypropylene and the less popular polyethylene fibers), and polyester. There are also glass, metallic, and carbon fibers. Acrylics and nylon contain nitrogen atoms and, like wool, produce hydrogen cyanide when burned. The thermoplastics do not char but shrink away from heat sources and melt, form holes near the heat source, and/or ablate, absorbing the thermal energy and degrading the product at the same time. If such fabrics burn, the upward flame spread tends to be slow. Molten polymer runs downward, moving the flames sideways and downward, or forms drops that may or may not flame. Compared to fabrics containing cellulose, thermoplastics are generally more difficult to ignite and the flames tend to cover smaller areas, travel more slowly, or self-extinguish, depending on the nature of the specific fiber. Glass, metal, and carbon fibers have relatively high heat resistance and do not ignite.

TEXTILE MANUFACTURING

All yarn manufacturing innovations during the past 20 years have been to increase productivity and reduce labor cost. Better control and testing of fiber properties using computers has resulted in higher quality products with greater consistency. Fiber frequency distributions of the cotton bale population establish better processing schemes. Cotton bales are selected for a proper mix using a number of blending algorithms that meet different blending strategies. A consistent fiber profile fed to the textile process will produce a consistent yarn quality. Fiber information is available from the USDA's regional classing offices and other sources of data. The impact of fiber selection and blending can be witnessed in all areas of the textile process and in the quality of the end product.

Many fibers are spun into yarns and then woven or knitted into a variety of fabrics, for example, plain or patterned fabrics, or pile, such as flannels, terry cloth towels, artificial furs, and carpets. Fibers also can be processed directly into useful structures, such as nonwoven fabrics or battings. Fabrics are usually scoured, bleached, dyed, and/or finished with chemicals that give them a stiffer or softer feel, permanent press characteristics, luster, or flame or weather resistance.[1]

Figure 6.5.1 shows the steps in manufacturing woven cotton and cotton blend materials. Additional details for the manufacture of cotton fabrics, along with their respective hazards, are provided in the succeeding paragraphs. Many of these steps apply to other types of fabrics.

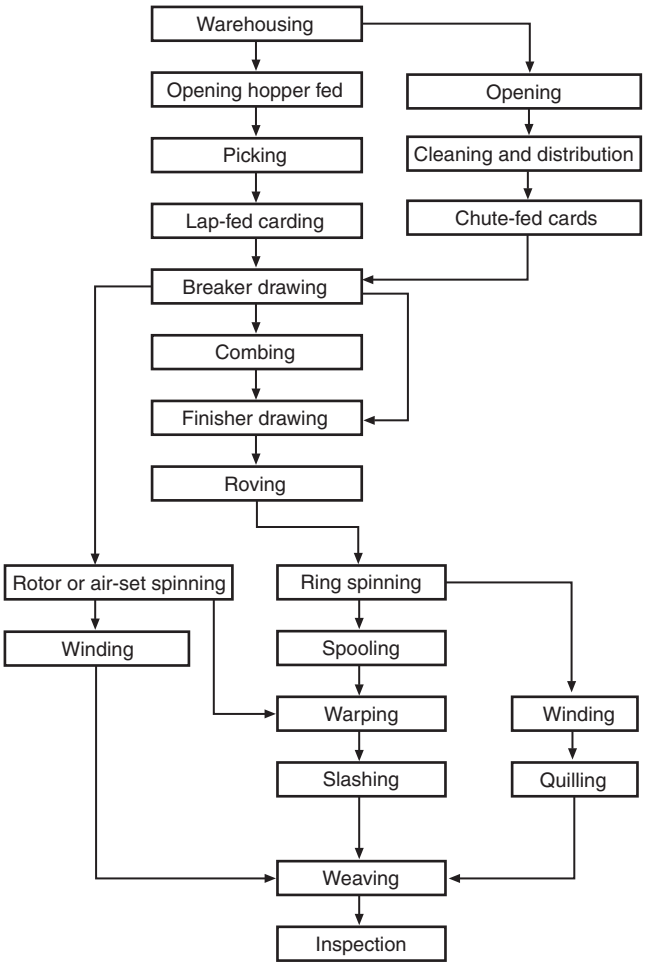

FIGURE 6.5.1 Cotton and Cotton Blend Woven Material Manufacturing

Opening, Picking, Cleaning, and Blending

Cotton received from the gin arrives in bales tightly matted and highly compressed. Debris in the form of dirt, leaf matter, grass, stones, baling wire, machine dust from the ginning process, and tool parts from the handling process can be present. When bales of cotton are brought from the warehouses into the opening rooms, bale ties and coverings are removed and bales are allowed to sit for several hours until they reach room temperature and adjust to the humidity of the area. To ensure uniformity in the end product, cotton must be blended from several bales to make the size, length, and color of the cotton as uniform as possible. This blending process, starting with opening, continues through most processing operations. Opening machinery loosens and separates the cotton into tufts, so it can be effectively cleaned and further processed.

Removing impurities, short fibers, and "dust" from the cotton fiber is essential to ensure product quality and to allow the use of high-speed spinning machines. The cleaning operations are performed pneumatically and mechanically, while the fibers are further separated by spiked and saw-toothed rollers. The dust and light impurities are sucked away, while heavy waste is removed by inertial traps. The efficiency and high speeds of these cleaning machines critically depend on the airflow within the equipment and within the dust-removal system.

In the chute-feed system, bales are automatically fed into openers connected to various mixers and blenders. The material is then air-driven through ductwork to the carding process, where card lines are fed from individual mixers/reserve hoppers. Usually, hand-fed waste-opener hoppers reintroduce usable waste to the process.

These chute-fed card systems could easily transport fires throughout the entire process, particularly with the high speed of the equipment. Causes of fires in these processes include foreign material in the stock being processed, friction, and defective electrical equipment. Fire in cotton can spread fast and flash over an entire group of open bales before it can be extinguished. Tramp metal in the cotton is a notable cause of fires in opener and picker rooms. The development of strong and reliable permanent magnets in the 1940s brought about the use of magnetic separators, which significantly contributed to reducing the risk of fire caused by foreign materials. Magnets, however, are not the complete answer to the problem. Nonferrous objects, such as stones, can still produce sparks if they strike any rapidly moving steel part of the opening or cleaning machinery. Gravity traps, which use gravity and inertia to separate heavy foreign materials from the cotton, can be strategically installed to remove these foreign materials.

Carding

Carding machines separate and lay the cotton fibers parallel to each other. During the carding process, two surfaces of wire or metallic card cloth, moving in the same direction but at different speeds on the card machine, comb the cotton into a fine web of generally parallel fibers. A rapidly vibrating vertical comb and a doffer roll remove the fibers from the main drum in a thin film known as the "web." The web is drawn through a tapered cylindrical device called a "trumpet," which condenses the web into a soft, fleecy, rope-like strand of cotton known as a "sliver." The sliver is coiled into storage cans and moved to subsequent equipment.

Fire hazards in a card room are not as great as in opener rooms. However, card room fires can occur and can be severe, as a result of higher operating speeds, insufficient maintenance, or insufficient cleaning.

Combing

Combing, an optional process used before drawing, produces a fine, high-quality product. Revolving or oscillating combs equipped with needles perform the combing operation. The purpose is to separate the shorter fibers from the longer ones for removal. The resulting combed fibers are more uniform.

Drawing and Roving

The purpose of "drawing" or "drafting" is to further straighten the cotton fibers, reduce the size of the sliver, and accomplish some degree of blending and additional paralleling of fibers. Usually six or more strands of "card sliver" are fed into the drawing frame and passed through many sets of rolls. The roving process is similar to drawing, except the end result is a condensed sliver about ⅛ in. (3.2 mm) thick.

Spinning

There are three spinning methods used by the textile industry:

- Conventional ring-spinning
- Rotor (or open-end) spinning
- Air-jet spinning

Each spinning system consists of:

- Drafting to reduce the size of the input material and deliver the proper yarn count
- Consolidating to provide the necessary coherence between fibers and strength
- Winding to form the yarn package

Rotor and air-jet spinning eliminate the need for combing, roving, and bobbin winding.

The yarn discharging from the spinning head can be wound directly onto spools to eliminate the need of a winding operation. Ring-spinning is performed on a spinning frame by reducing the roving strand to the desired size, imparting twist. The finished yarn or thread is wound on a bobbin. Although air-jet spinning is up to 10 times faster than ring-spinning, ring-spinning produces a stronger, more uniform yarn.[2]

Many mills have installed suspended ceilings above the spinning frames to better maintain temperature and humidity control. Unfortunately, cotton fiber and lint can accumulate above the ceiling tiles and create a potential fire hazard.

Warping

Warping is the first step in preparing for the weaving process. The end threads are tied into continuous lengths that are then threaded through guides and eyelets and wound in parallel on the "section beam." Warper beams are sometimes stored in a high-piled rack configuration consisting of cantilever beams.

Slashing

Before the warp yarns can be used in a loom, they must be treated and coated to prevent the yarns from breaking from tension forces and rubbing or chaffing during the weaving process. In this process, yarn is run through a hot solution of starch, gum, and a softening agent, then dried and wound on the "loom beam." The coating applied is called "sizing."

Loss exposure from fire in these areas is moderate due to combustible loading. However, improperly handled starch can result in a dust explosion. The use of starch has diminished greatly. Polyvinyl alcohol (PVA) is being used in its place.

Weaving

Weaving converts yarn into cloth by interlacing two sets of yarn on a loom. One set is the "warp," the long longitudinal threads; the other is the "filling" or "weft," which runs the width of the loom.

Fire losses in plain weave rooms, which are second only to cotton opening rooms, are usually small and contained in one machine. Two notable hazards are (1) defective electrical equipment and (2) excessive friction.

Knitting, Braiding, and Tufting

Knitting involves the interlooping of one yarn system that continuously connects vertical columns (wales) and horizontal rows (courses) of loops to form a knitted fabric structure. There are two general types of knitting: weft knitting and warp knitting.

In weft knitting, fabrics are made by feeding a multiple number of ends into the knitting machine and each loop is progressively made by the needle or needles. The previously formed yarn loop becomes an element of the knitting process with the latch needle. This process yields either flat knit fabrics or a circular tube, depending on how the equipment is set up. Warp knitting is accomplished by preparing a warp beam that contains several hundred ends. Stitch formation on a warp knit differs from weft knitting in that a complete course of loops is formed rather than individual needles acting on loops within a course. Knit fabrics offer relative high extension and recovery compared to woven fabrics; knit fabrics also generally involve a more open structure permitting greater air permeability but still at high levels of insulation.

Braiding involves diagonally overlaying different yarns and is used to produce narrow-width fabrics or cords and other three-dimensional fabrics. Tufting involves sewing a system of yarns into a fabric leaving the yarn loops to produce different surface effects on fabrics. These raised structures can result in greater flammability when ignitable fibers are used.

Nonwoven Fabrics

Nonwoven fabrics are textile structures produced by bonding and/or random interlocking of fibers. This can be accomplished mechanically, chemically, thermally, or by using solvents or adhesives. There are four common methods of making nonwoven fabrics: needlepunching, hydroentangled spunlacing, resin bonding, and thermoplastic bonding.

Needlepunched nonwovens work well with longer fiber length. Fiber finish is critical in needling. Bleached cotton or other fibers with good lubricity are needed to prevent fiber damage and needle breakage. Raw unbleached cotton can also be used with proper needle selection.

Hydroentangled spunlaced fabrics have many characteristics that are similar to woven fabrics. They are easily dyed and finished using conventional textile methods because they have good strength characteristics.

Resin-bonded webs can be bonded by spraying, foaming, gravure roll padding, or by aqueous dispersion equipment, depending on the end product performance desired. The newly formed web is dried, heat cured, and may be calendered. Some iron-on fabric adhesives are made in this manner.

Thermoplastic bonded nonwoven fabrics contain either cut staple or filament fibers with low melting points. Blends with natural fibers like cotton with polyolefin, polyester, or bicomponent fibers can be used. The fabric is produced by needle punching or other mechanical means. Once in mat formation, heated calenders or high-speed embosser calenders cause the fibers to bond by controlled melting and softening. Some materials use adhesives or latex to further stiffen the fabric. Unbleached cotton cannot be effectively bonded due to natural waxes on the raw fiber, which interfere with adhesion. The higher the cotton content, the lesser the bonding, thereby reducing the fabric strength.

Nonwoven fabrics are widely used in many ways, for example, as hazmat protective clothing, medical clothing, disposable clothing, stiffeners, and backings in clothing and rugs.

Nonwoven fabrics generally do not include paper or wool felt materials, even though the processes are somewhat similar. Loose, highloft fibers are used as filling materials and personal hygiene products.

TEXTILE COMBUSTIBILITY

There are 27 generic manufactured fibers and over 100 trade names. See Table 6.5.6 for common fiber types. Some trade names are as common as the generic names due to overuse. Some trade names refer to more than one generic fiber. One such fiber, Nomex®, can be nylon or aramid. Nylon is a long-chain polyamide in which less than 85 percent of the amide linkages are attached directly to two aromatic rings. If more than 85 percent are linked, it becomes an aramid fiber.

The ignitability, flame spread and heat release rates, total heat produced, heat shrinkage, and ease of fire extinction in textiles depend on the type of fibers used, their percent content, the configuration of the fabric, its weight, and its construction. The finish generally does not alter these properties significantly, unless the fabric is treated with a flame retardant. Flame-retardant treatments can be either durable or nondurable. Normal laundering and dry cleaning may reduce flame retardancy.

Characteristics of common textile fibers, including their burning behavior and end uses, are listed in Table 6.5.7. Table 6.5.8 provides burn characteristics and fire residue characteristics for selected fabrics.[2] The data have been collected from a variety of sources.[3,4] The descriptions of burning behavior in Tables 6.5.7 and 6.5.8 and the discussions throughout this chapter are based on small-scale tests and may be misleading when large fires or strong radiation sources are encountered. In such cases, even fabrics that are considered flame retardant may burn readily.

The orientation of a fabric also influences its combustibility. Fabrics generally burn faster in the vertical position than in the horizontal position. The edge of the fabric will also ignite much more easily than the surface, given the ability of the flame to contact more than one side. Some fabrics melt when burned,

TABLE 6.5.6 Common Natural and Manufactured Fibers

	Manufactured		
Natural	*Cellulosics*	*Noncellulosics*	
Cotton	Acetate	Acrylic	Nylon
Linen	Rayon	Anidex	Olefin
Silk	Triacetate	Aramid	PBI
Wool		Azlon	Polyester
		Glass	Rubber
		Lastrile	Saran
		Lyocell	Spandex
		Metallic	Sulfar
		Modacrylic	Vinal
		Novoloid	Vinyon

TABLE 6.5.7 Fire Hazard Properties of Common Textile Fibers

Fiber Designation	*Decomp. Temp. °F (°C)*	*Melting Temp. °F (°C)*	*Ignition Temp. °F (°C)*	*Burning Temp. °F (°C)*	*Burning Behavior*	*End Uses*
A. *Natural Fibers*						
Cellulosic: cotton, hemp, jute, linen, sisal, etc.	580–610 (305–320)	— —	490–750 (255–400)	1560 (850)	Chars, burns, sometimes afterglow	Apparel, furnishings, towels, cordage
Protein: wool, mohair, cashmere, camel hair, etc.	450 (230)	— —	1060–1110 (570–600)	1720 (940)	Chars, intumesces, burns less readily than cellulosics	Apparel, blankets, carpets, furniture covers
B. *Manufactured Fibers*						
Acetate	570 (300)	500 (260)	842 (450)	1720 (940)	Shrinks, melts, and burns	Apparel, lingerie, furnishings
Acrylic	540–590 (280–310)	420–490 (215–255)	860–1050 (460–565)	1560 (850)	Chars, intumesces, burns, and drips	Apparel, furnishings, carpets, blankets, pile fabrics
Nylon	600–790 (315–420)	420–490 (215–255)	840–1060 (450–570)	1600 (870)	Melts, ablates, burns	Apparel, lingerie, furnishings, carpets, cordage, industrial uses
Anidex	—	—	—	—	—	Elastic fiber used in apparel, home furnishing, and laces
Aramid	660 (370–400)	3700 (2040)	800–1040 (427–560)	—	Does not melt (decomposes)	—
Lyocell	350 (175)	450–500 (230–260)	860 (460)	—	—	Dresses, slacks, coats, jeans
Modacrylic	500 (287)	—	1025 (550)	—	—	Children's sleepwear, carpets, blankets, draperies
Novoloid	—	Nonmelting	—	—	—	Protective equipment
Rubber	200 (93)	—	—	—	—	—
Triacetate	>572 (>300)	550 (288)	>842 (>450)	1560 (850)	Shrinks, melts, and burns	—
Vinal	Similar to nylon	—	—	—	—	Good chemical resistance
Vinyon	—	—	—	—	—	Good chemical resistance
Olefin (polypropylene)	750 (400)	330 (165)	930–1060 (500–570)	1540 (840)	Melts, ablates, burns	Knitted sportswear, carpets, cordage, furniture covers, industrial uses
Polyester	680–750 (360–400)	480–570 (250–300)	840–1040 (450–560)	1290–1330 (700–720)	Melts, ablates, burns	Apparel, lingerie, furnishings, carpets, blankets, fiberfill, cordage, industrial uses
Rayon (viscose)	550 (290)	—	790 (420)	1560 (850)	Chars, burns	Apparel, lingerie, furnishings
Spandex	581–671 (305–355)	446–482 (230–250)	780 (415)	—	Melts, burns	In apparel and lingerie where stretch is desired

TABLE 6.5.8 Textile Identification by Burning Characteristics

Fiber	*Burn Characteristics*	*Residue*
Acetate	Shrinks, melts, and burns	Dark, hard, solid bead; acrid odor (hot vinegar)
Acrylic	Shrinks, melts, and burns	Hard, irregularly shaped bead; black smoke; acrid odor
Aramid	Shrinks, melts, and burns	Hard, black bead; self-extinguishing
Cotton	Burns	Fine, feathery gray ash; odor similar to burning paper
Flax, hemp, jute, ramie	Burns	Fine, feathery gray ash, odor similar to burning paper
Glass	Shrinks slowly, melts at very high temperature	Flame-resistant fiber, heat from lighter will not cause fiber to melt
Modacrylic	Shrinks, melts, and burns	Hard, black, irregular bead; self-extinguishing; acrid chemical odor
Novoloid	Shrinks, burns at high temperature	Retains shape but turns black; heat from lighter will not cause fiber to burn
Nylon	Shrinks, melts, and burns	Hard, cream-colored bead; if fibers are overheated, bead will become dark; flaming usually caused by finish present; drops of melted fiber may fall from heated portion of sample; celery odor
Olefin	Shrinks, melts, and burns	Hard, tan bead; black smoke; chemical odor
Polyester	Shrinks, melts, and burns	Hard, cream-colored bead; if fibers are overheated, bead will become dark, drops of melted fiber may fall from heated portion of sample; black smoke; chemical odor
Rayon	Burns	Fine, feathery gray ash
Rubber	Shrinks, melts, and burns rapidly	Tacky, soft black residue
Saran	Shrinks, melts, and burns	Hard, black, irregular bead; self-extinguishing; chemical odor
Silk	Shrinks and burns	Black, hollow, irregular bead which crushes easily to a gritty black powder
Spandex	Burns and melts	Soft, black ash
Triacetate	Shrinks, melts, and burns	Dark, hard, solid bead; chemical odor
Vinal	Shrinks, melts, and burns	Hard, tan bead; chemical odor
Vinyon	Shrinks, melts, and burns	Hard, black, irregular bead; acrid odor
Wool, mohair, cashmere, alpaca	Shrinks and burns	Black, hollow, irregular bead which crushes easily to a gritty black powder

form a pool, and require other combustibles to act as a wick before their full combustibility can be exhibited.

