- ☐ Avoid designs with lifts in excess of 17 ft. (Above this height vapor pressure will begin to exceed atmospheric pressure and cavitation will occur, making pumping virtually impossible.)
- ☐ Consider friction loss at high lifts. (Calculate losses using Mannings formula or Hazen-Williams equations.)
- ☐ Position the pump intake at a higher elevation than the hydrant connection. (Doing so will eliminate air bubbles, which will limit flow and also prevent the operator from getting wet.)
- ☐ When rock is encountered, adjust installation to fit the rock profile. (Additional bends may be necessary.)

FIGURE 13.4.9 Dry Hydrant Design Features Checklist

Advantages of Dry Hydrants. Knowing the quantity of available water in area streams, ponds, and cisterns gives the fire department an advantage only if the water is readily accessible. Where a water site is located so that MWS apparatus will be the water transportation method, the amount of available water will be less than it would be if pumped directly onto a fire from the same water site. Whenever MWS apparatuses are used, critical factors become the supply of an uninterrupted flow, the supply of a predictable amount of water being transported, and the maintenance of the supply for the duration of the fire or until a lesser flow is required.

Improved Access. Installation of as many dry hydrants as possible where permits can be obtained and the sites made all-weather accessible will ease both the complexities and the lesser availability of water that will be incurred when comparing shuttle operations to water transported directly to the fire scene by hose from a water site. Additionally in those areas without water mains and domestic fire hydrants, dry hydrants can provide a simple, cost-effective solution to water sources without delay.

Time Saving. The time saving is considerable. Multiple lengths of hard suction hose extending to the water are not needed; usually one section to the dry hydrant is enough. The strainer is also permanently attached, saving more time. Fewer people are needed to make a hookup compared to the number needed to make a conventional direct drafting hookup. Planned placement of dry hydrants with the proper accessibility will allow fire departments to supply water for fire protection to all areas where coverage can effectively be provided.

Cost Saving. The saving can be financial, as well. Fire departments can save money by reducing fuel and equipment costs through shorter transportation distances and lower operational demands. Because dry hydrants use untreated water, communities can preserve more of their treated water supplies. Homeowners may also save on their insurance rates.

Planning Considerations. Planning for dry hydrants involves several considerations and should involve all affected agencies and private concerns so a coordinated effort can take place. Some factors to consider are:

- Current and future population and building trends
- Protection of property values
- Potential for loss
- Fire history of the area protected
- Current water supply systems
- Other potential water sources
- Cost of project
- Equipment and personnel of the local fire department
- Training needs of the fire department
- Other specific factors of local concern

Location of Dry Hydrants. The location of individual dry hydrants is also influenced by several factors. After conducting a water source survey of the area, the fire department should use a county road map to mark potentially good sites. These sites should be marked in a priority order, since most fire departments

will not have sufficient funding for all the dry hydrants that may be desired. The following features should be considered when considering dry hydrant sites.

Maximum Travel Distance Between Dry Hydrants. The travel distance between dry hydrants can vary for several reasons. For use in shuttle operations, it has been found that the amount of water transported by MWS apparatus to the fire scene, regardless of the size of the water tank on the MWS apparatus, will not be appreciably increased when water fill sites are further than 3 mi (4.8 k) from the fire site. This distance would produce a travel time of about 6 minutes between the water and the fire, assuming an average safe constant speed for a loaded truck of 35 mph (56 kph).

Water Depth at the Source. Careful note should be made about the useful depth of a lake or pond, which is from the minimum foreseeable low-water surface level to the top of the suction strainer (not the bottom of the lake). The low-water mark considers tides, drought, freezing, and other considerations, such as when the water level is lowered to generate power. The absolute lowest level must be not less than 2 ft (0.6 m) to prevent a vortex or whirlpool, which could allow air to enter the pump and cause loss of pump prime. Consideration for the height of the "low" water level above the strainer should be made for conditions such as ice and for floating leaves during the fall of the year. Plans for these or for any other conditions, even if seasonal, that could cause clogging of the strainer or cavitation of the pump should be made.

Composition of Bottom Material. For long-term useful hydrant operation, the best composition for the bottom of a lake, stream, or pond is sand, gravel, rock, or a combination of these. Decaying vegetative matter could clog the suction screen.

Ease of Digging. Surface area and condition in the vicinity of the dry hydrant site is a factor in the installation of a dry hydrant. A backhoe or whatever machinery is to be used to "trench the dry hydrant" will need to get close enough to the water's edge so as to be able to dig out below the surface of the water to the needed depth for the dry hydrant.

Protection of the Connection. A location that is conveniently accessible to fire apparatus may also be exposed to accidents from passing vehicles. An impact barrier constructed of partially buried posts may be needed to prevent a vehicle from damaging a dry hydrant in a heavily traveled area. Special markings, as deemed appropriate by the authority having jurisdiction, should be used to avoid damage from snowplows.

Cost. The cost of a dry hydrant installation depends on local practices and the length of pipe needed. This cost must be factored in when deciding where to locate dry hydrants.

Presence of Other Utilities. The presence of other utilities in the digging area must be considered. A careful check should be made for the presence of buried lines and pipes; utility companies should be notified before digging is started. The numbers to call in each state can often be found in the local telephone company phone book and are found with a title similar to "Call Before You Dig."

Ownership of the Land. The water supply officer or other authority should contact the legal property owner to secure written permission in conjunction with the attorney representing the government entity in whose legal area the land lies. If a possible dry hydrant site is along a road right-of-way, then town, county, or state approval may be required. In some cases Corps of Engineers or power company approval may also be needed. Obtaining written permission is an important requirement that may take some time.

AGREEMENTS/PERMITS

Regardless of the type of water source used and the water site from which it is obtained, a document granting permission by the owner for the use of the area as well as documents listing any other locally applicable considerations should be on file. A written explanation of what is needed and what the fire department will do to install the dry hydrant can be mailed or delivered personally. Conditions for the best use of the particular site should be set forth. This explanation will usually provide the prospective property owners with information that will make them more comfortable with the conversations and legal technicalities that will follow.

The attorney representing the local government whose fire department will be utilizing the site should formalize all legal issues. The local government attorney should consider all actions that can reasonably be assumed to be involved and to arise out of the use of water source site and should enumerate them in the legal paperwork. The agreement should be signed by the property owner, the head of the government entity (or his or her designated representative), the chief of the fire department, all other departments of the entity (or contractors if they are to be used) that will have a part in the development/improvement of the site, and the entity's attorney. At a minimum these people should be listed on the agreement since they will deal with the greatest number of actions involved in the completion of each site for fire department use and continued operations.

ESTIMATING AVAILABLE WATER SUPPLY CAPACITY

A simple method for estimating the flow of water in a creek is to measure the width and depth of the creek, drop a cork or any light, floating object into the water, and then determine the time it takes the cork to travel 10 ft (3.1 m). To obtain complete accuracy, the sides of the creek should be perpendicular, the bottom should be flat, and the floating object should not be affected by the wind. Where the sides and bottom of the stream are not uniform, the width and depth can be averaged. For example, consider a creek with a width of 4 ft (1.2 m) and a depth of 6 in. (15.2 cm) and where the flow of water is such that it takes 45 seconds for a cork to travel 10 ft (3.1 m). The following equation applies:

$$\text{Volume of water} = W \times D \times TD = \text{ft}^3\ (\text{m}^3)\ \text{of water}$$

$$\text{Flow rate} = (\text{Volume of water})/T$$

where

W = Width (ft [m])

D = Depth (ft [m])

TD = Travel distance (ft [m])

T = Time (sec)

$$4\ \text{ft} \times 0.5\ \text{ft} \times 10\ \text{ft} \times 20\ \text{ft}^3\ \text{of water}$$

or

$$1.2\ \text{m} \times 0.15\ \text{m} \times 3.1\ \text{m} \times 0.56\ \text{m}^3\ \text{of water}$$

Since the cork takes 45 seconds to travel a 10 ft (3.1 m) distance:

$$\text{Flow rate} = 20\ \text{ft}^3/45\ \text{sec} = 0.444\ \text{ft}^3\ \text{of water/sec}$$

or

$$\text{Flow rate} = 0.558\ \text{m}^3/45\ \text{sec} = 0.0124\ \text{m}^3\ \text{water/sec}$$

and

$$1\ \text{ft}^3 = 7.5\ \text{gal and } 60\ \text{sec} = 1\ \text{min}$$

Therefore,

$$(0.444\ \text{ft}^3/\text{sec}) = (0.444\ \text{ft}^3/\text{sec})(60\ \text{sec/min})(7.5\ \text{gal/ft}^3)$$
$$= (0.444/0.00223)\ \text{gpm} = 199\ \text{gpm}$$

Also

$$1\ \text{m}^3 = 1000\ \text{L and } 60\ \text{sec} = 1\ \text{min}$$

Therefore,

$$(0.014\ \text{m}^3/\text{sec}) = (0.0124\ \text{m}^3/\text{sec})(60\ \text{sec/min})(1000\ \text{L/m}^3)$$
$$= (0.0124/0.0000167)\ \text{L/min} = 744\ \text{L/min}$$

A short-form method of estimating pool capacity is as follows:

$$L \times W \times D \times 7.5\ \text{gal}\ (1000\ \text{L})$$
$$= \text{Estimated capacity in gallons (liters)}$$

where

L = Length (ft [m])

W = Width (ft [m])

D = Estimated average depth (ft [m]) from water line (ft [m])

These dimensions should be estimated or rounded off if the pool is of stylized construction.

$$1\ \text{ft}^3 = 7.5\ \text{gal}\ (1\ \text{m}^3 = 1000\ \text{L})$$

For a noncircular pond of irregular shape, sketch the pond outline to scale on grid paper. Circumscribe straight lines to average the irregular outline as much as possible around the shape. Calculate the area of a rectangle covering the entire pond. Subtract the scaled grid squares that fall outside the pond area. Use the final figure as $L \times W$ in the foregoing formula.

To make a rough estimate of the water volume in a pond when exact dimensions are not known, visualize the relative size of a football field, if you can, and use that area as a starting point. A football field is roughly an acre. Every foot (0.30 m) of average usable depth would provide about 325,000 gallons (1,230,000 L).

WATER SUPPLY VEHICLES, WATER SHUTTLE OPERATIONS, AND DRIVERS

Mobile Water Supply (MWS) Apparatus

The term *mobile water supply (MWS)* will be used here as referenced in NFPA 1901, *Standard for Automotive Fire Apparatus.* Incident management system (IMS) terminology and designation of what has always been termed a *tanker* is a "vehicle" (aircraft or helicopter) that delivers water from above. For ease of use throughout, we will refer to a wheeled ground apparatus (vehicle) as an MWS apparatus. We will consider the MWS apparatus as being mounted on a single- or tandem-axle chassis. Issues dealing with tractor-trailer water supply vehicles are not addressed in this chapter.

Rural fire departments are often fortunate to have usable water supplies in their jurisdictions, but that water is rarely in the immediate area of a fire where it is needed. MWS apparatus are necessary for any fire department that wants a method to provide a water supply to areas where there is no existing water supply system. MWS apparatus can also be used to supplement areas where the existing water supply system may not provide the desired flow of water. MWS apparatus are necessary for most rural fire departments and can be useful to suburban departments with weak municipal systems.

MWS apparatus may be found in a variety of configurations, with or without pumps on board. Fire apparatus may be generally classified as pumpers or MWS apparatus, or they may be manufactured to provide both functions. Some vehicles used previously for transporting other liquids have been used by fire departments, but safety considerations should be more important than economic ones. The fire department should ensure that any vehicle used to transport water passes a safety inspection; that it has reliable brakes, chassis, and transmission; and that it is designed to carry the weight of the water that it will transport. Above all, the weight of water should never allow the total vehicle weight to be greater than the rated maximum weight rating of the vehicle.

Over the years, departments utilizing hauled water have tended to use any means to carry water and have exercised a great deal of ingenuity in doing so. Recently, there has been a trend in fire departments in rural areas to use standard pumpers and MWS apparatus with tanks in the 1000 to 1500 gal (3785 to 5678 L) range. Significant progress has been made in such MWS apparatus techniques as loading and unloading and in maintaining a continuous fire stream, based on the fire flow study, during the entire fire-fighting operation.

Specially built and designed MWS apparatus are ideal, but many fire departments are forced to fight fires without

adequate standard equipment. Since the job of putting out fires will require, on occasion, water-carrying capacity greater than a fire department's capability, a sound mutual-aid or automatic-aid program is necessary and is far superior to makeshift, unsafe equipment that is not designed for emergency service.

In building and buying nonstandard apparatus, serious consideration should be given to the safety and serviceability of the equipment as well as the safety of the members of the department. A department that depends on an assortment of MWS apparatus designed primarily for other use might need expert assistance in checking the equipment for safety before putting it in service.

If satisfactory service is to be obtained from MWS apparatus, the size of chassis necessary to safely carry the load, the horsepower of the engine necessary to perform on the road and at the fire site, the completed vehicle's weight distribution, and the gear train combination best suited for the operation in that specific locale are factors that should be carefully considered in the purchase or construction of the apparatus. The apparatus components, such as the baffling of the tank and the center of gravity, are just as important as the engine, axles, and other driveline components and should not be overlooked. Some fire departments that have pumpers equipped with large booster tanks have retrofitted these pumps with a dump system.

Water Shuttle Operations

Obviously, sufficient water supply for fire suppression services is a very critical component to the overall fire suppression capabilities of a fire department. Typically, rural areas do not have the necessary infrastructure to support "urban type" water delivery systems. Where fire hydrants exist, they are typically on smaller water lines with relatively low flow capacity and are generally spaced quite some distance apart. As a result, fire departments with large rural areas within their protection areas must rely on alternate means of providing adequate fire flow during fire suppression activities.

It is important for companies to be able to obtain water from sources other than hydrants at the fireground and operate a MWS apparatus shuttle to provide adequate water supply for fire-fighting operations. This is not limited to rural applications and may be necessary to supplement hydranted areas where there is inadequate water supply.

Key components in MWS apparatus shuttle operations in rural water supply include the following:

- Selecting water sources
- Selecting MWS apparatus travel routes
- Developing MWS apparatus fill and dump station operations
- Calculating and meeting waterflow requirements

A critical part of establishing a water supply on a continuous basis is the capability to deliver water to the scene within 5 minutes of the initial arriving fire apparatus. Calculating the rate of water delivery to the scene is based on the total water supply required. The rate of water delivery is a separate calculation from the water application rate.

The following are two primary factors to be considered in the development of MWS apparatus operations:

1. The amount of water carried on initial responding units
2. The amount of water that can be continuously delivered after initial response

A number of fire departments have developed water-hauling operations to the point where they have a maximum continuous flow capability (a sustained fire flow) of 1000 to 2000 gpm (3785 to 7570 L/min) at the fire scene. Such continuous flow requires several MWS apparatus to haul such large quantities of water with a developed water source near the fire site. To improve the safety factor by reducing congestion on the highways, the departments often send the MWS apparatus to the water source by one road and use another route for the MWS apparatus to return to the fire scene. Therefore, the time for the department to travel from the fire to the water source (T_1) might be a different time than the travel time back to the fire (T_2). The reduction of congestion on the highway provides for a safer operation and can increase the actual amount of water hauled.

The maximum continuous flow capability at the fire scene is calculated as follows:

$$Q = [V/(A + T_1 + T_2 + B)] \times k$$

where

Q = Maximum continuous flow capability (gpm [L/min])

V = Mobile water supply capacity (gal [L])

A = Time (in minutes) for the MWS apparatus to drive 200 ft (61 m), dump water into a drop tank, and return 200 ft (61 m) to starting point

T_1 = Time (in minutes) for the MWS apparatus to travel from fire to water source

T_2 = Time (in minutes) for the same MWS apparatus to travel from water source back to fire

B = Time in minutes for the MWS apparatus to drive 200 ft (61 m), fill MWS apparatus at water source, and return 200 ft (61 m) to starting point

k = 1.0 for vacuum/pressure MWS apparatus; 0.9 for all other MWS apparatus due to spillage, underfilling, and incomplete unloading

The dumping time (A) and filling time (B) for the formula should be determined by drill and by close study of water sources. Equipment does not have to be operated under emergency conditions to obtain travel time (T), which is calculated using the following equation:

$$T = 0.65 + XD$$

where

T = Time (in minutes) of average one-way trip travel

X = Average safe constant speed factor

D = One-way distance (miles [kilometers])

The factor 0.65 represents an acceleration/deceleration constant based on miles per hour developed by the Rand Corporation.

Where an apparatus is equipped with an adequate engine, chassis, baffling, and brakes, a safe constant speed of 35 mph (56.3 km/hr) can generally be maintained on level terrain, in light traffic, and on an adequate roadway. Where conditions will not permit this speed, the average safe constant speed should be reduced.

Using an average safe constant speed of 35 mph (56.3 km/hr), the *X* factor is calculated as follows:

$$X = 60/\text{average safe speed} = 60/35 \text{ mph} = 1.7$$

The formulas make it possible to determine water availability at any point in an area. As an example of how to calculate the water available from a supply where the water has to be trucked to the fire scene, consider the following applications of the formula.

EXAMPLE: If tank capacity (V) is 1500 gal (5678 L), the time (B) to fill the MWS apparatus with water is 3.0 minutes, and the time (A) to dump the water into a portable tank is 4.0 minutes.

The distance (D_1) from the fire to the water source is 2.1 mi (3.38 km). As the MWS apparatus returns by a different road, the distance (D_2) from the water source is 1.8 mi (2.9 km).

SOLUTION: First, solve for T_1, the time for the MWS apparatus to travel from the fire to the water source, and then solve for T_2, the time for the MWS apparatus to travel from the water source back to the fire.

Due to good weather and road conditions, the constant MWS apparatus speed traveling from the fire to the water source is 35 mph (56.3 km/hr).

Use the travel time formula as follows:

$$T_1 = 0.65 + XD_1$$

where

$X = 1.7$

$D_1 = 2.1$

and where at a constant speed of 35 mph (56.3 km/hr)

$$T_1 = 0.65 + 1.7D_1$$

$$T_1 = 0.65 + 1.7 \times 2.1$$

$$T_1 = 0.65 + 3.57$$

$$T_1 = 4.22$$

At a constant speed of 35 mph (56.3 km/hr), a MWS apparatus traveling 2.1 mi (3.8 km) will take 4.22 minutes. Due to traffic lights, the average MWS apparatus speed between the fire and the water source is 30 mph (48.3 km/hr).

Use the time travel formula as follows:

$$T_2 = 0.65 + XD_2$$

where

$X = 2.0$

$D_2 = 1.8$

and where at a constant speed of 30 mph (48.3 km/hr)

$$T_2 = 0.65 + 2.0D_2$$

$$T_2 = 0.65 + 2.0 \times 1.8$$

$$T_2 = 0.65 + 3.6$$

$$T_2 = 4.25$$

Use the following formula for calculating the maximum continuous flow capability:

$$Q = [V/(A + T_1 + T_2 + B)] \times k$$

where

Q = Maximum continuous flow capability (gpm)

$V = 1500$

$A = 4.0$

$T_1 = 4.22$

$T_2 = 4.25$

$B = 3.0$

Therefore,

$$Q = [1500/(3.0 + 4.22 + 4.25 + 4.0)] \times 0.9$$

$$Q = (1500/15.47) \times 0.9$$

$$Q = 97 \times 0.9 = 87 \text{ gpm } (329.3 \text{ L/min})$$

The maximum continuous flow capacity available from this 1500 gal (5678 L) MWS apparatus is 87 gpm (329.3 L/min).

To increase the maximum continuous flow capability of the MWS apparatus, any of the following changes can be made:

- Increase the capacity of the MWS apparatus
- Reduce the fill time
- Develop and provide additional fill points, thus reducing travel time
- Reduce the dump time

With rural fire response distances normally being very long, the number and size of MWS apparatus available to the department are of paramount importance. This information will assist the department in calculating the probable mobile water supply volume that will be available at various fire locations. Equally important in increasing the maximum continuous flow capability of a mobile water supply is the reduction of the distance between the source and the building or fire. The distance can be reduced by increasing the number of water supplies, drafting points, or both.

The minimum water delivery rate to the fire scene is based on the total water supply needed. Table 13.4.3 provides the rate at which water should be available at the fire scene to meet the demands of the fireground operations.

Driver Training

Drivers of emergency vehicles, especially those carrying large quantities of water, face circumstances that make driver training especially important. Fire departments often overlook this reality. Included in this oversight are some of the following factors:

- Few fire department members have been previously trained, drive vehicles of this type in their professional life, or are

TABLE 13.4.3 Minimum Water Delivery Rate to Meet Water Supply Needs

Total Water Supply Required	*Rate Water Is Available at Incident*
Up to 2,499 gal (9,459 L)	250 gpm (950 L/min)
2,500 to 9,999 gal (9,460 to 37,849 L)	500 gpm (1,900 L/min)
10,000 to 19,999 gal (37,850 to 75,699 L)	750 gpm (2,850 L/min)
20,000 gal (75,700 L) or more	1,000 gpm (3,800 L/min)

aware of the action of liquids during transport. Only effective training can prepare them to handle this type of vehicle. Continuous testing should be planned to ensure personnel continue to meet qualifications.

- Because of the effect of the load on the vehicle's center of gravity, even a two- or three-axle vehicle used as an MWS apparatus will have driving characteristics unlike those of other vehicles or fire apparatus.
- The weight of the water can reduce handling characteristics and increase braking distances. Water weighs 8.3 pounds per gallon (1 kg/L); in a 1000 or 2000 gallon (3785 or 7570 L) tank, the extra weight can be a dangerous factor if it is not considered at all times.
- The occurrence of fires is usually infrequent, allowing specialized driving skills to deteriorate unless training is regular.
- Roadways in rural areas may not always be repaired as frequently as they are in urban areas. Potholes and washed-out areas can be extremely hazardous for a heavily loaded truck.
- Emergency situations produce dangerous distractions to apparatus drivers (and anyone else). There is a natural tendency that makes everyone want to perform each task faster so the fire can be stopped as quickly as possible. However, too much haste results in poor decisions, and numerous safety factors can be overlooked.

Vehicle Weight and Safety

The weight of any large fire apparatus, and especially the weight of water in an MWS apparatus, produces extra stress on the vehicle's chassis, transmission, and brakes. Drivers must be trained regularly on the special risks of driving emergency apparatus.

The fire department should check every bridge and culvert location in its response districts, both primary response and mutual aid, to ensure that all bridges and culvert locations are rated to safely carry the weight of every responding fire department vehicle/apparatus. The ability of fire department personnel to determine bridge ratings should not be the overwhelming task that it might initially appear to be. In view of the current use of computers by state highway departments to inventory their bridges, load limits should be readily available.

If there is any bridge or culvert that will not support the weight of a particular department unit, the driver of that unit should be made aware of this fact. The fire department should have other specific routes planned to ensure response to fires within the area involved or should take specific action to ensure that adequate water supply can be delivered by other means. Examples include using a pumper taking suction from the river to pump water across the bridge through large hose lines or servicing the area from another water supply site that has a safe bridge to the area or, ideally, that does not require the use of a bridge to respond.

Access to Water Supplies

The location of any water site and the water available from that source will be usable for fire department operations only if the site is accessible. Training at the site for fire department operations, including making personnel aware of any limitations of the site and/or of the waterflow, should be part of planned fire department operations.

Access Roadways. Often a suitable approach, which might call for a roadway, must be provided to allow the fire department to reach within 10 ft (3.1 m) of the water supply. However, at some sites and in some areas of the country, constructing a roadway may not be necessary due to soil conditions. Other sites might already have roadways provided or pavement installed with the construction of an entranceway or a gate to provide access to the water supply. Other sites may be reached on foot only and may require a path to be constructed and maintained so that portable pumps can be carried to the site. Each site should be evaluated by the fire department to determine the best way, within the fire department's means, for using the water supply.

Most artificial lakes are constructed with heavy earth-moving equipment. In order for the property owner to construct a roadway for fire department use, the fire department should make the property owner aware of the needs of the fire department while the heavy equipment is still on the job.

While the roadway to the water supply is being developed, consideration should be given to providing a 90-ft (27.4-m) diameter turnaround for the mobile water supply apparatus. Where conditions at the supply site do not make a turnaround feasible, adequate hose lengths from the pumping unit at the supply site will be needed to provide water for MWS apparatus to fill up at the location or locations where they will be stopped. Regardless of this fill-up location, adequate room must be provided for the MWS apparatus to maneuver during arrival at and departure from the parking/standing area. However, a turnaround or looped facility will still need to be provided at the fill point on the right-of-way.

In some states, a fire department cannot use a bridge to park a mobile water supply while it is being filled because it would block traffic on the road. However, the fire department might be able to use the water source by moving the fill point off the bridge and to the right-of-way. The fire department needs to check with the state department of transportation and abide by the appropriate laws governing the situation.

In some cases, such as in marsh or swamp areas, installing a dry hydrant with a suction line in lieu of an access road is desirable. The fire department will have access to the hydrant from the shoulder of the main road. So as not to block the road during pumper operations, a suitable parking area on the shoulder of the road should be provided. The basic recommendations in Table 13.4.4 can be useful in the design of such an area so that pumpers can be employed efficiently and safely.

Bridges. Bridges that were built years ago may have been built for farm-to-market use and were designed for much lighter vehicles than are in use today. Those bridges now carry not only greatly increased traffic loads but heavier vehicles as well. As a result of this situation, which exists in many suburban and rural areas and probably even in some urban areas in the United States, some bridge collapses have occurred. In addition, many states did not provide complete bridge inspection and maintenance programs. Because of these major factors, most states now subject bridges to certain types of inspections and mandate those inspections within specific time frames.

As a result of bridge failures, the U.S. Federal Highway Act of 1968 required, among other things, that all states, counties, and cities receiving federal highway funding implement a program to inspect each bridge in the federally funded system every two years. Additional bridge collapses prompted amendment of this law in 1976 to include all bridges on the public roads system.

During the last few years, a number of states have set up bridge inspection programs, and the current safe tonnage is now being posted. Throughout the entire country, a large number of bridges have been restricted to below the legal weight limit for which the road and bridge were originally designed. One state with over 15,000 bridges reported that 50 percent of all its bridges are now posted below the original maximum load limits, and 25 percent of these bridges are unsafe for use by a fully loaded school bus or fire department apparatus.

In some states, the state highway department has consulted fire officials, explained the situation, and required that the fire department list the unsafe bridges in order of their importance to the fire service. The highway departments then attempt to upgrade these bridges on the basis of fire department priority.

The long-range nature of the bridge problem makes it a matter for serious consideration when planning purchases of apparatus. MWS apparatus size must be restricted to volumes that will not cause overloading. State law determines whether a fire service is held financially responsible for damage to a bridge; however, a good policy for every fire department is to check the bridge load restrictions before purchasing a new piece of apparatus. The lighter the equipment, the more bridges the department can use. Although this may necessitate the purchase and use of smaller tank size MWS apparatus, prior planning will enable these units to be used just as effectively as MWS apparatus with larger tanks and should not be considered a limitation to fire service operations.

TABLE 13.4.4 Recommendations for Roads to Water Supplies

Road Feature	*Recommendation*
Width	Roadbed—12 ft (3.7 m) Tread—8 ft (2.4 m) Shoulders—2 ft (0.6 m)
Alignment	Radium centerline curvature—50 ft (15.2 m)
Gradient	Maximum sustained grade—8 percent
Side slopes	All cut-and-fill slopes to be stable for the soil involved
Drainage	Bridges, culverts, or grade dips at all drainageway crossings
	Roadside ditches deep enough to provide drainage
	Special drainage facilities (e.g., tile) at all seep areas and high water table areas
Surface	Treatment as required for year-round travel
Erosion control	Measures as needed to protect road ditches, cross drains, and cut-and-fill slopes
Turnaround	Designed to handle the equipment of the responding fire department with a minimum diameter of 90 ft (27.4 m)
Load-carrying load capacity	Adequate to carry maximum vehicle expected
Condition	Suitable for all-weather use

SUMMARY

Providing water for fire suppression purposes by using alternate water supplies enables fire departments to have a continuing water supply where none existed previously or may provide additional water for emergency or backup use. The alternate water supply sources include natural water sources, such as streams, springs, lakes, and ponds, and developed sources of water, such as cisterns, swimming pools, stationary tanks, driven wells, and dry hydrants.

Once the community's water needs have been determined, the water sources pinpointed, and agreements made with property owners, a plan should be worked out for moving the water to where it is needed. The chapter discusses the location, use, and preparation of water sites and the use of mobile water supply apparatus. The use of alternate water supply sources helps a community meet its water supply needs in time of emergency.

Wildland fires occur in every state of the United States at some time during the year. Information from the U.S. Department of Agriculture (USDA) and the U.S. Department of the Interior shows the yearly pattern of wildfires during "normal peak fire seasons" in the 1990s. But following a decade of increasingly severe wildfires, it is now becoming difficult to define "normal peak fire seasons." Eight to ten years ago, a wildland fire exceeding 100,000 acres (40,470 ha) was the sign of an unusually severe fire season. Today, these large-scale fires are no longer the exception; they are starting to define what a normal peak fire season may be for years to come.

As debate over "prescribed fire"—that is, how much, where, when, and at what cost to use—continued, the price of suppression systems for tackling wildfires climbed and more unprotected homes and structures were lost, even though federal and state land management agencies treated millions of acres to reduce the fire risk using prescribed fire and mechanical means (such as cutting and clearing). Fires in largely untreated areas were the problem.

This chapter provides a brief summary of past wildland fires and their significance. The historic review will set the stage for the current challenges that accumulating forest fuels, increased public recreation in state and national lands, and the threat of unwanted fires present to federal, state, and local fire agencies and residents in and near forested and grassy plains areas. After establishing both the usual and unusual characteristics of wildland fire, the chapter explores the many ways (e.g., prevention, education, research, legislation, and suppression) that we seek to prevent disasters, save lives, protect the environment, share the responsibilities of protecting our natural environment, and continue to enjoy safely the beauty of national and state forests, parks, rivers, and wildlife.

BRIEF HISTORY OF U.S. WILDLAND FIRES

General Trends

Multiple large forest fires, such as the one shown in Figure 13.5.1, involving hundreds of thousands of acres, are starting to define what a normal peak fire season may be for years to come. Fire seasons have been worsening for several years. In 2003, however, the numbers were down from the 10-year average. In 2003, the numbers of fires (62,000) and acres burned (3.8 million acres [1.5 million ha]) were below the average of 64,000 fires and 4.6 million acres (1.9 million ha) (see Figures 13.5.2 and 13.5.3). In the same year, less acreage burned than in recent years, but what did burn was acreage in populated areas.

Although the numbers may vary from year to year, the longer-term trends are important, and a definite and troubling trend is becoming evident. Although the number of fires appears to be dropping, the affected acreage is growing. This trend may mean fewer fires in the future but the fires may involve increasingly larger acreage. Larger fires may also have a significant future impact on the environment, fire suppression resources, fire fighter safety, and structural loss.

James C. Smalley is the manager of NFPA Wildland Fire Protection and the Firewise Communities Program (National Wildland/Urban Interface Fire Program). He is a member of the Society of American Foresters, the Institute of Fire Engineers, and the Society of Fire Protection Engineers.

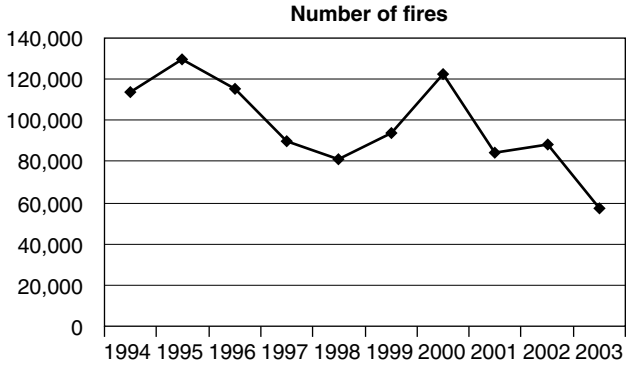

FIGURE 13.5.2 Number of Wildland Fires in the United States, 1994 to 2004

Considered the worst fire season in 80 years, 2000 was a landmark year, perhaps most remembered by the "escaped prescribed" fire in Bandelier National Monument near Los Alamos, New Mexico, that burned 47,650 acres (19,284 ha) and destroyed 235 homes. A moratorium on prescribed fire was put into effect following the blaze. The Cerro Grande fire was a harbinger of one of the most difficult seasons in the last half century. In 2002, the National Interagency Fire Center's annual summary included an average "worst" summary, noting that, based on previous years' activities, fire seasons of 85,000 fires and 6 million acre (2,428,200 ha) damage could be expected in the future.[1]

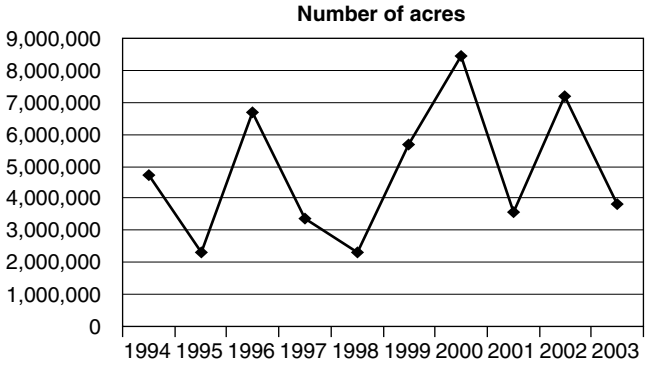

FIGURE 13.5.3 Number of Acres Burned in the United States, 1994 to 2003

Significant Historical Fires

Possibly the largest wildfires (known as the Miramichi and Maine fires) occurred in October 1825, burning from Maine through New Brunswick, Canada. A group of loggers ignited a fire in a drought area that soon burned out of their control and eventually destroyed 3 million acres (1.2 million ha) of forest and killed more than 160 people. The most devastating fire in U.S. history in terms of human lives and property lost was in Peshtigo, Wisconsin, in 1871. The fire killed over 1500 people in a single night and burned more than 1 million acres (404,700 ha). Other significant historical fires are summarized in Table 13.5.1.

CHALLENGES TO MANAGING U.S. WILDLANDS

There are 747 million acres (302,300,175 ha) of forestland in the United States, about 71 percent as much as there was in 1630. Today, the United States has about the same amount of land (or slightly less) covered by trees as in 1907. Over half (54%) of America's forests are owned by private individuals, 37 percent are under the management of public agencies, and 9 percent are owned by private industries.[2] With mixed ownership and changing expectations for public use and future of those lands, national policies regarding the management of those forests have changed dramatically over the last 100 years.

Four Threats to U.S. Forests

With progress in understanding better how fire shapes ecosystems, including watersheds, technology has made remarkable advances in assisting land managers and fire professionals in fire management through geographic information systems

TABLE 13.5.1 Significant Historical Fires

Year/Month	*Name*	*Location*	*Acres (ha)*	*Significance*
1871/October	Peshtigo	Wisconsin and Michigan	3,780,000 (1,529,760)	1500 dead in Wisconsin
1881/September	Michigan	Michigan	1,000,000 (404,700)	169 dead
1894/September	Hinckley	Minnesota	Undetermined	418 dead
1894/September	Wisconsin	Wisconsin	Several million	Undetermined, some dead
1902/September	Yacoult	Washington and Oregon	1,000,000 + (404,700)	38 dead
1903/April	Adirondack	New York	637,000 (257,790)	Large amount of acreage burned
1910/August	Great Idaho	Idaho and Montana	3,000,000 (1,214,100)	85 dead
1918/October	Cloquet-Moose Lake	Minnesota	250,000 (101,175)	450 dead
1933/August	Tillamook	Oregon	311,000 (125,861)	1 dead; same area burned again in 1939
1947/October	Maine	Maine	205,678 (83,238)	16 dead, 9 towns leveled, 3500 displaced, 2500 homeless, 851 homes and 397 summer homes destroyed, 20,000 fire fighters engaged in fire suppression
1949	Mann Gulch	Montana	4,339 (1,756)	13 smoke jumpers killed
1967	Sundance	Idaho	56,000 (22,663)	50,000 acres burned in just 9 hours
1961/November	Bel Air	California		505 homes destroyed
1970/September	Laguna	California	175,425 (70,995)	382 structures destroyed
1977/July	Sycamore	California	805 (326)	234 structures destroyed
1980/November	Panorama	California	23,600 (9,551)	325 structures destroyed
1985/May	Black Friday Fires	Florida	110,000 (44,517)	1 dead, at least one fire in nearly every county of the state, 600 homes lost (400 of those lost in 1 day)
1987	Siege of '87	California	640,000 (259,000)	Valuable timber lost on the Klamath and Stanislaus National Forests
1988	Yellowstone	Montana and Idaho	1,585,000 (641,450)	Large amount of acreage burned
1988	Canyon Creek	Montana	250,000 (101,175)	Large amount of acreage burned
1990/June	Painted Cave	California	4,900 (1,983)	641 structures destroyed
1990/June	Dude Fire	Arizona	24,174 (9,783)	6 dead, 63 homes destroyed
1991/October	Oakland Hills	California	1,500 (607)	25 dead and 2,900 structures destroyed
1992/August	Foothills Fire	Idaho	257,000 (104,000)	1 dead
1994/July	South Canyon Fire	Colorado	1,856 (751)	14 dead
1994/July	Idaho City Complex	Idaho	154,000 (62,324)	1 dead
1996/August	Cox Wells	Idaho	219,000 (88,629)	Largest fire of the year
1996/June	Millers Reach	Alaska	37,336 (15,110)	344 structures destroyed
1997/July	Inowak	Alaska	610,000 (246,867)	Threatened 3 villages
1998	Volusia Complex	Florida	111,130 (44,570)	Thousands of people evacuated from several counties
1998	Flagler/St. John	Florida	94,656 (38,307)	Forced the evacuation of thousands of residents
1999/August	Dunn Glen Complex	Nevada	288,220 (116,643)	Largest fire of the year
1999/August–November	Big Bar Complex	California	140,947 (57,041)	Series of fires caused several evacuations during a 3½-month period
1999/September–November	Kirk Complex	California	86,700 (35,087)	Hundreds of people evacuated by this complex of fires that burned for almost 3 months
2000/May	Cerro Grande	New Mexico	47,650 (19,284)	Originally a prescribed fire, 235 structures destroyed and Los Alamos National Laboratory damaged
2003/October	19 fires throughout the state	California	730,000 + (295,431)	More than 3,600 homes destroyed, 22 people dead, more than 200 injured, more than 500 farms and commercial properties damaged

(GIS), globally positioned satellites (GPS), remote sensing of weather and fire conditions, fire and related land management simulation models, and the Internet. A major consideration in the twenty-first century is what Americans want and expect from their national forests and grasslands.

In a presentation to the Idaho Environmental Forum in 2004, USDA Forest Service Chief Dale Bosworth pointed out four major threats to the forestlands in the United States: fires, invasive species, loss of open space, and unmanaged outdoor recreation.[3]

Fires. Since 2000, the United States has had some of the worst fire seasons in 50 years. In 2002, record-breaking fires burned in four different states, and a fifth came close to breaking past records. In 2003, the fire season in southern California resulted in the deaths of at least 20 people and more from the debris flows that followed when rains fell on slopes where fires had burned away the vegetation.

Because many of the nation's fire-dependent ecosystems have become overgrown and unhealthy, the proper response is to reduce fuels *before* the big fires break out. The use of thinning techniques and the effective and safe reintroduction of fire into the ecosystem will help reduce the damage that fire makes each year in nearly every state.

Invasive Species. Plant species that evolve in one place and show up in another, where the ecological controls they evolved with are missing, take advantage of their new surroundings to crowd out or kill off native species, destroying habitat for native wildlife. Where cheatgrass takes over, for example, the range loses forage value for deer and elk, affecting the nation's heritage at a cost of billions of dollars.

Loss of Open Space. Every day, America loses about 4000 acres (1619 ha) of open space to development, about 3 acres (1.2 ha) per minute, and the rate of conversion is accelerating. In some places, the loss is to large, relatively undisturbed forests that provide needed habitat for animals like marten, bear, and cougar. In other places, the loss is to rangeland needed by many other animals and plants. Where private open space is lost, recreational pressures on public lands tend to grow.

Unmanaged Outdoor Recreation. Ninety-nine percent of recreational users are careful to protect the land. However, with millions of users, even a tiny percentage of problem use becomes relatively huge. Each year, the national forests and grasslands get hundreds of miles of unauthorized roads and trails due to repeated cross-country use. Every season, more erosion, water degradation, and habitat destruction occur. Conflicts between users and among land managers are rising. The challenge is to improve land management in order to get the most desirable and responsible recreational use based on sound outdoor ethics.

Causes of Wildland Fires

Leading Causes. Causes of forest fires differ from region to region but nationally they maintain a consistent ranking within percentage ranges (Table 13.5.2).[4] The leading cause of wildfires in the United States is intentional burning, or arson, which accounts for one-quarter to one-third of the fires and burned-over area. Debris burning accounts for an additional one-fourth of the fires, whereas lightning accounts for another one-tenth to one-seventh of the fires but affects a larger share of the burned area. Other prominent causes of fires include equipment use, careless smoking, children playing with matches, campfires, and railroad use.[5]

Nearly all of these fires are controlled at a size of 100 acres (40 ha) or less. However, roughly 2 percent of fires result in two-thirds of the total burned-over area. Altogether, hundreds of thousands of wildfires occur each year in the United States, burning millions of acres of forest, brush, and grass-covered lands.