All common natural fibers, except glass, contain organic compounds and the elements carbon and hydrogen and often also oxygen and nitrogen. Coating added to textile fabrics can greatly alter their combustibility. A number of other coatings are commonly applied to fabrics or bonded to fabrics to create laminates. Coated or laminated fabrics exhibit combustibility characteristics of the coating or film and the fiber(s) used. Chlorine is found in vinyl-coated fabrics.

Thermoplastics are hard to ignite. There are, however, many situations in which thermoplastics can burn readily. This occurs when they are stiffened by finishes or heavy dye application, causing them to lose their ability to evade flames and ablate. It also occurs in blends of thermoplastic and char-forming fibers (even when the latter are flame-retardant), for example, in the popular polyester/cotton blends, which burn more like 100 percent cotton than 100 percent polyester. A thermoplastic fiber fabric in contact with a char-forming fabric, for example, a polyester/cotton skirt in contact with a nylon slip,[5] or a polyester curtain in contact with a foam lining, can burn readily. If a burning outer garment is not in contact with a nylon or polyester undergarment, the latter may not ignite, but it may become limp, shrink, make close contact with, and possibly stick to, the skin, causing injury even without burning. Finally, if an ablated thermoplastic fabric still flames when it falls, it can ignite garments or furnishings near it.

However, with such noted exceptions, many thermoplastics can be considered relatively safe with respect to small-flame ignition, as compared to cellulosics and if used as single-layer apparel. Thus, incidents in which children's nightwear was the first item to ignite were significantly reduced by the introduction of the children's sleepwear standard,[6] and the subsequent change from cotton to primarily thermoplastic nightwear, at no additional cost of the garment.[7] Modacrylic fiber is used for fire-retardant sleepwear. Its characteristics include the following:

- Low heat conductivity
- Weaker strength than acrylic
- Good elastic recovery
- Extremely sensitive to heat
- Inherently flame retardant (self-extinguishing)

The revision of the children's sleepwear standard to allow untreated cotton sleepwear if it passes a test for "snug" fit has reraised concerns about the risks to small children from these products. On the other hand, thermoplastics, even if they are hard to ignite, should not be used in garments that are intended to protect against heat, such as fire fighter or industrial uniforms,

because of their tendency to shrink, melt, and stick when exposed to elevated temperatures.

In addition to the burn behavior, Table 6.5.7 lists temperatures that have been cited for onset of decomposition, melting, ignition, and the burning temperature of the flames. The ranges are often quite wide for any one fiber because of the differences in methods for measuring such temperatures, as well as the variety of polymer compositions used in each fiber group for various end uses. In the case of nylon, there are two major types, Nylon 6 and Nylon 66, which vary in the structure of the base molecule. For the ignition temperature of cotton, one finds two values in the literature, that is, 490 and 750°F (255 and 400°C); it is possible that the lower value was obtained with aged cotton. (It is well known that the ignition temperature of wood decreases with aging, and that may hold for cotton as well.) The ignition temperature of blends tends to be similar to that of the component with the lower ignition temperature. Thus, measured by one method, the ignition temperature for 14 different fiber types ranged from 750°F (400°C) for cotton to 1110°F (600°C) for wool; 50/50 blends of cotton and another fiber ranged from 770 to 860°F (410 to 460°C).

Noncombustible Textiles

Noncombustible fabrics, listed in Table 6.5.9, include those made entirely from inorganic materials. Glass-based fabrics listed by testing laboratories for use as draperies are woven from uncoated glass yarns that do not burn or propagate flame. If a sufficient quantity of combustible coating or decorative material is applied to glass fabrics or to other noncombustible fabrics, however, the fabrics will support continued flaming. The inherent brittleness of glass and the other fibers listed in Table 6.5.9 eliminates them from use in clothing fabrics. They are used as reinforcement for plastics and, in the case of relatively low-priced glass fibers, for curtains and draperies.

High-Temperature and Flame-Retardant Textiles

Some fibers are engineered to be flame retardant for industrial purposes. Fabrics made from glass, aramid, novoloid, sulfar, and saran fibers do not burn with a flame and can withstand high temperatures but may char and degrade. Because of their high cost, texture, and appearance, they are used in specialty gear and industrial applications but are not commonly found in consumer clothing and household textiles.

TABLE 6.5.9 Noncombustible Fibers

Beta Fiber	*Stainless Steel*
E-glass	Super alloy
Quartz	Refractory-whiskers
Carbonaceous residue	Alumina
Carbon	Zirconia
Graphite	Boron

PBI (polybenzimidaxozole) fabric and its blends are used for firefighters' turnout gear, space suits, and aluminized crash/fire and rescue suits. (See Section 12, Chapter 9, "Fire and Emergency Services Protective Clothing and Protective Equipment.")

Aramid has excellent strength and low flammability. It does not melt but decomposes at temperatures above 660°F (349°C). Several of the fibers that resist high temperatures and are used in textiles are listed in Table 6.5.10[8,9] and in Table 6.5.11, along with their ignition temperatures, limiting oxygen index (LOI), and some other physical properties.

The LOI is a way to measure the tendency of a fabric, once ignited, to continue burning after the ignition source is removed. LOI is defined as the minimum volume concentration of oxygen in a mixture of oxygen and nitrogen that will just support sustained combustion of the material when ignited in a vertical position at its uppermost edge.[10] Cotton fabrics, for example, have a LOI of 19 percent, which means that, if the oxygen is reduced below 19 percent, the cotton will not continue to burn after the ignition source is removed. The higher the LOI of a fabric, the greater the probability that it will cease to burn once the ignition source is removed. Fabrics with high ignition temperatures and high LOIs can be expected to be safe for clothing and furnishings, since they will not ignite readily and will not continue to burn after an ignition source is removed. However, it should be noted that the use of the LOI test for textiles has abated in recent years; full-scale tests of the various items are considered more reliable.

As previously discussed, many synthetic fabrics shrink when exposed to temperatures approaching their melting or decomposition temperatures. When shrinkage brings the fabric into contact with the skin, the insulating layer of air is eliminated and the amount of heat transferred to the skin is increased significantly. Thermal shrinkage is a particularly important property to consider when selecting fabric for use in protective clothing. Another important property of fabrics used in protective clothing is the ability to maintain integrity during a fire. Fabrics that weaken by charring may split apart and fall away, leaving the skin directly exposed to heat.

FLAME-RETARDANT TREATMENTS

The flame-retardant treatment of theater scenery, curtains, and draperies in places of public assembly is commonly required by local fire authorities. Treated fabrics are used in hotels, hospitals, and other occupancies in the interest of preservation of lives and property.

Many businesses specialize in the flame-retardant treatment of theater scenery, draperies, and other fabrics, using standard chemicals. However, some of these businesses may not treat fabrics properly or may use relatively ineffective or nonpermanent chemicals. It is, therefore, advisable to deal only with businesses of known reliability or, if dealing with an unknown concern, to have treated fabrics tested for adequacy of treatment.

The resistance of such treatments to aging, laundering, and dry cleaning must be ensured. Also, it must be emphasized that such treatments are only expected to make fabrics resistant

TABLE 6.5.10 High-Temperature, Flame- and Chemical-Resistant Fibers

	Ryton	*Ultrate*	*Nomex*[a,b]	*Kevlar*[a,b]	*PBI*[b]	*P-84 Polyimide*	*Kynol*[b,c] *Phenolic*

FR cotton	28–32	450 (230)	Chars	—

to ignition by small flames, and that they may burn readily in larger fires.

The effects of chemical treatments in reducing the flammability of combustible fabrics are varied and complex, and all phases are not fully understood. There are five different ways in which chemicals or mixtures retard spread of flame and afterglow: (1) they generate noncombustible gases that tend to exclude oxygen from the burning surface; (2) radicals or molecules from degradation of the flame-retardant chemical react endothermically and interfere with chain reactions in the flame; (3) the flame-retardant chemical decomposes endothermically; (4) a nonvolatile char or liquid is formed by the chemical, which reduces the amount of oxygen and heat that can reach the fabric; and (5) finely divided particles are formed that change the combustion reactions. Usually a flame-retardant chemical or mixture affects flammability in more than one of these ways. A review of flame-retardant treatments for textiles can be found in *Fire Safety Journal.*[11] Flame-retardant treatments can increase the LOI of cotton from 19 to 28 or 32, and of wool from 28 to 32 or 34.

Hundreds of different chemicals have been suggested as flame-retardants for textiles. It must be emphasized that no one system works for all fibers, as can be seen from Table 6.5.12. In addition, some chemical systems change textile properties, for example, resistance to sunlight, absorption, color, and flexibility, or lose some of their effectiveness when exposed to high temperatures or repeated launderings. Much progress has been made in overcoming most of these undesirable effects. Loss of strength, for example, has become a minor problem in correctly treated flame-retardant cotton fabrics. However, concern that some flame-retardants may be skin irritants, carcinogens, or too expensive can deter wider use.

TABLE 6.5.12 Flame-Retardant Chemicals for Textiles

Fiber	*Typical Flame-Retardant Chemical*
Cotton	Tetrakis (hydroxymethyl) phosphonium salt insolubilized with ammonia gas
Cotton-rayon (disposable, nondurable finish)	Diammonium phosphate; ammonium sulfamate; boron compounds
Rayon (modified fiber)	Hexapropoxy phosphazene
Polyester (modified fiber)	Oligomeric phosphonate decabromodiphenyl ether (DBDPE) and antimony oxide
Polyester, acetate, nylon	Oligomeric phosphonate decabromodiphenyl ether (DBDPE) and antimony oxide
Nylon (nondurable finish)	Thiourea
Wool	Ti, Zr compounds, dibromoterephthalic acid
Modacrylics (modified fibers)	Vinylchloride, vinylidene chloride, vinylbromide as comonomer

It must be emphasized that treatments that protect against ignition of textiles by small flames do not necessarily impart resistance to smoldering ignition by cigarette. For example, flame-retardant treatment of cotton generally lowers the charring temperature of cotton but often decreases the cigarette ignition resistance.

RELATIONSHIP OF FLAMMABILITY AND END USE

Understanding the characteristics of fibers and textiles provides a foundation for determining their behavior when contacted by heat or flame in end items. The specific application of a textile fabric will affect how the end item is evaluated for flame and heat properties.

Clothing

Congress passed the *Flammable Fabrics Act of 1953,*[12] after a rash of serious fire incidents in which rayon-pile fabric made into children's cowboy chaps and sweaters was involved. All wearing apparel sold since 1953 has had to pass a test described in the Consumer Product Safety Commission's (CPSC) "Standard for the Flammability of Clothing Textiles."[13] The test excluded the rayon-pile fabrics and other extremely flammable fabrics, such as very high-pile cotton flannels, stiffened nylon nets, and very light fabrics. However, all normal apparel fabrics must pass this test.

Several studies indicated that additional protection of young and old populations would be desirable. For example, in a study of 463 fire fatalities that occurred from 1972 through 1977 in the State of Maryland,[14] deaths from clothing ignitions comprised 5.5 percent of the fatalities. Of those victims, 21.6 percent were 9 years old or younger, and 20.5 percent were 60 years old or older. Persons aged 50 years and older were more likely to become fire casualties. The number of fire deaths in this age group was approximately twice the predicted number, based on 1970 census data for Maryland. Factors that contributed to the increased proportion of fire fatalities at both ends of the age spectrum were inability to rapidly and successfully cope with the fire situation and lowered tolerance to toxic combustion products. This applied especially to the older population, where increased cardiopulmonary weakness contributed to lower tolerance to toxic exposures. In addition, it was shown that many victims of garment fires wore sleepwear at the time of the incident.

Consequently, a children's sleepwear standard was promulgated for sizes 0 through 6x in 1971, followed by a standard for sizes 7 through 14, three years later.[5] At the time of promulgation, this standard strained the state of the art, but thermoplastic and flame-retardant garments were soon produced that passed this rather severe test. The results have been unexpectedly beneficial. As noted earlier, however, changes to the standard to allow untreated cotton sleepwear for children based on a test for snugness when sold raised the possibility that the problem of hazardous children's sleepwear might be introduced, but no evidence of this problem has surfaced.

Since the introduction of the children's sleepwear standard, the number of burn deaths among children under age 15 due to ignitions of any type of clothing has dropped to five or fewer a year. However, a serious problem still exists for older adults. From 1983 through 1985, for example, clothing-ignition burn deaths accounted for roughly one fire death of every 20 fire deaths overall, but for one of every eight fire deaths for people age 65 and over. Since people age 65 and over also have twice the fire death rate of the whole population, this means that they have five times the rate of death due to burns from clothing ignition fires.[15]

The style or type of garment is an important factor in evaluating its fire hazards. For example, a full-length gown containing several yards of flammable fabric could be quite hazardous, whereas a tightly fitting blouse or shirt made of the same material might be far less dangerous. Not only would the gown present much more fuel for burning, but its size and loose shape would make it far more vulnerable to contact with typical ignition sources. The wearer is unaware that an ignition source is in contact with the garment. Flared skirts, large bows, and full-sleeved kimonos are other examples of easily ignitable garments. The availability of oxygen on both sides of loosely fitting garments accelerates flame spread. This fact was the principle behind the recent change to the children's sleepwear requirements, but there is no guarantee that a garment sold as snug will still be snug after multiple wearings, washings, and hand-me-downs.

Heat- and Flame-Resistant Protective Clothing

Protective clothing used to protect against thermal hazards (flame, heat, and molten metal exposure) spans a range of required performance depending on the specific application. Common applications requiring special clothing with flame and heat protective properties include the following:

- Chemical processes and refining
- Electrical utilities
- Fire fighting
- Welding
- Smelting and foundry operations

Protective clothing for these and other applications is distinguished between primary protective clothing, where the clothing is specifically required to protect against a thermal hazard in which exposure is likely, and secondary protective clothing, where exposure might be incidental and accidental. For example, uniform clothing worn by workers at a petrochemical facility would be considered secondary protective clothing whereas the turnout clothing worn by firefighters is considered primary protective clothing.

In general, all forms of heat- and flame-resistant protective clothing must demonstrate some level of heat and flame resistance based on standardized test methods. Heat resistance indicates that materials used in the construction of clothing resist adverse effects from exposure to heat, such as ignition, melting, dripping, and separation. Quantitative effects from heat exposure can be determined by measuring the amount of shrinkage and weight loss. The temperature at which this testing is performed will discriminate performance among different materials. The level of flame protection required is usually sufficient to either indicate resistance to ignition by flame contact or to show that materials will not continue to burn once the flame source is removed.

Additional types of thermal performance will depend on the intended end use. Primary protective clothing is generally required to provide insulation from heat exposure, whether the heat exposure is through convection, conduction, radiation, or a combination of these forms of heat transfer. In addition, primary protective clothing might be required to resist the effects of contact with molten metal that can range from droplets (welding splatter) to splashes of molten metals in significant volumes (during smelting operations). For example, clothing materials used around molten aluminum must not only limit the amount of heat transfer through accidental contact but also permit the molten metal to run off and not ignite during the exposure.[16] Some intrinsically flame-resistant clothing materials are unsuitable for this application because the molten aluminum adheres to the fabric, causing localized damage to the fabric and high levels of heat transfer.[17]

Fire-fighting protective clothing is often called on to provide multiple forms of heat insulation performance because of the variety of hazards that can be encountered during emergency response operations. All materials used in this multilayered clothing must individually be resistant to flame and heat. As a composite, the materials must provide a sufficient amount of insulation to relatively high heat and flame exposures to offer a sufficient level of protection to the wearer. The relative protection will depend on the level of exposure and will be a function of energy level and time of exposure. Abbott characterized three distinct ranges of heat exposure to structural firefighters including routine, ordinary, and emergency conditions based on ranges of air temperature and thermal radiation.[18] Veghte further characterized these fire-fighting conditions by estimating the tolerance times that exist for firefighters working under these exposure conditions, including 10–20 minutes for routine conditions, 3–5 minutes for ordinary conditions, and 10–30 seconds for emergency conditions.[19] The type of heat environment will further vary with the type of fire fighting. Fire fighters in wildland situations are expected to have lower levels of heat exposure but must wear their protective clothing for much longer periods of time. On the other hand, fighting fires involving aircraft or bulk flammable fuels or gases, can produce extremely high levels of radiant heat and dictate the use of reflective or aluminized materials.

Secondary protective clothing involves use of flame-retardant-treated or intrinsically flame-resistant clothing materials. For petrochemicals workers, this type of clothing is required because of the potential for flash fire. Early studies indicated that the principal injuries to workers exposed to flame fire was the continued burning of their clothing as opposed to the flash fire exposure itself.[20,21] Therefore, this clothing in resisting ignition over the relative short duration of a flash fire provides a much larger level of safety for the wearer. Utility workers who can come into contact with high-voltage sources in electrical power generation stations must be protected from the thermal impulses associated with electrical arcs. These arcs are capable of generating 1.6 MW/m^2 in a fraction of a second.[22]

Table 6.5.13 is a list of specifications providing requirements for various types of heat and flame protective clothing. Each of these specifications cites specific test methods for evaluating clothing heat and flame resistance. Currently, there are no specifications for some types of protection including welding and fire entry suits.

Mattresses and Upholstery

The ignition of mattress and upholstery textiles is a well-documented cause of fires, particularly from cigarettes. Mattresses and bedding are a leading first product ignited in many house fires according to NFPA statistics.[23] Mattresses and bedding were the items first ignited in 17,490 home structure fires, 413 civilian deaths, 1990 civilian injuries, and $357.4 million in direct property damage per year between 1999 and 2002. These fires have declined steadily since 1980, mirroring the overall trend in home fires. Two of the major causes of mattress and bedding fires—heat source too close to combustibles and careless discarding of materials—can probably be explained by the high percentage of mattress and bedding fires initiated by cigarettes. Twenty-two percent of all mattress and bedding fires were the result of cigarette ignition. Matches and lighters caused another 28 percent of these fires. Similar, but proportionally less, statistics have been posed for upholstered furniture.

A mattress or upholstery fire poses two main dangers. The materials used to make mattresses and upholstered furniture allow fire to penetrate deeply and smolder for a long period of time, and they tend to be slow burning. Both result in production of the toxic gases and difficulty in extinguishment that are associated with slowly burning materials.

The overall decline of mattress and upholstery fires has been due in part to regulations that introduced the use of improved flame-resistant materials in these products. The U.S. government and some states have had standards regarding the flammability of mattresses exposed to smoldering cigarettes found in 16 CFR Part 1632.[24] More recently, California has introduced testing to limit the peak heat release of mattresses or mattress sets during fires. When mattresses have a limited contribution to the fire, the available time for occupants to discover the fire and escape substantially reduces the risks associated with mattress fires. The federal government has adopted similar procedures as part of new regulations in 16 CFR Part 1633.[25]

Curtains, Draperies, and Wall Coverings

Curtains, draperies, and wall coverings can ignite from such ignition sources as electrical malfunction or wastepaper-basket fires. Flames can rapidly spread to walls and ceilings. It has been shown that large differences exist between the potential of various domestic curtain materials to ignite wall-covering materials and the production of heat and smoke this creates.[26] Curtains in public occupancies are regulated by local authorities and conforming materials do not seem to present major problems during the initial stages of a fire. The test most prescribed by regulatory authorities for curtains and draperies is NFPA 701, *Standard Methods of Fire Tests for Flame Propagation of Textiles and Films.* NFPA 701 recently addressed that, even if single layers of curtain fabrics pass the requirements of the standard, the combination of two or three layers, often found in motels, may burn vigorously. This was illustrated in a full-scale test.[27] Other improvements in test methodology have been incorporated into recent revisions.

Carpets and Rugs

Until 1960 there was very little fire experience to indicate that carpets were a significant factor in fires. Consequently, floor coverings were customarily exempted from coverage in building codes regulating life safety from fire. Since 1960, although there were only a small number of fires reported in which carpets spread fire, those that have been reported indicate that carpets can be the prime material involved in the development or spread of a fire. In 1970 a fire in a California dwelling was first seen by an occupant when it was a few feet in diameter on carpeting in front of the fireplace.[28,29] As the occupant applied water with a garden hose to the burning carpet, the fire spread rapidly on the carpet and, within ten minutes after discovery, enveloped the entire room including furniture and wood paneling. Because of such experiences, carpet flammability has been for some time regulated at the federal, state, and municipal levels. The persistence of fatal carpet and rug fires noted in Table 6.5.4 primarily occurs in the much less regulated home environment.

Among the many factors in carpet construction that may affect ease of ignition and ability to spread fire are fiber type, area unit weight density (or, loops per square inch), pile height, backing material, padding, type of adhesive, single versus double back, and type of dye. (Carpet flammability tests for residential and special occupancies are discussed later in this chapter.)

TEXTILE FLAMMABILITY TESTS

The severity of the hazard of a fabric in a particular type of product, such as a dress, curtain, or carpet, depends greatly on the ease of ignition of the product, the speed with which flame spreads, the amount of heat generated and the rate at which it is released, susceptibility to melting, and the quantity and composition of the smoke and gaseous products of combustion. No individual test method gives a complete evaluation of the hazard, and there are no nationally recognized test methods to measure some of the hazards. Many of the more important test methods for textile products have been summarized.[30–32] With the exception of the test methods for mattresses and upholstered furniture, those in common use in the United States are described below. Table 6.5.14 provides a list of several methods used for flammability of textile materials.

Clothing

The federal Flammable Fabrics Act of 1953 was signed into law in 1953 and amended in 1967.[12] The act prohibits the sale of all wearing apparel and fabrics subject to the act that are classified "highly flammable" when tested according to 16 CFR Part 1610, which was formerly designated Commercial Standard CS 191-53.[13] The specified test is designed to measure ease of ignition and rate of flame spread. It does this by impinging a ⅝ in. (16 mm) long gas flame for 1 second against the lower end of the upper face of a 2 by 6 in. (51 by 152 mm) specimen that is suspended at a 45-degree angle from the horizontal in a test chamber. Figure 6.5.2 shows a schematic diagram of the fabric flammability tester. If the fabric is ignited by the 1-second exposure, the time required for the flame to spread 5 in. (127 mm) on the fabric is used to classify the fabric (ASTM D1230, *Test Method for Flammability of Apparel Textiles,* embodies the same procedures but uses a slightly different classification system). This test has been successful in excluding inordinately flammable garments from interstate commerce. However, it neither discriminates nor is it intended to address differences in the burning characteristics of various apparel fabrics. For example, pile fabrics, such as cotton/polyester terry fabrics and cotton flannels cut into gowns, robes, and pajamas, gave considerably higher burn injury estimates (percentage of body surface burned weighted by depth of burn) than estimates obtained with almost 60 other common apparel fabrics when burned on an instrumented mannequin.[33,34] The same fabrics ranked high on the flammability scale when tested in 12 laboratory fabric flammability tests, but easily passed the Part 1610 requirements. One-hundred percent nylon and polyester fabrics also passed the test, as well as some blends containing wool or modacrylic fibers, which produced very low injury estimates on the mannequin and low flammability results in the other laboratory tests.

The test method in the 1980 edition of NFPA 702,* *Classification of the Flammability of Wearing Apparel,* is the same as that in Part 1610,[12] with two important exceptions. The committee that drafted the NFPA-wearing apparel standard noted that many fabrics, particularly those without raised fiber surfaces, were not ignited when the top surface was touched by a small test flame for 1 second. Those fabrics could not be evaluated for rate of flame spread. Furthermore, the committee concluded that the lower edge of a fabric should be easier to ignite than the surface. Consequently, the test flame in NFPA 702 was brought in contact with the lower edge of all samples and, in the case of those without raised fiber surface, was held there until ignition occurred. Many fabrics that do not ignite in Part 1610[14] ignite in the NFPA 702 test.[34]

*NFPA 702 was withdrawn as an NFPA document and is no longer available.

TABLE 6.5.14 Comparison of Flame-Resistance Test Methods for Textile Materials

Test Method	*Material Orientation*	*Flame Type*	*Exposure Type*	*Exposure Length*	*Measurements*	*Application*
16 CFR Part 1610	45 degrees	16 mm butane	Fabric face	1 sec	Rate of flame spread	Clothing textiles
16 CFR Part 1615	Vertical	38 mm butane	Cut edge	3 sec	Char length	Childrens' sleepwear
16 CFR Part 1616	Vertical	38 mm butane	Cut edge	3 sec	Char length	Childrens' sleepwear
16 CFR Part 1630	Horizontal	Methenamine pill	Fabric face	Varies	Char distance	Carpets, rugs
ASTM D1230	45 degrees	16 mm butane	Fabric face	1 sec	Rate of flame spread	Clothing, textiles
ASTM D2859	Horizontal	Methenamine pill	Fabric face	Varies	Char distance	Carpets, rugs
ASTM D3659	Vertical	38 mm methane (fan burner)	Cut edge (loose)	3 sec	Burn time Loss of mass	Clothing textiles, curtains, drapes
ASTM D4151	Horizontal	16 mm butane	Fabric face	1 sec	Observation of ignition Condition of test paper	Blankets
ASTM D6413	Vertical	38 mm methane (bunsen burner)	Cut edge	12 sec	Afterflame Afterglow Char length	FR textiles
ASTM E84	Horizontal	Series of gas burners	Fabric face	10 min	Flame spread index	Interior textiles
ASTM F1358	Vertical	38 mm methane (bunsen burner)	Folded edge	3 sec, 4 sec wait, then 12 sec	Afterflame Afterglow Burn distance	Multilayered non-FR clothing
NFPA 255	Vertical	Gas fee flame (1.2 m)	Wall-mounted	10 min	Flame spread index	Wall textiles
NFPA 256	Vertical	Gas burner	Wall-mounted	5 min @ 40 kW 10 min @ 150 kW	Flame spread index and smoke development index	Wall textiles
NFPA 286	Vertical	Gas burner	Wall-mounted	5 min @ 40 kW 10 min @ 160 kW	Flame spread index and smoke development index	Wall textiles
NFPA 701 Method 1	Vertical	Tapered Meker burner	Cut edge	45 sec	Char length	Building fabrics
NFPA 701 Method 2	Vertical	Burner meeting ASTM D5025 criteria	Cut edge	2 min	Char length	Outdoor fabrics
NFPA 702	45 degrees	16 mm butane	Cut edge	1 sec or greater	Rate of flame spread	Clothing textiles

Stringent standards were introduced for children's sleepwear in the early 1970s; Parts 1615 and 1616[5] are much more restrictive than Part 1610.[13] Fabric samples 10 by 3 in. (254 by 89 mm) are suspended vertically in a cabinet and subjected to a test flame along the bottom edge (Figure 6.5.3). A fabric passes the test if the average char length of five specimens does not exceed 7 in. (178 mm), and no specimen has a char length of 10 in. (254 mm). The barrel of the test flame burner is ¾ in. (19 mm) below the lower edge of the sample and the test flame is adjusted to extend 1½ in. (38 mm). The sample is exposed for 3 seconds. Char length is the distance from the fabric's lower edge to the end of the void or tear in the charred, burned, or damaged area. The tear is made by lifting the sample by one of the corners near the lower edge after weights had been attached to the opposite corner near the lower edge. Note again that this test is no longer required for U.S. children's sleepwear.

The United States thus has two apparel flammability standards: (1) the children's sleepwear standard, which has greatly reduced the incidence of accidents but restricted the

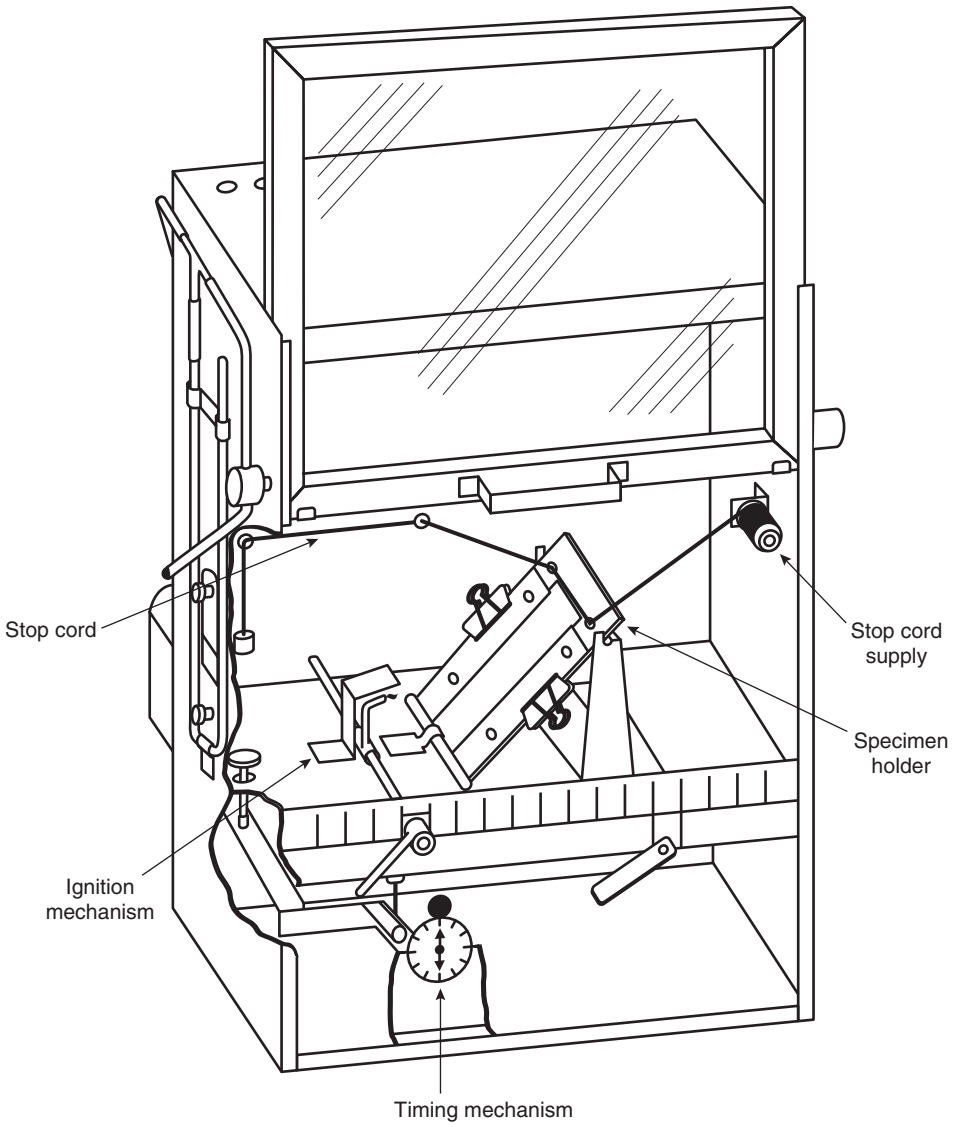

FIGURE 6.5.2 NFPA 702 Flammability Tester (Source: Adapted from NFPA 702, *Classification of the Flammability of Wearing Apparel,* 1980 edition, Figure 2-1.1)

choice of fabrics and which has been withdrawn and (2) the general apparel standard, which has eliminated inordinately flammable, limited-use fabrics, but does not significantly affect fabric choice. Attempts to further categorize fabric flammability hazards have been made; some have based such categorization on flame-spread rate measurements.[34,35] Flame-spread rate measured on remainders of garments involved in fire incidents, however, did not correlate with the size of the victim's burn injury.[36] Researchers have developed methods for measuring the rate of heat release from burning fabrics.[37–38] Braun et al.[39] suggested that fabrics with a low rate of heat release could be used in all garments; those with short ignition times and higher rate of heat release could be used only in tightly fitting garments; and finally suggested the elimination of fabrics with short ignition time (½ sec or less) and high-heat release rate.

Heat- and Flame-Protective Clothing

The types of test methods used to demonstrate the performance of heat- and flame-protective clothing fall into four general categories:

- Flame resistance tests
- Heat resistance tests
- Heat insulation tests
- Molten metal tests

The principal flame resistance test used in the protective clothing industry to demonstrate the adequacy of resistance to ignition and acceptable burning characteristics is ASTM D6413, *Standard Test Method for Flame Resistance of Textiles (Vertical Test).*[40] This test was developed based on Federal Test Method Standard (FTMS) 191A, 5903.1.[41] The test involves suspending

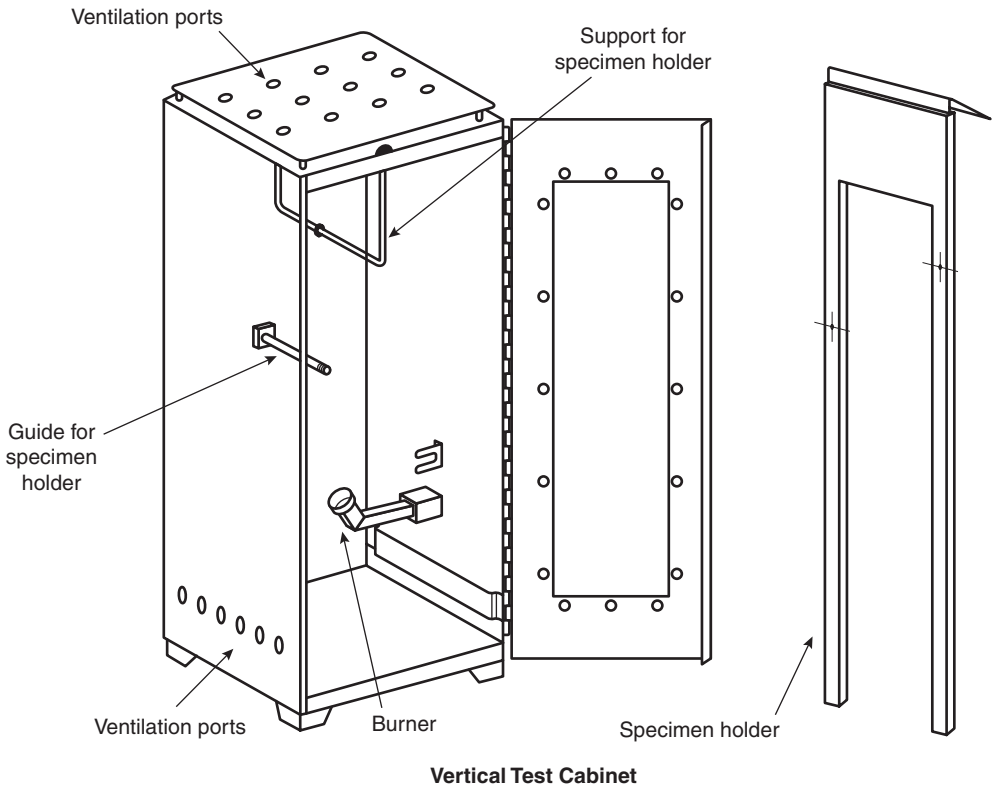

FIGURE 6.5.3 Apparatus for Testing Children's Sleepwear

the edge of a 3 in. by 12 in. (76 mm 305 mm) specimen vertically within a cabinet ¾-in. (19-mm) into a 1.5-in. (38-mm) high, methane-fueled flame for 12 seconds (Figure 6.5.4). The specimen is then removed from the flame and observed for afterflame and afterglow as measured in seconds. The damaged length of the specimen is determined as char length, where a specific weight is hung on a corner of the fabric causing a tear in the charred portion of the specimen. The length of this tear becomes the char length. Typically, afterflame time, afterglow time, and char length are used as criteria for establishing minimum acceptable performance. In the case of most primary protective clothing, a maximum char length of 4 in. (100 mm) is used in conjunction with the afterflame time being 2 seconds or less. A few specifications permit longer char lengths, up to 6 in. (150 mm). Acceptable material performance is often also based on burning behavior. Many protective clothing standards prohibit the use of fabrics that show evidence of melting and dripping when tested according to ASTM D6413.