The relative importance of the fire causes just mentioned varies considerably among the different geographical regions of the country. In terms of the number of fires and burned areas, lightning is the leading cause in the northwestern part of the country, as well as in Arizona and New Mexico. For the entire eastern half of the United States, intentional burning, or arson, and debris burning are the chief causes. In California, equipment use and arson rank highest, and debris burning and lightning are the main problems in the central Rockies. Alaska's wildfires can be blamed chiefly on debris burning and lightning.

In Canada, thousands of wildfires occur each year, burning millions of acres of wildlands. About one-third of these fires are caused by lightning, although fires started by lightning account for most of the burned-over area.

Role of Lightning. On a global scale, lightning is common; 8 million cloud-to-ground discharges occur per day around the world. One percent of these strikes results in wildland fires. In fact, dry lightning is responsible for 80 percent of all fires in wildland areas. Dry lightning occurs during thunderstorms when the humidity is so low (the air is so dry) that rain evaporates before it reaches the ground. Even though the rain does not reach the ground, the lightning does. Although the energy per lightning bolt varies greatly, 250 kilowatt-hours is a good estimate of the average energy discharged in each stroke. Almost 75 percent of a lightning bolt's energy is converted to heat during discharge. This is more than sufficient to ignite most fuels.

There are two types of discharge: cold and hot stroke. Cold strokes exhibit high voltage of short duration, generally with

TABLE 13.5.2 Causes of Wildland Fires

Cause	*Percentage Range*
Arson	25–39
Trash burning	18–23
Careless smoking	17–19
Miscellaneous/unknown	10–14
Lightning	9
Machine use	7–8
Railroads	5
Campers	3–6

mechanical or explosive effects. Hot strokes discharge a lesser current for a longer duration, thus starting more fires. Approximately 21 percent of all lightning moves from cloud to ground. Of this amount, 20 percent is hot stroke, according to studies in the northern Rockies. Therefore, in the northern Rockies, one stroke in 25 has the electrical characteristics to start a fire, depending on where or what it strikes and on the local weather conditions.

PRINCIPLES OF COMBUSTION

Fire is a chemical reaction in which energy is produced. When forest material burns, the oxygen in the air combines chemically with wood, pitch, and/or other burnable elements in the fuel. In the forest, several stages in the fire process are normally encountered: first, the igniting spark; then a period of smoldering; and, finally, the more rapid combustion of fuels. This process may continue to involve leaping flames, dense smoke, intense heat, loud noises, and occasional explosions. Throughout its life, the action of a fire is governed by certain natural laws or principles of combustion. An understanding of these principles is basic in judging the effect of various environmental factors on fire behavior.

The Fire Triangle

Three elements—heat, oxygen, and fuel—are required in proper combination for ignition and combustion to occur.* If any one of the three is absent or if they are not in proper balance, ignition or combustion will not occur. Variations in balance among heat, oxygen, and fuel govern the violence of a fire and determine whether the fire will smolder and spread slowly or flame brightly and travel rapidly.

Heat. Because of the variation in the nature of forest fuels, specifying the amount of heat required to ignite the fuels is difficult. Vegetative material is high in carbon content and ignites at relatively low temperatures, provided the moisture content is low and the substance is freely exposed to the air. During the forest fire season, a large part of the vegetative matter in a forest—duff, dead limbs, pine needles, tree branches, rotted logs, and so on—is dry enough to be ignited easily. The temperature requirement for ignition of forest fuels varies from approximately 500 to 750°F (260 to 399°C). Many common ignition sources can provide the required heat, including a burning match, a glowing cigarette, or a lightning bolt.

Ignition often depends on the length of time the fuel is exposed to heat. Dry pine needles may be ignited in a few seconds by the heat from a flaming match. Moist pine needles also may be ignited by a match if subjected to the heat for several minutes. When wood fuels are exposed to heat for a long time, the normal ignition temperature may be lowered. Studies have shown that wood exposed to a temperature of 400°F (204°C) for approximately 30 minutes may ignite.

The ease of ignition of forest fuels exposed to heat for a considerable time has an important influence on fire behavior. In a coniferous forest, a hot fire burning in a tangle of downed logs and dry limbs may generate enough heat to make the green tree crowns above the fire easily ignitable. All that is needed to cause the tree crowns to ignite is a flying ember and a gust of wind. Similarly, a fire smoldering in a pile of leaves may generate enough heat to lower the normal ignition temperature of the entire pile. When the leaves are stirred up, the whole pile breaks into flame. The stirring of the pile lets in enough oxygen for the preheated leaves to be ignited easily.

Oxygen. The atmosphere is about 21 percent oxygen and since most wildland fires burn in a free-burning state in an uncontained environment (unlike structure fires), removing the oxygen side of the triangle (smothering the fire) is usually impractical to extinguish a wildland fire. In the forest, there is usually enough oxygen to permit ignition and combustion. However, some of the forest fuels may be arranged so that oxygen is not available in sufficient amount to support a fire. In deep, tightly compacted duff, only the top particles can get enough air to permit a fire to burn. In this situation, a fire will burn from the top down as each layer is exposed to the air. By contrast, in a very loose layer of pine needles, the entire mass is fairly well exposed to air and, consequently, combustion will take place rapidly.

The air mass near a fire, as represented by weather elements that can be measured, is perhaps the most variable component of the fire environment.[2] When wind blows on a fire, it usually speeds up the combustion process. Wind forces oxygen around fuel particles where the flow of air normally may be restricted. In addition, wind has a physical reaction on the flames, often bending them into positions that create more favorable situations for the spread of the fire.

Fuel. Under forest conditions, fuel is a major variable in the fire triangle. The fire fighter must become acquainted with the general nature of forest fuels to understand their burning characteristics.

The ease of ignition and rate of combustion of forest fuels depend mainly on the type of fuel—is it logging slash or dense duff in a green forest? On fuel continuity—is the fuel distributed more or less evenly over the area, or is it only present in patches? On moisture content—does it feel damp when touched, or does it crackle and appear very brittle? On fuel temperature—is the fuel exposed to the heat of the sun, or does it lie in cool shade?

Combustion Process. When fuels are heated to their ignition temperature, they produce gases that will ignite if combined with oxygen. When a log burns, the flames may appear to be coming directly from the fuel. Actually, the flames come from the ignited fuel gases emerging from the heated log.

In forest fires, the two common stages of combustion are smoldering and flaming. In the smoldering stage, heat is

*Although it is recognized that there is a fourth component involved in the combustion process (a chemical chain reaction), for the purposes of this chapter only, the components that make up the commonly referred to "fire triangle"—heat, fuel, and oxygen—will be addressed. The process of breaking the chemical chain reaction is not normally addressed in relation to wildland fire suppression methods. For a discussion relating to the fire tetrahedron and the chemical chain reaction process, see Section 2, Chapter 1, "Physics and Chemistry of Fire."

liberated, and a rise in fuel temperature occurs, whereas flames are absent or appear only intermittently. The absence of flames is caused by insufficient oxygen or by moisture in the fuels, which slows the oxidation process.

When a fire is in the flaming stage, all the elements of the fire triangle—that is, heat, oxygen, and fuel—are in proper combination for rapid oxidation to occur. The flames of very hot fires may be observed intermittently in the smoke at a considerable distance above the fire. This occurs when oxygen is consumed so rapidly near the base of the fire that combustion of the gases is incomplete. As these superheated gases rise, they reach a fresh oxygen supply and break into flames, giving the appearance that the smoke itself is flaming.

Reignition of apparently dead fires is an important factor in forest fuels. Although neither flames nor smoke may be observed, a fire can break out again if sufficient heat remains. Reignition occurs easily where fuels have been subjected to heat for a considerable length of time. To prevent reignition, an experienced fire fighter feels out fuels by hand before leaving the area. If heat continues to be present, the danger of reignition exists, and the control job remains incomplete.

Breaking the Fire Triangle

In fire control operations, the objective is to prevent combustion by breaking the fire triangle. If a sufficient volume of water is applied, the fuel temperature can be lowered below the ignition point. Smothering fires with dirt deprives them of oxygen. Building a line in which all flammable material is removed from the path of the fire prevents further spread by robbing the fire of fuel.

In forest fire fighting, the actual method of suppression is often dictated by the equipment and fire fighters available. The most effective methods for each stage of a suppression operation can be determined by keen observation of the combustion process.

Reducing Heat. Water being used to reduce fuel temperatures should be applied directly on the fuels being consumed. It is a mistake to apply water on the flames rather than the fuels. If the liberation of these gases is to be stopped, the fuels themselves must be cooled by the water. Although some of the water played on the flames may reach the fuels, a large part will either miss its mark or be lost through vaporization. If water is being used for cooling purposes, the ultimate target is always the fuel.

In a very hot fire accompanied by leaping flames, the nozzle user may not be able to get close enough to the fuels to apply water directly on the trouble spot. In such cases, a fog nozzle should be used to knock down the flames. The water particles help cool the heated gases being liberated by the fuels. Once the flames have been knocked down, the water should be used to thoroughly cool the heated fuels that are generating flammable gases.

Reducing Oxygen. Fires burning in forest fuels are difficult to smother completely. Soil thrown on burning forest materials may retard combustion by shielding portions of the fuel surface from the air, but the porous nature of most soils makes it difficult to completely shut off the supply of oxygen in this manner. Throwing dirt on a fire is nevertheless an important means of reducing the rate of combustion, after which the control operation may be continued by attacking one of the other legs of the fire triangle.

In very fine fuels such as dry grass, the oxygen supply may be reduced easily. Fuels of this nature do not retain heat for long periods and, therefore, combustion normally may be checked by temporarily shielding the fuel surface from the air. Gunnysacks, fire swatters, and a shovelful of dirt correctly applied are effective implements in smothering grass fires. When larger accumulations of flammable materials, such as dead stems and leaves, lie beneath a stand of grass, the danger of reignition exists. The understory material may hold enough heat to cause the fire to reignite once an adequate supply of oxygen becomes available. This danger can be determined by the careful observation and "feeling out" of the fuel.

Removing Fuel. In wildland fire suppression, the removal of fuel from the path of the fire is a common method of attacking the fire triangle. The fire continues to burn until its fuel is consumed, but it is prevented from spreading any further. A slowly advancing fire burning in sparse ground fuels may be checked simply by constructing a fireline down to mineral soil (soil with little humus or organic matter). A hot or fast-running fire may require several fuel removal operations. Snags of trees or tall brush that could cause spot fires may have to be felled. Thickets of reproduction or dry brush may need to be weeded out. Low-hanging limbs may have to be removed to prevent the build-up of a crown fire. Concentrations of limbs and logs may have to be broken up. The objective of these operations is to remove or reduce the flammable substances that could allow the fire to either build in intensity or continue to spread.

Heat Transfer

The rate and amount of heat transferred influence the rate of spread and the intensity of a fire. Combustion cannot be sustained unless heat continues to be transferred. Heat transfer occurs by three means: radiation, convection, and conduction.

Radiation. In forest fires, radiation is the most significant means of transferring heat from burning fuels to exposed fuels. The location and width of firelines must be governed, in part, by the rate of radiant heat transfer. Potentially hot fires and spots where dangerous flare-ups might occur can often be prevented by the breaking up of the fuels to reduce the radiant heat transfer between them.

The degree of slope influences the amount of radiant heat transmitted to fuels upslope and downslope of the fire. Most forest fires will burn in the direction of the wind, partly due to the effects of radiant heat. Wind influences radiant heat transfer in two ways: (1) it increases the rate of combustion, thus creating a hotter fire; and (2) it bends the flames, thus decreasing the distance between the heat source and the fuels lying in the path of the fire. The dual effect of the hotter fire and the bent-over flames dries and heats the fuels laying ahead to such an extent that rate or spread may be greatly accelerated.

Often a fire will burn into the wind because the wind increases combustion to such a degree that a large amount of ra-

diant heat may be transmitted to the fuels lying on the upwind side. On the upslope side of a fire, the fuels receive more radiant heat, which is one reason fires often spread more rapidly up steep slopes than on level ground.

Convection. In a forest fire, the fuels lying in the path of convection currents are heated and, thus, transformed into a more ignitable condition. The hot air mass rising from a surface fire transfers a large amount of heat to the tree crowns, thus bringing them nearer to the ignition temperature.

When fires break out in tree crowns and in other aerial fuels, heat transfer by convection is usually increased. Sparks and burning embers (firebrands) from burning tree crowns and snags will also drop and start new fires in fuels on the ground. As these ground fires gain in intensity, more hot air masses rise through the aerial fuels, and a type of chain reaction may be created. Fire fighters must always be alert to the danger of hot surface fires burning underneath a forest canopy. These surface fires must be cooled promptly, and fuel masses must be broken up to reduce convective heat transfer.

Heat transfer through convection is also increased by wind, which moves hot masses of air ahead of the fire. Wind both increases the rate of combustion and accelerates the transport of hot air masses. When driven by wind, the hot convection currents may move closer to the ground fuels and, thus, create more flammable conditions in the understory vegetation of the forest.

Fuels located above the fire on steep slopes also receive heat by the movement of convection currents up the slope and are, thus, subjected to an accelerated rate of heating and drying. This fact is one more reason why fires often burn very rapidly up the sides of steep slopes.

Conduction. Wood is a poor conductor of heat, and the conduction method of heat transfer is relatively minor in evaluating forest fire behavior.

TOPOGRAPHY

Topography provides a useful and easily recognized indicator of fire behavior. Fires often have distinctive behavior characteristics according to aspect, elevation, position on slope, steepness of slope, and shape of the surrounding countryside. These topographic features are usually easy to identify in the field and, thus, are important factors in the evaluation of fire behavior.

Differences in topography may cause local variations in climate and day-to-day weather conditions. These variations, in turn, influence the character of forest growth and the flammability of fuels. In rough terrain, such as the northern Rocky Mountains, topography has a great influence on fire behavior.

Aspect

Aspect, sometimes referred to as exposure, describes the direction a slope faces. Fire conditions vary greatly according to aspect because different aspects receive varying amounts of sunshine and wind.

In general, southern and southwestern slopes provide favorable conditions for the ignition and spread of fires. Because these slopes receive direct sunshine, the air and fuel temperatures are somewhat higher and cause snow to melt earlier on southern slopes. For these reasons, vegetation on south-facing slopes is not only sparser but also drier and more flammable than vegetation on north-facing slopes.

There are also variations in temperature and relative humidity on northern and southern slopes. On south-facing slopes, the average July through August temperature is higher, and the relative humidity is lower. The time of day is also critical. South- and west-facing slopes are most dangerous in the afternoon and early evening. When the combined effects of aspect and elevation are considered, some striking indicators of fire behavior become evident.

Elevation

In the Rocky Mountains, there is a vertical difference of more than 10,000 ft (3048 m) between the lowest valleys and the highest mountains. At Lewiston, Idaho, the elevation is only 757 ft (231 m) above sea level. Along the Continental Divide, there are many peaks over 10,000 ft (3048 m), and in northwestern Wyoming, some peaks are over 13,000 ft (3962 m) above sea level. Between these extremes of elevation is a variety of weather and fuel conditions that creates distinctive fire control problems.

Position of Fire on Slope

Fire behavior at various positions on a slope may be influenced not only by aspect and elevation but also by the magnitude of the fuel body and by topographic barriers. When a fire starts at the bottom of a slope, an entire mountainside of fuels may lie in its path. Once a fire starting at the base of a slope gains headway, the availability of a continuous fuel body makes a large burn possible.

Steepness of Slope

Other conditions being equal, fires burn more rapidly on steep slopes. In general, as the steepness of the slope increases, the rate of fire spread increases. As explained previously, combustion is accelerated on steep slopes primarily due to increased heat transfer through radiation and convection. A fire will double in rate of spread on a 30 percent slope. On a 55 percent slope it will double again.

Shape of Country

In rugged, mountainous areas, the shape of the country is of great importance to the fire fighter who must evaluate fire behavior. Narrow canyons, side drainages, sharp ridges, and massive, irregular slopes all have a bearing on the direction of travel, rate of spread, and general behavior of fires.

Experience has shown the following topographic features to be of special importance:

- *Narrow canyons.* Wind direction normally will follow the direction of the canyon. Wind eddies and strong upslope air movement may be expected at sharp bends in a canyon. Radiant heat transfer from one slope to another is great and, as a result, fires may spot across the canyon easily. Near the bottom of the

canyon, there is little difference between conditions on various aspects.

- *Wide canyons.* Prevailing wind direction will not be altered to any great extent by the direction of the canyon. Cross-canyon spotting of fires is not common except in high winds. Strong differences will occur between general fire conditions on northern and southern aspects.
- *Box canyons.* Fires starting near the base of box canyons will react similarly to a fire in a stove. Air will be drawn in from the canyon bottom, thus creating very strong upslope drafts. These same conditions may occur at the heads of narrow canyons and at the heads of high mountain valleys.
- *Ridges.* Fires burning along lateral ridges may change direction when they reach a point where the ridge drops off into a canyon. This change of direction is caused by the flow of air in the canyon. In some cases, a whirling motion by the fire may result from a strong flow of air around the point of a ridge.

FUELS

Keen observation of variations in forest fuels is essential in reliably estimating fire behavior. Fuel is the material of primary concern to fire control agencies. A good fire fighter must be able to evaluate flammability and difficulty of control in the various fuel situations encountered in a forest area.

Flammability Analysis

In a forest, great differences exist in the character of flammable materials. Deep duff, newly fallen dead leaves, clumps of grass, litters of dry twigs and branches, downed logs, low shrubs, green tree branches, hanging moss, snags, and many other types of material are present. Each of these materials has distinctive burning characteristics. The flammability of a particular fuel body is governed by the burning characteristics of individual materials and by the combined effects of the various types of materials present.

Before flammability can be analyzed, the physical characteristics of combustible forest materials must be classified. Such a classification permits the identification of the fuel factors that influence flammability. After the fuel has been classified properly, topographic and weather factors must be considered before the rate of spread and the general behavior of fires in that fuel can be determined.

Because forest fuels are so varied and complex, developing a systematic approach to flammability analysis is necessary. First, the fuel body is subdivided into two broad classes: ground fuels and aerial fuels. Then each of these classes is evaluated according to the arrangement, compactness, continuity, volume, and moisture content of the principal materials involved. Aspect also affects the flammability of fuels. Southwest-facing slopes heat up to a greater extent. With practice, this procedure can be performed quickly and easily.

Ground Fuels

Ground fuels include all flammable materials lying on or immediately above the ground or in the ground. The principal materials are duff, tree roots, dead leaves, grass, fine deadwood, downed logs, stumps, large limbs, low brush, and reproduction or young stands of timbers.

Duff. Duff is composed of partially decayed vegetative matter found on the forest floor. Duff seldom has a major influence on the spread rate of fire as it is typically moist and tightly compressed so that little of its surface is freely exposed to air and its rate of combustion is slow. In forest fires, most of the duff is consumed down to mineral soil. Occasionally, duff contributes to the rate of spread by furnishing a path for the fire to creep along between patches of more flammable material.

The smoldering characteristics of duff fires make them somewhat difficult to control. Firelines must be dug down to mineral soil in duff areas unless the lower layers of duff are too wet or too tightly compressed to burn. Duff fires inside a fireline are best mopped up by turning over the duff with a shovel, loosening the material for better exposure to air, and allowing it to burn out. Water may be used effectively, but great care must be taken to stir the fuel to ensure that all particles are thoroughly soaked. Extinguishing duff fires by smothering them with dirt is very difficult to accomplish.

Tree Roots. Tree roots are not an important factor in rate of fire spread, as the greatly restricted air supply prevents rapid combustion. However, fires can creep slowly in roots—in fact, some fires have escaped control because a root provided an avenue for the fire to cross the control line. The most flammable roots are the large laterals stemming from dead snags. Root fires are controlled simply by cutting the root where it crosses the fireline. Mop-up of persistent fires may require complete excavation of roots.

Dead Leaves. As leaves decay on the ground, they gradually become part of the duff layer. Before this decay takes place, however, leaves are a highly flammable material and should be considered separately in evaluating ground fuels. In northern Rocky Mountain forests, the cover of dead leaves on the ground is composed primarily of needles dropped from coniferous trees. Ponderosa pine needles are the most flammable because their large size and shape lead to a loose arrangement allowing free circulation of air. Smaller needles, such as those from Douglas fir, are generally less flammable as they are more tightly compacted on the ground.

Needles that are still attached to dead branches are especially flammable because they are exposed freely to air and are not typically in direct contact with the more moist material on the ground. Needles remaining on fallen limbs form highly combustible kindling for larger material. For this reason, logging slash containing dry needles is dangerous fuel.

Many techniques are necessary to control fires for which leaves or needles are the primary fuel. The advance of a fast-running fire may be checked temporarily by smothering it with dirt or by cooling it with water. Only a light cover of dirt thrown with the sweeping motion of a shovel is necessary to slow down a needle fire.

When water is used to check the advance, a spray or fog-type stream is most effective, with the water being aimed at the base and directly in front of the flames. A penetrating straight stream of water is most effective for mopping up a needle fire. Careful

stirring of all flammable material is required. A fireline is essential around all fires burning in a continuous cover of needles.

Grass. Grass, weeds, and other small plants are important ground fuels that influence the rate of fire spread. The key factor in these fuels is the degree of curing. Succulent green grass acts as a fire barrier. During the course of a normal fire season, however, grass gradually becomes drier and more flammable until the stems and leaves die due to lack of moisture. At this time, the major part of the grass cover becomes highly flammable. Cured grass, if present in large and uniform volume, provides the most flammable ground fuel in the region.

Grass and other small plants occur on the floor of almost all forests. Fire fighters need to observe the volume and continuity of the grass cover. In dense forests where little sunlight reaches the ground, very little grass is found. In more open forests, such as in mature stands of ponderosa pine, there may be a large amount. If there is a more or less continuous cover of dry grass on the forest floor, the spread rate of a fire will be governed largely by that cover rather than by the heavier fuels normally associated with a forest.

The ease with which fires in dry grass can be controlled depends mainly on the volume of grass. When the volume is low, the fire is often cool enough to permit fire fighters to work near the edge of the flame front. When the volume of grass is great, however, the resulting hot fire may prevent work close to the fire front.

In grass fires, smothering with dirt or swatters and cooling with a spray or fog stream of water are effective control methods. Both methods require follow-up to ensure that no hangover fires remain. Wherever forest material, such as a mat of dead pine needles, twigs, or small limbs, is intermixed with the stand of grass, a fireline dug down to mineral soil is usually required.

Fires in dry grass often have high rates of spread. For this reason, special safety measures need to be observed.

Fine Deadwood. Fine deadwood consists of twigs, small limbs, bark, and rotting material. Normally, the fine deadwood classification is confined to material with a diameter of less than 2 in. (50.8 mm). These fine dead ground fuels are among the most important of all materials influencing the rate of fire spread and general fire behavior in forest areas. Fine deadwood ignites easily and often provides the main avenue for carrying fire from one area to another. It is the kindling material for larger, heavier fuels.

In areas where a great volume of fine deadwood exists, a fire can rapidly develop tremendous heat. The greatest volume of fine deadwood is usually found in areas containing logging slash. Under dry conditions, fires in such areas burn violently, and the strong convection currents created by the intense heat pick up burning embers and throw them out ahead, causing spot fires beyond the main fire front. In some areas, the occurrence of fine deadwood may be spotty. Troublesome situations may be avoided by breaking up the worst bunches of fine deadwood before a fire reaches them.

Granulated dry rotten wood, although not an especially important factor in the rate of fire spread, is a highly ignitable fuel. Flying embers from the main fire often cause spot fires in rotten wood lying on the ground or in hollow places on old logs or stumps. Fire fighters searching for spot fires should seek out and carefully check these areas.

In most forest fires, the control job must be aimed largely at checking the spread of fires in fine deadwood and in the associated material—that is, duff and leaves—lying underneath. Unless a large volume of dry grass is present, the fine deadwood is the most important fuel and should receive the first and most concentrated attention. If the fire is very hot, the first action may be to smother it with dirt or cool it with water. Final control requires a fireline dug down to mineral soil in nearly all cases.

Downed Logs, Stumps, and Large Limbs. Heavy fuels, such as downed logs, stumps, and large limbs, require long periods of hot, dry weather before they become highly flammable. When such material reaches a dry state, however, very hot fires may develop. The most dangerous heavy fuels are those containing stringers of dry wood, shaggy bark, or many large checks and cracks. Smooth-surfaced material is less flammable as it dries out more slowly, has little surface exposed to air, and contains less attached kindling fuel. Extremely hot fires may develop in piles of downed logs and large limbs or in crisscrossed windfalls as the various fuel components radiate heat to each other. Individual limbs and logs will not burn very hot unless the fire is supported by large accumulations of fine deadwood.

The control of an advancing fire seldom rests on the fire fighters' ability to suppress the fire in heavy fuels. Usually, fires will not advance from log to log unless finer fuels are present or the area is covered with logs that radiate heat to each other.

Once a fire becomes well established in heavy fuels, complete suppression becomes difficult. A control line around the area is essential. Smothering with dirt or cooling with water is effective, but both these methods require very large volumes of suppression agent. In some cases, it is necessary to allow the fire to burn out until the heat has subsided sufficiently to permit final mop-up operations to take place. When a fire is allowed to burn out in logs containing stringers of bark, a careful lookout must be kept for spot fires caused by embers carried in the strong convection currents. If at all possible, hot fires in such areas should be cooled promptly by any available means.

Low Brush and Reproduction. Low brush, tree seedlings, and small saplings are classified as ground fuels because they are so closely intermixed with the flammable material on the forest floor. This understory vegetation may either accelerate or slow down the spread rate of a fire. During the early part of a fire season, the shade normally provided by understory vegetation prevents other ground fuels from drying out rapidly. As the season progresses, however, continued high air temperature and low relative humidity dry out both the fuel lying on the ground and the understory vegetation. When this happens, most of the low vegetation, particularly small coniferous trees, becomes fire carriers.

The understory vegetation in a forest often provides a link between ground fuels and aerial fuels. The crowns of small trees may catch fire and, in turn, spread the fire to aerial fuels in the forest canopy. Either thickets of reproduction or dead brush may provide the first means for a surface fire to flare up and spread into the crowns of the overstory trees. In anticipation of this

possibility, alert fire fighters break up reproduction thickets and dead brush along the fireline or, wherever possible, locate control lines to prevent fire from spreading into these danger areas. It is not uncommon for fire to creep through ground fuels under low brush or reproduction during periods when there is a low burning index, such as during the night. Heat from the creeping fires dries out the leaves and stems of the low brush and reproduction. Then, on the following day, as the burning index increases, a reburn occurs. Often on the reburn, the dried, low vegetation burns hotly and carries the fire to the aerial fuels, causing a crown fire.

Aerial Fuels

Aerial fuels include all green and dead materials located in the upper forest canopy. The main aerial fuel components are tree branches, crowns, snags, tree moss, and high brush.

Tree Branches and Crowns. The live needles of coniferous trees are a highly flammable fuel. Their arrangements on the tree branches allow free circulation of air. In addition, the upper branches of trees are more freely exposed to wind and sun than most ground fuels. These factors, plus the volatile oils and resins in coniferous needles, make tree branches and crowns important components in aerial fuels.

Tree branches and crowns are fuels that can flash quickly with changes in relative humidity. Crown fires seldom occur when relative humidity is high. However, coniferous needles dry out quickly when exposed to hot, dry air. The dryness of needles is influenced by the transpiration process in a tree. When the ground is moist, trees pump a large amount of moisture into the air through the leaves. As the ground becomes drier, the transpiration process slows and, as a result, leaves and branches become drier and more flammable.

Dead branches on trees are an important aerial fuel. Concentrations of dead branches, such as those found in insect- or disease-killed stands, may cause fire to spread from tree to tree. Concentrations of dead branches on the lower trunks of trees may provide an additional avenue for fires to spread from ground fuels into tree crowns. The most flammable dead branches are those still containing needles.

Fires in the upper crowns of trees are extremely difficult to control. The main control method must be aimed at suppressing the fire in ground fuels and preventing the fire from entering the tree crowns. Removal of limbs on the lower trunks of trees is one method of preventing crown fires. Limbs should be removed wherever a concentration of ground fuels makes a crown fire likely.

Snags. Snags, or tree stumps, are one of the most important aerial fuels that influence fire behavior. Although green trees greatly outnumber snags in most forests, more fires start in snags because they are drier and are arranged for easier ignition.

Snags vary widely in character and, consequently, in their effect on fire behavior. Smooth, solid snags that contain very little bark and few checks or cracks are not highly flammable. On the other hand, broken-topped, shaggy-barked, or partially decayed snags ignite easily and have a major influence on the spread of fires. Burning embers blown from shaggy-barked snags are prolific starters of spot fires. In areas containing large numbers of snags, fire may spread from one trunk to another because of the intense radiation of heat.

Fires in burning snags must be controlled promptly. Wherever possible, the main control effort on the fire must be designed to prevent the blaze from getting into snags. When fires become established in snags, the control method usually requires that the snags be felled. Snag felling is especially important if shaggy bark might be carried from the burning trunk by wind or strong convection currents.

Tree Moss. Moss hanging on trees is the lightest and flashiest of all aerial fuels. Moss is important principally because it provides a means of spreading fires from ground fuels to other aerial fuels or from one aerial component to another. Like other light fuels, moss reacts quickly to changes in relative humidity. During dry weather, crown fires may develop easily in heavily moss-covered stands. Methods of controlling moss fires are aimed primarily at breaking up ground fuels to prevent fire from entering the tree crowns through hanging moss. In addition, lower limbs containing tree moss should be removed at all danger spots.

High Brush. Crowns of high brush are classified as aerial fuels because they are separated distinctly by distance from ground fuels. In the northern Rocky Mountain region, heavy stands of brush may develop in old burns, and they often form the principal vegetative cover in such areas. Crown fires in brush fuels ordinarily do not occur unless heavy ground fuels are present to develop the required heat. In some brush stands, however, a high proportion of dead stems may create a sufficient volume of fine dead aerial fuels to permit very hot and fast-spreading crown fires. Key factors in evaluating the behavior of fires in high brush are volume, arrangement, the general condition of ground fuels, and the presence of fine dead aerial fuels.

Fuel Conditions

Fuel Continuity. Fuel continuity describes the distribution of fuels in a given area. Fuel continuity is an important factor in fire behavior because the distribution of fuels influences the potential area where a fire may spread, as well as the rate of spread. If a dangerous fuel is uniformly distributed over an entire area, a high potential exists for a complete burn to occur at a rapid rate of spread. If the fuel body is broken up by patches of bare ground or much less flammable material, both the potential area of the burn and the rate of fire spread are reduced.

A wide range of fuel continuity conditions is found in most forest areas. For the sake of simplicity in making fire behavior estimates, the following two broad fuel continuity classes are recognized:

- *Uniform fuels.* Uniform fuels include all fuels distributed continuously over the area being evaluated. Areas containing a network of stringers, or blocks, which connect with each other to provide a continuous path for the spread of fire, are included in this classification.

- *Patchy fuels.* Patchy fuels include all fuels distributed unevenly over the area being evaluated. Definite breaks should be present, such as patches of rocky outcropping or plots where the dominant vegetation is of much lower flammability than the main fuel body.

Volume. As the amount of flammable materials in a given area increases, the amount of heat a fire produces also increases. The hottest fires, as well as those most difficult to control, occur in areas containing the greatest quantity of fuel.

In evaluating fuel volume, fire fighters should observe the quantity of both small- and large-sized fuel components. A great volume of small materials, such as fine deadwood, indicates ample kindling for the ignition of other fuels. A great volume of either small- or large-sized material indicates a high potential for a hot fire. Where fires develop in areas containing a great volume of large-sized material, there is intense radiation of heat to fuels lying in the path of the fire.

Fuel Compactness. Fuel compactness—that is, the number of individual fuel particles per unit of volume—varies greatly in all kinds of fuel, but it is significant principally in duff and dead leaves lying on the ground. Fires burn rapidly in loosely compacted fuels because more of the individual fuel particles are freely exposed to air.

Live Fuel Moisture. Two conditions of fuel moisture have major influence on the rating of fuel types. One concerns the greenness, or curing stage, of vegetation. The other relates to the shade and protection furnished by green timber.

In grass fuels, moisture content is a critical factor in determining flammability. Fires spread only at a low rate, or not at all, in grasses that are green, but when the same grasses become cured and dry, fires will race through them at an extremely rapid rate. The degree of curing of grass is difficult to evaluate and requires keen observation of the grass stand. For purposes of considering fire behavior, the moisture content of grass can be judged according to the state of curing, as follows:

- *Green.* The condition can be recognized by the green color and the cool, moist feel when crushed in the hand.
- *Curing.* As hot, dry weather prevails, grasses ordinarily progress through a period of gradual curing. This stage is detected by close observation of the individual grass clumps or stems. For cheatgrass, the curing stage is typified by a lavender tinge commonly referred to as "the purple stage." For most other grasses, the curing stage begins when the tips of grass blades become tan or brown, or when individual grass blades take on a cured appearance.
- *Cured.* In the cured stage, grasses are dried completely to a tan or brownish hue, and the stems feel dry or crackly when crushed or rubbed in the hand.

Soils influence curing primarily because of soil moisture relationships. In the deep, moist soils bordering creeks, curing is much slower than in the thin soils on slopes. Some grasses seldom reach a dangerous cured condition. The shade and protection afforded by timber stands influence fuel type ratings due to the favorable fuel moisture conditions that are created. In a dense forest, ground fuels are protected from the sun and wind. Temperatures and wind velocities are lower so that moisture does not evaporate as rapidly from the dead fuels on the ground. Lower ratings are assigned to fuels situated beneath dense timber canopies.

The moisture content of fuels is influenced also by aspect, altitude, time of year, time of day, and other factors. For the purpose of fuel type classification, these factors are disregarded, and fuel types are classified on the basis of the physical characteristics of the fuels themselves.

Dead Fuel Moisture. Dead fuel moisture is changed by the moisture content of the air. Time lag is the time it takes for the moisture content of the dead fuels and the surrounding air to equalize. Time lag is expressed as a rate (usually in hours) (Table 13.5.3).

SPECIAL FIRE BEHAVIOR FACTORS

Spot Fires

The development of spot fires depends not only on topographic and weather factors but also on the character of the fuels in the main fire and fuels beyond the main fire. In the main fire, rotten, shaggy-barked snags, such as broken-topped hemlock snags, and large quantities of ground fuels, such as heavy logging slash, are the fuels most likely to cause spot fires. Spot fires frequently are started by crown fires. Widespread crown fires, with their intense heat and strong convection currents, can throw burning embers far out ahead of the main fire. In many wildland/urban interface fires, significant structure loss occurs primarily from ember (firebrand) exposure.

Fuels that are ignited most readily by embers thrown out ahead of the main fire, listed in order of susceptibility, include the following:

1. Rotten wood on the ground, on logs, and in snags
2. Moss and lichens in treetops
3. Slash, particularly when compacted in tight piles
4. Duff
5. Cured grass

Spot fires become more frequent and severe with lower fuel moisture and increased wind. On an average dry, late summer afternoon, the smallest sparks quickly ignite rotten wood or tree moss. In compacted slash, in duff, and in cured grass, larger

TABLE 13.5.3 Dead Fuel Moisture: Time Lag Relationship to Fuel Size

Size Time Lag	*Diameter of Fuel*	*Examples*
1 hr	Less than ¼ in.	Annual grass
10 hr	¼ to 1 in.	Coastal sage, juniper, and chaparral
100 hr	1 to 3 in.	Logging slash
1000 hr	3 to 8 in.	Logs and mature standing timber

Note: For SI units: 1 in. = 25.4 mm.

burning embers are required to start spot fires unless sufficient wind exists to fan smoldering material into flames.

Crown Fires

Many forests contain a combination of aerial and ground fuels that favors the development of crown fires. Fuel conditions that influence the probability and character of crown fires include the following:

- Volume and arrangement of the timber canopy
- Volume and arrangement of fine dry aerial fuels, such as moss and dead twigs
- Position of aerial fuels above ground fuels
- Character of ground fuels

In open forests where single trees or small clumps of trees are well isolated from each other, crown fires are usually confined to single trees or to small groups of trees. Crowning, in such cases, increases rate of spread by intensifying heat and causing spot fires, but it will not result in racing crown fires like those that sometimes occur in dense forests.

When the timber canopy is sufficiently dense and continuous to carry broadcast crown fires, the severity of the crown fire is influenced by the quantity, character, and arrangement of dry fuels in the air and on the ground.

An important consideration in evaluating fuel conditions is the likelihood of reburns in tree crowns over previously burned ground fuels. A combination of fuel, weather, and topographic conditions may confine a fire to ground fuels for a considerable period of time. While the fire is burning on the ground, the aerial fuels may be scorched and singed and may become critically dry. If conditions change, a crown fire may develop and sweep back over the area. This type of crown fire may develop rapidly and burn more explosively because the aerial fuels have been dried by surface fire.

WILDLAND/URBAN INTERFACE (WUI)

Wildland/Urban Interface (WUI) Defined

The potential dangers of the wildland/urban interface (WUI) depend on a specific set of physical conditions that vary according to season (time of year), weather (humidity, winds), vegetation, and the structures in proximity of vegetation (construction, density). Attempts to define the interface as a geographic location or locations fail to account for the other factors that contribute to the potential for significant fire losses and unusual fire behavior. As defined in NFPA 1144, *Standard for Reducing Structure Ignition Hazards from Wildland Fire,* the wildland/urban interface is the "presence of structures in locations in which the AHJ [authority having jurisdiction] determines that topographical features, vegetation fuel types, local weather conditions, and prevailing winds result in the potential for ignition of the structures within the area from flames and firebrands of a wildland fire."

WUI as a National Concern

The destruction of an average of more than 900 homes per year over the last three decades is the result of the wildland/urban fire interface. Although of growing concern and attention, the problem is not new. Significant home destruction and numerous human fatalities had occurred for over a century before 1984. Historical records indicate that for the years between 1921 and 1984, over 5000 homes were destroyed by wildfires. During the 50 years prior to that (1870–1920), thousands of lives were lost and numerous communities were destroyed.[6]

In 1985, more than 1400 homes were lost to wildfires burning primarily in two states, California and Florida. Of the 1400 homes destroyed, 600 were in Florida, and 400 of the 600 were destroyed in 1 day. Never in the twentieth century had a loss of this magnitude occurred in a southeastern state.

As tragic as wildfires seem, today's wildland/urban fire losses are not as economically significant as other natural events, such as hurricanes and earthquakes, and the life and property losses from individual residential fire events. Severe hurricanes that impact urban areas do more damage in a matter of hours than severe wildfires do in a matter of days or weeks. Property damages and loss of life from even the most severe wildland/urban fire seasons do not come close to the magnitude of America's annual structural and life losses from even residential fires.* But there is more to the modern issue of wildfire disaster than just the economic impact of homes burning, because communities are more than homes and subdivisions. These communities include the surrounding natural environment, which allows and supports the economic, ecological, and social mechanics of a functioning community.

After these significant structural losses and resulting environmental damages from wildfires in California and Florida, wildland/urban fire received national attention from federal and state lands and forestry agencies, researchers, planners, insurance companies, and other key fire and safety organizations.[7] Since that time, the momentum has evolved into a national program, highlighted by Firewise Communities™, supported by numerous agencies from wildland/forestry and structural fire services, to emergency management and national security. Other regional/state programs like FireSafe Councils (California and Nevada) and FireFree (central Oregon) have been organized and funded to educate and implement programs to reduce community losses and damages from wildfire.

The term "wildland/urban interface" can distort the perception of the primary issue, directing attention to *where* homes are located (e.g., at the edge of communities near wildlands) rather than *if they are ignitable.* And that distraction may often result in a concentration on factors that won't make a big difference in reducing home loss (i.e., how fire fighters and equipment get there, what type of fire equipment is needed, road signs). In other words, knowing the width of roads and the location of hydrants is of little value if more homes are at risk than equipment is available to protect them or if it's too dangerous for fire fighters to be safely there in the first place. The wildland/urban interface is a set of conditions that may exist in many communities. The community illustrated in Figure 13.5.4, which is located in the Pine Barrens area of central New Jersey, escaped an 1800 acre fire through a quick response

*Comparison of data available from Insurance Service Offices, NFPA, and the Institute for Business & Home Safety.

FIGURE 13.5.5 Increasing Residential Density Resulting from Development into Formerly Wild or Rural Areas That Creates Volatile Interface Conditions (Photo: James C. Smalley)

by fire fighters and adequate separation between the vegetation and structures.

The essence of the wildland/urban interface issue is not where homes and domestic landscapes adjoin wildlands but rather the location, density, and availability of ignitable homes. A meaningful question, then, is: which homes are at greatest risk? Ignition-resistant homes closely bordering the wildlands are at less risk than a dense subdivision with wood shingle roofs several miles away from wildland fuels.

WUI Conditions

The wildland/urban interface fire problem is a volatile set of conditions leading to loss of life, property, and resources in the United States every year. These conditions include the following:

- Residential density is increasing. This condition is resulting from the rapid movement of development into formerly wild or rural areas, without consideration of how the potential of wildfire will impact this development (Figure 13.5.5). When a wildfire occurs, public perception tends to be that the fire came from federal or state agency-managed lands that have fire-fighting resources and that the losses are someone else's responsibility and outside a resident's authority and control.
- Community infrastructure, supporting rapid and expanding growth, is aging. This condition is placing pressures on basic protective aspects, such as roads for evacuation, water supplies for fire suppression, and storm water drainage.
- Inadequate planning and construction techniques plague existing homes and communities in the wildland/urban interface.
- Property owners and residents in the wildland/urban interface practice poor landscaping and landscape maintenance.
- Wildland conditions, including drought, insect infestation, invasive species, and overgrowth, contribute to more frequent and intense wildfires. A perception that needs our continued scrutiny is that all trees and forests are "natural" and should not be cut, thinned, or altered in any way. This thinking leads to overcrowded forest stands of native and nonnative tree species that bring with them a variety of undesirable consequences, including reduced water tables and stressed trees prone to insect and disease infestations and vulnerable to dangerous and devastating wildfires.
- Extreme weather events are being brought about by global climate changes over time. Long-term ecosystem changes have altered natural fuel beds and now severe wildfires burn outside natural fire regimes and can damage soils and the natural cycles of plant succession. For instance, when excessive wildland vegetation is allowed to grow unchecked for long periods of time, a fire that would normally burn surface fuels under the canopies of trees may ignite ladder fuels and reach the tree canopies, becoming a crown fire that causes devastating tree and forest mortality.