A related flame-resistance test is ASTM F1358, *Standard Test Method for Effects of Flame Impingement on Materials Used in Protective Clothing Not Designated Primarily for Flame Resistance.*[42] This test method was developed for evaluating protective clothing that is used in nonthermal applications but may accidentally be exposed to a flame source.[43] The test method uses the same cabinet and burner as ASTM D6413 but presents a folded edge of the specimen to the flame. The test is conducted in two parts with an initial 3-second exposure, followed by reapplication of the flame to the same specimen for 12 seconds. The method reports afterflame time, afterglow, and burn distance (like char length, but without the use of a weight to tear the specimen). The test is particularly useful for composite clothing materials where the inner layers may not be flame resistant.

European and international approaches for measuring flame resistance typically use a horizontal or angled burner to contact the fabric face or edge. The fabric specimen is vertically held in place by stand-off pins. Common measurements applied to protective clothing include afterflame times, afterglow times, and specific observations of specimen damage. Char length or related measures are not used to characterize material performance because of concerns with measurement precision.

Heat resistance testing assesses a material's resistance to degradation when exposed to heat. In this testing, a 6-in. (150-mm) or 15 in. (380 mm) specimen is placed in a forced air convection oven set at a specific temperature. The material is then removed and examined for visual evidence of ignition, melting, dripping, and separation. In the United States, the testing is most commonly performed on materials at 500°F (260°C) for a 5 minute duration. In Europe, a 5-minute 355°F (180°C) exposure is used. The determination of dimensional changes in specimens after the heat exposure can also assess heat damage (to provide an indication of thermal shrinkage resistance). Although a part of several NFPA standards on emergency responder protective clothing, this method is embodied in ISO 17493, *Clothing for Protection against Heat and Flame: Test*

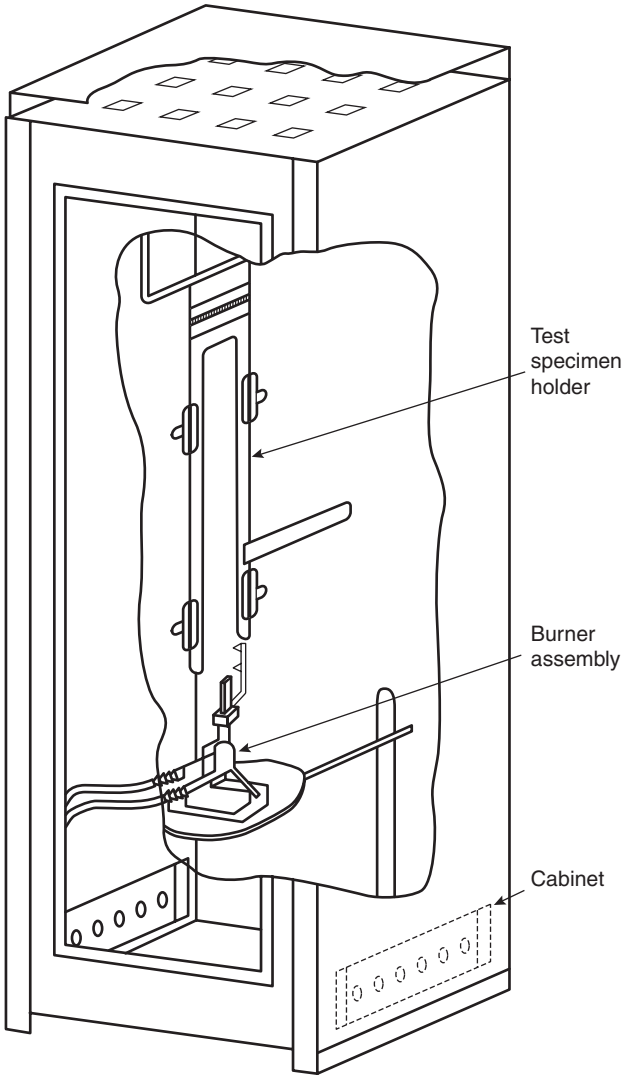

FIGURE 6.5.4 Test Apparatus Used by ASTM D6413 (Source: Copyright ASTM International. Reprinted with permission.)

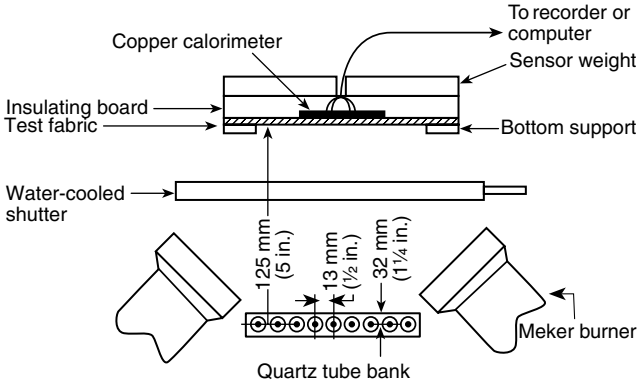

FIGURE 6.5.5 Thermal Protective Performance Test. Note: When used, the spacer is positioned between the material specimen and the sensory assembly. (Source: NFPA 2112, *Standard on Flame-Resistant Garments for Protection of Industrial Personnel Against Flash Fire,* 2007 ed., Figure 8.2.4.1.5)

Method for Convective Heat Resistance Using a Hot Air Circulating Oven.[44]

Many types of protective clothing are used for protecting workers from continued exposure to heat. The type of environments where heat exposure occurs will vary with the type and levels of heat. The Thermal Protective Performance (TPP) test was developed to simulate the types of exposure encountered in a flash fire.[45,46] This test exposes a horizontally positioned specimen over a combined convective and radiant heat source with a heat flux of 7.4 Btu/ft^2/sec (2.0 cal/cm^{2}s or 84 kW/m^2), as shown in Figure 6.5.5. Heat transfer through the specimen is measured with a copper calorimeter and the rate of temperature rise is then related to empirical human skin tolerance data to predict the times to sensation of pain and development of a second degree burn injury.[45,47] Different methods have been used for configuring the sample, but generally single layer materials are tested either in contact with the sensor or with a spacer that separates the sensor and interior material surface by ¼ in. (6 mm), whereas multiple layer specimens are tested in contact with the specimen. The test is extensively used, but some controversy has arisen over its predictive capabilities for whole clothing.

A full manikin test was developed to provide a complete evaluation of protective garments in simulated flash fire. The thermal manikin testing, developed by DuPont, employs a full human-form manikin that is outfitted with over 100 calorimeter-like sensors. In the test, the clothed manikin is subjected to flame and heat from multiple propane-fueled burners from 3 to 12 seconds.[48,49] The response of the individual sensors is then evaluated to determine those areas of the manikin where second- and third-degree burn injury would be predicted (Figure 6.5.6). This approach has been standardized as ASTM F1930, *Standard Test Method for Evaluation of Flame Resistant Clothing for Protection against Flash Fire Simulations Using an Instrumented Manikin.*[50] Due to some inconsistencies between TPP testing ranking of materials and performance of garments on manikins, this testing has led to investigation of other approaches for measuring material performance to short duration, extreme flame/heat exposures.[51]

Two other types of heat exposure are evaluated in other standardized tests. Heat transfer through contact with hot objects is measured using ASTM F1060, *Standard Test Method for Thermal Protective Performance of Materials for Protective Clothing for Hot Surface Contact.*[52] In this test, a weighted block with a copper calorimeter measures the heat transfer through a protective clothing composite set on a hot plate at a specified temperature. Calorimeter output is used to measure the time to pain sensation and time to second-degree burn injury. Radiant heat transfer through clothing material samples is evaluated with ASTM F1939, *Standard Test Method for Radiant Protective Performance of Flame Resistant Clothing Materials.*[53] Again the same principle is used as in TPP and conductive heat

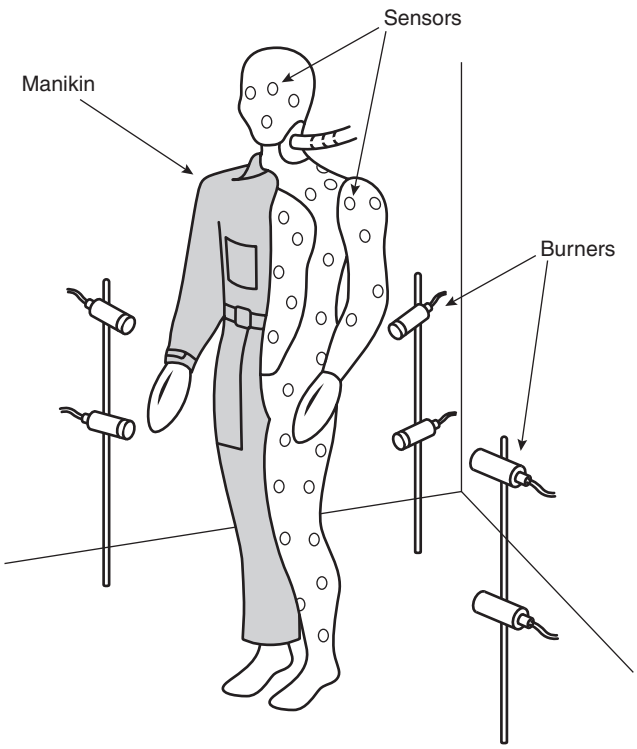

FIGURE 6.5.6 Instrumented Manikin Used in ASTM 1930 (Source: Copyright ASTM International. Reprinted with permission.)

transfer tests; however, in this case, the specimen is vertically oriented with a primarily radiant heat source. Both tests have been applied to various types of protective clothing with success in ranking materials or determining material acceptability for protective applications.[54,55]

Molten metal protection is measured using ASTM F955, *Standard Test Method for Evaluating Heat Transfer through Materials for Protective Clothing upon Contact with Molten Substances.*[56] The test involves pouring 1 kg of molten metal (e.g., aluminum, copper, iron) onto an inclined material specimen and observing the effects of the molten metal on the fabric. Calorimeters under the molten metal also measure heat transfer. While the test is useful for visualizing effects on materials, the large amount of molten metal is considered excessive and prevents quantitative comparison of heat transfer effects for some fabrics.[57,58] Analogous methods have been developed in Europe and internationally.

A summary of test methods for protective clothing heat properties other than flame resistance are provided in Table 6.5.15. This table also includes European and international test method standards. Many of the European methods are similar if not identical to the analogous international standard.

Blankets

In ASTM D4151, *Test Method for Flammability of Blankets,*[59] a small flame is brought down on the center of a specimen for 1 second. The specimen is covered with a paper monitor with a 2-in. (50-mm) circular cutout. If the paper monitor does not char or become discolored, the material is Class 1, and is considered acceptable.

Mattresses and Upholstery

Test methods for mattresses are provided in Consumer Product Safety Commission regulations, 16 CFR 1632 and 1633. In 16 CFR 1632, the test method measures the ignition resistance of a mattress or mattress pad by exposing the surface to lighted cigarettes in a draft-protected environment. The surfaces to be tested include smooth, tape edge, and quilted or tufted locations, if they exist on the mattress or mattress pad surface. A two-sheet test is also conducted on similar surface locations. In the latter test, the burning cigarettes are placed between the sheets (Figures 6.5.7 and 6.5.8). Criteria provided in 16 CFR 1632 require that individual cigarette test locations pass the test if the char length is not more than 2 in. (50 mm) in any direction from the nearest point of the cigarette. The newer 16 CFR 1633 is a full-scale method where a twin or larger size mattress is exposed to a pair of T-shaped burners, intended to simulate burning bedclothes, which are placed on the top and side of the mattress respectively. The peak heat release rate is measured for 30 minutes and cannot exceed 200 kW, whereas the total heat released during the first 10 minutes cannot exceed 15 MJ.

Upholstery flammability is commonly measured according to NFPA 260, *Standard Methods of Tests and Classification System for Cigarette Ignition Resistance of Components of Upholstered Furniture,* where individual components of the upholstery, including the cover fabric, padding, under fabrics, and welting, are subjected to cigarettes held in a test fixture relative to the test fabric. Fabric performance classification is based on whether ignition occurs and, if ignited, the length of the vertical char. The method is based on a similar protocol established by the Upholstered Furniture Action Council (UFAC). NFPA 261, *Standard Method of Test for Determining Resistance of Mock-Up Upholstered Furniture Material Assemblies to Ignition by Smoldering Cigarettes,* uses a similar protocol but specifies different test locations to simulate furniture geometry such as horizontal crevices in seat cushions and arm rests. This standard similarly classifies upholstery material performance on the basis of ignitability and char length.

Curtains, Draperies, and Wall Coverings

Curtains and draperies for public occupancies are generally regulated by local or state fire authorities, but the most widely used tests are described in NFPA 701. This standard has undergone significant changes over the years. Whereas the standard used to employ both a small- and large-scale test, there are now Methods 1 and 2. Method 1 is used for fabrics with a weight of 21 oz/yd^2 (700 g/m^2) or less. In this test, a 45-second tapered Meker burner exposure is used. Test 2 uses a longer, 2 minute exposure and is intended for heavier fabrics and those used in outdoor applications.

ASTM D3659, *Standard Test Method for Flammability of Apparel Fabrics by Semi-Restraint Method,*[60] has been suggested as a possible small-scale test for evaluating curtain and

TABLE 6.5.15 Test Methods for Evaluating Protective Clothing Properties Other Than Flame Resistance

Test Method	*Property Evaluated*	*Type of Exposure*	*Measurements*
ASTM F955	Molten metal resistance	1 kg molten metal	Time to second-degree burn Visual ratings
ASTM F1060	Conductive heat resistance	Hot plate (temperature user selected)	Time to pain Time to second-degree burn
ASTM F1930	Full manikin flame/heat	Simulate flash fire (84 kW/m^2)	% predicted body burn (second and third degree)
ASTM F1939	Radiant heat exposure	21 to 84 kW/m^2 (radiant burner)	Time to pain Time to second-degree burn
EN 348	Molten metal resistance (small droplets)	Simulated welding splatter	Time to 40°C rise
EN 366	Radiant heat transfer	5 to 80 kW/m^2 (radiant burner)	Visual effects or time to 10°C rise
EN 367	Flame heat transfer	80 kW/m^2 (flame)	Heat transfer index
EN 373	Molten metal resistance	50 g increments of molten metal	Damage to skin simulant
EN 702	Conductive heat resistance	Hot plate (temperature user selected)	Time to 10°C rise
ISO 6942	Radiant heat transfer	5 to 80 kW/m^2 (radiant burner)	Visual effects or time to 10°C rise
ISO 9150	Molten metal resistance (small droplets)	Simulated welding splatter	Time to 40°C rise
ISO 9151	Flame heat transfer	84 kW/m^2 (flame)	Heat transfer index
ISO 9185	Molten metal resistance	50 g increments of molten metal	Damage to skin simulant
ISO 12127	Conductive heat resistance	Hot plate (temperature user selected)	Time to 10°C rise
ISO 17492	Thermal protection	80 kW/m^2 (flame and radiant panel)	Time to burn; TPP rating
ISO 17493	Heat resistance	Oven heat (180 or 260°C)	Visible effects

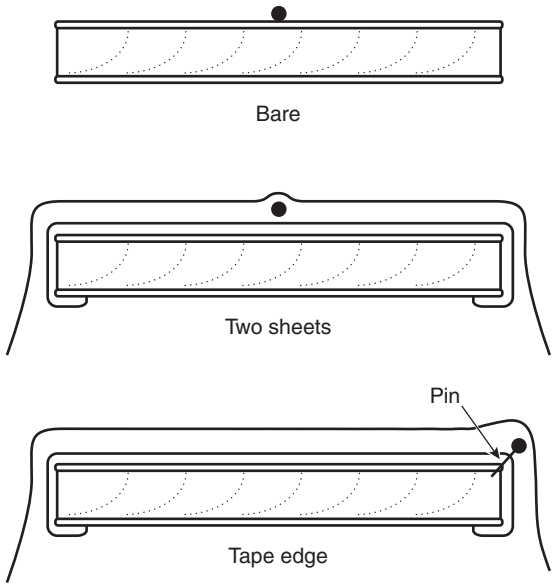

FIGURE 6.5.8 Location of Cigarette on Mattress to Be Tested for Cigarette Ignition

drapery fabrics. In this test, the 15 in. by 6 in. (380 mm by 150 mm) specimens are attached to a bar on the top of the test apparatus and are lightly restrained from movement by use of chains to the corners of the specimen. The method measures burn time and loss of mass.

Many jurisdictions require that wall coverings including fabrics be tested by ASTM E84, *Standard Test Method for Surface Burning Characteristics of Building Materials,*[61] or NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials.* A study was undertaken to compare the burning characteristics of a number of textile wall coverings in full-scale tests, yielding results of two bench-scale tests—the cone calorimeter and the lateral ignition flamespread test (LIFT).[62] In this test, specimens approximately 32 in. by 6 in. (800 mm by 150 mm) are mounted on an inert insulating material, with the longer dimension horizontal. A radiant panel is mounted at an angle to the specimen so that the heat flux over the specimen is varied. Flame spread and heat flux at which ignition occurs are measured. Use of such tests may eventually obviate the use of the more complex tunnel tests in which the materials—unrealistically for wall coverings—are mounted horizontally in a tunnel.

NFPA has developed several useful tests for understanding the burning characteristics or contributions of wall coverings and building materials. NFPA 255 provides procedures for comparing the surface burning characteristics of a material by evaluating flame spread over the surface when exposed to a test fire. Testing is conducted in a chamber that consists of a horizontal duct that has an induced draft. Specimens are exposed to a gas feed flame for 10 minutes. Afterwards, the distance of the flame front is measured. The material's flame spread results are compared to two other materials—cement board and red oak. Material acceptability is determined based on its flame spread index (FSI < 25) and smoke development index (SDI < 450). NFPA 265, *Standard Method of Fire Test for Evaluating Room Fire Growth Contribution of Textile Coverings on Full Height Panels and Walls,* determines the contribution of textile wall coverings to room fire growth. A 12 ft by 8 ft by 8 ft (3.7 m by 2.4 m by 2.4 m) room is used with the specimen mounted on two or three walls. A gas burner placed in a corner exposes the specimens to an open flame for 5 minutes at 38 Btu/s (40 kW) and 10 minutes at 142 Btu/sec (150 kW). Passing performance occurs when flame spread to the ceiling does not occur during the 38-Btu/sec 40-kW exposure. The specimen also cannot spread to its outside edge, form burning droplets, or cause a flashover in the room. A related standard, NFPA 286, *Standard Method for Fire Tests for Evaluating Contribution of Wall and Ceiling Interior Finish to Room Fire Growth,* uses a slightly higher second exposure at 152 Btu/s (160 kW) for the last 10 minutes and also quantifies the smoke release rate.

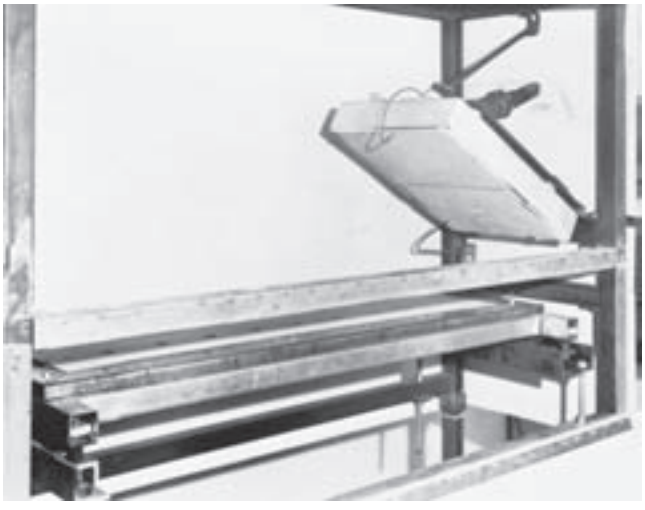
Carpets and Rugs

Carpets and rugs are currently regulated in the United States by federal regulations.[63] Separate parts of the regulations apply to particular sizes. In testing these carpets and rugs, a 9 in. by 9 in. (230 mm by 230 mm) sample is placed on the floor of a test chamber, and a flat steel plate with an 8-in. (203-mm) diameter hole in the center is placed on the sample. A methanamine tablet is placed in the center of the hole and ignited. The sample passes the test if the charred portion does not extend to within 1 in. (25 mm) of the edge of the hole at any point. Seven of eight specimens of other-than-small carpets and rugs must pass if carpets made of the tested material are to be sold. In the case of small carpets and rugs, those that do not pass the test may be sold if they carry a permanent label stating that they failed to pass and should not be used near an ignition source. This requirement eliminated only a small percentage (usually low quality) of the carpets on the market at the time the standard was introduced. A similar testing approach is provided in ASTM D2859, *Standard Test Method for Flammability of Finished Textile Floor Covering Materials.*[64]

Hospitals and other institutions receiving federal financial aid are required to comply with flammability limits for carpets and other floor coverings used on patient-occupied areas and exit ways. The flame spread rating of floor coverings must not exceed 75, as determined by ASTM E84.[61] This test is similar to NFPA 255 and is commonly referred to as the Steiner Tunnel Test.

NFPA *101®*, *Life Safety Code®*, suggests that where limitations are to be placed on the flammability of floor coverings, the test method in NFPA 255 is to be used. Objections have been raised regarding its use to evaluate floor coverings, because positioning the test specimen on top of the tunnel bears no resemblance to its position when in place in a building. The method is also criticized because it may result in delamination, melting, and dripping of test specimens, which removes combustible material from the reach of the burner. The Canadian carpet test places the specimen on the floor of a tunnel.[65]

In an effort to more correctly assess the flame spread hazard of flooring materials, the concept of critical radiant flux was de-



FIGURES 6.5.9 Flooring Radiant Panel Test Apparatus Showing Carpet Specimen and Gas-Fueled Panel (Source: NFPA 253, *Standard Method of Test for Critical Radiant Flux of Floor Covering Systems Using a Radiant Heat Energy Source,* Figure 4.1(b))

veloped. In their work on model corridor fire tests, the National Bureau of Standards (now NIST) found that the radiant energy impacting on a floor covering had a significant influence on the propagation of flame across the floor covering. This work led to the development of the flooring radiant panel test (FRPT).

The flooring radiant panel test as embodied in NFPA 253, *Standard Method of Test for Critical Radiant Flux of Floor Covering Systems Using a Radiant Heat Energy Source,* subjects a horizontal floor-covering specimen to a radiant energy flux from a gas-fired panel at a 30-degree angle (Figures 6.5.9 and 6.5.10). The radiant energy flux decreases along the length of the specimen according to a standard energy flux versus distance profile. A pilot flame ignites the specimen at the end with the higher radiant energy flux. The flame front is allowed to travel until it is no longer reinforced by the radiant energy flux and extinguishes. The heat flux at this point of the specimen is called the "critical radiant flux." For corridors and exitways in such occupancies as hospitals and nursing homes, a minimum of 0.45 W/cm^2 is recommended (except one- and two-family houses—where the recommendation is 0.22 W/cm^2).[66] The critical heat flux of carpets then is believed to have aggravated the initial fire conditions; for example, the Baptist Tower fire was found to be 0.1 W/cm^2.[67] However, the above requirements are well within the state of the art of carpet manufacture.

Textiles in Aircraft

The flammability of textiles in the crew and passenger compartments of aircraft is regulated by the Federal Aviation Administration (FAA). The vertical test method 5903.1 is used;[41] average char length for three specimens must not exceed 8 in. (203 mm), afterburn time must be less than 15 seconds, and the time that drippings may continue to flame must be less than 5 seconds. In addition, the FAA has specified a new test for passenger seats.[68] For the purpose of this test, a unique oil burner that has the following specifications is used: (1) kerosene consumption, 2 gal per hour (7.57 L/h); (2) nozzle diameter, 6 in. (152 mm); (3) distance of nozzle from side of seat to be tested,

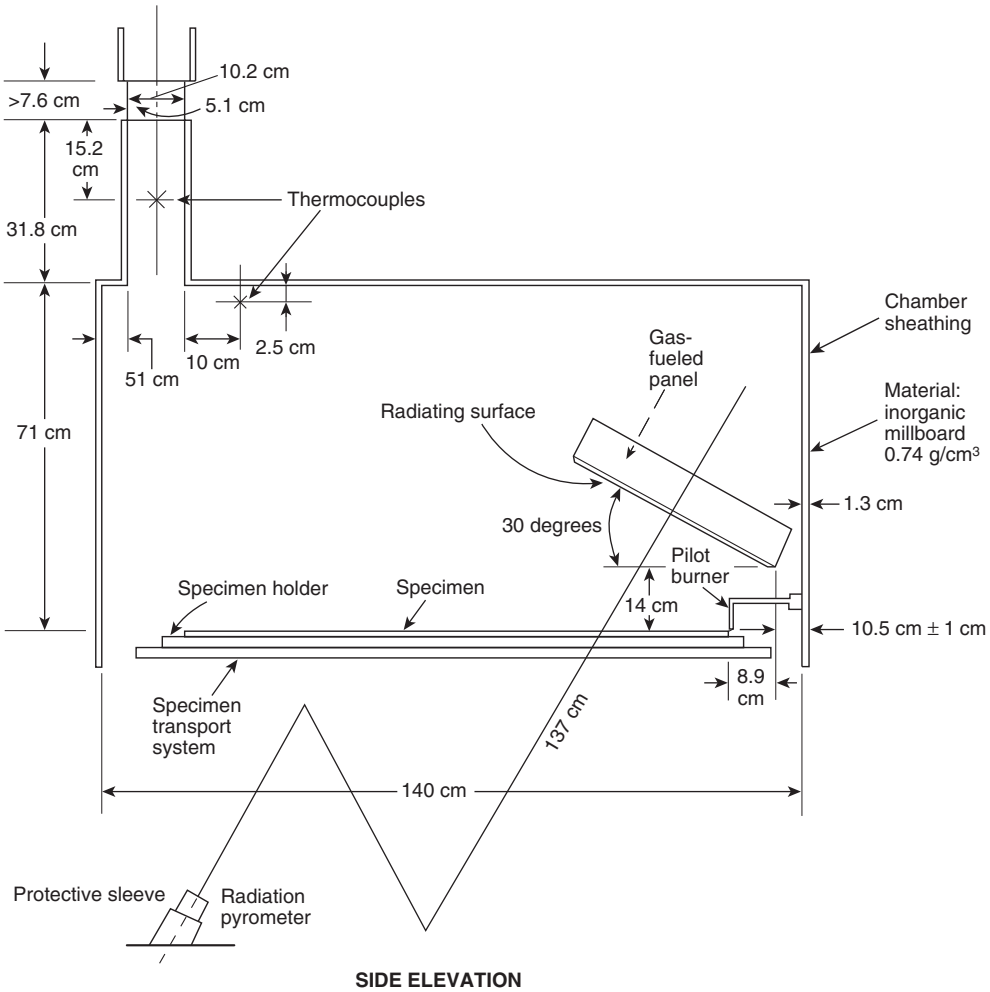


FIGURE 6.5.10 Flooring Radiant Panel Test Apparatus (Source: NFPA 253, *Standard Method of Test for Critical Radiant Flux of Floor Covering Systems Using a Radiant Heat Energy Source,* Figure 4.2.1(a))

4 in. (102 mm); (4) heat delivery to seat specimen, 10 Btu per ft^2 per second (115 kW/m^2 per second); and (5) temperature at specimen, 1850°F (1010°C). At least three seats must be tested. For at least half of the number tested, the flame spread must not reach the side of the cushion opposite the burner, the average weight loss must not exceed 10 percent, and there must be no flaming melt drip below the cushion. Among the seat assemblies that pass this test are (1) those that contain the widely used wool/nylon fabric; (2) interlayers consisting of aluminized or ordinary Nomex® or PBI fabrics, which prevent pyrolysis gases from venting toward the flames; and (3) polyurethane foam. An interliner made from Vonar® neoprene-type foam sheet also makes it possible to pass this test, but the lighter fabrics are more cost effective in this application. Other interliner materials are under development, and the use of interliners has spread to institutional furniture as well.

Textiles in Motor Vehicles

Materials used in the occupant compartments of passenger cars, multipurpose passenger vehicles, trucks, and buses in the United States must not burn or transmit a flame front across the surface at a rate of more than 4 in. (100 mm) per minute when tested according to the motor vehicle safety standard of the Department of Transportation (DOT).[69] In that standard, a specimen is suspended in a horizontal position in a test chamber, and one end is ignited by a Bunsen burner flame. The specimen is held in a U-shaped clamp and the assembly is suspended so that the top of the barrel of the burner is ¾ in. (17 mm) below the exposed edge of the specimen. The burner flame is adjusted to 1½ in. (38 mm) high, and the flame temperature to that of a natural gas flame. The specimen is exposed to the test flame for 15 seconds. Timing begins when the flame from the burning specimen reaches a point 1½ in. (38 mm) from the open end of the specimen, and timing ends when the flame has progressed to 10 in. (250 mm) or self-extinguishes. As previously mentioned, burn rate must not exceed 4 in. (100 mm) per min. This test can be considered to provide only minimum protection, and work is in progress to develop a more realistic test, especially for school buses.

Tents, Tarpaulins, Air-Supported Structures

NFPA 102, *Standard for Grandstands, Folding and Telescopic Seating, Tents, and Membrane Structures,* requires that the textiles used in these structures meet the appropriate flame-resistance requirements when tested in accordance with NFPA 701. NFPA 102 covers (1) tents and air-supported structures used for assembly, (2) tents and air-supported structures in which animals are stabled, (3) tents and air-supported structures located in a portion of the premises used by the public, (4) tents and air-supported structures in places of assembly in or about which fuel-burning devices are located, and (5) all tarpaulins used in connection with (1) through (4).

The test method in NFPA 701 uses specimens 7 ft (2.1 m) long and 5 in. or 25 in. (127 mm or 635 mm) wide, depending on whether the specimen is to be tested as a flat sheet or is to be hung in folds. The flat specimen is suspended vertically in an open-ended metal stack and its lower edge is exposed to a 11-in. (280-mm) high flame from a Bunsen burner, the top of whose barrel is 4 in. (100 mm) below the bottom of the specimen. A folded specimen is tested with its folds ½ in. (12.5 mm) apart in the same metal stack and with the same burner arrangement. For both single-sheet and folded specimen, the test flame is applied for 2 minutes, then withdrawn, and the duration of flaming combustion recorded. Length of char, that is, the distance from the top of the test flame to the top of the charred area resulting from spread of flame or afterglow, is also recorded. To pass the test, afterflame time cannot exceed 2 seconds, and the char length cannot exceed 10 in. (250 mm). For specimens in folds, maximum afterflame time cannot exceed 2 seconds, and maximum char length cannot exceed 35 in. (890 mm), but afterglow may spread in the folds.

In addition, the Canvas Products Association International (CPAI) has developed CPAI, *A Specification for Flame-Resistant Materials Used in Camping Tentage.*[70] The test for wall and top material is essentially the same as the 5903.1 test;[41] and for flooring, the methanamine tablet carpet test is prescribed. Maximum char length for walls and tops varies from 4.5 in. (110 mm) for light fabrics to 9 in. (225 mm) for heavy fabrics. For floors, the Part 1630 criteria apply.[63] Provisions for leaching, weathering, and simulated sunlight exposure are part of this voluntary standard. Conforming tents carry the CPAI label.

A comprehensive specification for tentage materials is provided in ASTM D4372, *Standard Specification for Flame-Resistant Materials Used in Camping Tentage.*[71] As with carpets and rugs, flooring material flame resistance is measured using a methenamine pill as the ignition source. Tent wall and top material are evaluated using a vertical flame resistance test similar to ASTM D6413.[40] Floor criteria are based on extent of damage from the edge of the hole for the flattening frame, while wall/top requires afterflame times to be less than 40 seconds and damaged length as based on the weight of the fabric.

International Testing Methods

Different testing methods are used in Europe and internationally for the evaluation of textile flammability, heat resistance, and thermal insulation. The majority of these test methods are based on ISO standards, which use different approaches in testing. For example, most international textile flame resistance tests use a different burner, burner/specimen orientation, and exposure time, as well as measure different textile characteristics than the analogous tests used in the United States. Some representative procedures used in other countries to test for flame resistance and other characteristics include the following:

- EN 533, Protective clothing—Protection against heat and flame—Limited flame spread material and material assembles
- EN 1101, Textiles and textile products—Burning behavior—Curtains and drapes—Detailed procedure to determine the flame spread of vertically oriented specimens
- EN 1625, Textiles and textile products—Burning behavior of industrial and technical textiles—Detailed procedure to determine the ignitability of vertically oriented specimens
- ISO 6940, Textiles and textile products—Burning behavior—Determination of ease of ignition of vertically oriented specimens

- ISO 9150, Protective clothing—Determination of behavior of materials on impact of small splashes of molten metal
- ISO 12127, Clothing for protection against heat and flame—Determination of contact heat transmission through protective clothing or constituent materials
- ISO 17493, Clothing and equipment for protection against heat—Test method for convective heat resistance using a hot air circulating oven

TEXTILES IN SPECIAL ENVIRONMENTS

Certain ambient atmospheric conditions influence the behavior of treated textiles in fire situations. They are (1) oxygen-enriched atmospheres, (2) compressed-air atmospheres, (3) atmospheres where flammable inhalation anesthetizing agents may be present, and (4) exposure to weather.

Action of Treated Textiles in Oxygen-Enriched Air

Some industrial processes require work in atmospheres enriched above the normal oxygen content. Such atmospheres present a high fire hazard, particularly to the clothing worn by the workers. The effect of flame-retardant treatments on the combustibility of the fabrics has been studied.[72]

An indication of the resistance to burning of flame-retardant textiles in oxygen-enriched atmospheres can be inferred from the limiting oxygen indices in Table 6.5.10.

Nomex® high-temperature-resistant nylon fiber in both high-pressure air environments and oxygen-enriched atmospheres at greater-than-normal pressures retains its flame-retardant qualities under air pressure of four atmospheres (59 psig or 400 kPa). At this pressure and in higher oxygen concentrations (40 percent and greater), Nomex® did support combustion, but at a substantially slower rate than did untreated, readily combustible fabrics. NASA has further improved the state of the art in this area and uses materials such as PBI, flame-retardant cotton, etc., in the oxygen-rich atmospheres.