Sequence of Events in WUI Fire Disasters

The term "disaster" is a defining event in which resources have become overwhelmed and economic loss, property damage, or loss of life occurs. When lightning starts a severe wildland fire in a remote area, well away from communities (i.e., human presence), it is seen as a natural event rather than a disaster. The definition of today's wildland/urban interface fire disaster seems to depend on fire fighters being unable to prevent homes from burning.

A sequence of events typifies most WUI fire disasters. Although some variation exists in each severe occurrence, the following sequential elements are generally always present and the impacts are consistent time after time:

1. *Severe fire conditions exist.* Certainly, home loss from wildfires can occur without severe fire conditions and behavior, but the large-loss disasters most always occur under severe conditions—that is, the worst-case combination of fuels, weather, and/or topography.

2. *Wildland fire occurs.* Once a fire ignites under the worst-case conditions, it can spread rapidly through vegetation with growing intensity.

3. *Wildland fire becomes an urban fire.* The change from wildland to urban fire is the point in the combustion process that fuel types move from vegetation to constructed materials (i.e., homes). It is the point at which a "wildland fire" becomes a "wildland/urban interface fire." Preventing the ignition of those constructed materials is the best opportunity to prevent the inevitable disaster. If the homes don't burn, there is no interface disaster.

4. *Fire suppression resources are overwhelmed.* During extreme fire conditions with dry wildland fuels and high winds, fire fighters, equipment, and water supplies can become depleted as numerous homes ignite and burn. Fire-fighting forces struggle to position themselves to stop large flames pushed by strong winds. Suppression effectiveness is dramatically reduced in these conditions as tactics shift and fire-fighting forces initiate life/safety procedures by evacuating the public.

5. *Fire protection effectiveness is reduced.* Fire engines and crews cannot simultaneously evacuate residents and effectively take suppression action in a subdivision of homes igniting within a few minutes of each other. With multiple ignitions, the effectiveness of fire protection forces in these situations becomes compromised.

6. *Disaster!* In these disaster scenarios, when fire protection forces are overwhelmed and standard operating procedures fall short, fire protection forces cannot stop the large flames from these intense wildland fires from entering a residential area and cannot prevent numerous homes from becoming ignited. Valiant efforts may save a few homes but, most often, hundreds of homes are threatened or destroyed in a matter of hours and numerous lives may be lost.

Preventing the Disaster

When individual homes ignite or a single wildland ignition occurs, local fire agencies' standard operating procedures (SOPs) are very effective. The success rate in containing these ignitions is routinely in the 98 to 99 percent range. When ignitions occur in dense fuels (whether structural or vegetative) during periods of severe fire conditions, numerous homes may become involved. Rapidly spreading fire cannot be stopped and suppression efforts are dramatically reduced. The world sees the resulting "wildland/urban fire disaster."

Disaster Prevention Factors. Future wildfires will continue to enter communities, but homes and adjacent vegetative fuel beds do not have to ignite. A community made up of ignition-resistant homes, healthy surrounding forests, and noncontinuous fuels (i.e., breaks in the fuels from vegetation to single homes to multiple homes) becomes less vulnerable to encroaching wildfire. Vegetation doesn't combust near homes, houses don't ignite from firebrands, and severe structural property losses and human fatalities are dramatically reduced or potentially eliminated.

Fire Fighter Safety and Suppression Effectiveness in the WUI. Standard fire suppression operations are largely ineffective against severe wildland fire behavior, driven by high winds and producing huge flames, along with intense heat and showering firebrands. Often, during these situations, fire fighters must "fall back" to implement their own necessary life safety procedures. Because fire suppression strategies and tactics in interface fires may differ from those employed during structure fires or forest fires individually, fire departments join with forestry agencies to provide basic wildland fire training and to hold joint training sessions.

WUI Fire "Watch-Out Situations." Because of the ways that vegetation and structures interact in a fire in the wildland/urban interface, the following additional cautions for "watch-out situations"[8] were developed for both wildland and structural fire crews and officers:[9]

- Poor access and narrow one-way roads
- Bridge load limits
- Wooden construction and wood shake roofs
- Power lines, propane tanks, and HazMat threats
- Inadequate water supply
- Natural fuels 30 feet or closer to structures
- Structures in chimneys, box canyons, narrow canyons, or on steep slopes (30% or greater)
- Extreme fire behavior
- Strong winds
- Evacuation of public (panic)

Reducing Home Ignitions in WUI Fires. Case studies and experimentation by the USDA Forest Service and other organizations point to some general aspects of house construction and landscaping that can minimize risk of ignition. One of the most critical aspects is roofing. Findings from California studies have indicated that houses with flammable roofing have an 81 percent chance of being destroyed in wildfires, whereas the ratio of houses with nonflammable roofing is much lower at 30 percent. Moreover, 62 percent of houses without a maintained vegetation clearance of at least 30 ft (9 m) were destroyed as opposed to those (22%) whose vegetation clearance is maintained to at least 30 ft (9 m). In all, the effect of these two elements together provides the minimum guidance for homeowners, developers, and builders.[9,10] The combined effects are displayed in Table 13.5.4.

FIREWISE AND FIREWISE COMMUNITIES/USA

Development of the Firewise Programs

After the extreme fire season of 1985, representatives of NFPA and the USDA Forest Service met to discuss the increasing trend of wind-driven fire in populated areas and formed what is now the National Wildland/Urban Interface Fire Program. In 1992, the advisory group for the program adopted the term "Firewise" to describe the state of being knowledgeable and prepared for wildfire in residential or urban settings. In 1999 the advisory group became the Wildland/Urban Interface (WUI) Working Team of the National Wildfire Coordinating Group, which oversees the National Wildland/Urban Interface Fire Program and its Firewise Communities program. The Firewise website was launched in 1996, and the national workshop series began

TABLE 13.5.4 Effects of Roofing and Vegetation on Destruction of Structure in Wildfire

Factor	*Percent of Houses Destroyed*
Flammable roof and vegetation clearance not maintained	96
Nonflammable roof and maintained vegetation clearance	14

in 1999. Today, the Firewise Communities team continues its mission of wildland/urban interface fire education through its website, workshop series, community recognition program, and information resources.

Firewise Approach

The best approach to wildfire preparedness involves utilizing the wide range of Firewise practices that individuals and communities can take to reduce their vulnerability to wildfire. The National Firewise Communities Program offers a series of practical steps and/or supporting documents in the following areas:

- Land use and community development planning
- Improved planning for fire protection infrastructure
- Cooperative approaches to forest management adjacent to wildland/urban interface communities
- Regulation, codes, deed restrictions
- Improved education of interface residents (including landscaping and home construction and design)
- Response to and evacuation of interface areas
- Firewise Communities and Firewise Communities/USA Recognition Program

By implementing at least one recommended mitigation measure or planning element, individuals and communities can begin to protect against the risk of fire in the wildland/urban interface. Examples of Firewise techniques for property owners include the following:

- Creating a defensible space around residential structures by thinning trees and brush
- Choosing fire-resistant plants
- Selecting ignition-resistant building materials
- Positioning structures away from slopes
- Working with fire fighters to develop emergency plans

Firewise Communities Workshops

From 1999 through 2003, the National Firewise Communities Program offered national workshops and continues to support regional and local organizations interested in hosting Firewise workshops using materials supplied by the national program. Firewise Communities workshops prepare community leaders and fire service professionals to recognize WUI fire hazards, make homes and landscapes Firewise, deliver fire education to residents, and incorporate Firewise planning into existing and developing areas of communities. These dynamic workshops can feature interactive discussions, mapping, and wildfire simulations. Firewise workshops are most successful when they are attended by a variety of community representatives, such as planners, business leaders, homeowner association members, and emergency service professionals.

Firewise Communities/USA Recognition Program

To facilitate local solutions to wildfire preparedness goals, the Firewise Communities/USA program recognizes communities for working together to protect residents and property from fire in the wildland/urban interface. To be recognized as a Firewise Communities/USA site, local communities must create and implement a local plan with cooperative assistance from state forestry agencies and local fire staff. In addition, communities are required to continue regular maintenance and education to retain recognition status.

Community Definition. Homeowner associations and towns of 500 residents or fewer are the most appropriate venue for the Firewise Communities/USA Recognition Program. Individual homeowner commitment is the cornerstone of a successful Firewise Communities/USA program. Residents of a smaller geographic unit can more easily create and execute a plan that reflects the needs of its specific locale. The program is intended to engage residents in playing an active role in shaping and implementing the neighborhood plan and supporting the larger Community Wildfire Protection Plan (CWPP).*

Recognition Criteria. Working with local wildland fire staff, communities can earn an annually renewable Firewise Communities/USA status by meeting the following criteria:†

- Enlist a wildland/urban interface (WUI) specialist to complete a community assessment and work together to create a plan that identifies agreed-upon achievable solutions to be implemented by the community. Development of a local WUI plan may take up to 6 months.

*The Healthy Forest Restoration Act of 2003 (HFRA) (P.L. 108-148) recommended that interface communities develop, in cooperation with local, state, and federal fire agencies, a Community Wildfire Protection Plan (CWPP). The HFRA provides communities with an opportunity to influence where and how federal agencies implement fuel reduction projects on federal lands. A CWPP is the most effective way to take advantage of this opportunity. Communities with CWPPs in place will be given priority for funding of hazardous fuels reduction projects carried out under the auspices of the HFRA. The "communities" involved in a CWPP are political jurisdictions ranging in size from small incorporated towns to largely urbanized counties. A handbook on developing CWPPs is available from the Society of American Foresters (http://www.safnet.org). The handbook outlines how to convene other interested parties, what elements to consider in assessing community risks and priorities, and how to develop a mitigation or protection plan to address those risks.

†Becoming a Firewise Communities/USA recognition site begins with the community itself. A community representative completes an online request form on the Firewise Communities/USA website or contacts the state forestry agency. Applications and renewal forms are downloadable in PDF format at http://www.firewise.org/usa.

- Organize a multidisciplined Firewise board/committee. The team should include homeowners and fire professionals. Participation by planners, land managers, urban foresters, and/or members of other interest groups is also encouraged.
- Observe a Firewise Communities/USA Day each year that is dedicated to a local Firewise project.
- Invest a minimum of $2.00 per capita annually in local Firewise projects. The investment may be met through financial donations, state grants, or an equivalent amount of volunteer labor. Work by municipal employees or volunteers using municipal and other equipment can be included, as can state/federal grants dedicated to that purpose. A specialist can work with the community to identify and seek project implementation funds, should they be necessary.
- Submit an annual report to Firewise Communities/USA that documents continuing compliance with the program.

WILDLAND FIRE ORGANIZATIONS

Public Land Agencies

In the United States, wildland fire protection is handled by federal, state, county, and in some cases, city agencies, as well as by private corporations and career/volunteer fire departments. The U.S. Forest Service protects about 200 million acres (81 million ha) of national forest and other lands. Approximately 587 million acres (236 million ha) of other federal lands, mostly in the public domain, are protected by the Department of the Interior agencies: Bureau of Land Management (BLM), the National Park Service (NPS), the U.S. Fish and Wildlife Service, and the Bureau of Indian Affairs.

States, local governments, corporations, and career/volunteer fire departments protect about 840 million acres (340 million ha) of the country's essentially undeveloped lands. About 158 million acres (64 million ha), or roughly 9.5 percent, of the wildlands in the United States are not protected.[11]

In Canada, wildland fire protection is handled by 10 provinces, 2 territories, and Parks Canada, as well as by private corporations and career/volunteer fire departments.

U.S. and Canadian Coordinating Organizations

Wildland Fire Leadership Council (WFLC). The Wildland Fire Leadership Council (WFLC) was established in April 2002 by a Memorandum of Understanding between the Secretaries of Agriculture and the Interior. The purpose of the council is to support the implementation and coordination of the National Fire Plan and the Federal Wildland Fire Management Policy.

WFLC is a cooperative interagency organization dedicated to achieving consistent implementation of the goals, actions, and policies in the National Fire Plan and the Federal Wildland Fire Management Policy. WFLC provides leadership and oversight to ensure policy coordination, accountability, and effective implementation of the National Fire Plan and the Federal Wildland Fire Management Policy. Since its inception in 2002, the council has been successful through its collaborative work at reducing the interdepartmental differences for a seamless delivery of a coordinated fire protection program.

National Wildfire Coordinating Group (NWCG). The National Wildfire Coordinating Group (http://www.nwcg.gov) is made up of the USDA Forest Service; four agencies of the Department of the Interior: Bureau of Land Management (BLM), National Park Service (NPS), Bureau of Indian Affairs (BIA), and the U.S. Fish and Wildlife Service (FWS); and state forestry agencies through the National Association of State Foresters. The purpose of NWCG is to coordinate programs of the participating wildfire management agencies so as to avoid wasteful duplication and to provide a means of constructively working together. Its goal is to provide more effective execution of each agency's fire management program. The group provides a formalized system to agree on standards of training, equipment, qualifications, and other operational functions. Policies, standards, and procedures are implemented directly through regular agency channels.

The NWCG operates through subject- or task-focused "working teams," a concept that provides a means for the exchange of knowledge about all dimensions of fire management. Each working team is small (8 to 10 persons), interagency in nature, and geographically balanced. The current teams work in key areas, such as training, incident operations, fire use, fire equipment, wildland fire education, safety and health, incident business practices, information resource management, fire danger, fire weather, social science (task group), and the wildland/urban interface.

There are several avenues in which individuals or agencies can interface with the NWCG to retrieve information, make recommendations, or raise issues. Contact with NWCG can be made through agency representatives of the parent group and/or the working teams, working team chairpersons, or the executive secretary.

National Interagency Coordination Center (NICC). The National Interagency Coordination Center (NICC) is the focal point for coordinating the mobilization of resources for wildland fire and other incidents throughout the United States. Located in Boise, Idaho, the NICC also provides products designed to be used by the internal wildland fire community for wildland fire and incident management decision making.

Wildfire suppression is built on a three-tiered system of support—the local area, one of the 11 geographic areas, and the national level. When a fire is reported, the local agency and its fire-fighting partners respond. If the fire continues to grow, the agency can ask for help from its geographic area. When a geographic area has exhausted all its resources, it can turn to NICC at the National Interagency Fire Center (NIFC) for help in locating what is needed, from air tankers to radios to fire-fighting crews to incident management teams.

The center coordinates activities through 11 geographic-area coordinating centers: Southern Eastern, Northern Rockies, Rocky Mountain, Southwest, East Basin, West Basin, Northwest, Alaska, Northern California, and Southern California.

National Multi-Agency Coordination Group (NMAC). The NMAC comprises representatives from the Bureau of Land Management, Bureau of Indian Affairs, National Park Service, Forest Service, U.S. Fish and Wildlife Service, Federal Emergency

Management Administration, and the State Foresters. The NMAC group at NIFC prioritizes and allocates resources when there are critical shortages of national resources such as smoke jumpers, air tankers, or Type 1 incident management teams (IMTs).

Canadian Interagency Forest Fire Centre (CIFFC). CIFFC was opened on June 2, 1982, with a mandate to provide operational forest fire management services to member agencies that would, by agreement, gather, analyze, and disseminate fire management information to ensure a cost-effective sharing of resources. It would also actively promote, develop, refine, standardize, and provide services to member agencies in order to improve forest fire management in Canada.

CIFFC operates as a private, nonprofit corporation with two levels of management that direct the operation. The board of corporate trustees is made up of deputy-ministers responsible for forestry representing each of the provinces, territories, and the federal government. This group sets policy, gives direction, and approves annual budgets for CIFFC. The board of directors is made up of the directors responsible for forest fire management for each of the provinces, territories, and a representative of the federal government. This group prepares budgets and policies and controls the operation and expenditures of CIFFC. CIFFC staff operate and implement programs approved by the board of directors and the board of corporate trustees. In addition, CIFFC coordinates and directs working groups assembled to address specific tasks.

LEGISLATION AND POLICY

National Fire Plan (NFP)

Following a landmark wildland fire season in 2000, the National Fire Plan was developed with the intent of actively responding to severe wildland fires and their impacts to communities while ensuring sufficient fire-fighting capacity for the future. The NFP addresses five key points: fire fighting, rehabilitation, hazardous fuels reduction, community assistance, and accountability.

The National Fire Plan provides invaluable technical, financial, and resource guidance and support for wildland fire management across the United States. Together, the USDA Forest Service and the Department of the Interior work to successfully implement the key points outlined in the National Fire Plan by taking the following steps:

1. Assuring that necessary fire-fighting resources and personnel are available to respond to wildland fires that threaten lives and property
2. Conducting emergency stabilization and rehabilitation activities on landscapes and communities affected by wildland fire
3. Reducing hazardous fuels (dry brush and trees that have accumulated and that increase the likelihood of unusually large fires) in the country's forests and rangelands
4. Providing assistance to communities that have been or may be threatened by wildland fire[12]
5. Committing to the Wildland Fire Leadership Council, an interagency team created to set and maintain high standards for wildland fire management on public lands

Healthy Forests Restoration Act of 2003

The Healthy Forests Restoration Act of 2003 (P.L. 108-148) (HFRA) became law in December 2003. HFRA includes provisions to speed up hazardous-fuel reduction and forest-restoration projects on specific types of federal lands at risk of wildland fire and/or of insect and disease epidemics. The HFRA was designed to help states, tribes, rural communities, and landowners restore healthy forest and rangeland conditions on their respective lands. The provisions of HFRA can be applied to as many as 20,000,000 acres (8.1 million ha) of land managed by the Forest Service and the Bureau of Land Management.

With direct respect to hazardous fuels reduction and wildfire protection, HFRA provisions include the authority for expedited vegetation treatments on certain types of Forest Service and Bureau of Land Management lands that (1) are at risk of wildland fire, (2) have experienced windthrow, blowdown, or ice-storm damage, (3) are currently experiencing disease or insect epidemics, or (4) are at imminent risk of such epidemics because of conditions on adjacent land. The act also requires the Forest Service and Bureau of Land Management to maximize retention of larger trees in areas other than old-growth stands and to ensure that the agencies' actions are consistent with the objective of restoring fire-resilient stands and protecting "at-risk" communities and federal lands through collaboration among federal agencies and local communities, particularly when Community Wildfire Protection Plans (CWPPs) are prepared. At least 50 percent of the funding allocated to HFRA projects is to protect areas adjacent to communities at risk of wildland fire, with performance of these actions to be monitored when agencies conduct hazardous-fuel reduction projects. Multiparty monitoring is encouraged especially in projects that include communities and other diverse stakeholders (i.e., interested citizens and tribes).

In addition, HFRA encourages biomass removal from public and private lands following fuel reduction projects and provides technical, educational, and financial assistance to improve water quality and address watershed issues on nonfederal lands.

FEDERAL AGENCIES THAT AFFECT PUBLIC FIRE SAFETY

U.S. Department of Agriculture (USDA)

The fire protection programs of the U.S. Department of Agriculture (http://www.usda.gov) are aimed at fire prevention and education in rural areas; they are carried out by the USDA Forest Service and the Rural Housing Service.

USDA Forest Service. Known to millions through its familiar symbol Smokey Bear, the USDA Forest Service (http://www.fs.fed.us) provides fire protection to more than 200 million acres of forests, grasslands, and nearby private lands (National Forest System), conducts research and develops improved methods in forest fire management, provides technical and financial assistance to state forestry organizations to improve fire protection efficiency on nonfederal wildlands, and provides international

assistance in formulating policy and coordinating U.S. support for the protection and sound management of the world's forest resources.

Rural Housing Service (RHS). The Rural Housing Service (http://www.rurdev.usda.gov/rhs) operates a range of programs formerly administered by the Farmers Home Administration to support affordable housing and community development in rural areas. An agency in the U.S. Department of Agriculture, the RHS distributes loans and grants to improve housing and community facilities, including police stations and fire stations.

U.S. Department of the Interior (DOI)

The U.S. Department of the Interior (http://www.doi.gov) is composed of the Bureau of Land Management, the Bureau of Indian Affairs, the U.S. Fish and Wildlife Service, and the National Park Service (NPS).

Bureau of Land Management (BLM). The Bureau of Land Management (http://www.blm.gov) provides protection against wildfires on over 630 million acres (255 million ha) of public land, natural resources, and other values. It services and supports the National Interagency Fire Center in Boise, Idaho.

Bureau of Indian Affairs (BIA). The responsibility of the Bureau of Indian Affairs (http://www.doi.gov/bureau-indian-affairs.html) is the administration and management of 55.7 million acres (22.5 million ha) of land held in trust by the United States for American Indians, Indian tribes, and Alaska Natives. There are 562 federally recognized tribal governments in the United States. Developing forestlands, leasing assets on these lands, directing agricultural programs, protecting water and land rights, and developing and maintaining infrastructure and economic development are all part of the agency's responsibility.

U.S. Fish and Wildlife Service (FWS). The mission of the U.S. Fish and Wildlife Service (http://www.fws.gov) is to conserve, protect, and enhance fish, wildlife, and plants and their habitats. The service manages the 93-million-acre National Wildlife Refuge System of more than 520 National Wildlife Refuges and thousands of small wetlands and other special management areas; operates 66 National Fish Hatcheries, 64 fishery resource offices, and 78 ecological services field stations; and enforces federal wildlife laws.

National Park Service (NPS). The National Park Service (http://www.nps.gov) provides presuppression and suppression services and administers law enforcement, structural and wildland fire protection, and emergency medical services to protect visitors, national park employees, resources, and facilities.

National Interagency Fire Center

The National Interagency Fire Center (http://www.nifc.gov), located in Boise, Idaho, provides logistical support for the USDA Forest Service, the Department of Commerce's National Oceanic and Atmospheric Administration (NOAA), and the BLM, BIA, NPA, and FWS services of the Department of the Interior.

FIRE DETECTION, SUPPRESSION, AND RESOURCES

Fire Detection

In many wildland areas, lookouts in fire towers and aircraft patrols are the ones who discover, locate, and report fires. Additionally, travelers, campers, woodcutters, hunters, and others annually report thousands of fires. In the western United States and parts of Canada, lightning strikes are routinely detected electronically and their locations plotted by computer. Computer programs have been developed to assess the likelihood of ignition at various locations, as well as the characteristics of the strikes themselves. Automated fixed-point infrared detection systems have been developed but they have yet to be used extensively in North America, although they are used in some European countries. Although fire detection from satellites is technically feasible, the complication of discriminating between legitimate heat sources and incipient fires has not yet allowed the practical use of this technology.

Fire Suppression

Fire suppression includes all work to extinguish or confine a fire, beginning with its discovery. Suppressing or fighting a fire is usually difficult work that is inherently dangerous. However, knowing and applying safety principles and fire-fighting tactics serve to increase the safety and effectiveness of operations.

How agencies respond to a reported incident is well organized and planned in advance. As the incident requires, additional resources are dispatched from the local agency. Once the incident goes beyond the local agency's ability to continue supplying resources, requests for additional resources are forwarded to the nearest geographical area coordination center (GACC).

Suppression of Small Fires. Wildland fire management strategies are aimed at prompt, safe, aggressive suppression action of all wildfires. Small fires pose the same kind of suppression problems and require the same kind of practices as larger fires. Effective suppression of small fires involves the following steps: first attack, line location, line construction, burning out, mop-up, patrol, and declaring the fire out. Suppression strategies range from prompt control at the smallest acreage possible to containment using a combination of fireline and natural or constructed features, to merely ensuring that the fire remains confined to a defined geographical area.

Principles of Attack. The following principles of initial attack include sizing up a fire, selecting a point of attack and making an attack, mopping up, patrolling, and declaring the fire out:

- *Sizing up a fire.* Going around the fire as quickly and safely as possible or inspecting it from a vantage point. Fire fighters should not, however, go around the head of the fire if it is moving rapidly because entrapment is likely. Sizing up a fire should be performed from a vantage point or from the flanks of the fire.
- *Selecting a point of attack and making an attack.* The universal rules are to take prompt action on an attack point, to stay

with the fire, to take the most effective action possible with the available forces and equipment, to inform the dispatcher of the situation by radio, and to continue to work day or night, if night work can be done safely.

- *Mopping up.* After primary line construction work is completed and a fire is called "controlled," many things remain to be done to make the fireline "safe" and put the fire out. This work is called mop-up (Figure 13.5.6). The objective of mop-up is to put out all embers or sparks to prevent them from crossing the fireline. A certain amount of mop-up work is done while building the control line. Mop-up becomes an independent part of fire fighting as soon as the spread of the fire has been stopped and all lines have been completed. Ordinarily, mop-up is composed of two actions: putting the fire out and disposing of fuel, either by burning it to eliminate it or by removing it so it cannot burn.
- *Patrolling.* Patrolling is that portion of the mop-up job that consists of moving back and forth over the control line and the edges of burn areas to check for and put out any fire that may burn or blow across the line and, at the same time, to check for and put out spot fires outside the line.
- *Declaring the fire out.* Before abandoning a fire, and as a follow-up, the incident commander should take steps to ensure that the fire has been extinguished and that any fireline that has been constructed is adequate should a flare-up occur within the fireline.

Wildland Fire-Fighting Resources

Most agencies have full-time fire fighters but also hire a fair number of employees on a seasonal basis (generally from May to September). Almost without exception, regardless of the type of work seasonal employees are hired to do, everyone receives basic fire fighter training. During seasons when there are a lot of fires, people who have had basic fire training are called on to help organize fire crews.

FIGURE 13.5.6 Mop-Up, or Extinguishment of All Embers, Subsurface Fires, and Sparks, Being Performed by Fire Fighters to Ensure Safety of Fireline (Photo: James C. Smalley)

Hotshot Fire Crews. Hotshot fire crews are highly trained, skilled, and experienced crews made up of fire fighters who have had at least one season of experience as a wildland fire fighter. There are 68 hotshot crews nationwide—a total of 1360 fire fighters. These fire fighters are generally given assignments on the toughest part of a fire and use a variety of specialized hand tools, including chainsaws and fireline explosives. The crew members serve in all phases of wildland fire fighting—building firelines, burning out, setting backfires, and mopping up. Hotshot crew members are employed for a minimum of 130 days.

Smoke Jumpers. Smoke jumpers are airborne fire fighters who parachute from planes to attack wildland fires in remote and inaccessible areas. Generally, smoke jumpers are the initial attack force on remote, inaccessible fires. Competition for smoke jumper jobs in recent years is resulting in applicants with four to five seasons of wildland fire-fighting experience competing for the very limited number of jobs that become available each year.

Engine Crews. Engine crews are made up of three to five wildland fire fighters. A typical wildland fire engine is a heavy-duty off-road vehicle able to carry up to 800 gallons (3028 liters) of water. Engines also carry foam to use on wildland fuels. The foam can also be used to protect the exterior walls of a structure.

Hand Crews. Hand crews consist of about 20 individuals who have been organized and trained and are supervised principally for operational assignments on an incident (Figure 13.5.7). Generally, these crews are made up of people who have been trained to fire fight, but whose everyday job is something other than fire fighting, that is, timber, wilderness rangers, recreation, range management. There are approximately 500 hand crews in the United States.

Helitack Crew. Helitack crews are specially trained in the tactical and logistical use of helicopters for fire suppression. These crews can be rapidly deployed and are often the first to respond

FIGURE 13.5.7 Hand Crew Members Clearing Vegetation to Create a Fireline (Photo: James C. Smalley)

to a wildland fire. Helitack crews are also trained to rappel from a hovering helicopter in areas where the terrain or vegetation does not allow the helicopter to land. A primary job for the crew is to load and unload slings of equipment and supplies needed for fire fighting.

Aircraft Used in Wildland Fire Suppression

Helicopters. In a typical year, there are 15 to 20 heavy and medium helicopters under contract in the United States for wildland fire-fighting purposes. Also, there are 175 additional helicopters under contract on a call-when-needed basis. Helicopters support fire fighters on the ground by dropping water, foam, or retardant on flaming trees, brush, and even structures to cool hot spots and prevent a fire from spreading (Figure 13.5.8).

SEAT. The single engine air tanker (SEAT) is one of the newer tools in aerial fire fighting. The SEAT is a small agricultural "crop duster" airplane that has been modified to drop 500 to 800 gallons (1893 to 3028 liters) of fire retardant on wildfires (ideal for use on smaller, incipient fires). These aircraft are designed to fly low and slow, which is ideal for dropping retardants to slow or retard the spread of the fire.

Air Tankers. Air tankers are large planes fitted with tanks for transporting and dropping fire retardant or water. Their capability ranges from 2000 gallons (7,571 liters) to the larger aircraft that are capable of delivering 3000 gallons (11,356 liters). Air tankers drop their load in a long string, creating a line of retardant. The purpose of the retardant is to slow the fire down in order to give ground support forces the opportunity to build firelines. A pink dye is added to give the pilot an idea of where the drop landed. In a typical year, 40 to 50 air tankers are under contract to state and federal agencies for wildland fire-fighting purposes.

FIGURE 13.5.8 Helicopter Supporting Fire Fighters on the Ground by Dropping Water, Foam, or Retardant on Trees, Brush, and Structures to Cool Hot Spots and Prevent Fire from Spreading (Photo: James C. Smalley)

Modular Airborne Fire-Fighting System (MAFFS). A MAFFS unit is a pressurized 3000 gal (11,356 L) tank system containing either water or a water-based retardant designed to fit into a C-130 aircraft. Air tankers equipped with pressurized discharge systems are used to drop retardant or water on fires, under the direction of incident managers and guided by small aircraft known as lead planes. MAFFS units can only be utilized when there is imminent danger to life and property and other aerial resources are exhausted or committed (Figure 13.5.9).

Lead Planes. Lead planes, also called bird dogs, are used to lead the air tankers to and through their retardant drops and are also used for aerial reconnaissance of fire areas.

Infrared Aircraft. Infrared aircraft are equipped with highly specialized infrared mapping systems (Figure 13.5.10). The infrared scanners locate hot spots inside and outside a fire's perimeter. Infrared scanners can pinpoint a 6 in. (15 cm) hot spot from an altitude of 8000 feet (1.5 miles or 2.4 km) above ground

FIGURE 13.5.9 Air Tanker Equipped with Pressurized Discharge System Dropping Retardant on Fire (Photo: James C. Smalley)

FIGURE 13.5.10 Infrared Mapping System in Light Aircraft Used to Locate Hot Spots (Photo: James C. Smalley)

level and can cover almost 1 million acres (404,700 ha) in 1 hour. Flights are generally flown after sunset and before sunrise when temperatures between the terrain and the fire differ the most, making it easier to pinpoint heat sources.

Other Wildland Fire-Fighting Resources

Other wildland fire-fighting resources include incident management teams and remote automated weather stations (RAWSs).

Incident Management Teams. An incident management team is a team of highly trained, experienced individuals who are organized to manage large and/or complex incidents.

Remote Automated Weather Stations (RAWSs). Remote automated weather station (RAWS) units collect, store, and forward six critical weather elements hourly, via a geostationary operational satellite (GOES) 22,300 miles (35,887 km) above the equator, to a computer system located at the National Interagency Fire Center in Boise, Idaho. There are approximately 1150 RAWSs strategically positioned throughout the United States. The types of weather information involved include wind speed and direction, wind gusts, precipitation, air temperature, relative humidity, and fuel moisture. Resource managers also use RAWSs to monitor environmental conditions and air quality. Some RAWS units are used as early-alert warning systems for floods, mud slides, or hazardous material levels.

Fire Fighter Hand Tools. Most of the hand tools used by fire fighters are combination tools; that is, they have more than one purpose or use. Hand tools used by fire fighters must be effective, efficient, versatile, portable, simple, easy to maintain and repair, and standardized, so they can be pooled, traded, and transported quickly. The following are among the handtools that are repaired, sharpened, and stockpiled at the base camp for crews to use on the fireline:

- *Pulaski.* A Pulaski is a combination tool, ax, and mattock invented by Ed Pulaski in 1910. This tool enables fire fighters to cut trees and limbs with the ax side and to dig and scrape with the mattock side. Figure 13.5.11 shows cutting tools like Pulaski tools and shovels being sharpened.
- *McLeod.* The McLeod, a heavy-duty combination rake-and-hoe tool, is named after Ranter Malcolm McLeod. Fire fighters use this tool to cut through matted litter and duff and clear loose surface materials.
- *Ax.* Axes, the most common ones being the double-bitted, are used for cutting trees and limbs. The single-bitted or poleax is common in the East and is used for cutting trees and limbs and for driving wedges.
- *Shovel.* The shovel is a combination tool. The edges are sharpened so that the user can chop down small trees and cut limbs and roots. Fire fighters also use shovels to scrape away needles and other duff as they construct firelines down to mineral soil. They are specifically designed for fire use.
- *Drip torch.* Fire fighters use drip torches for igniting backfires or burnouts.
- *Backpack pump.* Fire fighters carry backpack pumps (Figure 13.5.12), usually made from collapsible neoprene, during mop-up operations. They are effective for cooling down hot spots.

FIGURE 13.5.12 Fire Fighter Using a Backpack Pump to Cool Down a Hot Spot (Photo: James C. Smalley)

Wildland Fire Fighter Training and Safety

Two reports, eight years apart, to the U.S. Congress about the roles of volunteers in protecting lives, property, and resources illustrate that the need for training is essential.[2] *Rural Fire Protection in America: A Challenge for the Future,* published by the National Association of State Foresters in 1994, listed training as the third most pressing problem and the second priority for any federal funding received by small rural fire departments. The report found that many communities have no funds to pay for the training and that most volunteers do not have the money to afford such training.

A more recent report by NFPA and the U.S. Fire Administration, *A Needs Assessment of the U.S. Fire Service: A Co-operative Fire Department Study,* confirmed that training

remains a problem. It showed that 30 to 50 percent of uncertified and untrained structural fire fighters are serving communities of 2500 or less. Consistently, both reports found over 40 percent of the rural fire fighters had no wildland fire training. Although some instances may have improved, a wide gap remains in attaining a trained fire-fighting force for small communities across America.

To help meet the need for wildland fire training in these small fire departments, the National Wildland/Urban Interface Fire Program[3] produced a three-part training program targeted at small community and volunteer fire departments, designed to raise the fire fighter's awareness of his or her surroundings in an interface fire. The program, complete with videotapes or DVDs, computer presentations, and handouts, was distributed free of charge to fire departments in over 10,000 small communities in the United States. It will eventually be offered as a Web-based, self-study course on the Firewise website (http://www.firewise.org).

Ten Standard Fire Orders. The 10 Standard Fire Orders* were developed in 1957 by a task force studying ways to prevent fire fighter injuries and fatalities. The standards discuss fire behavior, fireline safety, and organizational control and are delineated as follows:[9]

Fire Behavior

1. Keep informed on fire weather conditions and forecasts.
2. Know what your fire is doing at all times.
3. Base all actions on current and expected behavior of the fire.

Fireline Safety

4. Identify escape routes and make them known.
5. Post lookouts when there is possible danger.
6. Be alert. Keep calm. Think clearly. Act decisively.

Organizational Control

7. Maintain prompt communications with your forces, your supervisor, and adjoining forces.
8. Give clear instructions and ensure they are understood.
9. Maintain control of your forces at all times.

If 1–9 are considered, then . . .

10. Fight fire aggressively, having provided for safety first.

Eighteen Watch-Out Situations

Shortly after the 10 Standard Fire Orders were incorporated into fire fighter training, the 18 Situations That Shout Watch Out were developed. These following 18 situations are more specific and cautionary than the 10 Standard Fire Orders and describe situations that expand the 10 points of the fire orders:[9]

1. Fire not scouted and sized up
2. In country not seen in daylight
3. Safety zones and escape routes not identified
4. Unfamiliar with weather and local factors influencing fire behavior
5. Uninformed on strategy, tactics, and hazards
6. Instructions and assignments not clear
7. No communication link between crew members and supervisors
8. Constructing line without safe anchor point
9. Building line downhill with fire below
10. Attempting frontal assault on fire
11. Unburned fuel between you and the fire
12. Cannot see main fire, not in contact with anyone who can
13. On a hillside where rolling material can ignite fuel below
14. Weather gets hotter and drier
15. Wind increases and/or changes direction
16. Getting frequent spot fires across line
17. Terrain or fuels make escape to safety zones difficult
18. Feel like taking a nap near fireline

If fire fighters follow the 10 Standard Fire Orders and are alerted to the 18 Watch-Out Situations, much of the risk of fire fighting can be reduced.

Fire Fighter Fatalities

A very serious concern will continue to be the risk to fire fighters. Of the 999 fire fighters who died on duty between 1996 and 2005, 159 (or 15.9%) died as a result of wildland fires or control burns. As shown in Figure 13.5.13, the number of deaths in any one year was as low as 8 and as high as 26. Over the period, 25.5 percent of all fireground deaths occurred at wildfires and control burns. This examination of wildfire deaths was prompted by the large number of wildfire-related fire fighter fatalities in 2003 (26 of the 106 fire fighter deaths).[8]

The unusually high number of deaths among fire-fighting aircraft personnel, particularly in 2003, and the subsequent grounding of aircraft due to safety reasons in early 2004, may place more pressure on initial attack crews. In many cases, initial attack responders are from small community and volunteer fire departments. In addition, without traditional air support, ground crews may be expected to work harder, covering more acreage in shorter times at each fire. The concerns for fire fighter safety are extremely grave but, at the same time, may result in new methods of training in the future.

Wildland fire fighters carry special tent shelters, meeting the requirements of NFPA 1977, *Standard on Protective Clothing and Equipment for Wildland Fire Fighting.* In Figure 13.5.14, a fire fighter has deployed the shelter, stepped into the bottom, and is falling to the ground as a wildfire approaches. The deployment of shelters is a last resort and each deployment is recorded and investigated for the purpose of improving safety on the fireline.

Common Denominators of Fire Behavior

Four major common denominators of fire behavior have been noted in fires where a fire fighter has been killed or from which

*During the years since their inception, the Ten Standard Fire Orders were rearranged to provide fire fighters a mneumonic learning aid, so that the first letter of the first word of each order spelled out F-I-R-E-O-R-D-E-R-S. In May 2002, the NWCG approved the revision of the Ten Standard Fire Orders in accordance with their original arrangement. The original arrangement of the orders are logically organized to be implemented systematically and applied to all fires.

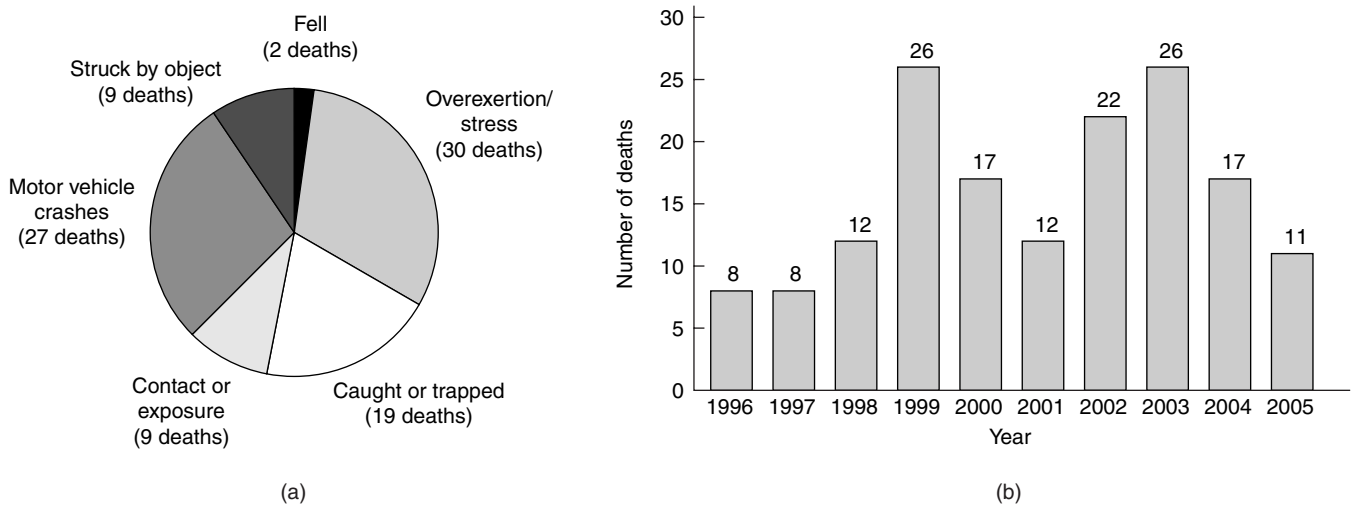

FIGURE 13.5.13 Fire Fighter Fatalities in Wildland Fires, 1996–2005: (a) On the Fireground, by Cause of Death; (b) by Year

FIGURE 13.5.14 Wildland Fire Fighter Deploying Special Tent Shelter (Photo: James C. Smalley)

fire fighters narrowly escaped. Such situations often occur in the following conditions:

1. On relatively small or deceptively quiet areas of large fires
2. In areas with relatively light fuels, such as grass, herbs, and light brush
3. When there is an unexpected shift in wind direction or wind speed
4. When the fire responds to topographic conditions and runs uphill

These factors should not be considered all-inclusive. For example, a sudden change of wind may change the direction of fire spread, regardless of topography. Each set of circumstances has the potential for creating a tragedy or near-miss fire. Often human behavior is the determining factor. Sociologists Jon Driessen, Lisa Outka-Perkins, and Leslie Anderson in their report, "Two Entrapment Avoidance Projects: Studying Crew Cohesion as a Social Human Factor," studied crew cohesion and how a breakdown in the crew affects the level of fatalities and injuries to wildland fire fighters.[13] Fire fighters who remain calm when the wind direction changes and move back into a burned area should survive. Those who try to outrun a fire under similar conditions may die. The difference between a tragic fire and a near-miss fire may be due to luck, skill, and/or advance planning. In all cases, it is important to be alert and aware of conditions that may signal a sudden change in fire behavior. In a few words, be alert and watch out for light fuels, wind shifts, steep slopes, and "chimneys." Those who remain alert and on the lookout for possible trouble have the best chance of survival.

FIRE PREVENTION

Challenge of Prevention

In the United States, about 2.5 million acres (1 million ha) of developed lands and wildlands burn every year. Often the carelessness of people leads to fires in wildlands. Some wildland fires are caused by campers who neglect to properly extinguish campfires. Other wildland fires result from lit cigarettes tossed onto the dry ground. Unwanted fires threaten valuable resources and, for this reason, fire prevention is an ongoing job. Fire prevention is one of the most important parts of a fire protection agency's responsibilities.

Smokey Bear Program

One of the most effective educational programs in the United States since 1944 has been Smokey Bear (Figure 13.5.15). This program has been a major factor in the prevention of thousands of unwanted human-caused fires, saving millions of dollars in damages and fire suppression costs. Nine out of every 10 wildfires is human caused. The program is managed by the partnership of the USDA Forest Service, the Ad Council, and National Association of State Foresters.

FIGURE 13.5.15 Smokey Bear (Source: U.S. Forest Service)

Following a series of changes in fire management policies and practices over the past decade, Smokey's message subtly changed from preventing forest fires to preventing wildfires, recognizing that unwanted fires on forests and grasslands (particularly those that destroy homes) are now the targets of prevention.

Over time, the Smokey program developed partnerships to reach new groups. Such partnerships include the American cowboy, pro-sports figures, and amateur athletes, all of whom have joined with Smokey to get the fire prevention message to the public. In 2005, Smokey Bear partnered with the Disney Corporation to deliver a fire prevention message with the DVD release of the Disney movie *Bambi.*

Specific prevention programs have been developed by different agencies and areas of the country. The Keep Washington Green Program, California Fire-Safe Councils, and central Oregon's Free Program are examples of programs developed to meet regional needs. Other individual states have very active wildfire prevention programs.

RESEARCH

Both Canada and the United States maintain fire research programs whose ultimate goals are to reduce the loss of life, property, and forest resources from wildfires and to introduce prescribed fire to achieve forest and range management objectives at reduced costs.

Joint Fire Science Program

The Joint Fire Science Program (JFSP), a partnership of six federal wildland and fire and research organizations, was established in 1998 to provide scientific information and support for fuel and fire management programs. All JFSP projects require scientist-manager partnerships along with strong emphasis on transferring research findings to the field. Guidance for the program includes the following four original principal purposes, all related to wildland fuels:

- Fuels inventory and mapping
- Evaluation of fuels treatments
- Scheduling of fuels treatments
- Development of protocols for monitoring and evaluation

Digital mapping (Figure 13.5.16) helps build inventories of forest health issues, fire-fighting resources, fuels, wildland/urban interface developments at risk from wildfire, and other forest and land management concerns. Mapping also provides the opportunity for spatial relationships to be examined, for example, the relationships between watersheds, wildlife habitat, and either a wildfire or the impact of a prescribed fire in the area.

In 2001, Congress further directed JFSP to expand its research efforts in postfire rehabilitation and stabilization, local assistance, and aircraft-based remote sensing. JFSP research also examines air quality, smoke management and social aspects of fire, and fuels management. In setting priorities for funding, the program responds to congressional direction, recommendations from advisory committees and member agencies, along with collective input from key agency personnel, workshops, and informational meetings. The program focus is on short-term, applied research that provides information and tools to specialists and managers, helping them make the best possible decisions and develop sound, scientifically valid plans.

Fire Behavior Research

Current U.S. Research. Current U.S. fire research is being conducted at six forest and range experiment stations. Much of the work is done at forest fire laboratories located in Macon, Georgia; Missoula, Montana; and Riverside, California. Major research projects include the following:

- *Fire behavior.* Fundamental studies in fuel chemistry, combustion and ignition processes, fire spread mechanisms, time-temperature heat flux interrelationships, and effects of fuel moisture, wind, and slope; development of systems to aid fire and land managers in dealing with the growth of large fires,

FIGURE 13.5.16 Digital Mapping Used to Provide Information on Forest and Land Management Concerns (Photo: James C. Smalley)

fuel consumption and energy release, probability of ignition by lightning, and fire spread in nonuniform fuels

- *Fire suppression.* Development of real-time and planning guidelines for individual suppression activities related to primary fuel and fire variables; integration of production rate knowledge into real-time and planning guidelines for fire suppression strategies and tactics; and development of design criteria for chemical formulations and for aerial and ground delivery systems for primary strategies and tactics
- *Fire effects, use, and ecology.* Research to determine how, when, and where prescribed fire may be used to improve tree growth, provide better wildlife habitat, reduce fire hazard, and accomplish other forestry goals; includes studies on soil to ascertain biological responses, impacts on soil, stand structure, and so on
- *Fire management planning.* Studies to relate wildland fires and social benefits desired from wildlands; to determine the effectiveness of fire prevention activities; to determine the influence of weather and climate on fire occurrence, control, and effects; and to determine the productivity and effectiveness of air tanker systems
- *Other.* Additional research projects involving smoke management for prescribed fires, reducing residues from forestry activities, evaluating the economics of fire protection systems, and aiding managers with systems for applying knowledge gained through research projects

Canadian Research. The Canadian Forestry Services (CFS) of Canada's Department of the Environment is the principal research organization in Canada. Its forest fire research program is centered at the Petawawa National Forestry Institute in Chalk River, Ontario. Fire research work is also carried out at regional forest research centers in Victoria, British Columbia; Edmonton, Alberta; and Sault Ste. Marie, Ontario. These research programs address the following six major areas:

1. *Fire behavior.* Fuel moisture physics, fire spread physics, prediction of fire danger by forest type, fire/weather interactions, fire danger rating system, and spatial weather models
2. *Fire ecology.* Postfire forest regeneration mechanisms, cyclic forest development from fire to fire, predictors of postfire forest development, and age-class distribution in fire-cycled forests
3. *Fire suppression.* Performance testing of fire management equipment, air tankers, fire retardant and water additives, aerial ignition devices, backfiring methods, and new suppression methods
4. *Prescribed fire.* Tree damage and mortality, use of fire for slash removal, seedbed preparation and vegetation control, design of prescriptions for proper burning conditions, and operational techniques
5. *Economics.* Estimation of values at risk, effect of fire on timber supply, relation between fire management costs and burned area, allowable cut effect, and ultimate impact on the forest economy
6. *Fire management systems.* Remote sensing applications; computerized systems for integrating weather, fuel type, and terrain into fire spread and growth models; prediction of lightning and human-caused fires; air patrol routing; resource deployment; and fire management strategies

Social Science Research. As national policies and practices changed over the past decade, a renewed interest developed in learning how the public would react to changes in fire policy, accepting the concept of good fire on the landscape and smoke in the air. To better understand and explain the interrelationships between people and natural environments, social research has been a focus of the U.S. Forest Service and other agencies in examining how people relate to, value, and impact the environment, that is, how the severity of forest and rangeland fires can be reduced through human interaction. Analogous to physical research that examines how fuel moisture in various types of vegetation affects flame lengths, social research examines the dynamics of changing values, public policies, and forest use, productivity, and management practices.

For more information on the overall research agenda, consult *Burning Questions: A Social Science Research Plan for Federal Wildland Fire Management.* In July 2000, the National Wildfire Coordinating Group commissioned an interagency research plan for understanding the human dimensions of federal wildland fire management. The resulting report describes the applicability of social science to wildland fire management problems, articulates high-priority needs for social science research, and organizes a research agenda that the NWCG advocates. This report is the foundation for NWCG's participation in the further development of a strong social science base to federal wildland fire management.

Programs such as Firewise Communities are based on steps that communities can take to reduce their risk from wildfire. Even in areas not traditionally considered at high fire risk, storm events, changing climate, and pest/disease outbreaks have focused attention on the potential for catastrophic fire. In addition, in areas where fire is viewed as a natural part of the ecosystem, the fact that more and more people choose these places to live means that there is a greater potential for significant fire impacts.

In research funded by the National Fire Plan, the North Central Research Station of the USDA Forest Service has found that actions to increase wildfire preparedness are affected by decisions made by individuals and the community. Individuals have resources that influence and are used to implement decisions regarding the siting of structures, building materials, landscaping, access, and other factors that impact wildfire preparedness. Communities also have resources that influence and are used to implement their decisions relating to zoning, planning, education, and other activities that impact wildfire preparedness. Agencies within these communities have resources that influence and are used to implement their decisions relating to the purchase and availability of equipment and gear, scheduling and conduct of training, and implementation of protocols. Decisions made at both the individual and community levels come together in a set of actions aimed at increasing wildfire preparedness. Figure 13.5.17 indicates that, as a result of these actions, communities can minimize losses from wildfire, and recovery or restoration following a fire will be quicker and more effective.

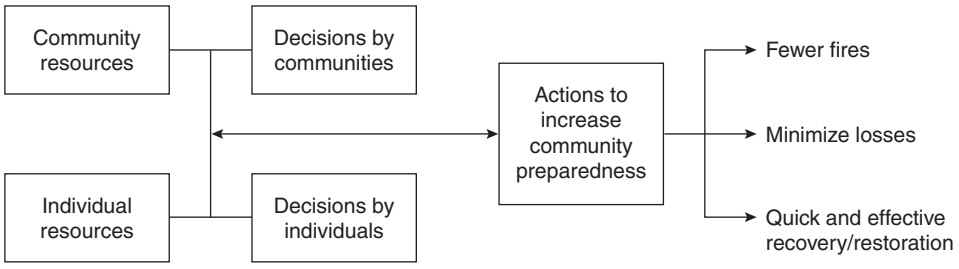

FIGURE 13.5.17 Model for Understanding Community Preparedness for Wildfire

Based on pilot studies in northern Minnesota on the Gunflint Trail; Bend, Oregon; and Waldo, Florida, to test the model, the focus turned to the following five community resources or characteristics that are critical to wildfire preparedness:

- *Social capital.* The community characteristics that contribute to collective social action; communities that are described as having social capital would have strong leadership within the community, networks to encourage coordination and cooperation, and the ability to mobilize resources
- *Human capital.* Knowledge and skills an individual obtains through education and training
- *Cultural capital.* Knowledge and skills possessed by individuals because of their heritage, experience, and attachment to place
- *Agency involvement.* Agency involvement (one agency working alone, a couple of agencies working separately but toward a common goal, or multiple agencies truly integrating their activities) was important in affording the local community access to the myriad of public programs providing funding and materials for wildfire preparedness; agencies also provide expertise and skills to the community to aid in wildfire preparedness
- *Landscape.* Vegetation and topography that have a huge influence on fire frequency and risk; there are also social aspects to landscape, for example, land ownership as a social characteristic of landscape that affects wildfire preparedness

The product of this and related research will be a more detailed understanding of the relationship of humans to the environment and recommendations for actions to increase wildfire preparedness based on the ecological characteristics of the landscape and the social characteristics of the community. The outcome of this research will be communities that, if they experience a wildfire, will minimize their losses and recover and restore their communities more quickly because they have taken steps to increase wildfire preparedness and have identified the necessary resources to implement these steps.[14]

SUMMARY

The historic and potential loss of human life, the financial impact on the national economy, and the increased value of natural resources make it undesirable to lose thousands of acres of valuable timber, rangeland, and watersheds. Continuing efforts to mitigate accumulating forest fuels, to guide growth of residences near forests, to prepare fire managers and fire fighters to use the beneficial aspects of prescribed fire, and the control of unwanted fires are growing in importance.

Because mitigating strategic fuels around communities requires action largely on private property, most fire agencies support and complement the national Firewise Communities program. The overarching objective of Firewise is, in a sense, to transfer the responsibility for mitigation and preparation for wildfires from the public sector to the private sector—that is, the homeowners and residents in hillside and grassy plains communities everywhere. Firewise Communities is a highly successful program emphasizing individual responsibility for fire hazard mitigation on community and private property through land use planning, building methods and materials, creative landscaping, intelligent zoning, and innovative community fire protection planning. The Firewise program educates and supports community leaders, fire professionals, planners, and individuals on wildland/urban interface fire issues; maintains an educational website; and provides varied assistance to organizations and individuals for wildland fire mitigation.

Chapter 6

Public Fire Protection and Hazmat Management

Michael S. Hildebrand ■ Gregory G. Noll

Chapter Contents

Definition of a Hazardous Material
Hazardous Materials Prevention and Enforcement Programs
Federal Hazardous Materials Laws
Hazardous Materials Regulations
Voluntary Consensus Standards

Key Terms

Clean Air Act, hazardous material, Hazardous Waste Operations and Emergency Response (HAZWOPER) Standard, Resource Conservation and Recovery Act, Superfund, Superfund Amendments and Reauthorization Act (SARA)

Public interest in the environment and major catastrophes involving hazardous materials (hazmats) have resulted in promulgation of a wide range of laws, regulations, and standards that mandate fire department involvement. Many laws created at the federal level assign overlapping responsibility for public safety to federal, state, and local agencies. Organizing an effective hazardous materials prevention and enforcement program within a fire department can be a difficult task. Consider the fact that the U.S. Congress has passed six major pieces of legislation concerning hazardous materials and public safety. These laws have produced seven different major federal agency regulations that contain no fewer than six different legal definitions for a hazardous material. Add the fact that there are also 50 individual state codes and over 70 different voluntary consensus standards, and it is easy to see why the code enforcement issue can be confusing.

This chapter has been written for the fire department prevention and enforcement specialist who wants to learn the fundamentals of hazardous materials laws, regulations, and standards. It begins by defining what a hazardous material is and provides an overview of the major elements of a hazardous materials prevention and enforcement program. The chapter provides an in-depth overview of the key elements of each of the major federal laws and regulations, as well as a general summary of the primary hazardous materials codes and standards.

See also Section 7, Chapter 5, "Hazardous Waste Control"; and Section 13, Chapter 8, "Managing the Response to Hazardous Material Incidents."

DEFINITION OF A HAZARDOUS MATERIAL

The first step in understanding hazardous materials from a prevention and enforcement perspective is to define what a hazardous material actually is. Many of the commonly used hazardous materials terms are sometimes used interchangeably, but they have distinctively different meanings. Various state and federal regulations govern the manufacture, transportation, storage, use, and cleanup of chemicals in the United States and Canada, and use numerous terms, definitions, and lists to convey information.

Hazardous materials: Any substance or material in any form or quantity that poses an unreasonable risk to safety and health and property when transported in commerce (U.S. Department of Transportation, 49 CFR 171).

Hazardous substances: Any substance designated under the Clean Water Act and the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) as posing a threat to waterways and the environment when released (U.S. Environmental Protection Agency [EPA], 40 CFR 302). It should be noted that the term "hazardous substances," as used within Occupational and Safety Health Administration (OSHA) 1910.120, refers to any substance defined by EPA within Section 101 of CERCLA; any biological agent or other disease-causing agent as defined by EPA within Section 101 of CERCLA; any substance listed by Department of Transportation (DOT) as

Michael S. Hildebrand, CSP, and **Gregory G. Noll,** CSP, are consultants specializing in hazardous materials emergency response issues. They are the authors of the textbook *Hazardous Materials: Managing the Incident* and serve on the technical committee for NFPA 472, *Standard for Professional Competence of Responders to Hazardous Materials Incidents.*

a hazardous material; and any hazardous waste, as defined by EPA in 40 CFR 261.3 or by DOT in 49 CFR 171.8.

Extremely hazardous substances (EHS): Chemicals determined by the EPA to be extremely hazardous to a community during an emergency spill or release as a result of their toxicities and physical/chemical properties (U.S. EPA, 40 CFR 355).

Hazardous chemicals: Any chemical that would be a risk to employees if exposed in the workplace (U.S. OSHA, 29 CFR 1910). Examples of a "physical hazard" are combustible liquids, compressed gases, explosives, flammables, organic peroxides, oxidizers, pyrophorics, unstables (reactives), or water-reactives. "Health hazard" means a mixture of chemicals or a pathogen for which there is statistically significant evidence, based on at least one study conducted in accordance with established scientific principles, that acute or chronic health effects may occur in exposed employees. The term "health hazard" includes chemicals that are carcinogens, toxic or highly toxic agents, reproductive toxins, irritants, corrosives, sensitizers, hepatoxins, nephrotoxins, neurotoxins, agents that act on the hematopoietic system, and agents that damage the lungs, skin, eyes, or mucous membranes.

Hazardous wastes: Discarded materials regulated by the EPA because of public health and safety concerns. Regulatory authority is granted under the Resource Conservation and Recovery Act (RCRA) (U.S. EPA, 40 CFR 260–281).

Marine pollutant: Materials that have an adverse impact on the marine environment.

Dangerous goods: An internationally used term under the International Maritime Dangerous Good Code (IMDG). In Canadian transportation, the U.S. term "hazardous materials" has basically the same meaning as "dangerous goods."

HAZARDOUS MATERIALS PREVENTION AND ENFORCEMENT PROGRAMS

A comprehensive and integrated public safety hazardous materials program should consist of four major program elements: (1) prevention, (2) preparedness, (3) response, and (4) recovery. The prevention program element usually consists of four subelements: (1) construction and design standards; (2) an inspection and enforcement program; (3) a public education program; and (4) handling, notification, and reporting requirements.

Process, Container Design, and Construction Standards

Almost all hazardous materials facilities, containers, and processes are designed and constructed to some engineering standard. This standard may be based on voluntary consensus standards, such as those developed by the National Fire Protection Association (NFPA) and the American Society for Testing and Materials (ASTM) or on government regulations. Many major petrochemical companies, hazardous materials companies, and industry trade associations have also developed their own respective engineering standards and guidelines.

All containers used for the transportation of hazmats are designed and constructed to both specification and performance regulations established by the U.S. DOT. These regulations are referenced in Title 49 of the Code of Federal Regulations (CFR). In certain situations, hazmats may be shipped in non-DOT-specification containers that have received a DOT exemption.

Inspection and Enforcement

Fixed facilities, transportation vehicles, and transportation containers are subject to some form of hazardous materials inspection. Fixed facilities will commonly be inspected by state and federal OSHA and EPA inspectors in addition to state fire marshals and local fire departments. It should be recognized that many of these inspections will focus on fire safety and life safety issues and may not adequately address either environmental or process safety issues.

Transportation vehicle inspection is generally based on criteria established within Title 49 CFR. The enforcing agency is usually the state police; however, some local fire departments and state fire marshal's offices are also involved in inspecting hazardous materials cargo tank trucks. This will vary according to the individual state, the hazardous materials being transported, and the mode of transportation.

Among the U.S. DOT agencies with primary hazardous materials regulatory responsibilities are the following.

U.S. Department of Transportation (DOT) Pipeline and Hazardous Materials Safety Administration (PHMSA): Responsible for safe and secure movement of hazardous materials to industry and consumers by all transportation modes, including the nation's pipelines.

Federal Motor Carrier Safety Administration (FMCSA): The mission of FMCSA is to improve truck and bus safety on the nation's highways and to reduce hazardous materials security risks that could potentially harm the public and the environment.

Federal Railroad Administration (FRA): Responsible for enforcement of regulations relating to hazardous materials carried by rail or held in depots and freight yards.

Federal Aviation Administration (FAA): Responsible for the enforcement of regulations relating to hazardous materials shipments on domestic and foreign carriers operating at U.S. airports and in cargo-handling areas.

U.S. Coast Guard (USCG): Responsible for the inspection and enforcement of regulations relating to hazmats in port areas and on domestic and foreign ships and barges operating in the navigable waters of the United States.

Public Education

Hazardous materials are a concern not only for industry but also for the community. The average homeowner contributes to this problem by improperly disposing of substances such as used motor oil, paints, solvents, batteries, and other chemicals used in and around the home. As a result, many communities have initiated full-time household chemical waste awareness,

education, and disposal programs. In other instances, communities have established used motor oil collection stations and chemical cleanup days in an effort to reclaim and recycle these materials.

Handling, Notification, and Reporting Requirements

These guidelines actually act as a bridge between planning and prevention functions. There are many federal, state, and local regulations that require those who manufacture, store, or transport hazmats and hazardous wastes to comply with certain handling, notification, and reporting rules. Key federal regulations include the facility reporting requirements of Superfund Amendments and Reauthorization Act (SARA), Title III, and the release notification requirements of CERCLA (Superfund). There are also many state regulations that are similar in scope and that often exceed the federal requirements.

FEDERAL HAZARDOUS MATERIALS LAWS

Laws are primarily created through an act of Congress or by individual state legislatures. Laws typically provide broad goals and objectives, mandatory dates for compliance, and established penalties for noncompliance. Federal and state laws enacted by legislative bodies usually delegate the details for implementation to a specific federal or state agency. For example, the U.S. Occupational Safety and Health Act enacted by Congress delegates rule making and enforcement authority on worker health and safety issues to the Occupational Safety and Health Administration.

History shows that hazardous materials laws have been enacted by Congress in response to specific catastrophes, such as Love Canal, New York; Bhopal, India; and the terrorist attacks of 9/11. Laws now regulate everything from finished products to hazardous waste.

Because of their lengthy official titles, many simply use abbreviations or acronyms when referring to these laws. The following summaries outline some of the more important laws impacting hazardous materials emergency planning and response.

Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA)

Known as "Superfund," this law addresses hazardous substance releases into the environment and cleanup of inactive hazardous waste disposal sites. It also requires those individuals responsible for the release of the hazardous materials (commonly referred to as the responsible party) above a specified "reportable quantity" to notify the National Response Center.

In 1980, Congress passed the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) and established a fund of $1.6 billion called the "Superfund" (PL 96-510) to be administered by the EPA. Under this legislation, the EPA is authorized to inventory all uncontrolled hazardous waste sites in the nation. If the substances at these sites pose an immediate danger to public health and/or the environment, and those responsible for the contamination cannot be identified or cannot pay for the cleanup, the EPA can use the Superfund to clean up chemical spills or toxic wastes.

Resource Conservation and Recovery Act (RCRA)

In 1976, Congress passed major legislation establishing a uniform national policy for hazardous and solid waste disposal. This act is called the Resource Conservation and Recovery Act (RCRA). Congress intended that states assume responsibility for implementing RCRA, with oversight from the federal government. The rationale was that states are more familiar with the regulated community and are in a better position to administer the programs and respond to specific state and local needs most effectively. The state program must be fully equivalent to the federal program. However, states may impose requirements that are "more stringent" or "broader in scope" than the federal requirements.

There are four major programs established under RCRA: (1) solid waste, (2) underground storage tanks, (3) medical waste, and (4) hazardous waste.

Solid Waste. Subtitle D of the act encourages states to develop and implement solid waste management plans. These plans, among other purposes, are intended to promote recycling of solid wastes and require closing or upgrading of all environmentally unsound dumps.

Underground Storage Tanks. Subtitle I of the act regulates petroleum products and hazardous substances (as defined under Superfund) stored in underground tanks. The objective of this section is to prevent leakage to groundwater from tanks and to clean up past releases. There are also performance standards for new tanks and regulations for leak detection, prevention, closure, financial responsibility, and corrective action at all underground tank sites.

Medical Waste. Subtitle J addresses the problem of medical waste mismanagement. Included are requirements pertaining to medical waste generation, treatment, destruction, and disposal.

Hazardous Waste. Subtitle C establishes a program to manage hazardous wastes from "cradle to grave." The objective of the program is to ensure that hazardous waste is handled in a manner that protects human health and the environment. These regulations cover the generation, transportation, and treatment, storage, or disposal of hazardous wastes. Any facility generating more than a minimum amount of hazardous waste must follow the RCRA requirements for storage, transportation, and disposal.

Regulations of both the DOT and the EPA govern the transportation of hazardous wastes. A hazardous waste manifest system, among other purposes, ensures that the material is properly identified; states the place of origin and destination for treatment, storage, or disposal; classifies the waste; provides the quantity and flashpoint of the substance; and gives special

handling instructions. Each shipper handling a hazardous waste cargo must sign the manifest certifying acceptance.

Comprehensive guidelines have been established by the EPA for tracking the movement, treatment, storage, and disposal of these waste products. Among the provisions of the guidelines are the following:

1. Identification and listing of materials classified as hazardous waste
2. A system of record keeping and labeling
3. Procedures for providing correct information regarding hazardous waste contents to and by persons transporting, storing, or disposing of this waste
4. A manifest and permit system regulating the transport of wastes to authorized sites
5. Requirements that transporters of hazardous wastes properly label hazardous waste shipments and carry them only to treatment, storage, or disposal sites licensed under RCRA
6. Requirements that operators of toxic storage disposal (TSD) facilities maintain records and comply with the manifest system. Only EPA-approved methods of treatment, storage, and disposal can be used as indicated in the permit issued by the EPA.
7. A mandate for producers and site operators to develop contingency plans in the event of a hazardous waste emergency. The plans must be the result of consultations with local fire, police, and hospital officials. These organizations must be included as part of the local response team. Contingency plans provide detailed information, such as the industrial site plan, the on-scene coordinator's phone number, and types of hazards present.
8. Encouragement for states to develop and manage their own hazardous waste programs consistent with RCRA guidelines. In the absence of a state plan, RCRA authorizes EPA to impose a federal plan for the state.

RCRA also requires hazardous waste generators to do the following:

1. Consult the list of hazardous and toxic organic and inorganic compounds published by the EPA to determine if a chemical waste is hazardous.
2. Subject all unlisted wastes to chemical analysis to determine if they possess any of the hazardous waste characteristics established in the regulations.
3. Declare a waste hazardous (based on knowledge of the material or processes used in its production).
4. Obtain an EPA identification number by filing with the EPA's regional administrator. Fire officials and local emergency-planning committees can obtain a list of hazardous waste generators in their area by contacting their EPA regional office. This list is updated on a regular basis and will provide the name and address of the facility, its EPA identification number, and its hazardous waste generator classification. Hazardous waste generators are classified in one of three categories, as follows:
   a. *Large-quantity generator (LQG).* Generates more than 2200 lb (1000 kg) of hazardous waste or more than 2.2 lb (1 kg) of acutely hazardous waste in a month. Once the first 2200 lb (1000 kg) has been accumulated, the waste must be shipped within 90 days. There is no limit to the amount that can be accumulated.
   b. *Small-quantity generator (SQG).* Generates less than 2200 lb (1000 kg) of hazardous waste in a month and/or less than 2.2 lb (1 kg) of acutely hazardous waste as listed by the EPA.
   c. *Conditionally exempt small-quantity generator (CESQG).* Generates less than 220 lb (100 kg) of hazardous waste or less than 2.2 lb (1 kg) of acutely hazardous waste in a month.
5. Apply for a facility permit if waste is accumulated on the generator's site for more than 90 days. The waste is considered to be stored at the site when it remains on the generator's property for more than 90 days. If this condition continues, the generator must secure a facility permit for storage of hazardous wastes, under RCRA Section 3005.
6. Treat, store, or dispose of hazardous wastes on site subject to requirements under RCRA Sections 3004 and 3005.
7. Transport hazardous wastes to other locations for use, storage, treatment, or disposal in properly labeled and approved containers, and prepare a hazardous waste manifest.

On November 8, 1984, Congress passed the Hazardous and Solid Waste Amendments Act of 1984, which modified waste-management practices and strengthened RCRA by:

1. Establishing tighter requirements for hazardous waste land disposal
2. Regulating underground storage tanks for new or waste products under RCRA
3. Bringing small-quantity generators (i.e., those generating between 220 and 2200 lb [100 and 1000 kg] of hazardous waste per month) under RCRA's authority
4. Giving the authority to order corrective action at RCRA-regulated facilities to the EPA
5. Setting forth "minimum technological standards," such as double liners, two-leachate collection systems, and groundwater monitoring, for new land-disposal facilities, as well as requiring interim-status facilities to either be retrofitted or stop receiving, storing, or treating hazardous waste
6. Establishing new requirements for delisting hazardous wastes

Clean Air Act (CAA)

This act establishes requirements for airborne emissions and the protection of the environment. The Clean Air Act Amendments of 1990 addressed emergency response and planning issues at certain facilities with processes using highly hazardous chemicals. This included the establishment of a national Chemical Safety and Hazard Investigation Board; EPA's promulgation of 40 CFR, Part 68, "Risk Management Programs for Chemical Accidental Release Prevention"; and OSHA's promulgation of 29 CFR 1910.119, "Process Safety Management of Highly Hazardous Chemicals, Explosives, and Blasting Agents." In addition, certain facilities are required to make information available to the general public regarding the manner in which chemical risks are handled within a facility.

Superfund Amendments and Reauthorization Act of 1986 (SARA)

SARA has had the greatest impact on hazardous materials emergency planning and response operations. As the name implies, SARA amended and reauthorized the Comprehensive Environmental Response, Compensation, and Liability Act of 1980 (CERCLA or Superfund). Although many of the amendments pertained to hazardous waste site cleanup, SARA's requirements also established a national baseline with regard to hazardous materials planning, preparedness, training, and response.

Title I of this act required OSHA to develop health and safety standards covering numerous worker groups who handle or respond to chemical emergencies and led to the development of OSHA 1910.120, "Hazardous Waste Operations and Emergency Response (HAZWOPER)."

Most familiar to the emergency response community is SARA, Title III. Also known as the Emergency Planning and Community Right-to-Know Act (EPCRA), SARA, Title III, led to the establishment of the State Emergency Response Commissions (SERC) and the Local Emergency Planning Committees (LEPC).

The Right-to-Know Act of 1986 includes four major sections affecting public safety. These include (1) Sections 301 through 303: emergency planning; (2) Section 304: emergency release notification; (3) Sections 311 and 312: community right-to-know reporting requirements; and (4) Section 313: toxic chemical release inventory.

Emergency Planning (Sections 301 through 303). Sections 301 through 303 of the act required the governor of each state to appoint a state emergency response commission (SERC) that, in turn, was required to designate local emergency planning districts and appoint a local emergency planning committee (LEPC) for each district. Membership in the LEPC is required to include elected state and local officials; members of fire, police, civil defense, and public health organizations; environmental, hospital, and transportation officials; and representatives of industry, business, the community, and the media.

The primary responsibility of the LEPC is to develop a comprehensive emergency response plan and submit it to the SERC. After being reviewed by the SERC, the plan is returned to the LEPC with approval or recommendations for revision. This emergency response plan is required to be revised and updated annually. The plan must include the following:

1. The identification of specific sites and transportation corridors in which extremely hazardous materials are stored, used, or transported
2. Emergency response procedures
3. Designation of a community coordinator and facility coordinator to implement the emergency plan
4. Emergency notification procedures
5. Procedures for determining the occurrence of a chemical release and the probable area and population that will be affected
6. Description of community and industrial emergency response equipment and resources and the identity of personnel responsible for them
7. Evacuation plans
8. Description and schedule of a chemical emergency response training program
9. Method and schedule for conducting emergency response plan exercises

Emergency Release Notification (Section 304). Section 304 requires facility owners or operators to give immediate notification to the community emergency coordinator of the LEPC, and to the SERC, of any release of a listed hazardous substance or its vapor that will extend beyond the facility's property and possibly endanger the general public. In most communities, the initial notification point will be to the emergency 9-1-1 telephone number or the local equivalent.

Under Section 304, the term "facility" means any building, structure, installation, equipment, pipe or pipeline (including any pipe into a sewer or publicly owned treatment works), well, pit, pond, lagoon, impoundment, ditch, storage container, motor vehicle, rolling stock, or aircraft, or any site or area where a hazardous substance has been deposited, stored, disposed of, or placed, or otherwise come to be located; this, however, does not include any consumer product use or any waterborne vessel.

Releases that result only in exposure to persons solely within the site on which the facility is located are not required to be reported to the LEPC or SERC but may require the owner or operator to notify the National Response Center, under Section 103(a) of CERCLA. Hazardous substances that are subjected to these reporting requirements can be found on a list of approximately 360 extremely hazardous substances that was published by the EPA in the Federal Register (40 CFR 355) or on a list of approximately 725 substances subject to emergency notification requirements, under CERCLA, Section 103(a), 40 CFR 302.4. There are additions and deletions to these lists on a periodic basis, and some of the substances can be found on both lists.

Initial emergency notification of a release by the owner or operator can be made by telephone, radio, or in person. To the extent it is known at the time of the notice, and as long as it does not result in a delay in responding to the emergency, the notification must include the following information:

1. The name or identity of the involved substance or substances
2. An indication of whether the substance or substances are on the extremely hazardous list
3. An estimate of the quantity of the substance or substances released into the environment
4. The time and duration of the release
5. The medium or media (air, land, water) into which the release occurred
6. Any known or anticipated acute or chronic health risks associated with the emergency, and, if necessary, advice regarding medical attention for exposed individuals
7. Proper precautions to take as a result of the release, such as evacuation
8. The name and telephone numbers of the person or persons to be contacted for further information

As soon as possible after a release that requires notice, the owner or operator must provide a written follow-up emergency

notice. As more information becomes available, the owner or operator must update the information originally required and include additional information with respect to the following:

1. Actions taken in responding to and containing the release
2. Any known or anticipated acute or chronic health risks associated with the release
3. When appropriate, advice regarding medical attention necessary for exposed individuals

Notification of releases of hazardous substances during transportation or during storage relating to the transportation of such substances must be reported by dialing emergency 9-1-1 or, in the absence of a 9-1-1 emergency telephone number, by calling the operator.

Community Right-to-Know Reporting Requirements (Sections 311 and 312). Section 311 requires that the owner or operator of a facility prepare or have available a material safety data sheet (MSDS) for each hazardous chemical covered under the Occupational Safety and Health Act of 1970 (and any regulations promulgated under that act) and submit an MSDS to each of the following:

1. The local emergency planning committee
2. The state emergency-response commission
3. The fire department with jurisdiction over the facility

If the hazardous chemical is a mixture, the owner or operator of the facility can fulfill the requirements of Section 311 by submitting an MSDS for, or identifying on a list, each element or compound in the mixture that is a hazardous chemical. The owner or operator may also submit an MSDS for, or identify on a list, the mixture itself.

In lieu of an MSDS, the owner or operator may submit a list of the hazardous chemicals grouped in categories of health and physical hazards according to OSHA or in terms of groups of hazardous chemicals that present similar hazards in an emergency, as designated by the EPA administrator. The list of hazardous chemicals must include (1) the chemical name or common name of each substance, as provided on the MSDS and (2) any hazardous component of each substance, as provided on the MSDS.

An MSDS or revised list must be provided when new hazardous chemicals become present at a facility in quantities at or above established threshold levels. Upon request by the local emergency planning committee, an owner or operator who submits a list of chemicals must provide the appropriate MSDS for any chemical on that list. If requested by any member of the general public, the LEPC must make available to that person an MSDS for any hazardous chemicals required to be submitted to them. This information may be given at a location designated by the LEPC during normal working hours.

Within three months following the discovery by an owner or operator of significant new information concerning an aspect of a hazardous chemical for which an MSDS was previously submitted to the LEPC, a revised MSDS must be provided to the LEPC.

Section 312 stipulates that owners or operators of a facility who are required to prepare or have available an MSDS for each hazardous chemical covered under the Occupational Safety and Health Act of 1970 (and any regulations promulgated under that act) prepare and submit an emergency and hazardous chemical inventory form to the local emergency planning committee, the state emergency response commission, and the fire department with jurisdiction over the facility.

The inventory form must include all hazardous chemicals above specified thresholds that were present at the facility at any time during the previous calendar year. The EPA has established threshold quantities for hazardous chemicals covered by Section 312. If the quantities of hazardous chemicals are below that set forth by EPA, a report is not required. Current threshold quantities are as follows:

1. For extremely hazardous substances: 500 lb (227 kg) or the threshold planning quantity, whichever is lower
2. For all other hazardous chemicals that meet or exceed 10,000 lb (4450 kg) for which OSHA requires an MSDS; it should be noted that there are over 500,000 chemicals and mixtures for which OSHA requires an MSDS be maintained

Facilities may file either a Tier I or Tier II inventory form. Tier I reporting requires owners or operators to submit the following information for each of the hazard categories set forth under OSHA regulations:

1. Fire, sudden release of pressure, reactivity, acute health hazard, chronic health hazard
2. An estimate (in ranges) of the maximum amount of hazardous chemicals in each category present at the facility at any time during the preceding calendar year
3. An estimate (in ranges) of the average daily amount of hazardous chemicals in each category present at the facility at any time during the preceding calendar year
4. The general location of hazardous chemicals in each category

The EPA administrator may modify the OSHA categories of health and physical hazards by requiring information to be reported in terms of groups of hazardous chemicals that present similar hazards in an emergency or require reporting on individual hazardous chemicals of special concern to emergency response personnel. Tier I inventory forms are required to be submitted on or before March 1 of each year and contain data with respect to the preceding calendar year.

Tier II inventory reporting forms are required if requested by a state emergency response commission, an LEPC, or a fire department with jurisdiction over the facility. If an owner or operator of a facility files a Tier II inventory form, a Tier I form is not required, as long as the same deadlines are followed. The public may also request Tier II information from the LEPC or SERC. Tier II information must include the following:

1. The chemical name or common name of each chemical, as provided on the MSDS
2. An estimate (in ranges) of the maximum amount of hazardous chemicals present at the facility at any time during the preceding calendar year
3. An estimate (in ranges) of the average daily amount of hazardous chemicals present at the facility at any time during the preceding calendar year

4. A brief description of the manner of storage of the hazardous chemical
5. The location at the facility of the hazardous chemical
6. An indication of whether the owner elects to withhold location information of a specific hazardous chemical from disclosure to the public

Upon request by a fire department with jurisdiction over any facility that files an inventory form under Section 312, the owner or operator must allow the fire department to conduct an on-site inspection of the facility and must provide to the fire department specific location information on hazardous chemicals at the facility.

Toxic Chemical Release Inventory (Section 313). Section 313 requires owners or operators of certain facilities to file an annual Toxic Chemical Release Inventory Form (Form R) with the EPA and to those officials designated by the governor of the state on or before July 1 of each year. A release is defined as any spilling, leaking, pumping, pouring, emitting, emptying, discharging, injecting, escaping, leaching, dumping, or disposing into the environment (including the abandonment or discarding of barrels, containers, and other closed receptacles) of any toxic chemical. Section 313 applies to facilities that have 10 or more full-time employees, fall under the Standard Industrial Classification (SIC) Codes 20 through 39, and that manufactured, processed, or otherwise used a listed toxic chemical in excess of specified threshold quantities during the previous calendar year. The threshold quantity is 25,000 lb (11,350 kg) per year for toxic chemical manufacturing or processing. The threshold quantity with respect to use at a facility is 10,000 lb (4450 kg) of toxic chemical per year. The initial List of Toxic Chemicals subject to the provisions of Section 313 was published in August 1986 for the Senate Committee on Environment and Public Works. Through rule making, the EPA has modified this list to date by adding nine chemicals and delisting six. Chemicals may be added to the list if there is sufficient evidence to establish any one of the following:

1. The chemical is known to cause, or can reasonably be anticipated to cause, significant adverse acute human health effects at concentration levels that are reasonably likely to exist beyond facility site boundaries as a result of continuous, or frequently recurring, releases.
2. The chemical is known to cause, or can reasonably be anticipated to cause, cancer or teratogenic effects, or serious or irreversible reproductive dysfunction, neurological disorders, heritable genetic mutations, or other chronic health effects in humans.
3. The chemical is known to cause, or can reasonably be anticipated to cause, because of its toxicity, its toxicity and persistence in the environment, or its toxicity to bioaccumulate in the environment, a significant adverse effect on the environment of sufficient seriousness, in the opinion of the EPA, to warrant reporting under Section 313.

The EPA has established and maintains a national toxic-chemical inventory database (TRI database) on the information submitted. The computer database is accessible by the public and government officials via computer telecommunications and is intended to help answer questions about toxic chemical releases in a community. The EPA is using the data to target problem pollution areas and as a screening tool for the development of regulations, guidelines, and standards. Researchers from the government or universities conducting environmental analysis can also access the data.

Toxic Substances Control Act (TSCA)

The Toxic Substances Control Act (TSCA—pronounced Tosca), passed by Congress in 1976, establishes regulations with respect to the inventory and testing of all chemical substances manufactured or processed in the United States. This act makes the EPA the central implementation arm of the federal government. TSCA authorizes the EPA to do the following:

1. Develop a uniform listing of all chemical substances.
2. Establish a testing procedure for chemicals already in use and any one of approximately 1000 new chemicals developed each year.
3. Determine if these chemicals present an unreasonable risk to the public's health or the environment.
4. Prohibit or limit the manufacture, processing, use, application, and concentration of such chemicals.
5. Recall or seize by civil action hazardous substances that are determined to be imminently harmful to the public's health or the environment.