Fabrics used for hospital operating room garments, or in other atmospheres with flammable gas contamination, should be electrically conductive to prevent accumulation of static electricity. Such accumulations, if discharged to ground, could provide a spark of sufficient energy to ignite the gas.

Weather-Exposed Textiles

Flame-retardant treatments for tents, awnings, tarpaulins, and other fabrics exposed to the weather must not leach out over a period of time. If water-soluble chemicals are used, the treatments must be renewed at frequent intervals. The NFPA 701 and CPAI[70] and ASTM[71] tests for tentage specify methods for determination of the effects of weathering.

A wide variety of chemicals can be used for treating fabrics exposed to the weather. Many of the formulas used include chlorinated paraffin, chlorinated synthetic resins, or chlorinated rubber, in combination with various water-insoluble metallic salts, plasticizers, stabilizers, synthetic resins, pigments, binders, mildew inhibitors, and so on. Such mixtures are not water soluble and are used with hydrocarbon solvents or are suspended in aqueous emulsions. The effective application of such treatments calls for techniques and equipment ordinarily available only for factory processing or to businesses specializing in flame-retardant applications. Application of paint to these treated fabrics may lessen their flame resistance.

SUMMARY

Almost all textiles are combustible. Fibers, which may be natural or manufactured, are the basic components of all textiles. Many fibers are spun into yarns and then woven and knitted into fabrics. This type of textile manufacturing involves many processes, including opening, picking, cleaning, blending, carding, combing, drawing and roving, spinning, and so on.

The ignitability, flame spread and heat release rate, total heat produced, heat shrinkage, and ease of fire extinguishment vary among different types of fibers. The finish generally does not alter these properties significantly unless the fabric is treated with a flame retardant.

The end use of a textile (e.g., clothing, curtains, draperies, wall coverings, and carpets and rugs) is very important when evaluating its flammability. There are several commonly used test methods for textile products.

Chapter 6

Upholstered Furniture and Mattresses

Vytenis Babrauskas

Chapter Contents

Statistical Background
Materials Used in Upholstered Furniture
Similarities of and Differences Between Upholstered Furniture and Mattresses
Smoldering and Flaming
Upholstered Item Flammability Standards
Testing Resistance to Flaming Heat Sources
Characteristics of Ignition Sources
Flame Spread
Heat Release Rate (HRR)
Improvements in Fire Performance of Furniture

Key Terms

cigarette ignition, Consumer Product Safety Commission (CPSC), fire resistance, fire-safe cigarette, flame spread, flame spread rating, flammability standard, heat release rate (HRR), mattress, upholstered furniture

Upholstered items, such as furniture and mattresses, play a special role in fire hazard. This hazard was first identified many years ago in a statistical study that determined that these items constitute the classes of burnable items accounting for the largest share of fire deaths in the United States.[1] However, there has been a substantial and fairly steady decline in reported U.S. home structure fires originating with upholstered furniture and with mattresses or bedding respectively.[2] Upholstered furniture and mattresses can be ignited by cigarettes, flames, or other means, with the ignition source having a direct bearing on test methods. This chapter addresses the performance of upholstered furniture and mattresses when exposed to cigarette and flaming sources of ignition.

The need for upholstered items to resist cigarette ignition is distinctive—other furnishings, such as carpets or curtains, are ignited by cigarettes comparatively less often. Unfortunately, resistance to cigarette ignition and resistance to flames are not necessarily achievable by the same means. Among common upholstery fabrics, medium and heavyweight synthetic thermoplastic fabrics (e.g., nylon, olefin, and polyester) generally resist cigarette ignition but do not resist flame ignition. Cellulosic materials (e.g., cotton, hemp, jute, linen, and rayon fabrics) have poor cigarette ignition resistance, but burn more slowly when used as covering for polyurethane foam. Only a smaller selection of fabric/padding combinations—such as wool fabric over advanced foams—combine good cigarette ignition resistance with relatively high resistance to flames. In specialized applications (e.g., aircraft seating, certain institutional furniture), interliners—also called barriers—have been used for several decades to improve fire performance.

For related topics, see also Section 6, Chapter 5, "Fibers and Textiles"; and Section 6, Chapter 7, "Fire-Retardant and Flame-Resistant Treatment of Cellulosic Materials."

STATISTICAL BACKGROUND

Tables 6.6.1 and 6.6.2 demonstrate the decline in reported U.S. home structure fires originating in upholstered furniture and mattresses or bedding.[2]* Tables 6.6.3 and 6.6.4 demonstrate similar declines, but much lower numbers for reported U.S. fires in structures other than homes.[2]* During 1999 to 2002, fires originating in upholstered furniture accounted for 19 percent of home fire deaths (the largest share for any burnable item), 3 percent of home fire incidents, 7 percent of home fire injuries, and 5 percent of direct property damage in home fires. In the same period, fires originating in mattresses or bedding accounted for 14 percent of home fire deaths (the second largest share for any burnable item), 5 percent of home fire incidents, 13 percent of home fire injuries, and 7 percent of direct property damage in home fires. Together, they accounted for nearly 1000 home fire deaths, 27,000 reported home fire incidents, more than 3000 home fire injuries, and roughly $640 million in direct property damage in home fires, all per year in 1999 to 2002.

Fires starting with both products were dominated by cigarettes, candles, matches and lighters, and radiated heat from nearby equipment, such as space heaters (Tables 6.6.5 and 6.6.6).[2]*

[a]"Homes" include one- and two-family dwellings, duplexes, manufactured homes, apartments, tenements, flats, townhouses, and condominiums. The home category does not include rooming, boarding, or lodging houses; hotels or motels; dormitories or fraternity or sorority houses; barracks or bunk houses; or any institutional property providing lodging.

[b]These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest hundred; civilian deaths and injuries are rounded to the nearest one; and direct property damage is rounded to the nearest million dollars. Fires reflect a proportional share of fires in which item ignited was unknown or unreported.

[b]These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest ten; civilian deaths and injuries are rounded to the nearest one; and direct property damage is rounded to the nearest hundred thousand dollars. Fires reflect a proportional share of fires in which item was ignited was unknown or unreported.

Source: National Fire Incident Reporting System and NFPA survey. Inflation adjustments have been made based on Table No. 697, "Purchasing Power of the Dollar: 1950 to 2003," U.S. Census Bureau's *Statistical Abstract of the United States: 2004–2005,* 124th Edition, 2004.

Not surprisingly, the cited factors contributing to these kinds of ignitions were led by abandoning of materials (such as improper disposal of a lit cigarette or used match), children playing with fire, and heat sources too close to the combustible products (Tables 6.6.7 and 6.6.8).[2]* Also significant, but not shown on these tables, because they are now recorded under different data elements, are intentional fires (typically juvenile firesetters too old to be called children playing with fire) and human factors

such as falling asleep, which lead to loss of control of the heat source.

Equipment heat sources were individually rare (Tables 6.6.9 and 6.6.10), but the leading equipment types for fatal fires starting with these products included portable and fixed space heaters, lamps or lightbulbs, and electrical cords or plugs.[2*]

*Rohr[2] and previous reports in the series, and special National Fire Incident Reporting System (NFIRS) analysis by National Fire Protection Association (NFPA) staff.

The victims of fires started by improper handling of a heat source are not always—or even usually—the people whose actions or errors started the fire. A majority of home fire deaths involve victims who were not in the room of fire origin. This fact is also true of a large minority of fire deaths started by smoking, open flame, or children playing with fire.[3] This circumstance also means that there is time and distance for fire protection measures, such as smoke alarms, sprinklers, and compartment barriers, to intervene and prevent these fires from causing fatal injury.

MATERIALS USED IN UPHOLSTERED FURNITURE

The fire characteristics of combustible goods are determined in part by the materials from which they are made. Apart from wood frames, furniture construction materials have changed greatly during the last 50 years. Most upholstered furniture continues to be hand-built on a wood frame. An industry interest in molded plastics during the 1970s was short lived, and the frames made today differ only slightly from frames made decades ago. In a few cases, manufacturers use molded plastic portions in conjunction with a frame otherwise made from wood. Polyurethane foams, which became common in the 1960s, were initially used plain. Today they often have a "topper" layer of polyester batting. Fabrics are a fashion item and change over the years. The last decade has seen an upsurge in the popularity of leather upholstery, whereas prior to that there was a trend for using loosely sewn, puckered fabrics. Loose fabrics showed some adverse flammability effects (though not extensively studied), but the trend appears to be currently diminishing.

In 1997, the U.S. Consumer Product Safety Commission (CPSC) published statistics on the fabrics (Table 6.6.11) and paddings (Table 6.6.12) used in upholstered furniture.[4] Recently, it has become common to use mixed-fiber fabrics for furniture upholstery, but the CPSC tabulation does not reflect this.

Small-scale tests on retail furniture indicate that only about 39 percent of items upholstered in cellulosic fabrics are resistant to cigarette-caused smoldering, but about 95 percent of thermoplastic-fabric upholstered furniture is resistant.[5–9]

Apart from modest use of fire-retardant-treated (FR) cotton batting in mattresses, there is currently little use of fire-retarded or flame-resistant materials in the U.S. consumer market. Although FR furniture is presently not available in retail showrooms in the United States, it is available for specialty markets such as hospitals, correctional facilities, and other

institutional uses. A different situation is found in the United Kingdom, where regulations passed in the late 1980s[10,11] mandated that upholstered furniture and mattresses (apart from tickings*) be resistant both to small flames and to cigarettes. The consequence has been that furniture on the U.K. market generally uses advanced, fire-retardant polyurethane foams and FR-treated fabrics. The official U.K. government survey[12] concluded that use of the improved materials raised costs by $24 to $32 per furniture item, but provided a 40:1 benefit/cost ratio. The U.K. analysis, however, was rebutted by a U.S. statistician whose reanalysis did not support the optimistic U.K. view.[13] The situation in the United States is expected to change rapidly with regards to mattresses, however, due to the enactment by CPSC in early 2006 of drastically new flammability regulations for mattresses, as discussed below.

*Mattress tickings were excluded from the regulation, but UK Product Safety Regulations in effect make manufacturers follow British Standards in this matter, which do encompass ticking performance.

SIMILARITIES OF AND DIFFERENCES BETWEEN UPHOLSTERED FURNITURE AND MATTRESSES

Ease of Ignition

Many aspects of flammability are similar for upholstered furniture and mattresses. However, some distinctions must be made: mattresses have predominantly flat surfaces that are not as likely to ignite by cigarettes as are crevices in furniture, such as the juncture of seat cushion and armrests and back of upholstered furniture. (In a similar vein, horizontal flat furniture surfaces are not as easily ignited by flame ignition sources as are vertical surfaces.)

On the other hand, cigarettes on mattresses may be inadvertently covered with sheets, blankets, or pillows. This increases the probability of ignition. Also, these intermediary materials may ignite from flames more readily than mattresses and then expose the mattress to a much more severe fire. Consequently, it

is more difficult to develop relevant ignition tests and standards for mattresses than for upholstered furniture.

Materials

Upholstered furniture can contain well over a dozen materials: for example, cover fabrics and fabrics between the cover fabric and the padding (interliners); different padding materials in the seat, sides, and back; weltcords; another fabric and type of padding below the seat cushion (decking); and frames, springs, stiffening for the sides, and so on. Mattresses are complex but contain fewer materials. In the ignition process, whether from a cigarette or a small flame, the cover fabric and material immediately below it—one or two layers of padding—are important. As the fire progresses, other materials, including the frame and springs, become involved, which can affect the manner in which the burning item collapses.

Another difference stems from industry practices. Until recently, it has been possible to find older materials (cotton batting, latex foam, vegetable-origin fibers, etc.) in mattresses from certain manufacturers. By contrast, these materials have become quite rare in upholstered furniture, wherein polyurethane foam is by far the dominant padding material. However, the new CPSC mattress regulation may cause the materials used in the mattress industry to become simplified across the board.

Radiant Heat Conditions

An important difference concerning mattresses is that radiant heat conditions can affect them more readily. This difference can mean that a mattress and a chair that show the same heat release rate when burned in a very large space will behave differently when placed in a small room. In the latter case, the mattress is likely to burn more severely than the upholstered chair.[14] More technical discussions of differences in mattress and upholstered furniture behavior have been published.[15]

SMOLDERING AND FLAMING

Smoldering of upholstered items, which is the typical consequence of exposure to a burning cigarette, can produce enough smoke and toxic gases to incapacitate and kill, but rarely does so before the fire transitions to flaming or, in the absence of such a transition, before the fire self-extinguishes or is put out.[16] Transition from smoldering to flaming does not occur in all cases; when it does, times from placement of the cigarette to flaming of 22 minutes to several hours have been reported.[17,18] In a closed room, flaming can revert to smoldering when the oxygen supply is exhausted. With sufficient oxygen, a single upholstered item of sufficient burning rate can lead to room flashover.

Another feature of upholstered furniture fires is the difficulty of ensuring extinction, because soaking or even immersion in water may not ensure extinguishment. Items should be removed from the premises, torn apart, and the pieces thoroughly wetted. Many fire victims have wetted down a smoldering area in an upholstered chair or sofa, retired for the night, only to be faced several hours later with impenetrable smoke or a full-scale fire.[17] This problem has been very serious with latex foam items, but must be addressed with other types of constructions as well.

A monograph on upholstered furniture flammability contains an in-depth discussion of cigarette and small flame ignition resistance and postignition behavior.[19]

UPHOLSTERED ITEM FLAMMABILITY STANDARDS

Some cigarette and flame ignition standards and tests for upholstered items are listed in Table 6.6.13. They can be classified as voluntary standards and tests, federally enforced standards, and state-imposed standards. A more extensive discussion of earlier

standards and also of international standards was presented in 1989.[20]

Testing Resistance to Smoldering Heat Sources

In the United States, mattresses made since June 1973 have had to comply with a cigarette-ignition test method that is published in Title 16, Code of Federal Regulations, Part 1632.[21] Originally, the test method was developed by the National Bureau of Standards (now the National Institute for Standards and Technology [NIST]), but after the establishment of the Consumer Product Safety Commission (CPSC) it was taken over by that agency. The pertinent test is still often known by its original designation as FF 4–72. The test is on a full-size article and involves placing nine cigarettes on the bare mattress and nine more sandwiched in between two sheets placed on the mattress. (See Figures 6.5.7 and 6.5.8 in Section 6, Chapter 5, "Fibers and Textiles.")

Additional voluntary standards have been developed by trade organizations, such as the Upholstered Furniture Action Council (UFAC) for residential furniture and the Business and Institutional Furniture Manufacturers Association (BIFMA) for business products. Two of these standards have also been developed as ASTM E1353, *Standard Test Method for Cigarette Ignition Resistance of Components of Upholstered Furniture Assemblies,* and ASTM E1352, *Standard Test Method for Cigarette Ignition Resistance of Mock-Up Upholstered Furniture Assemblies.* What became the BIFMA standard was originally developed by NIST in 1976 for CPSC as a proposed test for the resistance of upholstered furniture to cigarette ignition.

However, the furniture industry requested CPSC to allow a voluntary standard instead, and residential upholstered furniture items since the early 1980s have been available with the UFAC

hangtag. The presence of the hangtag indicates the manufacturer's certification that the item was manufactured in accordance with UFAC standards.[22] By the mid-1990s, CPSC found that 86 percent of all upholstered seating in the retail marketplace met all of the UFAC requirements.[23] Such furniture, of course, is not 100 percent ignition resistant, but CPSC did determine that there was approximately an 85 percent likelihood that a cigarette placed on any mid-1990s vintage furniture item would fail to ignite it.

The cigarette used in all U.S. smoldering ignition tests is a filterless, 85-mm commercial cigarette (Pall Mall® brand). It is representative of many other cigarette brands in its propensity to ignite. Cigarette tests generally specify placement of the cigarette in the most vulnerable configuration, which is the crevice formed by the horizontal and vertical upholstered surfaces except, of course, for mattress tests. The cigarette is covered with a piece of sheeting. This makes the test slightly more severe and more reproducible, presumably because of exclusion of air currents from the smoldering area. Pass/fail criteria are generally expressed in terms of char length or obvious ignition (i.e., sustained, expanding smoldering) for cigarettes.

For upholstered furniture, the state of California has a voluntary smoldering-resistance standard, Technical Bulletin 116, which is similar to the UFAC test methods but entails testing of the actual fabric/padding composites. The UFAC procedure, by contrast, while involving minimockups of composite material, tests only fabrics over "standard" foams and vice versa. For reasons not entirely clear, compliance with voluntary provisions for cigarette ignition resistance have been more successful in California than nationally. It is estimated that about 90 to 95 percent of the furniture sold in California is resistant to cigarette ignition.[5] California's T.B. 117 and the large-scale California tests—T.B. 121, T.B. 129, and T.B. 133—are discussed later. Most other states do not have any regulatory requirements.

Fire-Safe Cigarettes

Another strategy to reduce the risk of fires due to cigarette ignition of upholstered items is to regulate the cigarette itself, rather than the target fuel. CPSC asked NIST to examine the practicability of such "fire-safe" cigarettes as a consequence of two Congressional Acts, the Cigarette Safety Act of 1984 and the Fire Safe Cigarette Act of 1990. A fire-safe cigarette has a reduced propensity to continue burning when left unattended. In both cases, NIST produced voluminous studies on the topic, which elucidated many details of the problem. More important, at the end of the second study, the conclusion was that such cigarettes are not only feasible but also practicable.[6] NIST also developed a test method specifically for this purpose, which has become ASTM E2187, *Standard Test Method for Measuring the Ignition Strength of Cigarettes.*

In July 2000, the Philip Morris company started producing fire-improved Merit-brand cigarettes by using a patented cigarette paper, PaperSelect, that has thin bands of less porous paper that act as "speed bumps" to periodically slow down the burning rate. NIST tests[7] indicated that the cigarette does indeed show a reduced ignition potential, but the probability of ignition was still 3 to 50 percent, depending on the test substrate.