Federal Water Pollution Control Act (FWPCA)

In 1970, the Federal Water Pollution Control Act (PL 92-500) was amended in Section 311 to include oil and hazardous spills. Through this legislation, both the EPA and the U.S. Coast Guard are mandated to regulate spills of oil and/or other hazardous substances that threaten coastal waters and inland waterways.

Spill Prevention, Control, and Countermeasure Plan (SPCC)

This regulation was issued by the EPA in 40 CFR 112 and applies to facilities engaged in drilling, producing, gathering, storing, processing, refining, transferring, distributing, or consuming oil and oil products, which due to location could reasonably be expected to discharge oil in quantities that may be harmful into or upon navigable waterways or adjoining shorelines, or upon the waters on the contiguous zone.

Owners or operators of these facilities must prepare a Spill Prevention, Control, and Countermeasure (SPCC) plan that includes appropriate containment and/or drainage control structures or equipment to prevent discharged oil from reaching navigable water before cleanup occurs.

Facilities that are excluded from being required to have a SPCC plan are facilities that do not have an aboveground storage capacity of at least 1320 gal (4996 L) of oil. No single container at these facilities can hold more than 660 gal (2498 L) of oil.

Oil Pollution Act of 1990 (OPA)

Commonly referred to as OPA, this act amended the Federal Water Pollution Control Act. Its scope covers both facilities and

carriers of oil and related liquid products, including deepwater marine terminals, marine vessels, pipelines, and railcars. Requirements include the development of emergency response plans, regular training and exercise sessions, and verification of spill resources and contractor capabilities. The act also requires the establishment of Area Committees (AC) and the development of Area Contingency Plans (ACP) to address oil and hazardous substance spill response in coastal zone areas.

HAZARDOUS MATERIALS REGULATIONS

Regulations, sometimes called "rules," are created by federal or state agencies as a method of providing guidelines for complying with a law that was enacted through legislation. A regulation permits individual governmental agencies to enforce the law through inspections, which may be conducted by federal and state officials.

Laws delegate certain details of implementation and enforcement to federal or state agencies that are then responsible for writing the actual regulations that enforce the legislative intent of the law. Regulations will either (1) define the broad performance required to meet the letter of the law (i.e., performance-oriented standards) or (2) provide very specific and detailed guidance on satisfying the regulation (i.e., specification standards).

Federal Regulations

The following summary includes several of the more significant federal regulations that affect hazardous materials emergency planning and response.

Hazardous Waste Operations and Emergency Response (29 CFR 1910.120). Also known as HAZWOPER, this federal regulation was issued under the authority of SARA, Title I. The regulation was written and is enforced by OSHA in those 23 states and two territories with their own OSHA-approved occupational safety and health plans. In the remaining 27 "non-OSHA" states, public sector personnel will be covered by a similar regulation enacted by the EPA (40 CFR Part 311).

The regulation establishes important requirements for both industry and public safety organizations that respond to hazardous materials or hazardous waste emergencies. This includes fire fighters, law enforcement, emergency medical personnel (EMS), hazardous materials responders, and industrial emergency response team (ERT) members. Requirements cover the following areas:

1. Hazardous materials emergency response plan
2. Emergency response procedures, including the establishment of an incident management system, the use of a buddy system with backup personnel, and the establishment of a safety officer
3. Specific training requirements covering instructors and both initial and refresher training
4. Medical surveillance programs
5. Postemergency termination procedures

Of particular interest to hazardous materials managers and responders are the specific levels of competency and associated training requirements identified within OSHA 1910.120(q)(6).

First Responder at the Awareness Level. These are individuals who are likely to witness or discover a hazardous substance release and who have been trained to initiate an emergency response notification process. The primary focus of their hazardous materials responsibilities is to secure the incident site, recognize and identify the materials involved, and make the appropriate notifications. These individuals would take no further action to control or mitigate the release. First responder–awareness personnel must have sufficient training or experience to objectively demonstrate the following competencies:

1. An understanding of what hazardous materials are and the risks associated with them in an incident
2. An understanding of the potential outcomes associated with a hazardous materials emergency
3. The ability to recognize the presence of hazardous materials in an emergency and, if possible, identify the materials involved
4. An understanding of the role of the first responder–awareness individual within the local emergency operations plan; this would include site safety, security and control, and the use of the *Emergency Response Guidebook* (ERG)
5. The ability to realize the need for additional resources and to make the appropriate notifications to the communications center

The most common examples of first responder–awareness personnel include law enforcement and plant security personnel, as well as some public works employees. There is no minimum hourly training requirement for this level; the employee would have to have sufficient training to objectively demonstrate the required competencies.

First Responder at the Operations Level. Most fire department suppression personnel fall into this category. These are individuals who respond to releases or potential releases of hazardous substances as part of the initial response for the purpose of protecting nearby persons, property, or the environment from the effects of the release. They are trained to respond in a defensive fashion without actually trying to stop the release. Their primary function is to contain the release from a safe distance, keep it from spreading, and protect exposures.

First responder–operations personnel must have sufficient training or experience to objectively demonstrate the following competencies:

1. Knowledge of basic hazard and risk assessment techniques
2. Knowledge of how to select and use proper personal protective clothing and equipment available to the operations-level responder
3. An understanding of basic hazardous materials terms
4. Knowledge of how to perform basic control, containment, and/or confinement operations within the capabilities of the resources and personal protective equipment available

5. Knowledge of how to implement basic decontamination measures
6. An understanding of the relevant standard operating procedures and termination procedures

First responders at the operations level must have received at least 8 hours of training or have had sufficient experience to objectively demonstrate competency in the previously mentioned areas, as well as the established skill and knowledge levels for the first responder–awareness level.

Hazardous Materials Technicians. These are individuals who respond to releases or potential releases for the purposes of stopping the release (Figure 13.6.1). Unlike the operations level, they generally assume a more aggressive role, in that they are often able to approach the point of a release in order to plug, patch, or otherwise stop the release of a hazardous substance.

Hazardous materials technicians are required to have received at least 24 hours of training equal to the first responder–operations level and have competency in the following established skill and knowledge levels:

1. Capable of implementing the local employers' emergency operations plan
2. Able to classify, identify, and verify known and unknown materials by using field survey instruments and equipment (direct reading instruments)
3. Able to function within an assigned role in the incident management system
4. Able to select and use the proper specialized chemical personal protective clothing and equipment provided to the hazardous materials technician
5. Understand hazard and risk assessment techniques
6. Able to perform advanced control, containment, and/or confinement operations within the capabilities of the resources and equipment available to the hazardous materials technician
7. Understand and implement decontamination procedures
8. Understand basic chemical and toxicological terminology and behavior
9. Understand termination procedures
10. Understand basic chemical and toxicological terminology and behavior

Many communities and facilities have personnel trained as emergency medical technicians (EMT) who nevertheless do not have the primary responsibility for providing basic or advanced life support medical care. Similarly, hazardous materials technicians may not necessarily be part of a hazardous materials response team. However, if they are part of a designated team as defined by OSHA, they must also meet the medical surveillance requirements within OSHA 29 CFR 1910.120.

Hazardous Materials Specialists. These are individuals who respond with, and provide support to, hazardous materials technicians. Their duties parallel those of the technician, but they require a more detailed or specific knowledge of the various substances they may be called on to contain. This individual

FIGURE 13.6.1 Hazardous Materials Technicians Donning EPA Level A Personal Protection Clothing

would also act as the site liaison with federal, state, local, and other governmental authorities, with regard to site activities.

Similar to the technician level, hazardous materials specialists must have received at least 24 hours of training equal to the technician level and have competency in the following established skill and knowledge levels:

1. Capable of implementing the local emergency operations plan
2. Able to classify, identify, and verify known and unknown materials by using advanced field survey instruments and equipment (direct reading instruments)
3. Have knowledge of the state emergency response plan
4. Able to select and use the proper specialized chemical personal protective clothing and equipment provided to the hazardous materials specialist
5. Understand in-depth hazard and risk assessment techniques
6. Able to perform specialized control, containment, and/or confinement operations within the capabilities of the resources and equipment available to the hazardous materials specialist
7. Able to determine and implement decontamination procedures
8. Able to develop a site safety and control plan
9. Understand basic chemical, radiological, and toxicological terminology and behavior

Whereas the hazardous materials technician possesses an intermediate level of expertise and is often viewed as a "utility person" within the hazardous materials response community, the hazardous materials specialist possesses an advanced level of expertise. Within the fire service, the specialist will often assume the role of the safety officer or hazardous materials branch. Furthermore, the specialist must meet the medical surveillance requirements outlined within OSHA 129 CFR 1910.120. The reader should note that a hazardous materials specialist, as defined by OSHA, is different from "specialist employee," as defined by NFPA 472, *Standard for Professional Competence of Responders to Hazardous Materials Incidents.* The differences in these terms is often a source of confusion among industrial emergency responders. They are two different titles and have different levels of competency.

On-Scene Incident Commander. Incident commanders, who will assume control of the incident scene, must receive at least 24 hours of training equal to the first responder operations level. In addition, the employer must certify that the incident commander has competency in the following areas:

1. Know and be able to implement the employer's incident management system
2. Know how to implement the employer's emergency operations plan
3. Understand the hazards and risks associated with working in chemical protective clothing
4. Know of the state emergency response plan and of the federal regional response team
5. Know and understand the importance of decontamination procedures

Skilled Support Personnel. These are personnel who are skilled in the operation of certain equipment, such as cranes and hoisting equipment, and who are needed temporarily to perform immediate emergency support work that cannot reasonably be performed in a timely fashion by emergency response personnel. It is assumed that these individuals will be exposed to the hazards of the emergency response scene.

Although these individuals are not subject to the HAZWOPER training requirements, they must be given an initial briefing at the site prior to their participation in any emergency response effort. This briefing must include elements such as instructions in using personal protective clothing and equipment, the chemical hazards involved, and the tasks to be performed. All other health and safety precautions provided to emergency responders and on-scene workers must be used to ensure the health and safety of these support personnel.

Specialist Employees. These are employees who, in the course of their regular job duties, work with and are trained in the hazards of specific hazardous substances and who will be called on to provide technical advice or assistance to the incident commander at a hazardous materials incident (Figure 13.6.2). This would include industry responders, chemists, and related professional or operations employees. These individuals must receive training or demonstrate competency in the area of their specialization annually. Appendix E in 29 CFR 1910.120, *Hazardous Waste Operations and Emergency Response,* provides nonmandatory guidelines for an effective training curriculum.

Hazard Communication Standard (29 CFR 1910.1200). The Hazard Communication Standard (HCS) was originally issued by OSHA in November 1983. OSHA's most recent revision of the HCS was issued on March 11, 1994, and covers manufacturers, importers, distributors, and users of hazardous chemicals. The Hazard Communication Standard is commonly called the right-to-know law or HAZCOM.

HAZCOM is a federal regulation that requires hazardous materials manufacturers and handlers to develop written material safety data sheets (MSDSs) on specific types of hazardous chemicals. These MSDSs must be made available to employees who request information about a chemical in the workplace. Examples of information on an MSDS include known health hazards, the physical and chemical properties of the material, first aid, fire-fighting and spill control recommendations, protective clothing and equipment requirements, and emergency telephone contact numbers. Under HAZCOM, hazmat health exposure information should be provided to emergency responders during the termination phase of an emergency, and all exposures should be documented. The basic responsibilities are outlined in Table 13.6.1.

Hazard Determination. Chemical manufacturers and importers are required to review the scientific information on the chemicals they produce or import and to report the information they find to their employees and to employers who distribute or use their products. Downstream employers can rely on the evaluations performed by the chemical manufacturers or importers to establish the hazards of the chemicals they use.

FIGURE 13.6.2 Specialist Employees Working with Specific Hazardous Substances

TABLE 13.6.1 Responsibilities Outlined by Hazardous Communications Standard

Chemical Manufacturers/ Importers	*Determine the Hazards of Each Product*
Chemical manufacturers/ importers/ distributors	Communicate the hazard information and associated protective measures downstream to customers through labels and MSDSs
Employers	Identify and list all hazardous chemicals in their workplace Obtain MSDSs and labels for each hazardous chemical Develop and implement a written hazard communication program, including labels, MSDSs, and employee training Communicate hazard information to employees through labels, MSDSs, and formal training programs

The chemical manufacturers, importers, and any employers that choose to evaluate hazards are responsible for the quality of the hazard determinations they perform. Each chemical must be evaluated for its potential to cause adverse health effects and its potential to pose physical hazards, such as flammability. In addition, chemicals that have been evaluated and found to be suspected or confirmed carcinogens must be reported as such.

Written Hazard Communication Program. Employers that fall under the requirements of HAZCOM must develop, implement, and maintain a written hazard communication program that includes provisions for container labeling, collection, and availability of MSDSs and employee training. It also must contain a list of the hazardous chemicals in the workplace, the means the employer will use to inform employees of the hazards of nonroutine tasks, and the hazards associated with chemicals in unlabeled pipes. If the workplace has multiple employers on-site (e.g., a construction site), HAZCOM requires these employers to ensure that information regarding hazards and protective measures be made available to the other employers on-site, where appropriate.

Labels and Other Forms of Warning. Chemical manufacturers, importers, and distributors must be sure that containers of hazardous chemicals leaving their facilities are labeled, tagged, or marked with the identity, appropriate hazard warning, and the name and address of the manufacturer or other responsible party.

In the workplace, each container must be labeled, tagged, or marked with the identity of the hazardous chemicals contained within and must show hazard warnings appropriate for employee protection. The hazard warning can be any type of message, words, pictures, or symbols that convey the hazards of the chemical(s) in the container. Labels must be legible, in English (plus other languages, if desired), and prominently displayed.

Material Safety Data Sheets. Chemical manufacturers and importers must develop a material safety data sheet (MSDS) for each hazardous chemical they produce or import and must provide the MSDS automatically at the time of the initial shipment of a hazardous chemical to a downstream distributor or user. Distributors must also ensure that downstream employers are similarly provided an MSDS.

Each MSDS must be in English and include information regarding the specific identity of the hazardous chemical(s) involved and the common names. In addition, information must be provided on the physical and chemical characteristics of the hazardous chemical, known acute and chronic health effects and related health information, exposure limits, whether the chemical is considered to be a carcinogen, precautionary measures, emergency and first-aid procedures, and the identification of the organization responsible for preparing the MSDS.

Copies of the MSDS for hazardous chemicals in a given work site are to be readily accessible to employees in that area. Although OSHA has developed a model MSDS format (OSHA form 174), there is currently no specific MSDS form required by the regulation. OSHA's model MSDS is divided into nine separate sections: (1) chemical identity, (2) hazardous ingredients, (3) physical and chemical characteristics, (4) fire and explosion hazard data, (5) reactivity details, (6) health-hazard information, (7) precautions for safe handling, (8) use of the material, and (9) any control measures to be taken.

The American National Standards Institute (ANSI) has developed a standard on the preparation of MSDSs. ANSI Z400.1, *Hazardous Industrial Chemicals, Material Safety Data Sheet—Preparation,* is used by many chemical manufacturers as a standardized format for MSDS preparation.

Employee MSDS training must include methods and observations that may be used to detect the presence or release of a hazardous chemical in the work area (e.g., monitoring conducted by the employer, continuous monitoring devices, visual appearance, or odor of hazardous chemicals when released). Physical and health hazards of the chemicals used and measures that the employees can take to protect themselves from these hazards must be covered, as well as specific procedures the employer has implemented to protect employees from exposure to hazard.

Trade Secrets. A "trade secret" is something that gives an employer an opportunity to obtain an advantage over competitors who do not know about the trade secret or who do not use it. For example, a trade secret may be a confidential device, pattern, information, or chemical makeup. Chemical industry trade secrets are generally formulas, process data, or a "specific chemical identity." The last is the type of trade secret information referred to in the Hazard Communication Standard. The term includes the chemical name, the chemical abstract services (CAS) registry number, or any other specific information that reveals the precise designation. It does not include common names.

The HCS standard strikes a balance between the need to protect exposed employees and the employer's need to maintain confidentially of a bona fide trade secret. This is achieved by providing limited disclosure to health professionals who are furnishing medical or other occupational services to exposed employees, or employees and their designated representatives, under specified conditions of need and confidentiality.

Medical Emergency. The chemical manufacturer, importer, or employer must immediately disclose the specific chemical identity of a hazardous chemical to a treating physician or nurse when the information is needed for proper emergency or first-aid treatment. As soon as circumstances permit, the chemical manufacturer, importer, or employer may obtain a written statement of need and a confidentiality agreement.

Hazardous Materials Transportation Regulations (49 CFR 100 through 199). This series of regulations is issued and enforced by DOT. The regulations govern container design, chemical compatibility, packaging and labeling requirements, shipping papers, transportation routes and restrictions, and so on. The regulations are comprehensive and strictly govern how all hazardous materials are transported by highway, railroad, pipeline, aircraft, and water. There are some local fire departments that routinely perform inspections of hazardous materials cargo tank trucks using DOT regulations.

Retention of DOT Markings, Placards, and Labels (29 CFR 1910.1201). In 1994, OSHA issued requirements that those facilities that receive containers of hazardous materials, which are required to be marked, labeled, or placarded in accordance with DOT regulations, retain those markings, labels, or placards on the container until the container is sufficiently cleaned of residue and purged of vapors to remove any potential hazards.

National Contingency Plan (NCP) (40 CFR 300, Subchapters A through J). The National Contingency Plan (NCP) outlines the policies and procedures of the federal agency members of the National Oil and Hazardous Materials Response Team, also known as the National Response Team (NRT). The regulation provides guidance for emergency responses, remedial actions, enforcement, and funding mechanisms for federal government response to hazardous materials incidents. The NRT is chaired by the EPA, whereas the vice-chairperson represents the U.S. Coast Guard (USCG).

Each of the 10 federal regions also has a Regional Response Team (RRT) that mirrors the makeup of the NRT. RRTs may also include representatives from state and local government and Indian tribal governments.

When the NRT or RRT is activated for a federal response to an oil spill or hazardous materials incident, a federal on-scene coordinator (OSC) will be designated to coordinate the overall response. The OSC will represent either the EPA or the USCG, based on the location of the incident. If the release or threatened release occurs in coastal areas or near major navigable waterways, the USCG will usually assume primary OSC responsibility. If the situation occurs inland and away from navigable or major waterways, the EPA will serve as the OSC. Local emergency responders should contact EPA and USCG personnel within their region to determine which agency has primary responsibility and will act as the federal OSC for their respective area.

If the incident is a terrorism-related event, the Federal Bureau of Investigation (FBI) will assume the role as Federal On Scene Coordinator during the emergency response phase; the Department of Homeland Security/Federal Emergency Management Agency (FEMA) would assume the role for the postemergency response.

Process Safety Management of Highly Hazardous Chemicals (29 CFR 1910.119). Issued by OSHA in 1992, this regulation

applies mainly to hazardous materials manufacturing facilities, such as refineries and chemical plants. Other affected sectors include natural gas liquids, farm product warehousing, electric, gas, and sanitary services.

The requirements apply to companies that deal with any of more than 130 specific toxic and reactive chemicals in EPA-listed quantities. It also applies to flammable liquids and gases in quantities greater than 10,000 lb (4540 kg).

The regulation includes the following major requirements:

1. *Process safety information* must include information on the hazards of the highly hazardous chemicals used or produced by the process, information on the technology of the process, and information on the equipment in the process.
2. *Process hazards analysis* must include an initial process analysis (hazard evaluation) appropriate for the complexity of the process and must identify, evaluate, and control the hazards involved.
3. *Written operating procedures* must be developed and implemented that provide clear instructions for safely conducting activities involved in each process. Procedures must address initial startup and shutdown, operating limits, and safety and health considerations.
4. *Employee participation* must be solicited on the conduct and development of process management.
5. *Training programs* must include initial employee training on health and safety hazards, refresher training provided at least every three years on current operating procedures, and a training documentation program. The regulation also applies to contractors performing maintenance, repair, renovation, or specialty work on a process.
6. *Prestartup safety review* must be provided for new facilities and for modified facilities when the modification is significant enough to require a change in process safety.
7. *Mechanical integrity* must be provided for pressure vessels and storage tanks, piping systems, relief and vent systems and devices, emergency shutdown systems, controls and alarms, and pumps.
8. *Management of change* must be provided for written procedures to manage changes to process chemicals, technology, equipment, and so on.
9. *Incident investigation* must include a thorough investigation of incidents to identify the chain of events and causes, so that corrective measures can be developed and implemented.
10. *Emergency planning and response procedures* must be provided for handling spills and releases at the facility.
11. *Compliance audit* must be provided that includes mandatory process safety management reviews every three years to verify that procedures are adequate and being followed.

Risk Management Programs for Chemical Accidental Release Prevention (40 CFR Part 68). Promulgated under amendments to the Clean Air Act, this regulation requires that facilities that manufacture, process, use, store, or otherwise handle certain regulated substances above established threshold values develop and implement Risk Management Programs (RMPs). The regulation is similar in scope to the OSHA Process Safety Management (PSM) standard, with the primary focus being community safety as opposed to employee safety.

Risk Management Programs consists of the following three elements:

1. *Hazard assessment* of the facility, including the worst-case accidental release and an analysis of potential off-site consequences
2. *Prevention program,* which addresses safety precautions, maintenance, monitoring, and employee training; EPA believes that the prevention program should adopt and build upon the OSHA Process Safety Management standard
3. *Emergency response considerations,* including facility emergency response plans, informing public and local agencies, emergency medical care, and employee training

State Regulations

Each of the 50 states and the two U.S. territories maintain an enforcement agency that has responsibility for hazardous materials. The three key players in each state usually consist of the (1) state fire marshal, (2) state Occupational Safety and Health Administration, and (3) State Department of the Environment (sometimes known as Natural Resources or Environmental Quality). Although there are many variations, the state fire marshal is typically responsible for the regulation of flammable liquids and gases, due to the close relationship between the flammability hazard and the fire prevention code; the state environmental agency would be responsible for the development and enforcement of environmental safety regulations.

Most states have the equivalent of the federal OSHA. Approximately 23 states and two U.S. territories have adopted the federal OSHA regulations as state law. State governments also maintain an environmental enforcement agency that usually enforces the federal RCRA, CERCLA, and CAA laws at the local level. Increased state involvement in hazardous materials waste regulatory enforcement has significantly increased the number of hazardous materials incidents reported. This increase is expected to continue in the future and will generate more fire service activity at the local level in both enforcement and response.

VOLUNTARY CONSENSUS STANDARDS

Voluntary consensus standards are normally developed through professional organizations or trade associations as a method of improving the individual quality of a product or system. Within the emergency response community, NFPA is recognized for its role in developing consensus standards and recommended practices that impact fire safety and hazardous materials operations. In the United States, standards are developed primarily through a democratic process, whereby a committee of subject specialists representing varied interests writes the first draft of the standard. The document is then submitted to either a larger body of specialists or the general public, who then may amend, vote on, and approve the standard for publication. This procedure is known as the consensus standards process.

When a consensus standard is completed, it may be voluntarily adopted by government agencies, individual corporations, or organizations. Many hazardous materials consensus standards are also adopted as a reference in a regulation. In effect, when a federal, state, or municipal government adopts a consensus standard by reference, the document becomes a regulation.

Standards developed through the voluntary consensus process play an important role in increasing both workplace and public safety. Historically, a voluntary standard improves over time, as each revision reflects recent field experience and adds more detailed requirements. As users of the standard adopt it as a way of doing business, the level of safety gradually improves over time.

Voluntary consensus standards provide a way for individual organizations and corporations to self-regulate their business or profession. All of the national fire codes in the United States are developed through the voluntary consensus standards process; the two most active associations are (1) NFPA and (2) Western Fire Chiefs Association. Standards developed by these two associations address many hazardous materials issues, including hazardous materials storage and handling, personal protective clothing and equipment, and hazardous materials professional competencies.

NFPA Standards

NFPA has over 60 individual hazardous materials–related voluntary consensus standards. These standards are developed through the committee process, according to NFPA rules and procedures.

NFPA's hazardous materials standards are widely used by both industry and public safety organizations as recommended practices for inspection, safe handling, and installation, and so on. They do not have the force of law unless they are adopted by a government agency. For example, state governments that have approved state OSHA plans under Section 18b of the Occupational Safety and Health Act of 1970 must adopt standards to enforce requirements that are at least as effective as federal requirements.

The current OSHA regulations on flammable and combustible liquids adopt NFPA 30, *Flammable and Combustible Liquids Code,* by reference. Consequently, although NFPA does not specifically write regulations, NFPA standards often result as law through a similar adoption process.

Unfortunately, the pace of revising and updating federal and state regulations lags behind the development and approval of revised NFPA standards. Many state regulations that have adopted NFPA standards, such as NFPA 30 and NFPA 58, *Liquefied Petroleum Gas Code,* have adopted editions that are 5 to 10 years behind current editions. Most consensus standards reflect current and accepted practices, as opposed to "cutting-edge" technology, practices, and procedures. This means that an organization that adopts a 2003 edition of a standard, as a local or state regulation, is actually adopting a standard that may not be based on the most recent technology.

The following list summarizes current NFPA hazardous materials–related standards. They have been categorized by the authors for easier reference by the standards users and are not necessarily grouped by committee responsibility.

Flammable Liquids Related Standards

NFPA 30, *Flammable and Combustible Liquids Code*
NFPA 33, *Standard for Spray Application Using Flammable or Combustible Materials*
NFPA 34, *Standard for Dipping and Coating Processes Using Flammable or Combustible Liquids*
NFPA 326, *Standard for the Safeguarding of Tanks and Containers for Entry, Cleaning, or Repair*
NFPA 329, *Recommended Practice for Handling Releases of Flammable and Combustible Liquids and Gases*
NFPA 385, *Standard for Tank Vehicles for Flammable and Combustible Liquids*

Flammable Gases Related Standards

NFPA 51A, *Standard for Acetylene Cylinder Charging Plants*
NFPA 54, *National Fuel Gas Code*
NFPA 58, *Liquefied Petroleum Gas Code*
NFPA 59, *Utility LP-Gas Plant Code*
NFPA 59A, *Standard for the Production, Storage, and Handling of Liquefied Natural Gas (LNG)*
NFPA 306, *Standard for the Control of Gas Hazards on Vessels*

Dusts and Powders Related Standards

NFPA 91, *Standard for Exhaust Systems for Air Conveying of Vapors, Gases, Mists, and Noncombustible Particulate Solids*
NFPA 654, *Standard for the Prevention of Fire and Dust Explosions from the Manufacturing, Processing, and Handling of Combustible Particulate Solids*

Explosives and Reactive Chemicals Standards

NFPA 35, *Standard for the Manufacture of Organic Coatings*
NFPA 51, *Standard for the Design and Installation of Oxygen–Fuel Gas Systems for Welding, Cutting, and Allied Processes*
NFPA 53, *Recommended Practice on Materials, Equipment, and Systems Used in Oxygen-Enriched Atmospheres*
NFPA 55, *Standard for the Storage, Use, and Handling of Compressed Gases and Cryogenic Fluids in Portable and Stationary Containers, Cylinders, and Tanks*
NFPA 68, *Standard on Explosion Protection by Deflagration Venting*
NFPA 69, *Standard on Explosion Prevention Systems*
NFPA 430, *Code for the Storage of Liquid and Solid Oxidizers*
NFPA 432, *Code for the Storage of Organic Peroxide Formulations*
NFPA 490, *Code for the Storage of Ammonium Nitrate*
NFPA 495, *Explosive Materials Code*
NFPA 498, *Standard for Safe Havens and Interchange Lots for Vehicles Transporting Explosives*
NFPA 655, *Standard for Prevention of Sulfur Fires and Explosions*
NFPA 1124, *Code for the Manufacture, Transportation, Storage, and Retail Sales of Fireworks and Pyrotechnic Articles*

Nuclear Standards

NFPA 801, *Standard for Fire Protection for Facilities Handling Radioactive Materials*

NFPA 805, *Performance-Based Standard for Fire Protection for Light Water Reactor Electric Generating Plants*

Facilities and Related Manufacturing Standards

NFPA 30B, *Code for the Manufacture and Storage of Aerosol Products*
NFPA 32, *Standard for Drycleaning Plants*
NFPA 36, *Standard for Solvent Extraction Plants*
NFPA 45, *Standard on Fire Protection for Laboratories Using Chemicals*
NFPA 86, *Standard for Ovens and Furnaces*
NFPA 820, *Standard for Fire Protection in Wastewater Treatment and Collection Facilities*

Electrical Standards

NFPA 70, *National Electrical Code®*
NFPA 77, *Recommended Practice on Static Electricity*
NFPA 79, *Electrical Standard for Industrial Machinery*
NFPA 110, *Standard for Emergency and Standby Power Systems*
NFPA 496, *Standard for Purged and Pressurized Enclosures for Electrical Equipment*
NFPA 497, *Recommended Practice for the Classification of Flammable Liquids, Gases, or Vapors and of Hazardous (Classified) Locations for Electrical Installations in Chemical Process Areas*
NFPA 499, *Recommended Practice for the Classification of Combustible Dusts and of Hazardous (Classified) Locations for Electrical Installations in Chemical Process Areas*
NFPA 780, *Standard for the Installation of Lightning Protection Systems*

Emergency Response Standards

NFPA 471, *Recommended Practice for Responding to Hazardous Materials Incidents*
NFPA 472, *Standard for Professional Competence of Responders to Hazardous Materials Incidents*
NFPA 473, *Standard for Competencies for EMS Personnel Responding to Hazardous Materials Incidents*
NFPA 704, *Standard System for the Identification of the Hazards of Materials for Emergency Response*
NFPA 1991, *Standard on Vapor-Protective Ensembles for Hazardous Materials Emergencies*
NFPA 1992, *Standard on Liquid Splash-Protective Ensembles and Clothing for Hazardous Materials Emergencies*

Relevant Standards

NFPA 72®, National Fire Alarm Code®
NFPA *101®*, *Life Safety Code®*
NFPA 434, *Code for the Storage of Pesticides*

Hazardous Materials Emergency Response Standards. Within the hazardous materials community there are three major consensus standards that have been widely accepted as the baseline standard for hazardous materials response teams, as follows:

1. NFPA 471, *Recommended Practice for Responding to Hazardous Materials Incidents*
2. NFPA 472, *Standard for Professional Competence of Responders to Hazardous Materials Incidents*
3. NFPA 473, *Standard for Competencies for EMS Personnel Responding to Hazardous Materials Incidents*

As the titles imply, these standards primarily address the emergency response and field operational aspects of hazardous materials. Nevertheless, they provide an excellent basis for developing hazardous materials inspection and enforcement personnel.

NFPA 471, Recommended Practice for Responding to Hazardous Materials Incidents. The document covers planning procedures, policies, and application of procedures for incident levels, personal protective clothing and equipment, decontamination, safety, and communications. The purpose of NFPA 471 is to outline the minimum requirements that should be considered when dealing with responses to hazardous materials incidents and to specify operating guidelines.

NFPA 472, Standard for Professional Competence of Responders to Hazardous Materials Incidents. The purpose of NFPA 472 is to specify minimum competencies for those who will respond to hazardous materials incidents. The overall objective is to reduce the number of accidents, injuries, and illnesses during response to hazardous materials incidents and to prevent exposure to hazardous materials to reduce the possibility of fatalities, illnesses, and disabilities affecting emergency responders.

It is important to recognize that NFPA 472 covers all hazardous materials emergency responders from both the public and private sector.

NFPA 472 provides competencies for the following levels of hazardous materials responders. These levels parallel those listed within OSHA 1910.120, with the exception that the hazardous materials specialist has been deleted and the specialist employee has been expanded on and clarified, as follows:

1. *First responders at the awareness level.* These are individuals who, in the course of their normal duties, may be the first on scene of an emergency involving hazardous materials. They are expected to recognize the presence of hazardous materials, protect themselves, call for trained personnel, and secure the area.

2. *First responders at the operations level.* These are individuals who respond to releases or potential releases of hazardous materials as part of the initial response to the incident for the purpose of protecting nearby persons, the environment, or property from the effects of the release. They must be trained to respond in a defensive fashion to control the release from a safe distance and keep it from spreading.

3. *Hazardous materials technicians.* These are individuals who respond to releases or potential releases of hazardous materials for the purpose of controlling the release. Hazardous materials technicians are expected to use specialized chemical protective clothing and specialized control equipment (Figure 13.6.3).

4. *Incident commander.* This is the person who is responsible for directing and coordinating all aspects of a hazardous materials incident.

FIGURE 13.6.3 Hazardous Materials Technicians Cleaning Up a Spill in EPA Personal Protective Clothing

5. *Private sector specialist employee.* These are individuals who, in the course of their regular job duties, work with or are trained in the hazards of specific materials and/or containers. In response to incidents involving chemicals, they may be called on to provide technical advice or assistance to the incident commander relative to their area of specialization. The following are three levels of private sector specialist employees:

a. Level C are those persons who may respond to incidents involving chemicals and/or containers within their organization's area of specialization. They may be called on to gather and record information, provide technical advice, and/or arrange for technical assistance consistent with the organization's emergency response plan and standard operating procedures. The individual is not expected to enter the hot/warm zone at an incident.
b. Level B are those persons who, in the course of their regular job duties, work with or are trained in the hazards of specific chemicals or containers within their organization's area of specialization. Because of their education, training, or work experience, they may be called on to respond to incidents involving chemicals. The Level B employee may be used to gather and record information, provide technical advice, and provide technical assistance (including working within the hot/warm zone) at the incident consistent with the organization's emergency response plan and standard operating procedures and the local emergency operations plan.
c. Level A are those persons who are specifically trained to handle incidents involving chemicals and/or containers for chemicals used in their organization's area of specialization. Consistent with the organization's emergency response plan and standard operating procedures, the Level A employee must be able to analyze an incident involving chemicals within the organization's area of specialization, plan a response to that incident, implement the planned response within the capabilities of the resources available, and evaluate the progress of the planned response (Figure 13.6.4).

NFPA 473, Standard for Competencies for EMS Personnel Responding to Hazardous Materials Incidents. The purpose of NFPA 473 is to specify minimum requirements of competence and to enhance the safety and protection of response personnel and all components of the emergency medical services system. The overall objective is to reduce the number of EMS personnel accidents, exposures, injuries, and illnesses resulting from hazardous materials (HM) incidents. The following are the two levels of EMS/HM responders:

1. *EMS/HM Level I.* Persons who, in the course of their normal duties, may be called on to perform patient care activities in the cold zone at a hazardous materials incident. EMS/HM Level I responders provide care to only those individuals who no longer pose a significant risk of secondary contamination. Level I includes different competency requirements for basic (BLS) and advanced life support (ALS) personnel.

2. *EMS/HM Level II.* Persons who, in the course of their normal duties, may be called on to perform patient care activities in the warm zone at a hazardous materials incident. EMS/HM Level II responders may provide care to those individuals who still pose a significant risk of secondary contamination. In addition, personnel at this level must be able to coordinate EMS activities at a hazardous materials incident and provide medical support for hazardous materials response personnel. Level II includes different competency requirements for basic (BLS) and advanced life support (ALS) personnel.

NFPA Technical Committee on Hazardous Materials Protective Clothing and Equipment (NFPA 1991, NFPA 1992, NFPA 1994). This technical committee is responsible for the development of standards and documents pertaining to the use of personal protective clothing and equipment (excluding respiratory protection) by emergency responders at hazardous materials incidents. The committee scope includes personal protective equipment (PPE) selection, care, and maintenance.

The following three hazmat protective clothing standards have been developed:

FIGURE 13.6.4 NFPA 472 Level A Private Sector Specialist Employees Handling a Hazardous Materials Incident

1. NFPA 1991, *Standard on Vapor-Protective Ensembles for Hazardous Materials Emergencies*
2. NFPA 1992, *Standard on Liquid Splash-Protective Ensembles and Clothing for Hazardous Materials Emergencies*
3. NFPA 1994, *Standard on Protective Ensembles for First Responders to CBRN Terrorism Incidents*

Other Standards Organizations

There are many other important standards-writing bodies that develop hazardous materials safety and emergency response–related standards. The more significant organizations include the American Society of Mechanical Engineers (ASME), the American Society for Testing and Materials (ASTM), the American Petroleum Institute (API), the Compressed Gas Association (CGA), and the Safety Equipment Institute (SEI). Each of these organizations approves or creates standards, ranging from hazardous materials container design to personal protective clothing and equipment. Standards produced by these groups usually follow the standards development guidelines of the American National Standards Institute (ANSI). ANSI is an approval body and is recognized by the International Organization for Standardization (ISO).

SUMMARY

This chapter is aimed at the fire department prevention and enforcement specialist who needs to understand the fundamentals of hazardous materials laws, regulations, and standards. The chapter began by defining the term *hazardous materials* and continued with a discussion of the key elements of a hazardous materials prevention and enforcement program. The rest of the chapter was devoted to an overview of the major federal laws and regulations governing hazardous materials and the main hazardous materials codes and standards

Chapter 7

Aircraft Rescue and Fire Fighting (ARFF)

Jack Kreckie

Modern aircraft have evolved from the early days when gliders were crafted of wood and stretched fabric. This evolution has occurred rather swiftly since the Wright Brothers' first successful flight from Kitty Hawk in 1903. In a century, aviation has evolved from wind-powered aircraft (gliders), to man-powered aircraft (using pedals or cranks), to piston engine-driven propellers, to turbo props and jets. The days of supersonic transport (SST) have given way to the era of new large aircraft (NLA). These mammoth aircraft can be configured to carry over 800 passengers in double-deck cabins. Statistically, aviation is very safe. There are, however, certain risks associated with air travel. Mechanical failure, human error, and weather add an undeniable risk that a small percentage of commercial aircraft will be involved in aircraft incidents and accidents. The primary responsibility of aircraft rescue and fire-fighting (ARFF) personnel is to provide for the safety of all aircraft passengers at aircraft incidents that occur at an airport. This specialized career continues to become increasingly more complex.

This chapter discusses the mission of aircraft rescue fire fighters and provides an explanation of the tools, techniques, agents, and objectives that are used to satisfy that mission. Also provided is a review of the regulations and industry standards that influence the levels of training, staffing, and equipment at airports as well as information to help the reader gain an understanding of typical aircraft emergencies and ARFF response procedures.

See also Section 6, Chapter 2, "Combustion Products and Their Effects on Life Safety"; and Section 13, Chapter 2, "Organizing Rescue Operations."

OVERVIEW

Aircraft Rescue and Fire-Fighting (ARFF) Mission

Federal regulations and industry standards determine the minimum requirements for aircraft rescue and fire fighting (ARFF) at airports. ARFF fire fighters put these regulations and standards to practical use. The primary ARFF mission is to protect the lives of the flying public. However, airport fire fighters work under a variety of structures. Some are members of municipal or state-run fire departments that serve the community in which the airport is located. The airport assignment might be a bid position or one attained through seniority. Other airport fire departments are staffed by employees of the Airport Authority or Port Authority that holds the operating certificate for the airport. Private-contract fire departments are also used by a small number of airports, whereas military or federal fire fighters staff bases and mixed military-civil airfields.

In terms of total mission, there are several variables as well. Small airports might support the ARFF requirements using employees who serve dual roles. Maintenance, security, or airport operations personnel are often cross-trained to satisfy the requirements of the regulations governing

Jack Kreckie, a 31 year veteran of the fire service, served the last 28 years with Massport Fire Rescue at Boston Logan International Airport. He retired in 2007 at the rank of Deputy Fire Chief/Chief of Operations at Boston Logan International Airport and L.G. Hanscom Field in Bedford, Massachusetts. Deputy Chief Kreckie has served over 10 years on the management team of the ARFF Working Group, is a member of the FAA-Aviation Rulemaking Advisory Committee (ARAC), and co-chaired the ARAC ARFF Requirements Working Group tasked with developing recommendations for revisions to 14 CFR Part 139. He has served on a number of committees for the FAA and NTSB.

Key Terms

aircraft accident, aircraft fire fighting, aircraft rescue, aircraft rescue and fire-fighting (ARFF), aircraft rescue and fire-fighting vehicle, airport fire fighter, Federal Aviation Administration (FAA), International Civil Aviation Organization (ICAO), National Transportation Safety Board (NTSB), personal protective equipment (PPE), practical critical fire area (PCA), rapid response area, response time, theoretical critical fire area (TCA)

ARFF. Some airport departments are responsible for "all hazards," including structural, EMS, hazmat, confined space, technical rescue, and water rescue. Other departments handle only the ARFF response and depend on off-airport response for other types of emergencies. Dual-role departments, typically called public safety officers, provide both law enforcement and fire department functions. The argument as to which approach is better will never be satisfied. Regardless of how the service is provided, all ARFF fire fighters and the apparatus they depend on must meet the qualifications and requirements of the regulatory authority having jurisdiction.

The underlying mission of aircraft rescue fire fighters has not changed. Fire fighters, by their very nature, will exhaust every resource and their last ounce of energy to rescue the people they are sworn to protect. What has evolved over time, however, are the methods, agents, expertise, and equipment they use to satisfy that mission.

Aircraft Construction Design and Materials

The "jet age" arrived in 1958. Pan American Airways led the way with the introduction of the Boeing 707 as the first U.S. passenger jet. The B-707 burned kerosene fuel, which was half the cost of the high-octane gasoline used in more traditional planes of the era. The jet engines proved more reliable than the piston-driven engines and could carry up to 180 passengers traveling at speeds of up to 550 miles per hour.