New York was the first state to adopt regulations requiring that cigarettes sold in New York State comply with the ASTM standard. New York Fire Safety Standards for Cigarettes[8] went into effect June 28, 2004. After that, the entire country of Canada adopted regulations using the same ASTM standard; this regulation[9] came into effect October 1, 2005. Similar regulations have gone into effect in Vermont (effective May 1, 2006) and California (effective January 1, 2007), and it is likely that additional states will follow.

In March 2006, the NFPA launched the Coalition for Fire-Safe Cigarettes with the stated goal of establishing country-wide adoption of similar legislation. The coalition, coordinated by NFPA, has called for cigarette manufacturers immediately to produce and market only cigarettes that adhere to an established standard based on ASTM E2187 and for all states to file legislation adopting such standards in their next legislative session. As an indicator of the coalition's success, three states adopted such laws within the four months following the coalition's establishment (Table 6.6.14). For current information, see http://www.firesafecigarettes.org.

TESTING RESISTANCE TO FLAMING HEAT SOURCES

Small-Scale Tests

There are three testing strategies for determining the resistance of upholstered items to flaming heat sources: (1) component testing, (2) small-scale composite or mock-up testing; and (3) full-scale testing. A full-scale test is obviously definitive, subject only to the specification that the ignition source be well thought out. A small-scale composite or mock-up may capture much of the same behavior, but this—by itself—is unproven. For a small-scale test to be a reasonable reflection of what happens in real fires, it is necessary that a research program be conducted wherein full-scale performance and small-scale results are directly compared.[24] This is not a trivial task, because even the engineering units needed are not the same. For full-scale performance, peak heat release rate (HRR) is often considered to be

TABLE 6.6.14 Fire-Safe Cigarettes: State Legislation

State	*Percent of U.S. Population Covered*	*Legislation Signed*	*Effective Date*
New York	6.5	December 31, 2003	June 28, 2004
Vermont	0.2	July 17, 2005	May 1, 2006
California	12.2	October 7, 2005	January 1, 2007
Illinois	4.3	May 19, 2006	January 1, 2008
New Hampshire	0.4	May 31, 2006	October 1, 2007
Massachusetts	2.2	July 8, 2006	January 1, 2008
	25.9		

the governing variable that best describes the real-life hazard;[25] but for small-scale results another metric needs to be found, which can be, for example, the 3 minute average HRR, divided by the specimen's area, giving units of kW/m^2. Component tests involve testing of foam, fabrics, etc., in isolation, without considering their interactions in the actual item. Such tests usually have little merit, because the interaction between the layers of an upholstered item is highly complex, both thermally and chemically; ignoring it does not lead to reliable conclusions. The one known exception to this generalization has been the component testing scheme studied in the European CBUF research project.[14] However, to become reliable, the scheme had to become so highly complex that it was no longer a practical, simpler alternative to composite testing. Consequently, its use was not even espoused for that project's objectives.

For flame ignition component tests, ignition is often by a gas flame at the bottom of a vertical specimen, such as foam or fabrics.[10,26] Flaming ignition in furniture mock-ups is generally at the crevice location.

Some of the newer tests described in Table 6.6.13 are more severe than the state standards such as T.B. 116 and T.B. 117 in that they employ larger ignition sources or heating with radiative sources. These tests often include heat release rate, flame spread, and smoke measurements, and are frequently used for research, product development, and regulation of special occupancies by some state and local authorities.

There is also a hybrid possible of strategies 1 and 2, whereby a composite is tested, but not the actual composite. Instead, a "standard" foam is placed underneath the to-be-tested fabric, or a "standard" fabric is placed on top of the to-be-tested foam. Various other component combinations can also be constructed in similar manner. This arrangement has the benefit of reducing testing costs but also introduces uncertainty. Furthermore, there has not been any broad-based scientific study to validate this type of approach.

The hybrid testing approach is found in a few sections of the (old) California T.B. 117 standard (see below) and was also used in the regulations issued by the United Kingdom for upholstered furniture during 1988–1989.[10,11] The U.K. regulation is a complex scheme that involves cigarette, small-flame, and wood-crib tests for various materials, depending on the material. The test methods themselves are a slightly modified version of British Standard BS 5852, *Methods of Test for Assessment of the Ignitability of Upholstered Seating by Smouldering and Flaming Ignition Sources.*

California T.B. 117

California became a unique state in the regulation of furniture when it put into effect a mandatory regulation for furniture flammability in 1975. Furniture makers wishing to sell products in California became subject to the requirements of California standard T.B. 117.[26] The standard was quite complex and covered both smoldering performance and small-flame resistance of upholstered furniture. The smoldering portions became moot in the 1980s, when the UFAC procedures became the nationwide norm. Because the test requirements for smoldering within T.B. 117 were so weak that they did not even cover the fabric, manufacturers generally made furniture according to the UFAC requirements and such furniture was then suitable for all 50 states.

The unique small-flame resistance requirements in T.B. 117 entailed component testing of padding materials (i.e., naked foams) using a vertical Bunsen burner test. Adding a small amount of fire-retardant chemicals to foams normally suffices to produce a dramatic improvement in performance in this test and allows the product to meet the California regulation. Unfortunately, testing by CPSC indicated that furniture meeting the test requirements of California T.B. 117 will very often not meet the intended purpose of the test—actually to make the furniture resist ignition when presented with a small ignition flame.[23] This finding is not surprising, because an external flame will expose the fabric first, and only then will the padding be subjected to ignition. But T.B. 117 specified the CS-191-53 test procedure[27] for fabrics, which will essentially never fail a fabric that is sufficiently thick to be viable for upholstery purposes. By 1994, the former head of the California Bureau of Home Furnishings[28] that developed this test method acknowledged most of these shortcomings. In 1999 the bureau announced that the standard would be revised and strengthened. A draft version of an entirely new T.B. 117 was publicized in 2002, but then California suspended further development due to CPSC's renewed efforts to establish a federal standard for the resistance of upholstered furniture to small-flame ignition sources.

CPSC Proposed Small-Flame Ignition Test for Upholstered Furniture

In the early 1980s, U.S. fire deaths due to smoldering ignitions of upholstered furniture were about 1000 per year (Figure 6.6.1).[4] By the mid-1990s, the rate dropped down to around 600 per year. This can be attributed to the reasonable effectiveness of the UFAC program, a reduction in smoking, improved fire safety education, and more widespread use of home smoke alarms. By contrast, the number of deaths due to flaming ignitions of upholstered furniture had declined less substantially and less steadily, and multiyear averages showed a decline in deaths from 110–120 to 90–100.

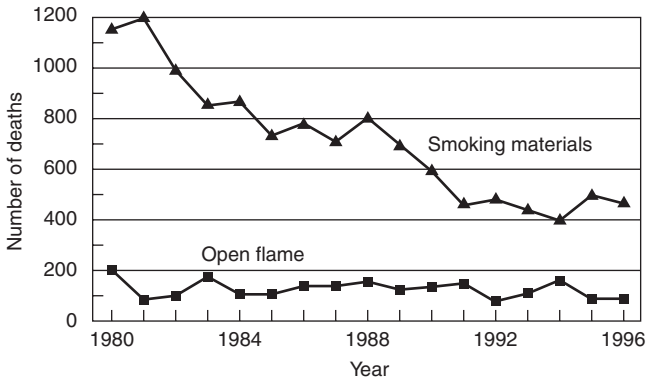

FIGURE 6.6.1 Annual U.S. Fire Deaths Due to Ignitions of Upholstered Furniture, as Estimated by CPSC

Statistics also indicate that although the number of upholstered furniture fires ignited by open flames has decreased (Figure 6.6.2), the risk of injury, given an ignition, has increased (Figure 6.6.3).

In view of the fact that deaths in open-flame fires were not clearly decreasing, the National Association of State Fire Marshals petitioned CPSC in 1992 and 1993 to establish some new national flammability standards for upholstered furniture. CPSC responded in 1994 by granting the part of the petition asking for a small-flame ignition test. The request for large open-flame resistance was not granted. CPSC first investigated the merits of California T.B. 117, which has been used since 1975. After a laboratory investigation of the method, CPSC concluded[29] that "T.B.-117 component results were not predictive of full scale performance," and that "T.B.-117 . . . would not, if federally mandated, ensure a substantial reduction in the risk of small open-flame ignition of finished articles of furniture." The same conclusion had emerged from earlier, private-sector studies on T.B.-117 complying furniture.[30,31]

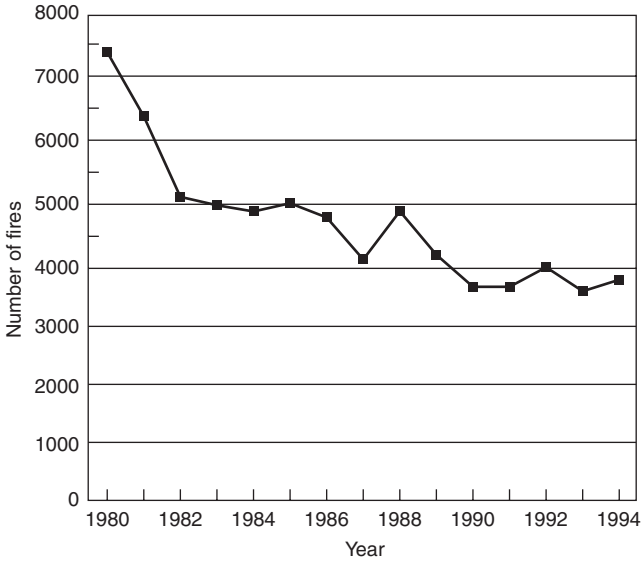

FIGURE 6.6.2 Annual Number of Furniture Fires Caused by Open Flames, as Estimated by CPSC

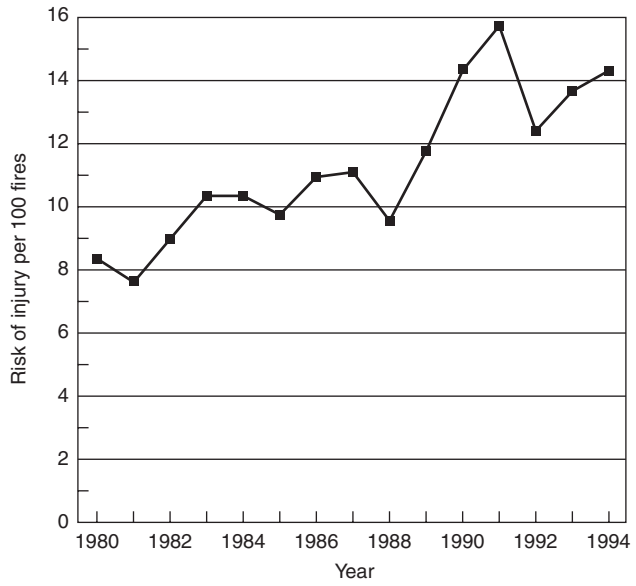

FIGURE 6.6.3 Risk of Injury, per 100 Upholstered Furniture Fires Ignited by Open Flames, as Estimated by CPSC

Consequently, CPSC then looked to the British approach for testing furniture, because it was considered that furniture complying with British regulations was better than the U.S.-marketplace furniture generally available to retail consumers.[4] The British regulations are both complex and discriminatory (e.g., latex foam is held to a lower standard than polyurethane foam). Thus, CPSC actively considered only the basic test setup and not the entire regulation and, over the next few years, developed a draft method that evolved from one of the mock-up tests used in the United Kingdom. A draft of this method was published in 1997[23] and elicited numerous comments from industry, primarily concerning the statistical reliability of the test.[32] The main test was a hybrid test of the fabric/foam composite used for the seat and back cushions, whereby a "standard" foam would be used in place of the actual foam. In addition, CPSC noted that a fire hazard also exists from flammable dust covers (a nonwoven fabric typically present below the seat cushion area), because children playing with fire sometimes ignite those from underneath. Thus, it proposed a separate dust-cover test. CPSC did offer limited support for its particular version of hybrid testing by conducting some preliminary testing[29] that found that "fabric ignition times were essentially the same when tested with and without . . . FR foams." The main CPSC test setup (Figure 6.6.4) uses a metal frame to create a seat and a back. The rig then holds a simulated back cushion of 305 by 458 by 76 mm, and a seat

FIGURE 6.6.4 Specimen Being Tested in the Proposed 1997 CPSC Open-Flame Test for Upholstered Furniture (Source: Photo courtesy K. Reimann, BASF)

cushion of 83 by 458 by 76 mm. A butane flame, about 35 mm tall, is applied for 20 seconds at the seat/back juncture.

During 1999–2000, CPSC conducted a round-robin study of the proposed test method, with nine test laboratories participating. The round-robin involved five upholstery fabrics and two types of dust cover. Generally, the laboratories were able to agree on "pass" or "fail" results for the test specimens. Two of the five fabrics were deliberately selected as borderline samples and, as expected, returned mixed results. Despite its long-term activity, CPSC did not publish much data on the performance of various materials in their draft test. Such an effort was undertaken by Reimann,[33] who examined 219 fabrics and conducted 408 mock-up tests. Of untreated fabrics only 4 out of 75 passed the test requirements at that time. Of fabrics stated to comply with BS 5852 (but not certified), 22 out of 52 passed. Of 11 cotton fabrics treated with a proprietary FR agent, 100 percent passed. Although not a part of the draft test method, testing with highly fire-retardant foams did not show an anticipated improvement in performance, presumably because advanced foam formulations cause improvements in heat release rate, not ignitability. Reimann also found a number of technical difficulties or shortcomings, especially that tensioning of the fabric is critical and may not be controlled adequately in the test method. In other industry testing,[34] it was found that only 17 out of 31 fabrics certified to meet BS 5852 met the CPSC requirements.

CPSC's development of a flaming-ignition standard was delayed when the furniture industry persuaded Congress to suspend its research on a test method and to focus on the question of whether fire-retardant chemicals to be used for making test-complying furniture might be hazardous from a toxicologic point of view. CPSC was consequently directed to cooperate with the National Research Council (NRC) in conducting a review of the literature on the topic. The focus was on fire-retardant agents used for fabrics, rather than foams, because (1) the CPSC test development effort focused on fabric improvements; and (2) the state of California had required FR-treated (or equivalent) furniture foams since 1975. Consequently, there is a wide database of consumer experience with FR-treated furniture foams. NRC studied in detail 16 FR agents deemed to be most likely used for treating furniture fabrics and published its findings in 2000.[35] The philosophy of the investigators was to examine whether there was an adverse health effect without considering at the same time the possibility of enhanced health effects due to the prevention of injuries from fire. This thinking is a conservative philosophy, yet the investigators found that 8 of the 16 chemicals warranted no further study, because they were clearly non-injurious to consumers. In their view, data were not sufficient to make the same statement about the other 8 chemicals, so they recommended that further research be done on those.

A government-sponsored study in the United Kingdom did set out to assess FR agents in a risk/benefit context.[36] The authors of that study concluded that "the benefits of many flame retardants in reducing the risk from fire far outweigh the risks to human health." But they too pointed out that FR agents need to be studied individually (or by chemical families)—it is clearly impossible to make a general statement about any and all chemicals proposed for use in a certain application.

Once the toxicity issue was settled, CPSC proceeded to issue new proposals in quick succession during 2001, 2003, 2005, and 2006.[37–41] The 2006 document proposes separate tests for flaming and smoldering resistance of upholstery composites, along with several variations and options that are still to be considered. Open-flame exposure specimen performance in the 2006 draft test method is illustrated in Figure 6.6.5. The specimens are identical except that an interliner was included in the specimen on the right, enabling it to pass the test criteria. Unlike for mattresses, there are no indications that CPSC would adopt HRR-based testing for upholstered furniture.

Large-Scale and Full-Item Tests

Testing for cigarette ignitability can be done satisfactorily on small samples (although reliability will perforce be higher if done on the full-scale item). However, for flaming behavior of

FIGURE 6.6.5 Performance of Two Specimens in the 2006 Draft Version of the CPSC Upholstered Furniture Test for Open-Flame Resistance of Upholstery Composites: Without Interliner (left); with Interliner (right)

fires, the situation is different. A small Bunsen burner or similar type of test cannot predict what will happen to real furniture. Thus, it had been recognized for a number of years that large-scale tests may be crucial.

The first large-scale fire test for upholstered furniture to gain widespread acceptability was California T.B. 133.[42] The test comprises a room in which an actual furniture item (or a full-scale mock-up) is fire tested. The original ignition source comprised 3.2 oz (90 g) of balled-up newspaper held in a wire cage placed into the crevice of the furniture. The criteria included room temperature rise, carbon monoxide (CO) concentration, and smoke density in several locations, and the weight loss of the test item. Following a research program at NIST,[43] the test method was revised in 1990 in three fundamental respects: (1) for improved reproducibility, the ignition source was replaced with a gas burner; (2) the main pass/fail criterion was set as a heat release rate value, taken at the 80 kW level; and (3) a new option was added for running tests in the hood of a large-scale furniture calorimeter, rather than inside of a burn room.

The California T.B. 133 test was originally voluntary. In 1992 it was made mandatory in California for certain public occupancies (but not for residential use). Its influence, however, extends beyond these limited applications. Most of the larger manufacturers of contract furniture now offer a significant selection of T.B. 133–complying furniture. Much of this acceptance has come from concerns about product liability litigation. The test has been adopted by ASTM International as ASTM E1537. An Underwriters Laboratories method (UL 1056) was originally published and entailed quite different test conditions. However, the UL method was changed to make it rather similar to the methods of ASTM. For actual testing, reference should be made to the ASTM method, because guidance to the laboratory is much more extensive there than in the California bulletin.

To meet T.B. 133 requirements, manufacturers have most often turned to using an interliner fabric (e.g., vinyl-coated glass fabric, or Nomex® or PBI (polybenzimidaxozole) nonwoven or woven fabrics) between the cover fabric and the padding. Foam improvements might be needed and care in selecting fabrics is also necessary. It is especially difficult to pass the T.B. 133 test with polyolefin (polypropylene) fabrics. It is important to realize that the test is a system test and not a materials test. Thus, using the same construction materials, it can be possible to pass the test with a smaller chair and fail it with a larger one. A number of other design variables, in addition to combustible mass, also enter into the picture.