The evolution of this new era continued with the introduction of wide-body (two aisles) jets. The Boeing 747 arrived in 1969, followed by the MacDonnell Douglas DC-10 and the Lockheed L-1011 in 1970. With the introduction of jet aircraft, injury and fatality rates relative to survivable accidents have increased. This increase was found to be largely attributable to seats, overhead bins, cabin partitions, and other cabin interior furnishings breaking loose at relatively low-impact loads. An example of a low-impact load incident could be a controlled descent terminating in a landing without landing gear deployed or a landing in a field or on other nonpaved irregular terrain. The resulting conditions injured or trapped occupants, thereby impeding or preventing their escape.

Since the arrival of the jet age, a great deal of attention has been paid to increasing survivability through aircraft construction design and materials. Composite materials have been developed that provide increased strength at lower weight; interior fabrics and finishes must meet more stringent flammability testing; and a layer of fire-resistive fabric has been added in seat construction to further reduce the risk to passengers in the event of a cabin fire.

Modern aircraft are now built with a number of redundant systems. Designs that incorporate redundant systems provide a margin of safety for incidents or accidents caused by mechanical failure. In such cases when a mechanical failure occurs, a backup system takes over, and the flight terminates safely.

Hazards and Risk

The hazards associated with aircraft vary with the size and type of loading of the particular flight. As is the case in structures, the risk is increased or decreased depending on the aircraft's contents and occupancy. Each offers its own set of unique challenges and risks for its occupants and for ARFF responders. Large aircraft carrying hundreds of passengers, small military aircraft carrying ordinance, cargo aircraft loaded with freight that may include manifested or unmanifested hazardous materials, general aviation, helicopters, and ultralights are all in the air, and all experience in-flight emergencies on a regular basis (Figure 13.7.1).

The one element that exists in every powered aircraft is fuel. The fire service prepares for the worst-case scenario based on greatest risk. This risk for occupants of a survivable crash is exposure to fire and the products of combustion from a fuel fire.

Escape Time and Survival Time

For passengers on board an aircraft involved in fire, time is the enemy. From the time of the crash or the outbreak of fire, the survival clock begins ticking. Human tolerance is a measurable effect. In 1965, Don W. Conley prepared a report for the Federal Aviation Administration (FAA) titled, " Post Crash Fire Fighting

(a)

(b)

FIGURE 13.7.1 (a) American Airlines, Boeing 757 Beginning Its Takeoff Roll at Boston Logan International Airport; (b) Aircraft Lining Up on Taxiway Awaiting Their Turn for the Departure Runway (Source: Courtesy of Rudy Chiarello)

Studies on Transport Category Aircraft."[1] Among the research items presented is a study on the parameters of human tolerance. ARFF fire fighters know it is crucial to remove victims from a toxic or dangerous environment or to remove the dangers and toxins from the victim's environment before the limits of human tolerance are reached. Understanding what those limits are is helpful for a better understanding of the urgency and complexity of the ARFF mission.

Escape Time. In a number of documented survivable crashes involving fire, occupants have escaped the hostile environment by their own means. Those surviving the impact have a certain period of time during which they can escape before being overcome by one of the life-threatening hazards of a postcrash fire. The amount of time available, which has been termed *escape time*, varies depending on the type of aircraft, the crash severity, and a variety of other conditions. Escape time is defined in the Conley study as "the elapsed time from the instant fire began to the instant when a human tolerance limit (based on heat or carbon monoxide) was reached that could cause an inability to escape on the part of the would-be occupant." The study calculates escape time and survival time in a number of categories. Each illustrates how little time an ARFF fire fighter has to effectively rescue an occupant who was unable to escape on his or her own.

Survival Time. The most dramatic of the findings relative to human tolerance levels or unbearable pain were data taken from a crash test program conducted by the National Advisory Committee on Aeronautics (NACA) in the early 1950s and referenced in the Conley study. During a fire test on a C-97, the temperature inside the aircraft cabin remained at 70°F (21.1°C) while the spill fire burned for 2 minutes. This occurred as a result of cabin insulation and closed major hatches. At 130 seconds, burn-through occurred and the temperatures soared. At 138 seconds, the temperature reached unsurvivable temperatures.

Many efforts have been made since the days of the Conley study to improve aircraft construction, insulation, and fire block material. In modern transport aircraft, the sidewall panels, partitions, overhead bins, and ceiling panels are typically composite assemblies with a Nomex core, phenolic-impregnated fabric facesheets, and colored thermoplastics. Seat fire-blocking is often polybenzimiazole or a blend of Nomex and Kevlar. All of these efforts are dedicated to improving cabin safety and increasing survival time. Ultimately, once the fire enters the cabin as a result of impingement and burn-through, an open door, or a hull fracture from the impact, the survival clock ticks faster than one can act.

With this in mind, it is understandable why the mission of an ARFF fire fighter is so critical and why lifesaving actions are measured in seconds. Seconds saved through training, technology, methods, and skills translate into lives saved at an aircraft accident.

ARFF REGULATORY AND STANDARD-DEVELOPING ORGANIZATIONS

As aircraft evolve, obviously so must the regulations that identify the minimum standard for ARFF equipment, personnel, and fire-fighting agents at airports around the world.

Federal Aviation Administration (FAA)

In 1970, the FAA administrator was given the statutory authority to issue airport operating certificates. This authority, found in Title 49, United States Code (U.S.C.) Section 44706, Airport Operating Certificates, was used to establish minimum safety standard requirements for the operation and certification of certain U.S. airports. Title 14, Code of Federal Regulation (CFR) Part 139 (14 CFR 139), *Certification and Operations: Land Airports Serving Certain Air Carriers*, spells out these requirements.

This statutory authority, which was limited to land airports serving passenger operations of an air carrier conducted with aircraft having a seating capacity of more than 30 passengers, was broadened by the FAA Reauthorization Act of 1996. The act allowed the FAA to certificate airports that serve any scheduled passenger air carrier operations operating aircraft designed for more than nine passenger seats. Alaska, however, is exempt from this authority.

International Civil Aviation Organization (ICAO)

In addition to the FAA for U.S-certificated airports, the International Civil Aviation Organization (ICAO), a specialized agency of the United Nations, was created on December 7, 1944, at the convention on International Civil Aviation in Chicago, to set international aviation standards. One of ICAO's principal goals is the establishment of international standards, recommended practices, and procedures covering the technical fields of aviation including aircraft rescue and fire fighting (ARFF), search and rescue, and aircraft accident investigation. These standards (related to ARFF) are under constant review and amended, as necessary, by the ICAO Rescue and Fire Fighting Study Group (RFFSG).

National Fire Protection Association (NFPA)

The NFPA develops standards relative to ARFF but the NFPA standards are not always in total agreement with the minimum standards set forth by the FAA. At every meeting of the groups that review federal aviation regulations, NFPA standards, and ICAO standards, there is a desire to harmonize the documents. Given the differences in the documents, it is difficult to have standardized equipment or training for all airports. Manufacturers of ARFF equipment struggle with different requirements for FAA-funded equipment and international customers.

REGULATORY REQUIREMENTS AND STANDARDS

Title 14 Code of Federal Regulations Part 139[2] lists the current U.S. requirements for ARFF personnel, agent quantities, response times, and related topics. "The Rule" is issued by the FAA and compliance is measured by the FAA's regional office, which dispatches a certification inspector to evaluate ARFF equipment, personnel, and training records. Failure to meet the minimum standards of 14 CFR Part 139 could threaten an airport's operating certificate.

Some of the key sections of Part 139 that are specifically related to ARFF are the airport certification manual, personnel requirements, and airport index determination. Comparisons of key differences between FAA, ICAO, and NFPA requirements and guidance are shown in Table 13.7.1.

Airport Certification Manual (ACM)

As set forth in Section 139.205, maintaining an ACM is one of the requirements for an airport certificate holder. The ACM must contain a description of how each requirement of Part 139 is satisfied. Included in that list of requirements are:

- A grid map or other means for identifying airport locations and terrain features that are significant for emergency operations
- A description of facilities, equipment, personnel, and procedures for meeting the rescue and fire-fighting requirements in Sections 139.317 and 139.319
- Procedures for complying with the requirements of Part 139.321, relating to hazardous materials and substances
- An emergency plan, as required by Section 139.325

Personnel

"The Rule" does not prescribe specific minimum staffing numbers. Section 139.303 does, however, require

That sufficient rescue and fire fighting personnel be available during all air carrier operations to operate the vehicles, meet the response times, and meet the minimum fire fighting agent discharge rates specified within the regulation.

Airport Index

As set forth in Section 139.315, an airport index is currently determined with a formula based on the overall length of the aircraft servicing the airport and the number of daily departures of that aircraft. If there are five or more average daily departures of air carrier aircraft in a single group serving that airport, the longest index group with an average of five or more daily departures is the index required for the airport.

If there are less than five average daily departures of air carrier aircraft in a single index group serving that airport, the next lower index from the longest index group with air carrier aircraft in it is the index required for the airport. The minimum designated index is Index A. The airport index (A through E) is determined through this formula; the minimum number of ARFF vehicles and quantities of agent carried are based on the index. A provision in 14 CFR Part 139.319 (ARFF Operational Requirements) allows for a reduction in rescue and fire-fighting capabilities.

TABLE 13.7.1 Comparison of ARFF Index Requirements of FAA, ICAO, and NFPA

FAA Index	*Aircraft Length*	*ICAO Cat.*	*Aircraft Length up to But Not Including*	*Aircraft Width up to But Not Including*	*NFPA Cat.*	*Aircraft Length up to But Not Including*	*Aircraft Width up to But Not Including*	*Sample Aircraft*
GA-1	NA	1	29 ft (9 m)	6.6 ft (2.00 m)	1	30 ft (9.0 m)	6.6 ft (2.00 m)	Cessna 182

		10	295 ft (90 m)	26.2 ft (8.00 m)	10	295 ft (90.0 m)	25.0 ft (8.00 m)	AN-225, A380

Source: *Final Recommendation to ARAC, Airport Certification Issues Group Relative to 14 CFR Part 139, Subpart D, March 2004 (6),* Table 2; Paper produced for the U.S. Department of Transportation, Federal Aviation Administration, by the Aviation Rulemaking Advisory Committee, Airport Certification Issues Group, ARFF Requirements Working Group.

> (c) During air-carrier operations with only aircraft shorter than the Index aircraft group required by paragraph (a) of this section, the certificate holder may reduce the rescue and fire fighting to a lower level corresponding to the Index group of the longest air carrier aircraft being operated.

This reduction in requirements is known as the remission factor. The remission factor was incorporated into regulatory language to reduce the financial burden for airports that have a low frequency of flight operations for the longest aircraft conducting scheduled operations at that airport. In January 2005, ICAO eliminated the remission factor from its standard. NFPA 403, *Standard for Aircraft Rescue and Fire-Fighting Services at Airports,* has no provision for remission. Table 13.7.1 provides comparisons among the requirements of the FAA, ICAO, and NFPA.

ARFF AGENTS

Original Quantity-Determining Formula

Determining the quantities of agent required to control or extinguish an aircraft fire must be approached using science, logic, historical data, and repeatable tests. Formulas derived from this process must be adaptable to different-sized aircraft. The theoretical critical area (TCA)/practical critical area (PCA) methodology has survived the test of time and remains the standard over three decades after its introduction. This is not to say that these formulas are adopted by every regulation or standard.

Current debate may require some expansion or modifications to these formulas. Some form of change needs to be brought about to sufficiently provide agent quantities for new large aircraft (NLA). Full-length, double-deck aircraft, like the Airbus Industries A-380, have drawn attention to the fact that the formula assumes a standard height when the number of gallons required for ARFF is determined. This assumption is not reasonable.

The Boeing 747 was the first aircraft with a double deck cabin. However, the original double deck was seen as a "bump" on the front of the fuselage, with a spiral staircase leading to a lounge or small seating area. It was seen as a novelty and never raised a flag as to whether tactical ARFF challenges or minimum agent requirements needed to be reconsidered. Typically, these aircraft flew into only larger airports, which usually maintain more than the minimum required quantities of agent.

Over the years, Boeing introduced new models of the 747, and the second deck grew to greater lengths. Finally, with the introduction of the A-380, the ARFF industry realized it could no longer treat variations in height as rare exceptions of no practical significance.

The number of ARFF vehicles and the minimum quantities of agent required at each index or category of airports are directly related to the ARFF departments' ability to control and/or extinguish an aircraft fire. FAA requirements and requirements mandated in standards established by the NFPA and ICAO differ significantly. To understand the rationale used to determine the actual quantities needed, a review of the historical and technical basis of TCA/PCA methodology employed by the NFPA since the early 1970s is helpful.

Theoretical Critical Area/Practical Critical Area (TCA/PCA) Methodology

Critical Fire Area. The critical area concept was used as a method for determining a level of protection for aircraft of every size. This was the minimum area that was to be protected post-crash to permit safe evacuation of the occupants of an aircraft. The critical fire area is a rectangle with its size determined by using a formula based on the length and width of the aircraft. This method of determining minimum agent quantities does not consider tactical fire attack challenges or conditions. It is simply a repeatable formula that could be applied to any category of aircraft. It is not intended to represent the minimum, average, or maximum fire area based on spill size. NFPA 403 defines *theoretical critical area (TCA)* as

> The fire area adjacent to the aircraft that must be controlled to ensure temporary fuselage integrity and to provide an occupant escape area.

The theoretical critical area served only to categorize aircraft by size and the area of the potential fire hazard that could become involved.

The data on hand indicated that the practical critical area (PCA) was approximately two-thirds of the TCA. NFPA 403 defines *practical critical area (PCA)* as

> The area used to calculate minimum agent quantities and flow rates. The PCA is defined as 2/3 of the size of the TCA, as determined by the ICAO RFFP-II committee.

Discharge and Application Rates. Once the area to be protected was determined, the ICAO RFFP-1 (Rescue and Fire Fighting Panel) began to focus on discharge rates and extinguishing agents during its first meeting in March 1970.[3] In order to determine quantities of agent needed, it was necessary to calculate the rate of discharge and the time required to control and/or extinguish the fire. The RFFP-1 determined that control and extinguishment needed to be considered separately. *Control time* is defined as the time required from the arrival of the first fire-fighting vehicle to the time the intensity of the fire is reduced by 90 percent. *Extinguishment time* is the time required from the arrival of the first fire-fighting vehicle to the time the fire is completely extinguished.

At the time of these studies, protein fire-fighting foam was typically carried. The committee based its recommendations on protein foam but acknowledged that when dual-agent attacks were utilized (foam and dry chemical, CO_2, or a halocarbon), a reduced application rate could be used.

In June 1972, the ICAO Rescue and Fire Fighting Panel met for a second time (RFFP-2). During these deliberations, an application rate of 0.13 U.S. gpm/ft^2 for aqueous film-forming foam (AFFF) was found to be suitable.[4] This application rate is still used for AFFF. The RFFP-2 also confirmed the application rate of 0.15 U.S. gpm/ft^2 for protein foam that was recommended by RFFP-1.

Additional Quantity-Determining Formulas

In determining the quantities of agent(s) required, additional formulas were agreed upon. The quantities required for each milestone in a tactical event are identified and calculated separately. These quantities are expressed as *Q1* and *Q2*.

Quantity *Q1*. Quantity *Q1* is the quantity required to obtain a 1-minute control time in the PCA. The formula for the water required for control (*Q1*) in the PCA is expressed as

$$Q1 = PCA \times R \times T$$

where

PCA = Practical critical area

R = Rate of application for specific foam

T = Time of application

Quantity *Q2*. Quantity *Q2* is the quantity required for maintaining control of the fire after the first minute, or as required for total extinguishment, or both. The RFFP-2 recognized that the exact quantity for *Q2* could not be accurately determined without considering a number of variables. These variables, expressed as *f* in calculating formulas, were assigned values for each category airport based on maximum gross weight, maximum passenger loads, maximum fuel loads, and analysis of previous aircraft rescue and fire-fighting operations.

$$Q2 = f \times Q1$$

The RFFP-2 used these factors (*f*) to determine *Q2* values for each airport category. The range of values for *f* ranged from 3 percent to 170 percent for Category 1 through Category 8 airports, respectively.

Quantity Q3. This general process is still in use today with revisions made over the years. The most significant revision was the introduction of Q3 quantities needed for interior fire-fighting operations.

The values of Q3 are based on accepted waterflow requirements for the type of fire-fighting operations to be experienced when combating an interior aircraft fire. They are determined as follows:

Airport Category	*Q3 Equals (U.S. gal)*
1	0
2	0
3	60 gpm 5 min = 300 gal
4	60 gpm 10 min = 600 gal
5	125 gpm 10 min = 1250 gal
6	125 gpm 10 min = 1250 gal
7	125 gpm 10 min = 1250 gal
8	250 gpm 10 min = 2500 gal
9	250 gpm 10 min = 2500 gal
10	500 gpm 10 min = 5000 gal

Agent Quantity Totals (*Q*). NFPA standards define the total quantity of water (*Q*) as

$$Q = Q1 + Q2 + \text{Q3}$$

Beyond this basic introduction of calculating agent quantities, additional factors are introduced to calculate area based on actual aircraft size and category. NFPA 403 provides a comprehensive description of the process. Table 13.7.2 compares the agent quantities as required (or recommended) by the FAA, ICAO, and NFPA. The quantities listed under NFPA are the only quantities that include gallons required for Q3. It should be noted that, although ICAO used the PCA/TCA formulas to calculate agent quantities required, it reduced its quantities in Category 5 through Category 10 by 1000 gallons. This reduction was made to lessen the financial impact on airports.

TABLE 13.7.2 Agent/Quantity Comparison

		Water (U.S. Gallons)

Complementary Agent Requirements

In addition to the requirements for water and foam, complementary agent must also be carried. Every index airport is required to carry a minimum of 500 lb of dry chemical powder or 500 lb of clean (halogenated) streaming agent, Halon 1211, or Halotron.

Dry Chemical Agents. Dry chemical fire-extinguishing agents are available in a variety of chemical compounds. Potassium bicarbonate and potassium bicarbomate–based powders have proven effective in quickly extinguishing flammable liquid fires when applied at the proper rate and with the proper technique.

Halogenated/Halon Alternative Agents. Halogenated agents are hydrocarbons that have had one or more hydrogen atoms replaced by atoms from the halogen series, usually fluorine (F), bromine (Br), or chlorine (Cl). The extinguishing mechanism of halogenated agents seems to interfere with the combustion process. Halogenated agents are discharged as a liquefied gas, which allows excellent penetration of difficult-to-access areas. Because it leaves no residue, it is an excellent choice for fighting fires in avionics compartments, electronic or electrical components, and engine fires.

ARFF VEHICLES AND EQUIPMENT

Apparatus Features

Fire apparatus is designed to satisfy the needs of the particular mission it primarily serves. Aircraft rescue and fire-fighting apparatus is specifically designed to satisfy its primary mission, namely, response to aircraft incidents and accidents. ARFF vehicles must be designed and built to be compliant with the standards required by the customer. If the apparatus is being funded by the FAA, it must be in compliance with the FAA Advisory Circular 150/5220-10D, "Guide Specification for Aircraft Rescue and Fire Fighting Vehicles." Most U.S. manufacturers will not build a truck that is not compliant with the relevant NFPA standard, in this case, NFPA 414. ARFF vehicles have a number of specialized features that are not typically on structural fire apparatus.

Large Water Tanks. Large water tanks are a functional requirement of the ARFF mission. Because of the critical relationship between time and survival factors, establishing water supply prior to initiating fire attack is not practical. Fire hydrants are not readily available on most runway systems. A hydrant is considered an obstruction near a runway and, for safety purposes, must be located a distance away from the runway. Underground hydrants are available on some airfields but are not practical during initial fire attack because of their inaccessibility and time delays in opening manholes, as well as groundwater and drainage issues. ARFF crews "bring their water with them"; apparatus manufactured today are available with tank sizes ranging from 1000 to 4500 gal. Each truck also has foam quantities commensurate with the water tank size. The standards call for a double shot of foam, so that ARFF vehicles can discharge two tanks of water without having to reservice the foam tanks (Figure 13.7.2).

Aqueous film-forming foam (AFFF) is the standard foam used at airports. The FAA now requires the foam used at certificated airports to meet mil specification MIL-F-24385. The primary reason for this is to guarantee compatibility of foam concentrates. Ensuring compatibility is important for both bulk foam storage tanks and apparatus-mounted foam tanks.

Many ARFF departments have bulk foam storage tanks tied into rapid reservice facilities. In order to maintain sufficient reserve quantities of foam concentrate, the tanks are never emptied. When the reorder level is reached, the tank is topped off. If the foam concentrates are not compatible, all the foam in the tank could become contaminated through a reaction of the two products.

This same logic is used in the refill of apparatus-mounted foam tanks. Many training, testing, or fire-fighting evolutions will consume foam concentrate but not empty the foam tank. As the vehicle is reserviced, the foam tank is topped off. If the foam being added is not guaranteed to be compatible (as mil spec foam is), it is possible to contaminate all of the foam in the tank.

AFFF foam is mixed with water, using foam-proportioning systems installed on the apparatus. These systems automatically proportion the foam to the selected percentage based on the discharge or discharges opened. Foam discharges on an ARFF vehicle can include primary turret (Figure 13.7.3), secondary turret, high-reach extendible turret (HRET), piercing nozzles, hand lines, hose reels, and undertruck nozzles. The nozzles used are both aerated and nonaerated, per airport choice.

With regard to the debate on the environmental concerns of the use of this foam, all AFFF on the market is currently in compliance with EPA requirements. However, the FAA is looking for a "greener" alternative to AFFF, but so far nothing else is as effective.

Source: *Final Recommendation to ARAC, Airport Certification Issues Group Relative to 14 CFR Part 139, Subpart D, March 2004 (6),* Table 7; Paper produced for the U.S. Department of Transportation, Federal Aviation Administration, by the Aviation Rulemaking Advisory Committee, Airport Certification Issues Group, ARFF Requirements Working Group.

"Pump and Roll" Capability. ARFF vehicles have "pump and roll" capability. This feature allows ARFF fire fighters to begin agent application prior to stopping the apparatus. The vehicle can be driven around the fire while agent is being discharged through turrets or undertruck nozzles. It also allows the truck to continue to pump for protection if a flowing fuel fire threatens the apparatus and its occupants and an escape becomes necessary.

Turrets. Traditionally, the primary turret on ARFF vehicles was located on the roof of the apparatus facing forward. Over the years, testing has been completed to evaluate the effectiveness of a low-attack, high-volume turret. These low-attack turrets, which are mounted below the windshield, have proven to be more effective than roof-mounted turrets. Fire fighters operating the newer turrets benefit by seeing the origin of their stream as well as the target. It also reduces the amount of agent falling on the windshield and obscuring the view.

Piercing Nozzles. Piercing nozzles are used to introduce agent into a fuselage without introducing oxygen to the fire through opening a door. Piercing nozzles are available as handheld tools attached to attack lines or mounted on high-reach extendible turrets (HRETs) operated by means of a joystick from the ARFF vehicle cab.

Vehicle Requirements

The number of vehicles required at an airport is driven by several factors. The minimum requirement of the regulatory authority provides a number based on the airport index or category, as illustrated in Table 13.7.3. If only the minimum number of vehicles is maintained at the airport, however, no provision exists for taking a piece of apparatus out of service for maintenance, repairs, or training. The size of the airport is a major factor. Some airports with large airfields maintain the minimum requirement of vehicles at each station in order to satisfy the timed response requirements for each runway.

RESPONSE TIME REQUIREMENTS

The successful mitigation of the effects of an aircraft accident depends on the successful completion of a number of actions. Swift notification with accurate location and conditions is critical. Time is the single most important factor to increase survivability of the occupants of an aircraft involved in a major accident. Requirements for response times to the scene of an accident are difficult to define or measure. Requirements for response are measured using known distances and conditions to demonstrate ability. The FAA, ICAO, and the NFPA all use different standards to establish response time requirements.

ICAO Standards and Recommendations

ICAO's International Standards and Recommended Practices (SARPs) for Annex 14 to the Convention on International Civil Aviation, Aerodromes[5] states:

> The operational objective of the rescue and fire fighting service *shall* be to achieve a response time not exceeding three minutes to any point of each operational runway, in optimum visibility and surface conditions.

In addition to these standards, ICAO also publishes recommendations. The following recommendation follows the preceding standards in the SARP.*

> The operational objective of the rescue and fire fighting service *should* be to achieve a response time not exceeding two minutes to any point of each operational

*The key words *shall* and *should* point out the difference between standards and recommendations.

> runway, in optimum visibility and surface conditions. The operational objective of the rescue and fire fighting service *should* be to achieve a response time not exceeding three minutes to any other part of the movement area in optimum visibility and surface conditions. . . . Any other vehicles required to deliver the amounts of extinguishing agents specified *should* arrive no more than one minute after the first responding vehicle(s) so as to provide continuous agent application.

NFPA 403, *Standard for Aircraft Rescue and Fire-Fighting Services at Airports*

Of the three sources, NFPA 403 is certainly the most stringent, as well as the clearest:*

> The demonstrated response time of the first responding vehicle to reach any point on the operational runway shall be 2 minutes or less and to any point remaining within the on-airport portion of the rapid response area shall be no more than 2½ minutes, both in optimum conditions of visibility and surface conditions. Other ARFF vehicles necessary to achieve the required discharge rate shall arrive at intervals not exceeding 30 seconds.

FAA's 14 CFR Part 139

The U.S. government has chosen not to adopt NFPA 403 and has filed differences to ICAO Annex 14 with respect to response time. The current response requirements from 14 CFR Part 139.319(h)(2) state

> (i) Within three minutes from the time of the alarm, at least one required airport rescue and firefighting vehicle shall reach the midpoint of the farthest runway serving air carrier aircraft from its assigned post, or reach any other specified point of comparable difference on the movement area which is available to air carriers, and begin application of agent;
>
> (ii) Within four minutes from the time of the alarm, all other required vehicles shall reach the point specified (above) from their assigned post and begin application of agent.

ARFF TRAINING REQUIREMENTS

Each airport must develop its own ARFF fire fighter training program that is designed to prepare the fire fighter for the specific mission of the airport. The program should be carefully developed to meet the qualifications and requirements of NFPA 1003, *Standard for Airport Fire Fighter Professional Qualifications,* and NFPA 405, *Standard for the Recurring Proficiency of Airport Fire Fighters.*

**Rapid response area* is defined by the NFPA as a rectangle 500 ft to either side of a runway centerline and extending 1650 ft beyond each runway end, remaining within the airport property line.

Fire Fighter Training

In 14 CFR Part 139.319(i)(2), the FAA requires that

> all rescue and firefighting personnel are properly trained to perform their duties in a manner authorized by the administrator. Such personnel must be trained prior to initial performance of rescue and firefighting duties and receive recurrent instruction every 12 consecutive calendar months. The curriculum for initial and recurrent training must include at least the following areas: airport familiarization; aircraft familiarization; rescue and firefighting personnel safety; emergency communications; use of fire hoses, nozzles and appliances; application of extinguishing agents; emergency aircraft evacuation assistance; firefighting operations; adapting structural firefighting equipment for ARFF; aircraft cargo hazards including haz mat; and ARFF responsibilities within airport emergency plan.

Each ARFF fire fighter must participate in at least one live-fire drill that simulates an aircraft fire of the size typical to the airport index certificate (Figure 13.7.4).

Training Records

Training records must be maintained by the airport fire department training officer for each member. During the annual airport certification inspection, the FAA inspector inspects the records for compliance. Inspectors can evaluate or test any member for proficiency in any or all of the training requirements. They will also conduct a surprise test run to see a demonstration of the department's ability to satisfy the response test requirements of 14 CFR Part 139.319.

Airport Emergency Exercise

14 CFR Part 139.325 requires all Class 1 airports to hold a full-scale airport emergency exercise at least every 36 months. This

FIGURE 13.7.4 Live-Fire Training Exercises (Source: Jack Kreckie)

FIGURE 13.7.5 Tri-Annual Emergency Response Exercise Being Conducted at Allentown Bethlehem International Airport (Source: Jack Kreckie)

exercise is required to test the airport emergency plan and to demonstrate the ability of those with responsibilities under the emergency plan to fulfill their obligations (Figure 13.7.5).

ARFF PERSONAL PROTECTIVE EQUIPMENT (PPE)

For years there has been debate in the industry relative to the proper personal protective equipment (PPE) for ARFF fire fighters. This issue is primarily raised by departments that serve dual roles of ARFF and structural. Many fire fighters felt that traditional ARFF PPE "silvers," or proximity fire-fighting ensembles (Figure 13.7.6), were too stiff and cumbersome and that they were safer in gear that allowed more freedom of movement. The opposition was typically from departments that were primarily dedicated to ARFF and spoke of the value of reflecting the heat away from the fire fighter.

Many research sources are available to understand the debate but, more importantly, to understand the laws that govern ARFF. The single most important factor is fire fighter safety. If the level of protection is lower than that which is required, fire fighter safety and level of effectiveness will not be maximized.

OSHA Requirements

In the United States, the Department of Labor's Occupational Safety & Health Administration (OSHA) oversees the safety of workers. OSHA standards are federal laws. On July 15, 1997, an Interpretation Record[6] was issued to interpret OSHA's position on proximity gear for ARFF fire fighters in Standard Number 1910.120; 1910.156:

- If a firefighter's primary job is crash and rescue, he or she must be adequately protected for that job (NFPA 1971, proximity protective ensemble). This is true even for those large combined fire departments with multiple tasks where personnel are rotated from station to station and expected to perform crash and rescue duties.
- If a firefighter's primary job is structural, then he or she must be adequately protected for that job (NFPA 1971, structural protective ensemble). This does not preclude being trained for incidental response to aircraft crashes as crashes do occur in unexpected locations.

FIGURE 13.7.6 ARFF Fire Fighter in Silvers (Source: Jack Kreckie)

An example given in the memo referred to the San Diego combined fire department. It stated that all 300 members can be tasked to do any type of fire fighting at any time (usually on a rotational basis). OSHA determined that in this case, all 300 members would have to be equipped to fight any type of fire. In another example where aircraft crash and rescue was less than 5 percent of the tasking, proximity fire fighting was incidental and not the primary job.

FAA Recommendations

FAA Advisory Circular 150/5210-14B, Airport Rescue and Fire Fighting Personnel Protective Ensemble for Proximity Fire Fighting,[7] identifies the standards for design, performance, testing, and safety of personal protective ensembles for proximity fire fighting. This document serves as a recommendation by the FAA for all airports. It is mandatory for PPE purchased under

federally funded projects and serves as an acceptable means of compliance with 14 CFR Part 139 as it pertains to PPE for airport fire and rescue personnel. It states:

> If ARFF personnel engage in any fire and rescue activity where there is any hazard or potential hazard of high radiant heat fuel fire, then the operational consideration and risk assessment mandates the use of proximity protective clothing.
>
> *Recommendations from Advisory Circular:*
> a. Proximity Protective Ensemble
> 1) Design, Performance, Testing and Certification Standards. Proximity Protective Ensembles as a minimum shall meet the most recent edition of NFPA 1971, *Standard on Protective Ensembles for Structural Fire Fighting and Proximity Fire Fighting.*
> 2) For Safety and Health Standards, Proximity Ensemble, as a minimum, shall meet the requirements of NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program.*

AIRCRAFT EMERGENCIES

The vast majority of responses by ARFF departments for aircraft emergencies are precautionary. Aircraft are designed and built with a number of redundant critical systems and can fly safely with certain systems shut down. Although the aircraft are capable of these things, it is still not considered normal, and failure of a system will cause an aircraft to return and land (if it occurs shortly after takeoff) and notify the tower of the problem. In order to provide appropriate levels of protection for the landing aircraft, the authority having jurisdiction (AHJ) at each airport must have established procedures to provide the necessary level of response to all types of aircraft emergencies.

Aircraft Emergencies with Prior Warning

The majority of aircraft emergency responses for ARFF departments are announced prior to the landing of the aircraft. There is often several minutes' warning that the aircraft is inbound and a description of the problem is provided. The calls are typically received from the air traffic control tower (ATCT) or flight service center (FSS).

Problem Information Provided. In most cases, the following information is provided:

- Make, model, and flight number of the aircraft
- Problem reported by the pilot
- Landing runway
- Number of "souls" on board (SOBs)
- Quantity of fuel on board
- Whether or not the pilot is "declaring an emergency" or "requesting the equipment" (requesting ARFF vehicles at the runway)
- Estimated time of arrival (ETA)

Response Objectives. Response to calls with advance warning results in apparatus response to designated runway standby positions. Runway hold-off positions should be designed to accommodate a number of objectives. These objectives are satisfied more easily at airports with multiple pieces of apparatus responding:

- Minimize delays in reaching burning aircraft in the event the aircraft crashes or has a fire on board.
- Provide observation points from different angles and sequences of landing to observe unsafe or reportable conditions.
- Minimize risk to ARFF personnel and vehicles by not locating several assets together. (An aircraft skidding off the runway could wipe out several vehicles if co-located.)
- Provide strategic locations planning for prestaging to include tactical consideration for rapid access to all sides of the aircraft as well as factoring in wind and terrain.

Aircraft Emergencies with No Prior Warning

Some ARFF responses to aircraft emergencies occur with little or no warning. Crashes due to catastrophic failures during landing and takeoff are examples. Another scenario would be an aircraft that experiences an emergency on takeoff roll or on short final (i.e., immediately prior to becoming airborne or immediately upon touchdown). A call from the tower might say, "He just aborted takeoff due to a bird strike! He's at the departure end of Runway 9. He's requesting equipment!" or "Aircraft is on Final for 4R, he has a Fire Warning Light for Number 1 engine. Pilot's declaring an emergency! He's over the numbers now!" (indicating the aircraft is still airborne but about to touch down). In these scenarios, the ARFF vehicles would respond directly to the aircraft rather than to runway standby positions.

ARFF ACTIONS

Size-Up/Set-Up

Initial Observations Reported. Every vehicle approaching an aircraft incident or accident should immediately perform a quick size-up. Initial observations reported to other responding units as well as the aircraft cockpit are among the most critical initial actions. Visible smoke, fire, physical damage, and fuel spills should all be reported immediately. These are items that will factor into decision making in the cockpit as to whether the aircraft should be evacuated or not.

Incident Action Plan. This information is also taken into consideration by the incident commander (IC). At a small airport, there may only be one truck and one person responding. In any case, the IC needs to make a decision based on the initial size-up. He or she must gather the assessment information and develop an incident action plan based on the resources available. The operational priorities for an aircraft accident are no different from any other emergency response:

1. Rescue
2. Fire control

3. Loss control
4. Environmental consideration

Set-Up Factors. The positioning of arriving ARFF vehicles is critical to the success of the mission. In many cases, the positioning of the first arriving piece dictates the position of the remaining apparatus. There are a number of factors to be considered in the set-up phase. Wind, grade, terrain, exposures, spilled fuel, passenger evacuation, and limitations of the apparatus all need to be considered. In addition, each piece of apparatus or specialized equipment needs to have access to the area it was designed to service. If a high-mounted engine is on fire, the best area for tactical deployment of a high-reach extendible turret or aerial device should be left accessible. If the department has a mobile stair truck, the rescue side of the aircraft must be determined and the safest door for deplaning must be left accessible for the stairs.

The decision as to where to position must be made within seconds. Once in position, it is difficult to move vehicles around due to their size and other vehicles at the scene. Although the decisions are made very quickly, the video from media helicopters and long-range lenses will be on display forever with subject matter experts and attorneys questioning every step and criticizing every decision. Decisions made relative to the positioning of apparatus need to be deliberate and for good reason. Training evolutions and critiques of incidents will help ARFF fire fighters develop good instincts and make rapid decisions at the next incident.

Aircraft Cabin Fires Requiring Aircraft Evacuations

Time Requirement. Interior fires on aircraft, whether postcrash or in-flight fires, pose obvious life-threatening hazards to occupants. In either case, the immediate objective of the aircraft crew is to evacuate the occupants of the aircraft. The certification of the aircraft includes a requirement that the aircraft design is such that a full evacuation of the aircraft using half of the exits is accomplished in 90 seconds or less. This ability must be demonstrated prior to certification for revenue service.

Escape Slide. According to an FAA study relating to aircraft cabin fire safety:[8]

> Accident data studies indicate that, in most survivable air transport crashes to date, occupant survival has been largely determined by the ability of uninjured passengers to leave their seats and find an exit before being overcome by fire or smoke.

Air carrier aircraft that make use of escape slides depend on them to satisfy the evacuation requirement. These inflatable devices are not fail-safe. They are subject to failure for mechanical reason or to damage due to the landing or crash. They are designed to be effective for an aircraft sitting on a runway, up on all of its gear. If the attitude of the aircraft is affected, or the gear collapsed upon landing, the value of the slides is reduced or negated. The slides are also affected by heat and wind.

During an emergency evacuation, fire fighters should be positioned at the base of the slides to secure them, help passengers to their feet, and direct them to a safe area of refuge. Fire fighters anchoring the slides from the effects of wind, providing a fire-free escape area, and assisting passengers to areas of safety will help to minimize injuries.

On June 27, 2000, the National Transportation Safety Board (NTSB) adopted a safety study entitled "Emergency Evacuation of Commercial Airplanes." This study collected data from accident investigations and from crew and passenger interviews from 46 emergency evacuations involving 2846 occupants that occurred between September 24, 1997, and January 24, 1999. During this period, an evacuation occurred on average, every 11 days. In the 46 study cases, 92 percent (2614) of the 2846 occupants were uninjured, 6 percent (170) sustained minor injuries, and 2 percent (62) sustained serious injuries.[9]

Removal from Hazardous Atmosphere. Postcrash aircraft accident fatalities are typically due to exposure to products of combustion. For the effects of such exposure, see Section 6, Chapter 2, "Combustion Products and Their Effects on Life Safety." In addition to the effects of the toxic atmosphere, the survival of the occupants depends on the level of air temperature in the aircraft cabin. In postcrash fires, the cabin air temperatures can increase as a result of the ignition of interior cabin components or as a result of fire gases entering the fuselage from outside fires.

To increase the chance for survival, occupants need to be removed from the hazardous atmosphere before they suffer effects of exposure to toxins in the atmosphere and prior to the air temperatures reaching the limits of human tolerance. The other option is to make the atmosphere in the cabin safe for occupants. This may be the only alternative if extrication is required for trapped victims.

Interior Fire Attack and Ventilation

According to the International Fire Service Training Association (IFSTA),[10] ARFF fire fighters should try to determine the location and extent of the fire prior to attempting entry. Ventilation should be immediately initiated to allow the smoke and steam created by interior fire attack to escape. Applying water to the fire will quickly cause the limited space in the cabin to fill with smoke and steam. This condition compounds the difficulty for rescuers making entry and puts occupants and rescuers at risk for steam burns. Making entry and initiating fire attack should be simultaneous to ventilation efforts. Entry, search and rescue, and interior fire attack should be initiated from the unburned side of the aircraft (Figure 13.7.7).

In order to affect interior fire attack in time periods that will increase survivability, efforts must be initiated immediately. The ability to immediately launch exterior fire-fighting efforts to protect escape paths, begin ventilation, and perform interior rescue and fire-fighting actions requires that properly trained and equipped teams be on hand very quickly. It also means that water supply to satisfy *Q1, Q2,* and Q3 quantities must also be available. The personnel and equipment required for these operations need to be on airport or prestaged to arrive in the first few critical minutes if they are to be effective.

FIGURE 13.7.7 Fire Fighters at Orlando International Airport Being Trained on Making Entry Through Emergency Over-Wing Exit (Source: Jack Kreckie)

ARFF personnel at certificated airports should be equipped, trained, and capable of interior aircraft fire fighting. Such operations should be performed in accordance with OSHA, as detailed in 29 CFR Part 1910.134(g)(4). The standard details certain procedures for interior structural fire fighting to ensure respiratory protection and safe practices when entering atmospheres that are immediately dangerous to life and health (IDLH):

> At least 2 employees enter the IDLH atmosphere and remain in visual or voice contact with one another at all times; At least two employees are located outside the IDLH atmosphere; and all employees engaged in interior structural firefighting use Self-Contained Breathing Apparatus (SCBAs)[11]

An interior fire on an aircraft is certainly IDLH. This OSHA regulation is known in the industry as the "two-in/two-out" rule. Federal Aviation Regulation FAR Part 139 certificate holders should develop and implement policies addressing aircraft firefighting operations.

CARGO AIRCRAFT

ARFF Requirements

Currently the FAA authority and, therefore, the applicability of Part 139 extend only to passenger-carrying aircraft under 49 USC 44706. This means that the U.S. requirements for index determination, agent/vehicle quantities, and aircraft training do not include cargo aircraft. To illustrate the point, an airport could conduct flight operations all day long with Boeing 747 cargo aircraft, but the FAA would not require any ARFF coverage.

Although there may not be any legal responsibility on the part of the certificate holder to provide ARFF coverage for these flight operations, most airports realize that they have a moral obligation to protect the aircraft occupants, the airport, and the surrounding communities. In some cases, the costs associated with providing this protection are carried by the cargo operators.

Cargo Aircraft Hazard

Cargo aircraft contain the same fuel loads as passenger aircraft of the same size or class; therefore, the potential for fire and associated damage on the ground is the same, regardless of whether the aircraft is configured for cargo operations or passenger service. Cargo aircraft may actually provide a greater risk for those on the ground since cargo aircraft frequently carry hazardous materials not permitted in passenger operations. Morally to suggest that the lives of the occupants of a cargo aircraft are not eligible for the protection or benefit provided by ARFF services is reprehensible. Human life must always remain the highest priority, regardless of the primary mission of the aircraft these individuals occupy.