For prison mattresses, California has long had a special large-scale test, T.B. 121. This test is run in the same test room as for the T.B. 133 test, but with a different ignition source, which is a wastebasket placed underneath the test specimen.[44] More recently, California developed a less severe mattress test suitable for other institutional occupancies. This test, T.B. 129,[45] uses a gas burner located alongside the edge of the specimen, with other test features being essentially identical to those of the T.B. 133, except for the pass/fail limit. For the California T.B. 129 test, this limit is set at 100 kW. The test has been adopted as ASTM E1590. The latest development is the new CPSC mattress test and regulation, discussed below.

A special category of concern is stacking chairs. These types of chairs are normally used in hotel ballrooms, churches, and other public assembly rooms. This chair type, when upholstered (some types are of solid molded plastic, without upholstery), usually has only a small amount of padding. Thus, it would seem that dangers associated with them would be small. After some significant fires, most notably the 1978 Cathedral Hill Hotel fire in San Francisco, California, however, attention was focused on the fact that such chairs are often found in their stacked configuration, where they can be many units high. Under these conditions, the hazards are much increased. This concern has led to a large-scale fire test method, ASTM E1822, *Standard Test Method for Fire Testing of Stacked Chairs.*[46]

In the area of transportation seating, there is a large-scale regulatory test promulgated by the FAA for airplane seats.[47] It specifies a 115 kW, 6 in. (152 mm) diameter kerosene burner flame directed for 2 minutes on the side of the seat. The flames must not spread across the seat, no flaming drips must fall, and a maximum weight loss is specified. This challenging test serves to ensure that airplane seats would not burn with a fierce fire. The other U.S. federal test for transportation seating is remarkable for its laxness. Motor Vehicle Safety Standard No. 302 uses a horizontal specimen and has minimal flame-spread requirements.[48] The consequence is that seating in automobiles is commonly easily ignitable and produces rapidly growing, high-heat-release-rate fires.

CPSC Open-Flame Ignition Test for Mattresses

In February 2006, CPSC issued new regulations governing the resistance of mattresses to open-flame ignition. The agency considers this the first regulation in that agency's history that has an impact of over $100 million on the national economy. The new federal standard, which went into effect on July 1, 2007, is described in a Federal Register notice.[49] This regulation has had a long and convoluted history. In 1991, California's Bureau of Home Furnishings and Thermal Insulation reported on extensive full-scale testing[50] of various bare mattresses (no bedding). Some of these specimens, however, easily passed the test, whereas the supposition was that in a real-life situation they might not have behaved similarly. An extensive study at NIST[51] in the 1970s had demonstrated that the bedding on a bed is the "driving force" causing flame spread and sustained combustion of the mattress. In the absence of bedding, a mattress fire may die out, yet the same specimen may burn vigorously when covered with bedclothes. Thus, presenting modest-sized flames to a bare mattress may produce unrealistically benign test results. Consequently, a few years later, the industry trade group International Sleep Products Association (ISPA) sponsored a new research project at NIST to develop a mattress test that duly recognizes the role of bedding on a mattress. Because of difficulties in ensuring a long-term supply of identical bedclothes, the NIST work focused on developing a substitute, which took the form of two "T-head" gas burners, one applied to the side of the mattress and one to the top. The top burner is run at a power of 18 kW, and the side burner receives 9 kW (Figure 6.6.6). This research work by Ohlemiller et al. has been documented in a series of NIST reports.[52–55]

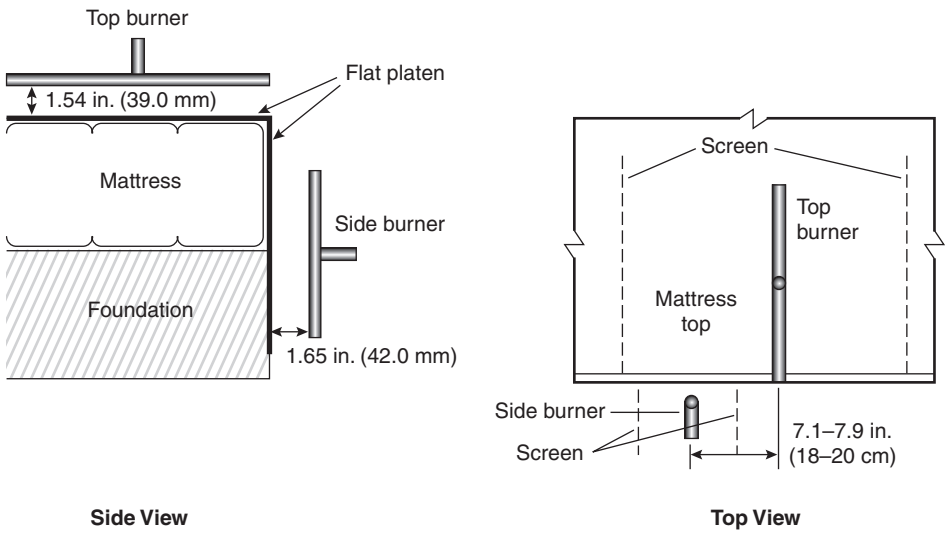

FIGURE 6.6.6 Two Burners Used to Provide a Simulated-Bedclothes Exposure to a Mattress Specimen in the CPSC Open-Flame Mattress Test

Even at this stage of development, the mattress test was of a substantially different nature than the small-flame tests for upholstered furniture used in California or investigated by CPSC. The latter simulate the application of a cigarette lighter, whereas the NIST procedures are based on a large open-flame ignition source. Similarly, the criterion is not nonignition (although a specimen that would resist ignition would obviously pass) but rather low heat release rate. In terms of material response, this criterion is a more difficult requirement, because it is easier to resist ignition from a small flame than to show very low fire development when presented with sizable flames from the ignition source.

The next step in the development took place when California passed a law in August 2001 (T.B. 603) that required all mattresses sold in California after January 1, 2004, to be effectively fire resistant so that they resist open-flame ignition sources, not just smoldering cigarettes. The California Bureau of Home Furnishings and Thermal Insulation was asked to develop regulations and a suitable test method. In response, it issued a standard, T.B. 603[56], that is essentially an implementation of the ISPA/NIST protocol. CPSC had, at the same time, ongoing work to develop a regulation for controlling the flammability of mattresses under open-flame conditions. Because the primary research being done at NIST was already adopted into the California regulation, CPSC decided to adopt essentially the same test method, but with certain modifications.

The California regulation permits testing in an open calorimeter, in the California-configuration burn room (10 × 12 ft [3.05 × 3.66 m]), or in the ASTM-configuration test room (8 × 12 ft [2.44 × 3.66 m]). CPSC reduced these options to two, either the open calorimeter or the California-configuration room. Because radiant heating from the upper portions of a room greatly exacerbates the burning of a mattress, however, it is clear that these configurations are not equivalent and, presumably, manufacturers will select to do testing in an open calorimeter. CPSC also slightly tightened the conditions for passing. The peak HRR value permitted is still 200 kW, but the 10-minute total heat release was reduced from 25 MJ to 15 MJ. The new CPSC test is in addition to the existing requirements for cigarette ignition resistance. Presumably, the California standard will become moot when the federal standard goes into effect, because it is slightly less restrictive than the federal version.

At this stage, it is not yet known what technologies manufacturers will use to meet these new regulations. Because the regulation was developed on the basis of the industry-sponsored research at NIST, it is reasonable to assume that the manufacturers do not foresee serious difficulties in meeting the requirements. It is likely that a common solution will be to use an interliner "bag," whereby a fire barrier material is used to encapsulate the padding.

Reducing the flammability of mattresses may not sufficiently reduce the risk of injury or death from a mattress fire, if the bedding burns with a high HRR. Thus, the California legislature also instructed the Bureau of Home Furnishings and Thermal Insulation to develop a companion regulation for the open-flame behavior of bedding. The Bureau issued a draft proposal, T.B. 604[57] in 2004, but thus far, a regulation has not been finalized. Somewhat unexpectedly, the draft regulation is not based on HRR, but rather on simple weighing of the specimen.

CHARACTERISTICS OF IGNITION SOURCES

The choice of the ignition source is crucial to fire testing. A test item that shows essentially no response under a given source may exhibit a runaway fire with just a slightly greater ignition source. Thus, the simulated source selected must be a realistic approximation of the actual fire conditions that may be encountered.

Table 6.6.15 shows the characteristics of some ignition sources that have been used in flammability experimentation with upholstered furniture items. The sources range over four orders of magnitude: from 0.05 to 500 kW. The maximum heat fluxes for the sources, except the methenamine pill, range between 18 and 42 kW/m^2. This range is rather small, and it can be generalized[58] that an "incidental" ignition source shows a typical flame flux of 35 kW/m^2. What varies when the ignition source strength is increased is not the flame flux, but rather the area over which the flux is applied. In the case of the polyethylene wastebasket, the area over which fluxes exceed 20 kW/m^2 is about 2.36 by 27.55 in. (60 by 700 mm); for a wood match this would be approximately 0.39 by 1.18 in. (10 by 30 mm). This relationship is generalized in Figure 6.6.7. It is seen that there is a linear relationship between the power output of the ignition source and its flame coverage area. It should be noted that the above data are all for "incidental" fire sources. Heat fluxes from specialized sources, such as oxyacetylene torches, may be much higher, for example, 140kW/m^2.

The reason the flame coverage area of the ignition source is important is that higher heat fluxes are required to raise small target areas to their ignition temperature than large areas. This coverage is especially true for fire-retardant-treated materials. Unfortunately, no theoretical guidance is yet available on this

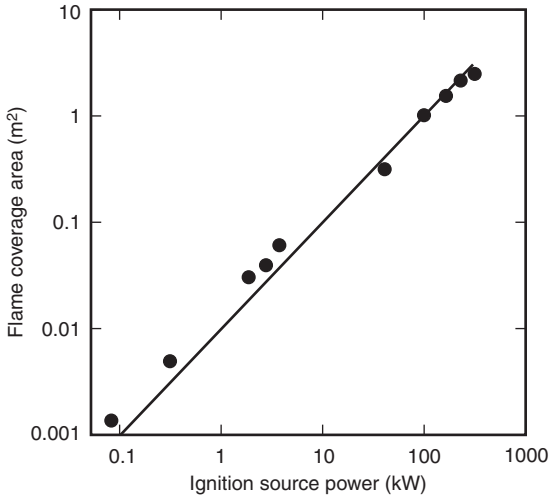

FIGURE 6.6.7 Flame Area as a Function of Ignition Source Power (for U.S. units: 1 ft = 0.305 m)

TABLE 6.6.15 Characteristics of Furniture Ignition Sources

	Typical Heat Output (W)	*Burn Time*[a] *(sec)*	*Maximum Flame Height (mm)*	*Flame Width (mm)*	*Maximum Heat Flux (kW/m^2)*
Cigarette 1.1 g (not puffed, laid on solid surface)

point, which is one reason why ignition source selection must be done on an empirical basis. Too-small ignition sources can be misleading for an additional reason. Many materials shrink or melt away from a small ignition source; this can lead to passing of a Bunsen-burner-type test. When presented with a larger ignition flame area, however, the same item may be unable to shrink back and can ignite and burn vigorously. Bunsen-burner-type tests are considered the appropriate simulation of residential accidents involving matches or lighters. But such tests should never be utilized for high-risk occupancies (e.g., health care) where acceptable performance under exposure from much larger flames is required.

FLAME SPREAD

Flame spread has long been the basis of flammability evaluation of building materials; however, little quantitative work has been done on the flame spread over upholstered items. Cotton and rayon cover fabrics by themselves were shown to have flame spread rates inversely proportional to their "basis weight" (i.e., oz/yd^2 or g/m^2);[59] however, when tested over polyurethane padding, the differences between flame spread rates were small. This result is another case whereby component tests can give rise to misleading results, as mentioned earlier.

In another experimental series, the flame spread over seat cushions of chair mock-ups was measured by counting the number of 3.93 in. (100 mm) squares covered by flames as a function of time from ignition.[60] This flame spread rate was found to correlate fairly well with bench-scale measurements on the same fabric/padding composites. There were major differences, however, in the behavior of charring and melting thermoplastic fabrics. Cotton and rayon, the cellulosic fabrics, charred ahead of the flame, and on the side of the chair opposite to the one that was burning. Eventually the char burst into flame. The thermoplastic fabrics initially shrank away from the ignition source, but being supported by the foam, the shrunken material bead burned and presented a relatively large ignition source for the foam padding. The fabric on the chair side opposite the burning side ablated, exposing the foam to the radiation. Thus, flames spread more rapidly over the thermoplastic fabric-covered mock-ups, even when the foam was neoprene and did not significantly flame during the test.

General flame spread theory has not been much applied to upholstered items, primarily because of the variety of configurations and interaction between fabrics and padding. Dimensions in these items are sufficiently large so flame spread and heat-release behavior are dominated by radiative, rather than convective, mechanisms. Recently, some studies of furniture flame spread in the "against the wind" mode, that is, in the opposite direction to the draft induced by the buoyancy of the flame, have been conducted.[61] These tests may find an application in advancing the theory of furniture fires.

HEAT RELEASE RATE (HRR)

Measuring the HRR

Heat release rate (HRR) is recognized as the single most important variable describing fire hazard.[25] The reason for this is not hard to understand. When confronted with a fire, normally the first question that arises is: how big is the fire? The HRR is simply the quantitative rephrasing of that question. It is important to note that by knowing the HRR of the full-scale object one does not separately need to inquire as to its flame spread characteristics. Items showing slow or incomplete flame spread reflect this in their HRR curves, which are low or slow growing.

In earlier days, it was not possible to discuss the HRR of burning items, simply because measuring tools did not exist for it. This situation was changed in 1982 when the present author and co-workers at NIST developed the furniture calorimeter,[62] which allowed simple, low-cost testing of whole furniture articles under realistic burning conditions. The HRR (measured in kilowatts [kW]) was measured, along with smoke and toxic gas evolution from the burning object. Subsequently, a European standard based on furniture calorimeter testing was published.[63] This standard was followed by the U.S. standards discussed earlier, wherein the furniture calorimeter testing methodology is further developed (ASTM E1537 and E1590). Furniture calorimeters are now available in many U.S. and foreign test laboratories and manufacturers' laboratories.

The furniture calorimeter is based on the *oxygen consumption* principle, which states that the combustion heat released is proportional to the amount of oxygen consumed to within about 5 percent. The proportionality constant is 13.1 10^3 kJ per kg of O_2 consumed. Note that the *heat of combustion* of a fuel can vary widely and the oxygen consumption principle does *not* require that this be known or be constant. The details of this principle, along with extensive additional information on HRR applications, are available.[64]

Measurements of HRR also use the identical oxygen consumption principle when performed in room fire tests, for example, in the room test option of the CPSC's new open-flame mattress regulation.

In recent years, most small-scale HRR testing has been done with the cone calorimeter[65] (Figure 6.6.8). The name *cone calorimeter* comes from the cone-shaped heater used to irradiate the specimen. The basic apparatus is standardized by ASTM as ASTM E1354 and by the International Organization for Standardization as ISO 5660.

The cone calorimeter standards describe the basic equipment and test procedures. As such, they are pertinent to applications ranging from spacecraft to trash containers. Upholstered furniture, however, presents a special issue in that the samples are intrinsically composites, often comprising many layers. Thus, special specimen preparation instructions must be carefully followed in order to obtain reliable and reproducible results. These instructions, first developed in the mid-1980s, were incorporated in the 1990 edition of NFPA 264A, *Standard Method of Test for Heat Release Rates for Upholstered Furniture Components or Composites and Mattresses Using an Oxygen Consumption Calorimeter,* now obsolete. In subsequent years, furniture on the market came more to encompass fire-improved formulations and special constructions. Fire barriers (interliners) have come into widespread use in contract furniture as a consequence of T.B. 133 requirements. The earlier specimen preparation techniques proved to be insufficient for these new products. Also, with the widespread use of cone calorimeters in

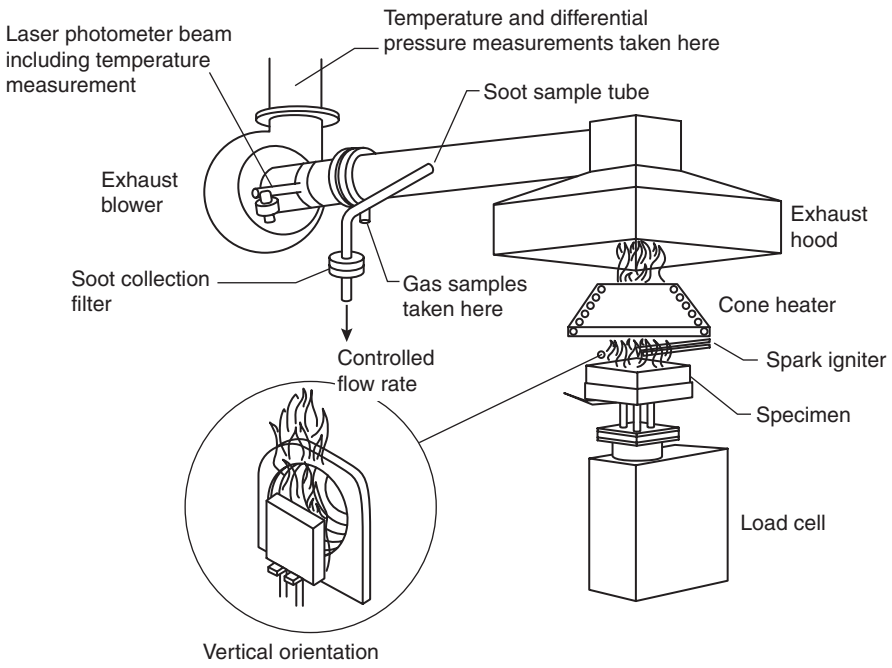

FIGURE 6.6.8 Cone Calorimeter Used for Small-Scale HRR Testing