Occupant Evacuation

Fires on cargo aircraft offer different challenges from those on passenger aircraft. The life hazard for occupants is obviously less due to the fewer number of people on board. Crew members will attempt to escape through normal exit doors or through the emergency exits in the cockpit. After determining that all occupants have escaped from the aircraft, all efforts can be placed on protecting exposures and attacking the aircraft fire.

Interior Fire Attack

In an intact fuselage, access through normal doors may not provide access to the area of the fire. "Space" on a cargo aircraft is the commodity from which cargo carriers generate their revenue. The intention of the cargo carrier is to fill every space with freight. An open aisle down the center of the fuselage is like flying a passenger aircraft with mostly empty seats. Profits depend on full aircraft. This factor complicates interior fire attack because of the access problem. Opening a cargo bay loading door on an aircraft with an interior fire may intensify the fire due to the introduction of oxygen and not provide any access to extinguish the fire due to the cargo load itself. On most fully loaded cargo aircraft, there are only a few inches between the cargo containers and the fuselage.

Incident Action Plan. Before initiating interior fire attack, crews should attempt to determine the quantities and types of hazardous materials on board. The airway bills and manifests are stored on board the aircraft, usually in the cockpit or adjacent to the main loading door. Aircraft that carry quantities or types of dangerous goods that are not allowed on passenger aircraft are usually stored in designated areas in the forward portion of the cargo bay. If the dangerous goods are in smaller quantities and of a class that would be allowed on passenger aircraft, they may be mixed throughout the aircraft. In all incidents involving a fire on a cargo aircraft, a hazardous materials team should be on site and involved in developing the incident action plan.

Aircraft Skin-Piercing Nozzles. The use of aircraft skin-piercing nozzles may be the best tactic to attack an interior fire on a cargo aircraft. The use of forward-looking infrared (FLIR) cameras is helpful in determining the location and severity of the interior fire. Penetrations in the skin, using handheld piercing

nozzles or those installed on ARFF vehicles equipped with high-reach extendible turrets, are an efficient way of introducing agent to an area that is not accessible due to cargo loading (Figure 13.7.8). It also minimizes the amount of air introduced to small holes punched in the fuselage by the piercing tip. The effectiveness of the fire attack can be monitored through the FLIR camera, which is focused on the "bloom," or heat signature, from the onboard fire. In most cargo aircraft fires, venting occurs when the fire burns through the roof of the fuselage. If the fire is attacked prior to burn-through, ventilation will have to be factored into the incident action plan.

ACCIDENT INVESTIGATION AND SCENE PRESERVATION

Fire Department and Law Enforcement Responsibilities

An aircraft accident is considered a crime scene until proven otherwise. Following ICS/NIMS protocol, the fire department is in charge until all rescue has been completed, the fire is extinguished, and the scene is made safe. At that time, command of the incident is handed over to law enforcement. Local, state, and federal law enforcement agencies are responsible for securing the scene, debris field, personal effects, cargo, and mail. They will collect documentation, gather intelligence, record the scene, and begin analysis of the accident site. Law enforcement looks specifically for anything that might have been a criminal or intentional act or an act of war or terrorism.

Fire fighters need to remain aware that when the scene is declared safe, every inch will be studied and scrutinized by trained investigators. Every bit of damage will be evaluated to determine the specific cause. Damage caused by rescuers during fire fighting, forcible entry, or extrication efforts should be documented for the investigation that will follow. The location of every piece of debris may be an important clue in determining the cause of the accident. The location of personal effects, survivors, bodies, or body parts may be the key to identifying a victim. Care should be taken to touch only things that must be touched to accomplish the critical tasks of the fire fighters' mission.

National Transportation Safety Board (NTSB)

The National Transportation Safety Board (NTSB) investigates every civil aviation accident in the United States. In compliance with international treaties, it also provides investigators to serve as U.S.-accredited representatives for aviation accidents overseas involving U.S.-registered aircraft or involving aircraft or major components of U.S. manufacture. The NTSB launches teams from its headquarters in Washington, DC, or from one of the ten regional offices in the United States. The NTSB maintains the U.S. government's database on civil aviation accidents. The NTSB Accident Incident Database is available to the public at http://www.ntsb.gov/avdata.

AIRCRAFT TECHNOLOGY ADVANCES

Aircraft technology advances, such as aircraft cabin-zoned waterspray systems and emergency locator transmitters (ELT), would increase survivability and are, therefore, justified from a safety or survival standpoint. The associated costs of some of these advances, however, are prohibitive and thus not likely to be implemented at this time.

Aircraft Cabin-Zoned Waterspray Systems and Aircraft Cabin Sprinklers

In the United States, building a structure designed for public assembly, which would accommodate up to 800 people, without fire sprinklers would be unthinkable. Yet in the twenty-first century, new aircraft carry these numbers of people. The area of assembly (the fuselage) is nestled between two wings that are loaded with jet fuel. This area of assembly is then lifted off the ground by powerful jet engines and travels at 30,000 to 40,000 ft above the ground at 500 mph. Based on a study performed by the FAA, "Fire Management/Suppression Systems/Concepts Relating to Aircraft Cabin Fire Safety" (Oct. 1983),[8] the cost of an aircraft cabin-zoned waterspray system for a wide-body jet was estimated to add $86,000 (approximately $140,000 in 2006 dollars) to the cost of the aircraft. The study indicated that, historically, major losses have occurred in postcrash or emergency landing fires.

Unfortunately, this initial cost is the least significant expense to be considered. The weight of a zoned waterspray system for a wide-body jet is 1190 gross lb. This weight is multiplied by the total number of miles flown throughout the anticipated life of the aircraft. The fuel cost and space allowance, combined with annual maintenance, inspection, and repair, reveal the actual cost to the airline. Although the concept of aircraft suppression systems has great merit in the areas of survivability and

loss reduction, it is difficult to calculate a favorable cost/benefit analysis due to the limited number of incidents on which to base benefits. Weight is money in aviation, and automatic suppression systems are not mandated by the FAA, so it is not likely such systems will be installed unless concerns for the number of people at risk in the new large aircraft (NLA) bring back the debate on this issue.

Smart ELT Technology

The key to survival for the occupant of an aircraft involved in a survivable crash is time. The occupant needs to be removed from the fuselage, which is rapidly filling with smoke and fumes (products of combustion), or the atmosphere of that space must be made safe. The elements of response for rescue crews include notification, activation, response, and control time. Notification of emergency crews is usually handled by the air traffic control tower (ATCT) that was handling the flight. Depending on location, visibility, weather, and other factors, this report might have very specific accident location, last known location, or perhaps best estimate location. In cases of survivable crashes, where delays in response and arrival are caused by the inability of the ATCT to provide specific accident location, survival risks are increased. American Airlines Flight 1420, Little Rock, Arkansas, is a perfect example. The following conclusion was published in the NTSB Abstract of the accident report:[12]

> A crash detection and location technology would help expedite the arrival of emergency responders at an accident scene, thus maximizing the possibility for saving lives and reducing the severity of injuries.

Most light aircraft are equipped with emergency locator transmitters (ELT). These ELTs transmit an emergency radio signal that can be tracked to help locate a downed aircraft. Commercial vessels are required by the U.S. Department of Transportation to be equipped with a Category I emergency position indicating reporting beacon (EPIRB). If a ship sinks, the EPIRB will separate itself from the vessel and float to the surface, as it sends out a signal to search and rescue assets.[13]

Technology exists today that combines ELT technology with differential global positioning systems. This smart ELT could be activated manually by the pilot or automatically by deceleration forces and could send out aircraft identification and location information.

Fire Fighter Preparedness

Post–9/11 thinking further complicates everything done in the fire service. On September 11, 2001, aircraft became weapons of mass destruction and airports became their launching pads. It is speculated that these terrorists, who have forever changed life in the United States, spent years watching U.S. airports, studying the system, and flying on airplanes. Much like ARFF fire fighters walking through parking garages and airport terminals on building familiarization, these terrorists walked the same routes. They found every weakness in the system and used it to cause thousands of deaths. Fire fighters everywhere need to reassess every incident they approach; complacency is the enemy. For every routine incident response, there are additional concerns that must be factored into the assessment:

- Could this be a diversion?
- Could there be a secondary device?
- Could this fire be a dispersal method for radiation or other weapons of mass destruction (WMD)?

Incident action plans and SOPs must always hold contingencies for the "what ifs." Transportation centers are critical infrastructure; therefore, airports are high-risk targets for terrorist acts. ARFF fire fighters are the front-line level of protection to minimize threats and mitigate effects of these acts.

There are no federal regulations or industry standards that prepare ARFF fire fighters for what could occur at airports, but they will be the first on the scene. In a multiple-hit scenario, additional events may occur in the cities outside the airport. These are the same cities that provide mutual aid to airports. In these cases, there may be no help coming. It has been said that the only difference between a WMD release and a hazmat incident is intent. The same could be said of a gas explosion in a terminal complex or airport hotel and improvised explosive devices (IEDs) detonated by suicide bombers in the middle of security checkpoints. The bottom line is simply that preparedness is key.

SUMMARY

The challenges presented in a survivable aircraft accident are great. ARFF fire fighters, through training and experience, will exhaust all available resources in an attempt to rescue every occupant. The enemy in this event is time. Most ARFF departments are not staffed with sufficient numbers of personnel to accomplish all the tasks critical to the survival of the occupants in the time allowed. Continued training and development of faster, more capable fire-fighting technology will contribute to their success, but advances in aircraft safety technology might provide the additional edge needed. This chapter discussed a number of pieces of technology, such as aircraft cabin-zoned waterspray systems or emergency locator transmitters, that would further increase survivability but have not been introduced to the fleet mix. Although it is clear that these items can be justified from a safety or survival standpoint, the associated cost will probably prevent their introduction.

This chapter discussed the mission of the aircraft rescue fire fighter and followed it by a review of the evolution of the aircraft itself. As the aircraft evolved, so did the regulations and consensus standards that ARFF protection at airports is modeled around. Basic ARFF response procedures as well as specific hazards to fire fighters and aircraft occupants alike were reviewed. For the ARFF fire fighter, all of the information provided and referenced here is nothing more than "ARFF 101." The basic requirements of the regulations that govern ARFF departments are a foundation for the knowledge base each ARFF fire fighter must develop to be proficient in his or her mission.

Responsibilities change daily with changes in fleet mix, passenger load factors, unknown cargo loads, and the new age threat of the day.

A simple review of the scenario that every ARFF fire fighter trains and prepares for shows how important proficiency in every required skill set is to the survival of the occupants of an aircraft involved in a survivable crash. Consider this:

- According to a study released in 1996,[14] which examined NTSB reports from 60 survivable aviation accidents, 78 percent of all fatalities occurred after impact, and 95.4 percent of them resulted from smoke inhalation or burns.
- In postcrash fires, cabin air temperatures can rise from both the ignition of the cabin interior and from fire gases entering the fuselage through open doors or fractured fuselage. In an FAA study,[8] the cabin air temperature at the ceiling reached 1300°F (704.4°C) in 50 seconds with open doors. Closing all but one door retarded the flow of heat, which still reached 400°F (204°C) in the same time.

Statistically, therefore, the fatalities that occur in a survivable crash will occur postcrash. The fire that is likely to occur will rapidly create an environment that cannot support life for those unable to escape by themselves. The lives of surviving occupants are totally dependent on the swift actions of highly trained and properly equipped ARFF fire fighters. Every action, every second spent or saved, from the moment of the impact until all survivors are safe will have an effect on who lives and who does not. For ARFF fire fighters, the minimum standard is never enough. Commitment to mission, training, coordination, and cooperation is the key to successful incident accident plans.

Chapter 8

Managing the Response to Hazardous Material Incidents

Charles J. Wright

Chapter Contents

Definitions
Hazard Classes and Divisions
Analyzing the Hazardous Material Problem
Planning the Response
Implementing the Planned Response
Evaluating Progress and Adjusting Accordingly

Key Terms

bulk packaging, damage assessment, decontamination, elevated temperature material, emergency, *Emergency Response Guidebook,* hazard class, hazardous material, hazardous material data sheet, incident management system (IMS), personal protective equipment, shipping paper, weapons of mass destruction (WMD)

Hazardous materials may be an important part of our high standard of living, but when a release occurs, it can harm people, including response personnel, property, and the environment. It can disrupt critical systems, damage reputations, and create a residual fear of hazardous materials. The effective management of hazardous materials and other chemicals in the community requires (1) prevention, (2) preparedness, (3) response, and (4) recovery activities. This chapter focuses on a risk-based response process, but the underlying concepts apply to the other hazardous material management activities as well.

The purpose of the response effort is "to change the sequence of events constituting the emergency before it has run its course naturally and to minimize harm that would otherwise occur."[1] To accomplish this purpose, the following four duties are undertaken (Figure 13.8.1):

1. Analyze the problem.
2. Plan the response.
3. Implement the planned response.
4. Evaluate progress and adjust accordingly.

Each duty involves a series of tasks and steps that must be considered and resolved by decisions and actions. These duties, when supported by the response community, are the framework for an appropriate, survival-oriented response to hazardous material incidents. Reasoned decisions based on this approach will minimize the harm resulting from a hazardous material incident and reduce the risk to responders.

See also Section 7, Chapter 5, "Hazardous Waste Control"; and Section 13, Chapter 6, "Public Fire Protection and Hazmat Management."

DEFINITIONS

The following terms are used in this chapter.

Bulk packaging is any containment system, including transport vehicles and freight containers, having a capacity meeting one of the following criteria: liquid—internal volume of more than 119 gal (450 L); solid—capacity of more than 882 lb (400 kg); or compressed gas—water capacity of more than 1000 lb (454 kg).

Containment systems (or containers) are a combination of a container and its closures used to isolate the contents from the surrounding environment. A closure is a device for closing the openings in a container.

Elevated temperature material (DOT) means a material that, when offered for transportation or transported in a bulk packaging, is (1) in a liquid phase and at a temperature at or above 212°F

Charles J. Wright is manager of hazardous materials training at the Union Pacific Railroad in Omaha, Nebraska.

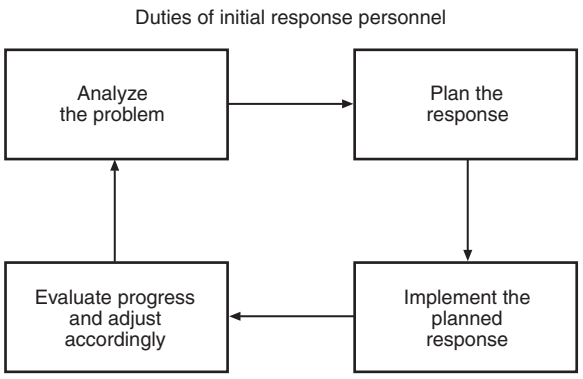

FIGURE 13.8.1 Response Duties Associated with Emergencies Involving Hazardous Materials

(100°C), (2) in a liquid phase with a flashpoint at or above 100°F (37.8°C) that is intentionally heated and offered for transportation or transported at or above its flashpoint, or (3) in a solid phase and at a temperature at or above 464°F (240°C).

Emergency is the term used for a sudden, generally unexpected disruption in a normal sequence of events requiring immediate action.

Hazardous material, for the purpose of this chapter, is a substance that on release has the potential of causing harm to people, property, or the environment, including weapons of mass destruction (WMD).

Hazardous material (DOT) means a substance or material that has been determined by the Secretary of Transportation to be capable of posing an unreasonable risk to health, safety, and property when transported in commerce, and that has been so designated. Table 13.8.1 lists the internationally accepted hazard classes and divisions associated with hazardous materials in transportation. This definition includes hazardous materials, hazardous substances, hazardous wastes, elevated temperature materials, marine pollutants, and dangerous goods internationally.

Hazardous substance (DOT) means a material, including its mixtures and solutions, in a quantity, in one package, that equals or exceeds the reportable quantity (RQ) listed in DOT's Hazardous Materials Regulations (49 CFR, Parts 171–172).

Hazardous waste (DOT) means any material that is subject to the Hazardous Waste Manifest Requirements of the U.S. Environmental Protection Agency (EPA) specified in 40 CFR, Part 262.

Hazardous material incident is an emergency involving the release or potential release of hazardous materials/weapons of mass destruction (WMD) with or without fire.

Marine pollutant (DOT) means a material that is harmful to aquatic life (listed in 49 CFR 172.101, Appendix B).

Nonbulk packaging is any containment system having a capacity meeting one of the following criteria: liquid—internal volume of 119 gal (450 L) or less; solid—capacity of 882 lb (400 kg) or less; or compressed gas—water capacity of 101 lb (454 kg) or less.

Outcomes are the direct and indirect results or consequences associated with an emergency. Direct outcomes include death, injury, property damage, and environmental damage. Indirect outcomes include system disruption, damaged reputations, and residual fear of hazardous materials.

Response community is composed of those individuals, agencies, or companies who have resources and can become involved in handling a hazardous material incident. These may include fire service personnel, law enforcement personnel, rescue and emergency medical personnel, private sector response personnel (carriers, manufacturers, and contractors), and local, state and federal government response personnel.

Weapons of mass destructions (WMD) are defined in NFPA 472, *Standard for Competence of Responders to Hazardous Materials/Weapons of Mass Destruction Incidents*, as (a) any destructive device, such as any explosive, incendiary, or poison gas, bomb, grenade, rocket having a propellant charge of more than four ounces (112 grams), missile having an explosive or incendiary charge of more than one quarter ounce (7 grams), or device similar to the above; (b) any weapon involving toxic or poisonous chemicals; (c) any weapon involving a disease organism; (d) any weapon that is designed to release radiation or radioactivity at a level dangerous to human life.

HAZARD CLASSES AND DIVISIONS

The following list presents the internationally accepted definitions of the nine numbered hazard classes and divisions. These definitions should not be used to determine compliance with the regulations, because they do not indicate the exceptions and specificity found in the regulations in all cases.[2]

Class 1 *(Explosives and Blasting Agents)*

Explosive means any substance or article, including a device, that is designed to function by explosion (i.e., an extremely rapid release of gas and heat) or that, by chemical reaction within itself, is able to function in a similar manner even if not designed to function by explosion. Explosives in Class 1 are divided into six divisions. Each division will have a letter designation (compatibility group letter.)

Division 1.1. Consists of explosives that have a mass explosion hazard. A mass explosion is one that affects almost the entire load instantaneously.

Division 1.2. Consists of explosives that have a projection hazard but not a mass explosion hazard.

Division 1.3. Consists of explosives that have a fire hazard and either a minor blast hazard or a minor projection hazard or both, but not a mass explosion hazard.

Division 1.4. Consists of explosive devices that present a minor explosion hazard. No device may contain more than 0.9 oz (25 g) of a detonating material.

Division 1.5. Consists of very insensitive explosives. These substances have a mass explosion hazard but are so insensitive that there is very little probability of initiation or of transition from burning to detonation under normal conditions of transport.

TABLE 13.8.1 International Hazard Classes and Divisions

Classes and Divisions	*Examples of Materials (by Hazard Class or Division)*	*General Hazard Properties (Not All-Inclusive)*
Class 1—Explosives and blasting agents		Explosive; exposure to heat, shock, or contamination could result in thermal and mechanical hazards
Division 1.1—explosives with mass explosion hazard	Dynamite, TNT, black powder	
Division 1.2—explosives with projection hazard	Projectiles with bursting charges	
Division 1.3—explosives with fire, minor blast, or minor projection hazard	Propellant explosives, rocket motors, special fireworks	
Division 1.4—explosive devices with minor explosion hazard	Common fireworks	
Division 1.5—very insensitive explosives	Ammonium nitrate–fuel oil mix, blasting agent	
Division 1.6—extremely insensitive explosives		
Class 2—Gases		Under pressure; container may rupture violently (fire and nonfire); may be flammable, poisonous, corrosive, asphyxiant, and/or thermally unstable
Division 2.1—flammable gases	Propane, butadiene, acetylene, methyl chloride	
Division 2.2—nonflammable, nonpoisonous (nontoxic) gas	Carbon dioxide, anhydrous ammonia	
Division 2.3—poisonous (toxic) gas by inhalation	Arsine, phosgene, chlorine, methyl bromide	
Class 3—Flammable liquids *(flashpoint less than 141°F [60°C])*	Acetone, amyl acetate, gasoline, methyl alcohol	Flammable; container may rupture violently from heat/fire; may be corrosive, toxic, and/or thermally unstable
Class 4—Flammable solids and reactive liquids and solids		Flammable, some spontaneously; may be water reactive, toxic, and/or corrosive; may be extremely difficult to extinguish
Division 4.1—flammable solids	Nitrocellulose, matches	
Division 4.2—spontaneously combustible materials	Phosphorus, aluminum alkyls, charcoal	
Division 4.3—dangerous when wet materials	Calcium carbide, potassium	
Class 5—Oxidizers and organic peroxides		Supplies oxygen to support combustion; sensitive to heat, shock, friction, and/or contamination
Division 5.1—oxidizers	Ammonium nitrate fertilizer	
Division 5.2—organic peroxides	Dibenzoyl peroxide	
Class 6—Toxic (poisonous) materials		Toxic by inhalation, ingestion, and skin/eye contact; may be flammable
Division 6.1—poisonous (toxic) material	Aniline, arsenic, tear gas, carbon tetrachloride	
Division 6.2—infectious substances	Anthrax, botulism, tetanus	
Class 7—Radioactive materials	Cobalt, uranium hexafluoride	May cause burns and biologic effects; may be in form of energy or matter
Class 8—Corrosive materials	Hydrochloric acid, sulfuric acid, sodium hydroxide	Disintegration of contacted tissues; may be fuming and/or water reactive
Class 9—Miscellaneous hazardous materials	Adipic acid, molten sulfur, dry ice, PCBs	

Division 1.6. Consists of extremely insensitive articles that do not have a mass explosion hazard. These articles contain only extremely insensitive detonating substances and demonstrate a negligible probability of accidental initiation or propagation.

Class 2 *(Gases)*

Division 2.1. *Flammable gas* means any material that is a gas at 68°F (20°C) or less and 14.7 psi (101.3 kPa) of pressure, or

a material that has a boiling point of 68°F (20°C) or less at 14.7 psi (101.3 kPa) that meets either of the following criteria:

1. Is ignitible at 14.7 psi (101.3 kPa) when in a mixture of 13 percent or less by volume with air
2. Has a flammable range of at least 12 percent in air at 14.7 psi (101.3 kPa) regardless of the lower limit

Division 2.2. Nonflammable, nontoxic (nonpoisonous) compressed gas, including compressed gas, liquefied gas, pressurized cryogenic gas, and compressed gas in solution means any material (or mixture) that exerts in the packaging an absolute pressure of 41 psi (280 kPa) at 68°F (20°C).

A *cryogenic liquid* means a refrigerated liquefied gas having a boiling point colder than –130°F (–90°C) at 14.7 psi (101.3 kPa) absolute.

Division 2.3. *Toxic (poisonous) gas* means a material that is a gas at 68°F (20°C) or less and a pressure of 14.7 psi or 1 atm (101.3 kPa), that has a boiling point of 68°F (20°C) or less at 14.7 psi (101.3 kPa), and that has either of the following characteristics:

1. Is known to be so toxic to humans as to pose a hazard to health during transportation
2. In the absence of adequate data on human toxicity, is presumed to be toxic to humans because, when tested on laboratory animals, it has an LC_{50} value not more than 5000 ppm

Class 3 *(Flammable Liquids)*

Flammable liquids are any liquids having a flashpoint of not more than 140°F (60°C).

In the United States and Canada, an additional worded hazard class, *combustible liquids,* has been added to designate liquids with flashpoints above 140°F (60°C) and below 200°F (93°C). Actually, the U.S. regulations allow shippers to reclassify liquids with flashpoints above 100°F (38°C) as *combustible liquids.*

Class 4 *(Flammable Solids and Reactive Liquids and Solids)*

Division 4.1. *Flammable solid* means any of the following three types of materials:

1. *Wetted explosives*. Explosives wetted with sufficient water, alcohol, or plasticizers to suppress explosive properties
2. *Self-reactive materials*. Materials that are liable to undergo, at normal or elevated temperatures, a strongly exothermal decomposition caused by excessively high transport temperatures or by contamination
3. *Readily combustible solids*. Solids that may cause a fire through friction and any metal powders that can be ignited

Division 4.2. *Spontaneously combustible solid* means either of the following materials:

1. *Pyrophoric material*. A liquid or solid that, even in small quantities and without an external ignition source, can ignite within 5 minutes after coming in contact with air
2. *Self-heating material*. A material that, when in contact with air and without an energy supply, is liable to self-heat

Division 4.3. *Dangerous-when-wet material* means a material that, by contact with water, is liable to become spontaneously flammable or to give off flammable or toxic gas at a rate greater than 1 L/kg of the material, per hour.

Class 5 *(Oxidizers and Organic Peroxides)*

Division 5.1. *Oxidizer* means a material that may, generally by yielding oxygen, cause or enhance the combustion of other materials.

Division 5.2. *Organic peroxide* means any organic compound containing oxygen (O) in the bivalent -O-O- structure and that may be considered a derivative of hydrogen peroxide, whereby one or more of the hydrogen atoms have been replaced by organic radicals.

Class 6 *(Toxic or Poisonous Materials and Infectious Substances)*

Division 6.1. *Toxic (poisonous) material* means a material, other than a gas, that is either known to be so toxic to humans as to afford a hazard to health during transportation, or in the absence of adequate data on human toxicity, is presumed to be toxic to humans.

Division 6.2. *Infectious substance* means a viable microorganism, or its toxin, that causes or may cause disease in humans or animals. Infectious substance and etiologic agent are synonymous.

Class 7 *(Radioactive Materials)*

Radioactive material is any material containing radionuclides where both the activity concentration and the total activity of the shipment exceed specific values.

Class 8 *(Corrosive Materials)*

Corrosive material means either a liquid or solid that causes visible destruction or irreversible alterations in human skin tissue at the site of contact, or a liquid that has a severe corrosion rate on steel or aluminum.

Class 9 *(Miscellaneous Hazardous Materials)*

Miscellaneous hazardous material means a material that presents a hazard during transport, but that is not included in another hazard class, including the following:

1. Any material that has an anesthetic, noxious, or other similar property that could cause extreme annoyance or discomfort to a flight-crew member so as to prevent the correct performance of assigned duties
2. Any material that is not included in any other hazard class (a hazardous substance or a hazardous waste)

ORM-D Materials

In the United States, the hazard class ORM-D material (Other Regulated Materials-D) is used to designate materials, such as consumer commodities and some small arms ammunition, that present a limited hazard during transportation, due to their form, quantity, and packaging.

Other Definitions

The following are *hazard zones* associated with gases (Class 2) and listed as poison-inhalation hazards:

- *Hazard zone A*. LC_{50} less than or equal to 200 ppm
- *Hazard zone B*. LC_{50} greater than 200 ppm and less than or equal to 1000 ppm
- *Hazard zone C*. LC_{50} greater than 1000 ppm and less than or equal to 3000 ppm
- *Hazard zone D*. LC_{50} greater than 3000 ppm and less than or equal to 5000 ppm

The following are *hazard zones* associated with liquid and listed as poison-inhalation hazards in Classes 3, 4, 5, 6, and 8:

- *Hazard zone A*. LC_{50} less than or equal to 200 ppm
- *Hazard zone B*. LC_{50} greater than 200 ppm and less than or equal to 1000 ppm

Forbidden means prohibited from being offered or accepted for transportation. Prohibition does not apply if these materials are diluted, stabilized, or incorporated in devices.

ANALYZING THE HAZARDOUS MATERIAL PROBLEM

Background

Responding to emergencies involving hazardous materials is not easy. Just the sheer numbers of these materials present an intimidating list for those who respond to the emergencies they create. Consider the following examples:

1. A review of the Chemical Abstract Service's (CAS) list indicates that out of 1.5 million chemicals or chemical formulations found outside of the laboratory, more than 63,000 are considered hazardous.
2. The U.S. Department of Transportation (DOT) regulates the transportation of some 4000 hazardous materials.
3. The Occupational Safety and Health Administration (OSHA) of the U.S. Department of Labor regulates about 600 hazardous substances on the basis of occupational exposure.

A national study by Industrial Economics, Inc., sponsored by the U.S. Environmental Protection Agency (EPA),[3] and subsequent regional studies indicate that the most commonly released chemical is vehicle fuel. The following are two other findings that are of interest:

- 49.5 percent of the rest of the releases involved only 10 chemicals in addition to vehicle fuels. (Table 13.8.2 lists these chemicals.) These additional 10 chemicals are typically produced in the largest volume.
- 74.8 percent of the releases occurred in facilities (production, storage, and use) whereas the remaining 25.2 percent occurred in transportation.

Regional differences from this national study may change the makeup of the list locally.

Overview

The process of analyzing the hazardous material problem (sizeup) provides a way of determining the specific hazards and the potential magnitude of the problem in terms of outcomes. An understanding of the magnitude of the problem is the basis for subsequent decisions on the handling of an incident. Failure to consider all the hazards increases the responder's risk.

The analysis process begins when a responder receives notification of a problem and continues throughout the incident, typically at the scene threatened by any hazardous materials involved. Pre-emergency planning, following the same tasks and steps, lessens the time expended to achieve a safe and cost-effective response at a hazardous material incident, and also increases the available response options for that response.

An analysis of the hazardous material problem involves completing the following tasks (Figure 13.8.2):

1. Detect presence of hazardous material.
2. Initiate command and control activities.
3. Survey hazardous material incident.
4. Collect and interpret hazard and response information.
5. Assess extent of damage to containment system.
6. Predict likely behavior of containment system or contents.
7. Estimate potential outcomes within engulfed area.

Detecting the Presence of Hazardous Materials

The first task in analyzing, and ultimately understanding and solving, hazardous material problems is that of recognizing

TABLE 13.8.2 Most Commonly Released Hazardous Materials with Percentage of Releases and Percentage of Deaths and Injuries Associated with the Material[3]

Chemical Name	*Percentage of Releases*	*Percentage of Deaths and Injuries*
PCB (polychlorinated biphenyls)	23.0	2.8
Sulfuric acid	6.5	4.7
Anhydrous ammonia	3.7	6.8
Chlorine	3.5	9.6
Hydrochloric acid	3.1	5.6
Sodium hydroxide	2.6	1.9
Methyl alcohol	1.7	0.4
Nitric acid	1.7	1.5
Toluene	1.4	2.4
Methyl chloride	1.4	0.0

Source: Based on Industrial Economics, Inc., database.

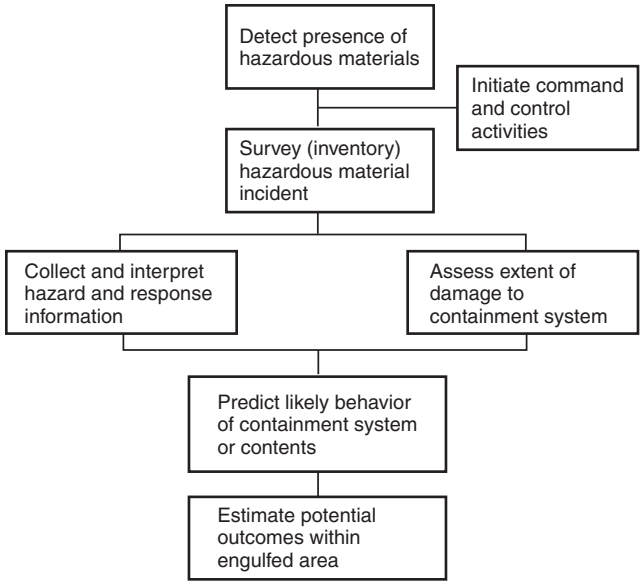

FIGURE 13.8.2 Tasks Associated with Analyzing a Hazardous Materials Problem

those situations where hazardous materials are present. This recognition task begins with the receipt of the initial notification of an emergency and continues throughout the handling of an emergency. Any emergency should be approached from a direction that will provide protection if hazardous materials are present. As with all tasks in the analysis process, detection should be performed from a safe location—upwind, uphill, and upstream, if possible.

The following steps should be taken when responding to any emergency:

1. *Review the initial information received for indications of hazardous materials.* Clues to the presence of hazardous materials may be provided by the caller or dispatcher.

2. *Review the occupancy, location, or local planning documents for indications of hazardous materials.* Planning documents, such as local emergency response plans, industry site-specific plans, and fire service pre-emergency response plans, may indicate the presence of hazardous materials. During pre-emergency planning activities, typical occupancies and locations where hazardous materials are manufactured, transported, stored, used, or disposed of in the community are identified.

3. *Look for containment system characteristics that indicate hazardous materials.* The hemispherical ends on the container or the protective housing around the fittings on top of a pressure tank car are indications of hazardous materials. An awareness of the various types of hazardous material containment systems is useful.

4. *Look for facility and transportation markings and color that indicate hazardous materials.* The use of color is not consistent nationwide; however, color markings may be consistent in local areas. Various markings indicate the presence of hazardous materials. Some examples are as follows.

Identification numbers are four-digit numbers assigned to a specific hazardous material or group of hazardous materials. They are used to cross-reference the name of a material in order to access hazard and response information for that material. In transportation, identification numbers must be displayed on the following:

- Nonbulk packages of hazardous materials (except limited quantities) printed adjacent to the required labels on the package
- Bulk packages of hazardous materials, such as cargo tanks, portable tanks, tank cars, and other bulk shipments; on bulk packages, identification numbers can be displayed on an orange panel, in the center of the appropriate placard, or in the center of a placard-sized, square-on-point white display (Figure 13.8.3)

On shipping papers, identification numbers are preceded by the prefix "UN" (United Nations) for domestic and international shipments or "NA" (North American) for shipments considered hazardous only within North America.

NFPA 704 *markings* are diamond-shaped symbols used within facilities to alert people to the type and degree of

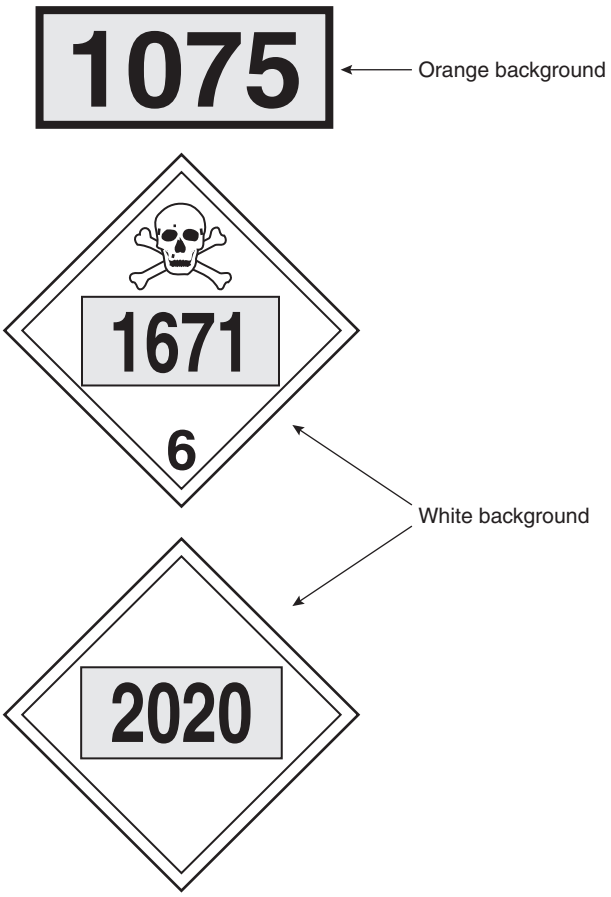

FIGURE 13.8.3 Identification Numbers. The rectangular box has an orange background. The diamonds have white backgrounds.

hazard. (See NFPA 704, *Standard System for the Identification of the Hazards of Materials for Emergency Response.*) They may be found on nonbulk packages; however, they are not used on transport vehicles. The diamond-shaped symbol is divided into four color-coded quadrants (Figure 13.8.4). The blue in the left quadrant refers to the health hazard; the red in the top quadrant indicates the flammability hazard; the yellow in the right quadrant refers to the reactivity hazard; and the bottom quadrant carries special information, such as "OX" for oxidizers or "W" for water-reactive materials. Each quadrant contains a number from 0 to 4 that represents the relative degree of hazard (0 is low; 4 is high) (Figure 13.8.5).

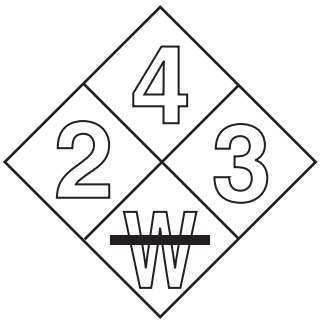

FIGURE 13.8.4 Sample NFPA Marking (Source: 2007 edition of NFPA 704, *Standard System for the Identification of the Hazards of Materials for Emergency Response*)

NFPA 704 Marking System

Scale	Health Hazard	Flammability Hazard	Instability Hazard
4	Materials that, under emergency conditions, can be lethal	Materials that will rapidly or completely vaporize at atmospheric pressure and normal ambient temperature or that are readily dispersed in air and that burn readily	Materials that in themselves are readily capable of detonation, explosive decomposition, or explosive reaction at normal temperatures and pressures. This includes materials that are sensitive to localized thermal or mechanical shock at normal temperatures and pressures.
3	Materials that, under emergency conditions, can cause serious or permanent injury	Liquids and solids that can be ignited under almost all atmosphere and temperature conditions. Materials in this degree produce hazardous atmospheres with air under almost all ambient temperatures or, though unaffected by ambient temperatures, are readily ignited under almost all conditions	Materials that in themselves are capable of detonation, explosive decomposition, or explosive reaction but that require a strong initiating source or that must be heated under confinement before initiation
2	Materials that, under emergency conditions, can cause temporary incapacitation or residual injury	Materials that must be moderately heated or exposed to relatively high ambient temperatures before ignition can occur. Materials in this degree would not under normal conditions form hazardous atmospheres with air but under high ambient temperatures or under moderate heating might release vapor in sufficient quantities to produce hazardous atmospheres with air.	Materials that in themselves undergo violent chemical change at elevated temperatures and pressures
1	Materials that, under emergency conditions, can cause severe irritation	Materials that must be preheated before ignition can occur. Materials in this degree require considerable preheating, under all ambient temperature conditions before ignition and combustion can occur.	Materials that in themselves are normally stable but that can become unstable at elevated temperatures and pressures
0	Materials that, under emergency conditions, would offer no hazard beyond that of ordinary combustible materials	Materials that will not burn. This includes any material that will not burn in air when exposed to a temperature of 1500°F (816°C) for a period of 5 minutes.	Materials that in themselves are normally stable even under fire conditions

FIGURE 13.8.5 Significance of Numbers on NFPA 704 Marking System (Source: 2001 edition of NFPA 704, *Standard System for the Identification of the Hazards of Materials for Emergency Response*)

Military markings are used to indicate hazardous materials for military shipments.

Special hazard communication markings are used in facility situations to indicate hazardous materials.

Warning labels indicate the presence of hazardous materials using words such as *warning, danger, caution,* and *poison.*

Pipeline markers mark the location of pipelines, especially where the pipeline crosses a street.

Container markings, such as the stenciled name of the contents, also may indicate the presence of hazardous materials.

5. *Look for placards and labels.* Placards and labels are diamond-shaped symbols that are used internationally to communicate the presence of hazardous materials in transportation. Placards 10.8 in. by 10.8 in. (273 mm by 273 mm) are required on some bulk packages, such as transport vehicles (e.g., cargo tanks, portable tanks, tank cars, and hopper cars). Labels, 4 in. by 4 in. (102 mm by 102 mm) or smaller for cylinders, are found on some nonbulk packages. Placards and labels convey information by their color, symbol, hazard class and division number, and either the hazard class wording or four-digit identification number. DOT Chart 12 provides examples of U.S. and Canadian placards and labels (Figure 13.8.6).

Transport vehicles and freight containers could contain up to 1000 lb (454 kg) of certain hazardous materials without a placard being applied. Limited-quantity, Division 6.2 (infectious substance/etiologic agents), and ORM-D shipments do not require placards. To determine load/empty status, use the shipping papers. Square white backgrounds are used behind Division 1.1, Division 1.2, Division 2.3, Division 6.1 Packing Group I Zone A, and Class 7 placards to indicate special handling. The dangerous placard indicates a mixed load of several classes of hazardous materials.

6. *Obtain and review facility documents or shipping papers.* Shipping papers accompany each shipment during transportation and provide detailed information about the contents of the shipment. These shipping papers are used in the various modes of

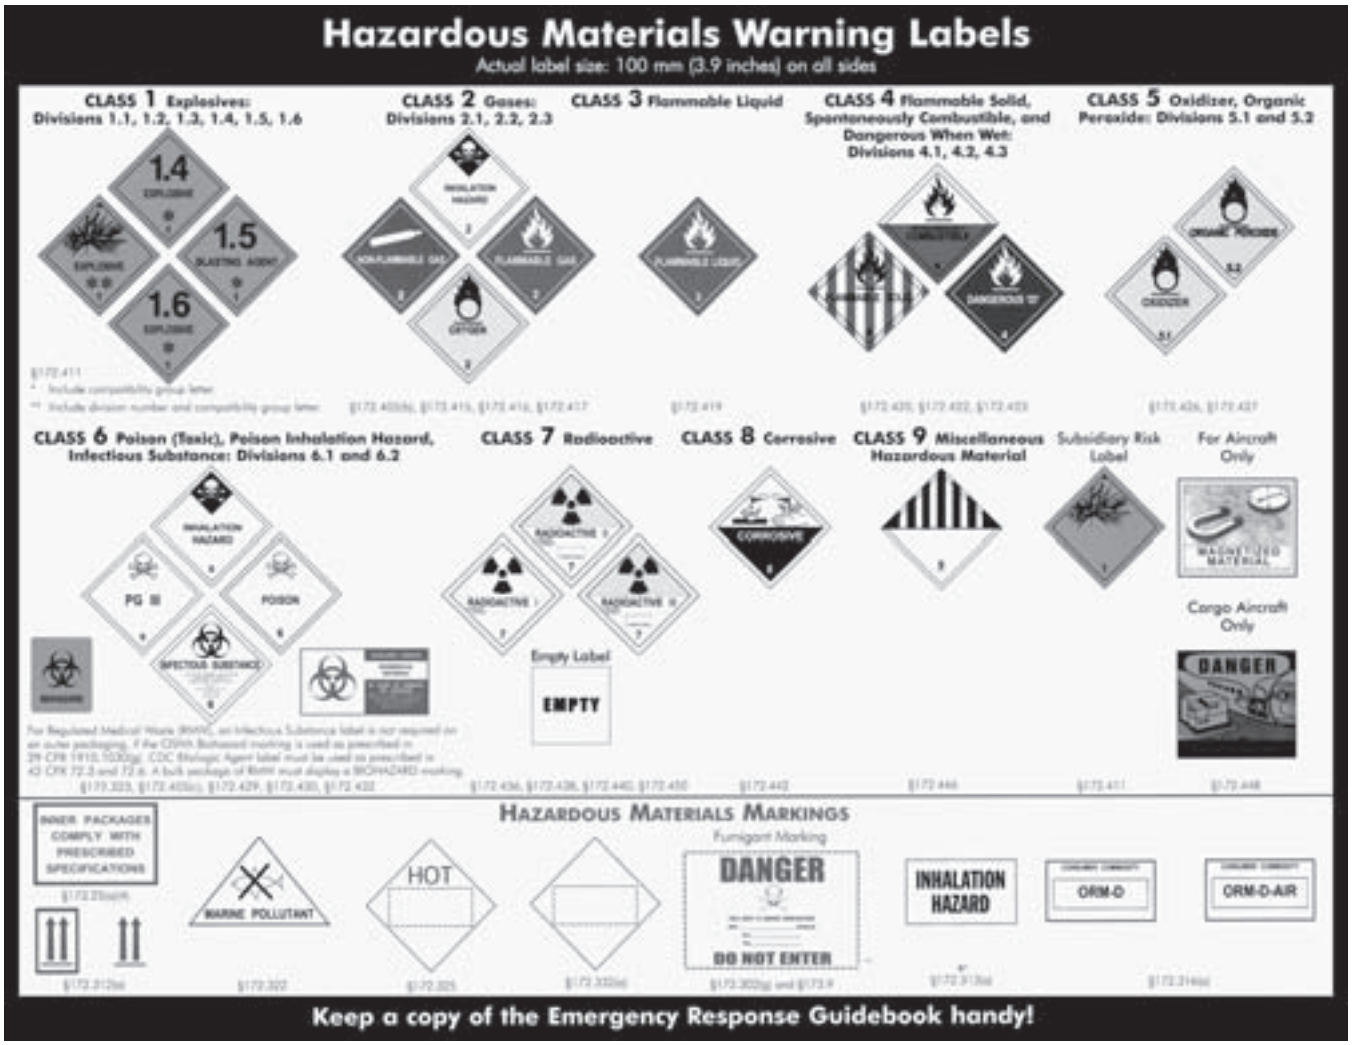

FIGURE 13.8.6 DOT Chart 12 Depicting Hazardous Materials Marking, Labeling, and Placarding

TABLE 13.8.3 Shipping Papers by Mode of Transportation, Title of Shipping Paper, Location, and Responsible Person

Mode of Transportation	*Title of Shipping Paper*	*Location of Shipping Papers*	*Responsible Person*
Highway	Bill of lading or freight bill	Cab of vehicle	Driver
Rail	Train list or train consist and/or waybill	With member of train crew (conductor or engineer)	Conductor
Water	Dangerous cargo manifest	Wheelhouse or pipelike container or barge	Captain or master
Air	Air bill with shipper's certification for restricted articles	Cockpit (may also be found attached to the outside of packages)	Pilot

transportation (highway, rail, water, and air) and are listed in Table 13.8.3 by mode of transportation, title of shipping paper, location of shipping papers, and the person responsible. Shipping papers may indicate the presence of hazardous materials through a variety of required entries (all of which are not always present). The most common entries include the proper shipping name, hazard class or division, identification number, packing group, and the total quantity (by weight, volume, or as otherwise appropriate).

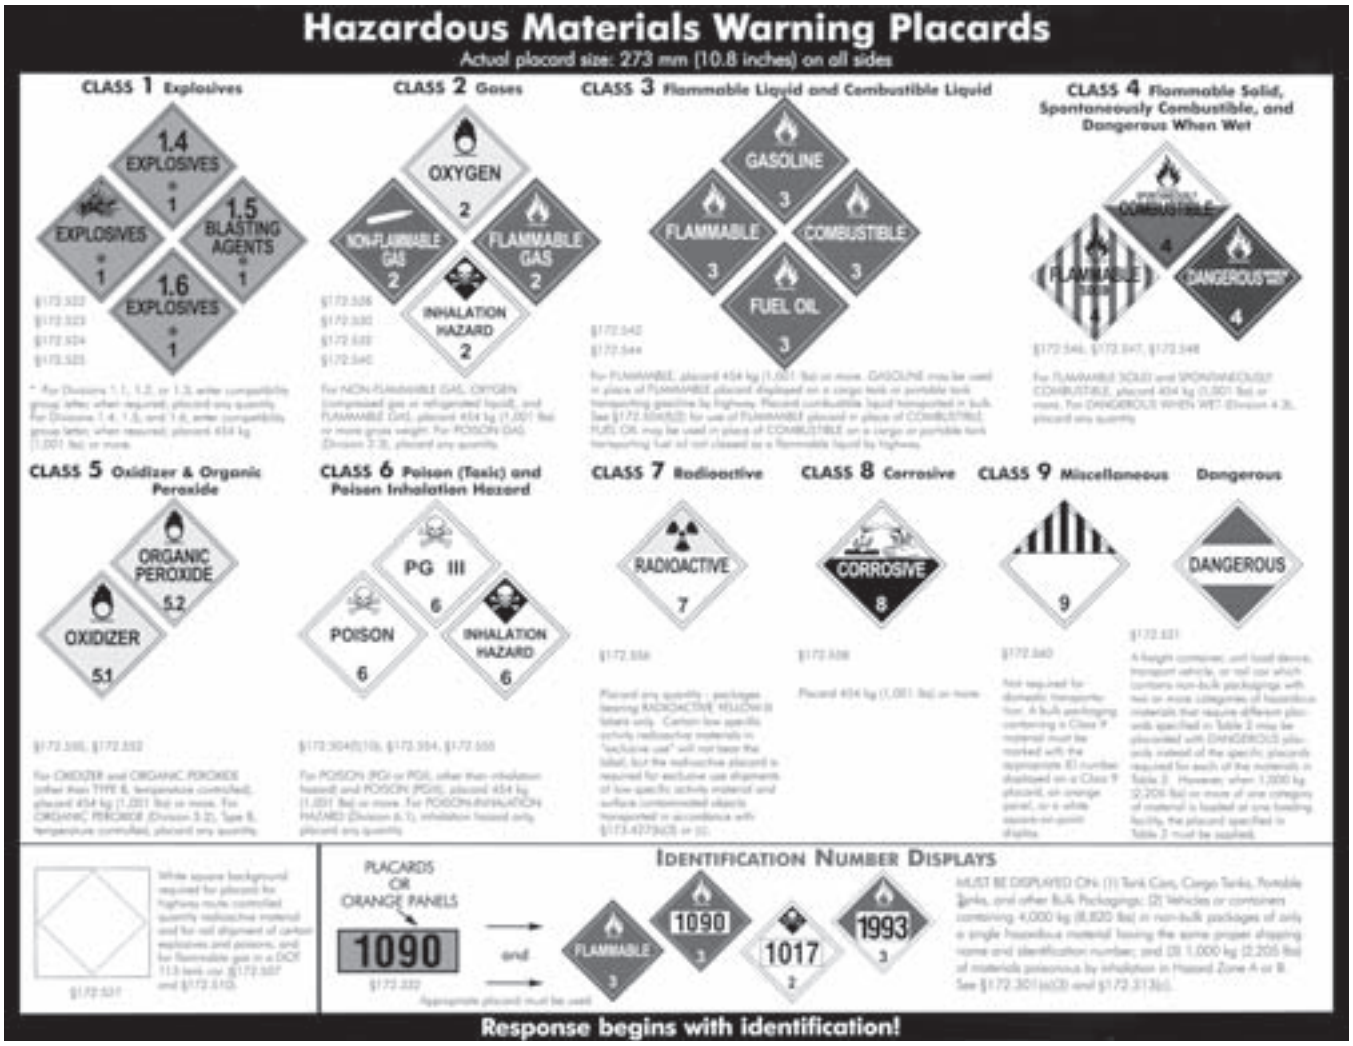

FIGURE 13.8.6 Continued

Additional entries may include technical and chemical group names, the letters RQ (reportable quantity notation) POISON—INHALATION HAZARD, LIMITED QUANTITY notation, DANGEROUS WHEN WET notation, and shipper contact information. Shipping papers also include telephone number and emergency-response information for the specific commodity.

Facility documents include the material safety data sheet (MSDS). The MSDS is a document that provides information about the composition, physical and chemical properties, health and safety hazards, emergency response, and waste disposal of materials required by OSHA in 29 CFR 1910.1200.

7. *Identify clues (other than occupancy/locations, container shape, markings/color, and placards/labels) that use sight, sound, and odor to indicate hazardous materials.* Sensual indications include chemical odors, dead animals and fish, vapor clouds, flames or smoke, irritation of the skin or eyes, the hiss of escaping gas, or the sound of an explosion.

As soon as the presence of hazardous materials is detected, move to the next task in the analysis process.

Initiating Command and Control Activities

Although not part of the analysis process, command and control activities should be initiated on detecting the presence of hazardous materials and simultaneously with the initial survey of the situation. These command and control actions are taken: (1) to protect the responder and others during completion of analysis and planning duties, (2) to provide for a command structure at the incident, and (3) to provide for notification of resources required to handle the situation. Specific procedures for initiating command and control activities are found in the local emergency response plan or organization's standard operating procedures.

To initiate command and control activities, take the following steps:

1. *Implement an incident command system.* This step provides organization of the incident scene and may begin prior to arrival on the scene.
2. *Locate personnel at a safe distance from the problem.* With consideration of the terrain and weather conditions, response personnel should stop at a safe location from the incident—uphill, upwind, and upstream. Suggested minimum "safe" distances should be specified in the local emergency response plan or the organization's standard operating procedures. At this point, the analysis process is not complete, and sufficient information is not available to determine safe distances.
3. *Initiate the notification process.* Specific procedures and contacts for notification of required resources should be developed prior to an emergency and listed in the local planning documents.
4. *Control access to the site.* Prevent unauthorized persons from entering the area to reduce the negative outcomes in the incident.

The command and control actions taken depend on both the responder's level of training and the resources available. They should be attempted without risk to the responder.

Surveying the Hazardous Materials Incident

After detecting the presence of hazardous materials in an emergency, and while initiating command and control activities, the next task is to survey or inventory the hazardous material incident. Completion of this task provides an inventory of the containment systems and materials involved, materials released, and surrounding conditions. This incident survey should be conducted from a safe distance, using aided vision, without exposure to the released materials.

The following steps should be completed during the survey of a hazardous material incident:

1. *Identify each containment system by type, identifier, and size.* Containment systems fit into one of three types: (1) nonbulk, (2) bulk, or (3) facility containment systems (Table 13.8.4). The containment system identifier (e.g., facility or carrier name and number) is used to differentiate one containment system from another and to allow tracking of that container throughout the incident. The quantity within, or capacity of, the containment system can be obtained from markings on the container or entries on the shipping papers or facility documents. The quantity information will help indicate the magnitude of the problem.

2. *Identify the name, identification number, or placard applied to each hazardous material containment system.* This information provides a means of accessing various sources of hazard and response information.

For facilities. Sources for identifying the material include pre-emergency planning document, markings and color, contact with the facility manager, and review of appropriate MSDS.

TABLE 13.8.4 Types of Nonbulk, Bulk, and Facility Containment Systems[4]

Transportation		*Facility Containment Systems*
Nonbulk	*Bulk*	
Bags	Bulk bags	Buildings
Bottles	Bulk boxes	Machinery
Boxes	Cargo tanks	Open piles (outdoors and indoors)
Carboys	Covered hopper cars	Piping
Cylinders	Freight containers	Reactors (chemical and nuclear)
Drums	Gondolas	Storage bins, cabinets, or shelves
Jerricans	Intermediate bulk containers (IBCs)	
Multicell	Pneumatic hopper trailers	
Tanks and storage vessels packages	Portable tanks and bins	
Wooden barrels	Protective overpacks for radioactive materials	
	Tank cars	
	Tank containers	
	Ton containers	
	Van trailers	

In transportation. The identity of the hazardous material can be determined from the identification number, commodity stencil, type of placard or label applied, shipping paper entries, and manufacturer, shipper, or consignee contacts using the 24-hour emergency telephone number on the shipping papers. Pipeline markers provide the name of the commodity or at least the name and telephone number of the pipeline company.

3. *Identify leaking containment systems.* Clues indicating leakage include material on the outside of the containment system, taste or smell, the presence of vapor clouds, or the operation of a pressure relief valve. If possible during the survey, note the form of the released material (solid, liquid, or gas) and the location of the release.

4. *Identify the surrounding conditions.* Surrounding conditions should be noted when surveying hazardous material incidents. These conditions include topography, land use (including utilities and fiber optic cables), accessibility, weather conditions, bodies of water (including recharging ponds), public exposure potential, and the nature and extent of injuries. If a facility is involved, look for information about floor drains, ventilation ducts, air returns, and so on, as appropriate.

For ease of collection, recording, and interpretation of information obtained during the survey of an incident, a hazardous material incident survey form or similar form may prove helpful (Figure 13.8.7).

Finally, the information collected in the incident survey should be reviewed to verify its accuracy. For example, if the shipping paper identifies the material as a gas and a solid is being released, some of the information obtained may not be correct. An understanding of the characteristics of various containment systems will help to verify information on the contents.

Collecting and Interpreting Hazard and Response Information

Once a hazardous material is identified, information about the material's hazards, behavior characteristics, and suggested response options is collected. This information, which may be collected simultaneously with determining the extent of containment system damage, is used to predict the behavior of that material. The information to be collected is divided into six basic groups: (1) material identification information, (2) physical properties, (3) chemical properties, (4) physical hazards, (5) health hazards, and (6) response information. The task of obtaining, recording, and interpreting hazardous material information can be lengthy and rigorous. Various forms are being used to record hazard and response information (Figure 13.8.8).

A number of resources are available for this task, including the following.

Printed Materials. Printed materials include various response guides and MSDSs.

Various *response guides* are available for use in obtaining hazard, behavior, and response information. A listing of the sources of the most common response guides is found in Table 13.8.5. As one will note from the X's in Table 13.8.6, no one printed material source provides all the information. Therefore, more than one resource may have to be consulted to obtain the needed information. An understanding of the type of information available from each resource is important. These references augment personal knowledge and experience.

Material safety data sheets (MSDSs) are available at facilities from the manager or other facility personnel and may be found in transportation. CHEMTREC, the Chemical Transportation Emergency Center, has more than 500,000 MSDSs on file if one is not available locally. MSDSs typically provide the following types of information:

1. Physical and chemical characteristics
2. Physical hazards of the material
3. Health hazards of the material
4. Signs and symptoms of exposure
5. Routes of entry
6. Permissible exposure limits
7. Responsible party contact
8. Precautions for safe handling (including hygiene practices, protective measures, and procedures for cleanup of spills or leaks)
9. Applicable control measures including personal protective equipment
10. Emergency and first aid procedures

Technical Resources. A number of technical resources are available, including the following:

1. CHEMTREC is part of the American Chemical Council (ACC). CHEMTREC operates around the clock to receive toll-free calls from the United States and Canada through a wide-area telephone service number (800) 424-9300. If in Washington, DC, or Alaska, call (202) 483-7617. CHEMTREC can usually provide immediate hazard information from the CHEMTREC files. CHEMTREC will also contact the shipper; therefore, be prepared to provide CHEMTREC with the following information when available:

- Caller's name and phone number where caller can be reached
- Name of the carrier, shipper, manufacturer, or facility operator
- Nature, location, and time of the incident
- Name of the material (or other identifying information)
- Container type, railcar or truck number, vessel name, or other identifying information such as a railcar's reporting marks (initials) and number

CHEMTREC can also provide a teleconferencing bridge, connecting technical specialists with those needing technical information.

2. *National Response Center* (NRC), operated by the U.S. Coast Guard, receives reports required from spillers of hazardous substances. The NRC also acts as the notification, communications, technical assistance, and coordination center for the National Response Team. After receiving a report, the NRC will immediately relay the information to the responsible, predesignated, federal on-scene coordinator and other resources of

7. *Hazardous material emergency response teams.* Assistance from these sources ranges from immediate telephone advice to the dispatching of emergency teams to actual assistance in field operations. Some common examples include the following:

- Pesticide Safety Team Network
- CHLOREP Teams
- U.S. Coast Guard Strike Teams
- Carrier Response Teams

- U.S. Environmental Protection Agency Regional Response and Technical Assistance Teams
- Association of American Railroads, Bureau of Explosives

On contact with these resources, provide as much information as possible; especially the full name, form, use, and concentration of the chemical, when available. An occupational-health physician may be required to obtain or interpret information from any of these sources. Assistance in contacting many of these technical resources may be obtained from CHEMTREC or the NRC, if not listed in the local planning documents.

Assessing the Extent of Containment System Damage

Information on the types and extent of damage to a containment system is used in predicting the likely behavior of the containment system and its contents. This task can be initiated simultaneously with collecting information about the materials involved. Provide appropriate personal protective equipment for the response personnel if they could be exposed to released materials. Contact technical personnel with knowledge of the type of containment systems involved for assistance.

The following steps will help determine the extent of damage to a containment system:

1. *Identify containment systems that are damaged.* Indications of damage include abnormal orientation or position of the containment system, damage to other containment systems in the area, or a change in shape of the containment system.

2. *Determine the construction of the damaged containment system.* Before inspecting the damaged containment system, review the containment system's basic design, construction, and secondary containment features.

3. *Determine the type and location of closures on the containment system.* Review the closures on the containment system by name and purpose. Use of standard terminology will help describe the problem to the technical resources.

4. *Determine the type and location of any damage to the container or its closures.* Dents, cracks, gouges, scores, corrosion, and punctures should be noted. Using appropriate personal protective equipment when necessary, the containment system must be evaluated for signs of failure or potential failure. If the containment system has not already failed, it may have been weakened and result in failure.

5. *Determine the extent of the damage to the container or its closures.* Information on the extent of damage (e.g., the radius of curvature for dents or the depth of scores and gouges on pressure tank cars) should be determined. It may be necessary to determine the pressure in a bulk packaging or facility containment system using either a pressure gauge or the temperature of the contents.

6. *Estimate the release rate.*

Figure 13.8.9 provides an example of a form used for determining the extent of damage to tank cars.

Predicting Likely Behavior

After information on the characteristics of the material and the extent of damage to the containment system has been collected, the next task is to predict their likely behavior. This prediction, or "mental movie," is used throughout the response activity as a reference point. A mental movie is made for each containment system and hazardous material involved and is based on the worst possible case. As additional information is obtained, the mental movie is modified. The steps for predicting the behavior of the containment system and its contents include the following:

1. *Identify the types of stress or potential stress on a containment system and/or its contents.* Stress is the applied force or system of forces that tend to strain or deform a body (either the containment system or the contents). The types of stress include thermal, mechanical, chemical, irradiation, and etiologic. Thermal, mechanical, and chemical stresses can typically be identified visually, whereas irradiation and etiologic are more difficult to identify. Considerations include type and characteristics of the containment system, type of stress, amount of stress applied, intensity of stress, and duration of stress.

2. *Predict the way in which the containment system will breach.* A breach is an opening (failure) caused by damage to the containment system through which matter and/or energy can or does escape. The types of breach include disintegration, runaway linear cracking, closures that open up, punctures, and splits or tears. Considerations include type and duration of the stress being applied, behavior of the containment system under the stresses applied, behavior of the contents, location of the applied stresses, force of opening of the containment system, size of breach, and speed of the breach event. Even if the containment system has already breached, this prediction step must be considered in light of a further breach.

3. *Predict the way in which the contents will be released.* Release is the escape of the contents through a breach in a containment system. The types of release include *detonation*—the disintegration of the containment system and/or detonation of the contents; *violent rupture*—the runaway cracking of the containment system or the rapid expansion of the contents that burst the containment system abruptly; *rapid relief*—pressurized flow of the contents through closures, splits or tears, and punctures; and *spill or leak*—gradual flow through closures, splits or tears, and punctures. Considerations include type of breach, location of breach, quantity of contents, flow characteristics of contents, release rate, length of release, and weather conditions.

4. *Predict the dispersion pattern that will create the engulfed area.* Dispersion is the scattering of the matter and/or energy (from the point of release) to form an engulfed area. The engulfed area is the actual or potential area of exposure from a hazardous material or its containment system. The types of dispersion patterns include hemisphere, cloud, plume, cone, stream, pool, and irregular. Considerations include type of release, form of the released contents, weather conditions, topography, release rate, solubility of material, secondary reactions,

melting point, freezing point, boiling point, vapor density, specific gravity, secondary containment, vapor pressure, and expansion ratio. For fixed facilities, consider tank spacing, impoundment and diking, tank venting and flaring systems, transfer operations, monitoring and detection systems, and fire protection systems.

5. *Predict the length of contact that exposures will have with the released contents. Contact* means to be exposed to something undesirable or injurious. Type of contact is considered in relation to time: short term refers to minutes and hours; medium term is associated with days, weeks, and months; and long term is in terms of years and generations. Considerations include form of the material on release, dispersion pattern, weather conditions, topography, distance to exposure, barriers or shielding, speed of dispersing materials, and quantity released.

6. *Predict the hazards that will cause harm.* Harm is the injury or damage caused by being exposed to the hazards of the released contents. Types of hazards include physical hazards, including thermal and mechanical effects; and health hazards, including chemical (poisonous, corrosive, and asphyxiation), radiation, and etiologic effects. Considerations include hazards associated with the released contents, concentrations of released materials, duration of contact, and how often the exposures will come into contact with the released materials.

To assist in predicting the behavior of the containment system and its contents, a behavior model form is suggested (Figure 13.8.10).

If unable to make all the predictions necessary to analyze the incident, seek help from the following resources: manufacturer, shipper and consignee, carrier, and federal, state, and local agencies involved with hazardous materials. A number of response guides also indicate the effects of mixing various chemicals.

Estimating Outcomes

This final task in the analysis process results in an indication of the magnitude of the problem in terms of outcomes within the engulfed area. The engulfed area is the actual or potential area of exposure from a hazardous material. The following steps should be taken to estimate outcomes in the engulfed area:

1. *Determine the dimensions of an engulfed area.* Using the Table of Initial Isolation and Protective Action Distances in the *Emergency Response Guidebook,* planning documents, or dispersion modeling programs, identify the potential size of the dispersion pattern (Table 13.8.7). Considerations include wind speed and direction and topography.

2. *Estimate the number of exposures within the engulfed area.* Exposures include people, property, the environment, and critical systems. Considerations include direction of wind, time of day, day of the week, setting (rural or urban), occupancies in area (schools, businesses, industry, transportation), bodies of water, sewer systems, and essential services.

3. *Determine the concentrations of a released hazardous material within the engulfed area.* Resources, such as monitoring equipment, computer dispersion modeling systems, toxic chemical release reporting forms, and a programmable calculator with equations, are available for this step. Information about odor may provide an insight on the level of concentration, but not without risk.

In some cases, monitoring equipment may be used to identify or classify unknown materials, verify the identity of hazardous materials, or determine the concentration of the hazardous materials. Monitoring equipment includes, but is not limited to, the following:

- Colorimetric tubes
- CO meter
- Combustible-gas meter
- Organic-vapor analyzer
- Oxygen meter
- Passive dosimeter
- Personal air-monitoring equipment
- Photoionization detectors
- pH papers and strips
- Radiation-detection instruments

Where monitoring equipment is available, personnel should be able to select the appropriate monitoring equipment considering its limitations, perform field testing procedures, operate the equipment to collect data, and record and interpret the results. If monitoring equipment is not provided, the potential sources of monitoring equipment and personnel to operate the equipment should be identified as part of the pre-emergency planning activities.

4. *Predict the extent of physical, health, and safety hazards within the engulfed area under the current conditions.* Predicting health hazards requires an understanding of the various exposure limits, including (1) immediately dangerous to life and health value (IDLH), (2) lethal concentrations (LC_{50}), (3) lethal dose (LD_{50}), (4) permissible exposure limit (PEL), (5) threshold limit value-ceiling (TLV-C), (6) threshold limit value-short-term exposure limit (TLV-STEL), and (7) threshold limit value-time weighted average (TLV-TWA).

5. *Predict the areas of potential harm within the engulfed area.* Considerations address likely concentrations, lethal concentrations, length of contact, frequency, and intensity of harm.

6. *Estimate the outcomes within an engulfed area* (Figure 13.8.11). Considerations include number of exposures in the engulfed area, age and condition of the exposures, anticipated reaction of exposures on contact with material, and weather conditions.

The purpose of analyzing the hazardous material problem is to determine the likely magnitude of the problem in terms of outcomes. Although time consuming, this process is an essential part of managing a hazardous material incident. As the incident conditions change, analysis information must be reviewed and updated. When decisions regarding protective actions and control measures are made before completing the analysis process, the risk to the responder is greater.

PLANNING THE RESPONSE

Overview

Based on the magnitude of the problem, appropriate preventive measures and control actions are identified. Control actions include containment, confinement, and extinguishment. The potential impact (benefits and losses) to people, property, equipment, and the environment of each decision is considered.

The result of the planning process is the direction that the response effort will take to influence the sequence of events in the emergency and favorably change the outcome. Response planning is a process for identifying and evaluating response objectives (strategy) and response options (tactics). This process considers the available resources (e.g., personnel, personal protective equipment, and other tools and equipment). The planned response should be consistent with the local emergency response plan and the organization's standard operating procedures.

The planning process begins as part of the pre-emergency response planning efforts prior to the incident and continues on the scene of the incident, again from a safe location. Federal, state, and local agencies, industry, and carrier personnel may be called on to help.

The process of response planning is based on the following tasks:

1. Determine the response objectives.
2. Determine the available response options that could favorably change the outcomes.
3. Identify the personal protective equipment for the response options.
4. Identify an appropriate decontamination process for each response option.
5. Select the response options within the response community's capabilities that will most favorably change the outcomes.
6. Develop a plan of action including safety considerations.

Determining the Response Objectives (Strategy)

The first task in planning the response is to determine the response objectives (strategy) based on the estimated outcomes. The response objectives, based on the stage of the incident, are the strategic goals for stopping the event now occurring or keeping future events from occurring. The following two basic principles apply to these decisions:

1. One cannot influence events that have already happened or change the outcomes of those events.
2. The earlier that the event sequence can be interrupted, the more acceptable the loss.

The following steps should be taken when determining response objectives:

1. *Estimate the exposures that could be saved.* The level of response and the acceptable risk associated with a response is based on the exposures that can be saved. The number of exposures that could be saved is based on the estimated outcomes minus the exposures already lost (Figure 13.8.11).

2. *Determine the response objectives.* The response objectives, based on the stage of the incident, are the strategic goals for stopping the event now occurring or keeping future such events from occurring. Decisions should focus on changing the actions of the stressors, the containment system, and the hazardous material.

Determining Response Option (Tactics)

Two types of response options are available. Corrective actions are taken to resolve the immediate problem, whereas preventive actions are taken to prevent the immediate problem from escalating. The following actions are intended to keep losses to a minimum:

1. *Determine the potential response options available by response objective.* Response options are the tactical activities for stopping the event now occurring or keeping a predicted event from occurring. Response options are associated with the specific events in the emergency (Figure 13.8.12). An understanding of the procedures, equipment, and safety precautions for each technique is critical to this decision. Response options include one of the following types: defensive, offensive, and nonintervention. Control options involve either containment or confinement options. The responder must determine which type is appropriate for the incident based on the analysis of the problem.

Response Objective Analysis Form	Containment
	Material

Event Sequence

Stress	Breach	Release	Engulf	Contact	Harm

FIGURE 13.8.12 Response Objective Analysis Worksheet. This worksheet is used for identifying response options in a hazardous material incident by response objective (Source: Adapted from Ludwig Benner's *Hazardous Materials Emergencies,* 1978[6])

2. *Estimate how each response option will affect the outcomes.* Before a response option is selected, the effect of that response option or combination of response options on the sequence of events and ultimately the outcomes should be reviewed (Figure 13.8.13).

The response options must be based on their expected effect on the outcomes.

Identifying Appropriate Personal Protective Equipment (PPE)

The purpose of identifying appropriate personal protective equipment for each response option is to determine the equipment required to implement the various response options identified. Again, pre-emergency planning cannot be overemphasized in the selection of personal protective equipment.

Estimating Effect of Each Response Option Worksheet

Exposures/Harm	Amount that could be saved	Amount that could be saved with option 1	Amount that could be saved with option 2	Amount that could be saved with option 3	Amount that could be saved with option 4	Amount that could be saved with option 5	Amount that could be saved with option 6

FIGURE 13.8.13 Worksheet for Estimating Effect of Each Response Option. This worksheet is used for estimating the effect of each response option on the outcomes of the incident.

The following PPE-related definitions are used for the purpose of this chapter.

Personal protective equipment is protective clothing and respiratory protection used to shield or isolate a person from the chemical and biological, physical, or thermal hazards that may be encountered at a hazardous material incident. No single combination of personal protective equipment is capable of protecting against all hazards. Personal protective equipment should be used in conjunction with other protective methods, such as medical monitoring and environmental surveillance. For any given situation, personal protective equipment should be selected to provide an adequate level of protection. Both overprotection and underprotection can be hazardous and should be avoided.

Protective clothing includes those pieces of apparel that are designed to protect the wearer from dermal (skin and eye) contact with the hazardous material. Protective clothing is divided into the following types:

Chemical-protective clothing

- Liquid splash-protective clothing
- Vapor-protective clothing

High temperature-protective clothing

- Proximity suit
- Entry suit

Structural fire-fighting protective clothing

Respiratory protection is the equipment designed to protect the wearer from inhaling the hazardous material. Respiratory protection is divided into the following six types:

1. Positive pressure self-contained breathing apparatus (SCBA)
2. Positive pressure air-line respirators with required escape unit
3. Closed circuit SCBA
4. Powered air-purifying respirators (PAPR)
5. Air-purifying respirator (APR)
6. Particulate respirator

Breakthrough time is the time it takes for the hazardous material to move through the protective material.

Penetration is the movement of a chemical through zippers, stitched seams, or imperfections, such as pinholes, in a protective equipment material.

Permeation is the process by which the chemical dissolves in and moves through a protective clothing material on a molecular level.

Degradation is the physical decomposition of the material due to exposure to chemicals, use, or ambient conditions, such as sunlight.

The identification of appropriate personal protective equipment requires completion of the following steps:

1. *Determine the name, concentration, and hazards of each of the materials involved.* This information should have been developed during the process of analyzing the hazardous material problem.

2. *Predict the types of exposure associated with each response option.* The types of exposure include the following:

- Immersion (e.g., standing in or handling the chemical)
- Splash (e.g., splash of a liquid from a drum or decontaminating people or equipment coming in direct contact)
- Airborne (e.g., exposure to airborne chemicals as a result of sampling)

3. *Determine the level of personal protective equipment required.* This step provides a list of the required pieces of personal protective equipment, including suits, gloves, and boots. If the chief threat is through liquid contact, the protective clothing should resist chemical degradation and penetration. For a threat from vapor contact, the protective clothing may have to be airtight and impermeable. The minimum requirement for respiratory protection, set by OSHA in 29 CFR 1910.120, for emergency conditions at hazardous material incidents (until concentrations have been determined) is positive-pressure self-contained breathing apparatus.

The U.S. Environmental Protection Agency identifies the following four levels of protection:

- *Level A* is the highest level of protection and should be worn when respiratory, skin, eye, and mucous membrane protection is needed.

- *Level B* is the second highest level of protection and should be worn when a lesser level of skin and eye protection is needed. It is the minimum level recommended for initial site entries until the hazards have been determined by monitoring, sampling, or other reliable methods of analysis.
- *Level C* is the third highest level of protection and may be worn only when the type of airborne substance is known, concentration measured, criteria for using air-purifying respirators met, and skin and eye exposure is unlikely. Periodic monitoring of the air must be performed while working in level C.
- *Level D* is the lowest level of protection and is primarily a work uniform. It should not be worn on any site where respiratory or skin hazards exist.

Responders must understand the advantages, limitations, and use of each of the levels of protection at hazardous material incidents. If the appropriate level of protection is not available, arrange to obtain it from other resources.

4. *Identify chemically compatible materials for the chemicals involved.* Look for breakthrough times of at least 2 hours. A breakthrough time of 2 hours represents the normal physical limits of a responder's capacity for effective work in protective equipment. Resources for identifying chemically compatible materials include *Guidelines for the Selection of Chemical Protective Clothing*[8] or the *Quick Selection Guide to Chemical Protective Clothing,*[9] various emergency response guides, and chemical compatability charts provided by the manufacturers of chemical protective clothing.

Figure 13.8.14 provides a worksheet for recording chemically compatible materials identified.

5. *Match the material requirements with personal protective equipment provided or available.* Using chemical-compatibility charts provided with the protective equipment available, identify the available equipment that provides the required protection. Multiple materials can be layered to provide the appropriate level of protection.

6. *Identify the appropriate personal protective equipment needed for each response option.* Keep in mind the requirement for the buddy system and backup personnel. Considerations include availability of sufficient equipment in the appropriate sizes and the potential of multiple layers providing required protection. The use of personal protective equipment itself can create significant responder hazards, such as heat stress, physical and psychological stress, as well as impaired vision, mobility, and communication.

Identifying Appropriate Decontamination Procedures

With the potential that personnel, personal protective equipment, apparatus, and tools and equipment may become contaminated in a hazardous material incident, a decontamination (contamination reduction) process is established.

Decontamination (Contamination Reduction). This is the act of removing or neutralizing contaminants from equipment or personnel to preclude the occurrence of foreseeable adverse health effects outside the engulfed area. Possible decontamination options include absorption, adsorption, chemical degradation, dilution, neutralization, or solidification.

Decontamination procedures should be tailored to the specific hazards of the incident. They may vary in complexity and number of steps, depending on the level of hazard and the level of exposure to the hazard. The steps to be taken to select an appropriate decontamination (contamination reduction) process include the following:

1. *Identify what needs to be decontaminated.* This includes injured persons, response personnel, personal protective equipment, other equipment, and emergency-care facilities.

Chemically Compatible Materials Identification Worksheet

Chemical	Chemical concentration	Chemically compatible clothing material required		
		> 8 hr	> 2 hr	Less than ½ hr

FIGURE 13.8.14 Chemically Compatible Materials Identification Worksheet. This worksheet is for recording the chemically compatible protective clothing materials by hazardous material.

2. *Determine the contaminant and the type and amount of contamination.* Considerations include whether the material is organic or inorganic, in the solid, liquid, or gas form, a dermal or inhalation hazard, a local or systemic material, and whether the contaminant is life threatening, injurious, or irritating. Another consideration is whether physical trauma is involved.

3. *Seek appropriate advice.* Immediate decontamination guidelines are found in the *Emergency Response Guidebook*[7] (under first aid on the numbered guide pages), the NIOSH *Pocket Guide to Chemical Hazards,*[10] or local planning documents. Follow-up guidance can be obtained from local poison control centers, the shipper or manufacturer through CHEMTREC, or the Agency for Toxic Substances and Disease Registry.

4. *Identify methods for isolating and securing and then disposing of clothing and equipment that cannot be decontaminated.* The local emergency response plan or the organization's standard operating procedures provide guidelines on decontamination (contamination reduction) procedures. Other resources should be identified in pre-emergency planning activities. Follow-up resources include the Agency for Toxic Substances and Disease Registry, poison control centers, and the shipper or manufacturer through CHEMTREC.

Selecting Response Options

The selection of response options to change the outcomes favorably must be consistent with the local emergency response plan and the organization's standard operating procedures and also within the capability of available personnel, personal protective equipment, and control equipment. The steps to be taken in selecting the response options include the following:

1. *Determine the required resources to implement each response option.* Required resources include the time to implement the option, availability of sufficient personnel with the appropriate training, and appropriate personal protective equipment, materials for decontamination (contamination reduction) activities, and control equipment.
2. *Inventory the resources available and identify those resources available.* These resources should be readily accessible.
3. *Determine how to obtain the needed resources.* A review of the planning documents should provide these answers.
4. *Select the response option(s) consistent with the available resources.* Evaluate the potential reaction of the hazardous material to the control action and the ability to contain the side effects of the response option. Surrounding conditions, including topography and weather conditions, and response times can also affect the decision to select the response options.

Developing a Plan of Action

After selecting the response option for a hazardous material incident, a plan of action including safety and health considerations should be developed. This plan of action describes the response objectives and options and the personnel and equipment required to accomplish the objectives. The plan provides a permanent record of the decisions made at the incident. An organization's standard operating procedures provide the basis of this plan of action. Input from all segments of the response community is considered in developing the plan. Based on the specific incident conditions, the standard operating procedures are modified without having to write an entire plan for each incident.

A plan of action also outlines the safety and health procedures to protect responders and the public from the potential hazards at an incident. These procedures should address incident management, communications protocol (both internal and external), control zones for incident security, personal protective equipment use, decontamination procedures, and documentation. They also include designation of a safety sector and a safety officer, emergency medical care procedures, environmental monitoring, emergency procedures, and personnel monitoring.

Components for a typical plan of action include the following:

1. Site description
2. Entry objectives
3. On-scene organization and coordination
4. On-scene control
5. Hazard evaluation
6. Personal protective equipment
7. On-scene work assignments
8. Communication procedures
9. Decontamination procedures
10. On-scene safety and health considerations including designation of the safety officer, emergency medical care procedures, environmental monitoring, emergency procedures, and personnel monitoring

Response personnel at a hazardous material incident must recognize and understand the potential hazards associated with the incident. They must also be familiar with the procedures contained in the plan of action. Therefore, prior to working on-scene, all personnel must be provided a safety briefing. The safety briefing will describe the assigned tasks and their potential hazards, coordinate activities, identify methods and precautions to prevent injuries, and plan for emergencies. The plan of action can serve as a guide to this safety briefing.

The result of planning a response to a hazardous material incident is a plan of action consistent with the local emergency response plan and the organization's standard operating procedures and within the capability of the resources available. Development of a written plan ensures that all safety aspects of the response are thoroughly examined. Plans should be modified as necessitated by changing conditions on the scene.

IMPLEMENTING THE PLANNED RESPONSE

Overview

Once the plan of action is determined, response personnel must implement the response options in that plan. The following tasks are associated with implementing the planned response to a hazardous material incident:

1. Implement the incident management system (IMS).

2. Implement the selected protective actions.
3. Establish and enforce scene-control procedures.
4. Implement planned control actions.

Initiating the Incident Management System

The incident management system (IMS) is an organized approach to control and manage operations effectively at an emergency through a system of roles, responsibilities, and standard operating procedures. The incident management system should be developed as part of pre-emergency planning efforts, including the local emergency response plan and an organization's standard operating procedures.

One individual is in charge of managing the incident. This individual may delegate responsibility for performing various tasks to others on the scene. All communications are routed through the command post. Delegation of tasks may be by location or by function. Some of the functions include: medical services, evacuation, water supply, resources, media relations, safety, and site control. The incident management system reduces confusion, improves safety, organizes and coordinates actions, and facilitates effective management of the incident.

The National Incident Management System (NIMS) provides an example that includes the following elements of an incident management system used to coordinate response activities:

1. Common terminology
2. Modular organizations
3. Integrated communications
4. Unified command structure
5. Consolidated action plans
6. Manageable span of control
7. Predesignated incident facilities
8. Comprehensive resource management

Responders should understand the roles and responsibilities of the various positions in the local incident management system as defined in the local emergency response plan or the organization's standard operating procedures.

The incident management system includes the procedures for notification and use of other than local resources, including private, state, and federal government personnel. The incident commander should be familiar with and comply with the requirements of the following plans:

1. Organization's emergency response plan
2. Organization's standard operating procedures
3. Local emergency response plan
4. State emergency response plan
5. Regional emergency response plan, including the resources available from the regional response team
6. Federal emergency response plans

Response personnel should be aware of the primary local, state, regional, and federal government agencies and understand the scope of their regulatory authority (including the regulations) pertaining to the production, transportation, storage, and use of hazardous materials and the disposal of hazardous wastes. They should also be aware of private sector resources offering assistance during a hazardous material incident and identify their role and the type of assistance or resources available.

The incident management system should provide a focal point for information transfer to the media and local elected officials. A public information officer should be designated to provide appropriate information to the media and local, state, and federal officials.

Implementing Selected Protective Actions

Protective measures are those taken to preserve the health and safety of emergency responders and the public during an incident involving the release of hazardous materials. Protective actions include the following:

1. *Isolate the hazard area and deny entry.* Keep all persons away from the area if they are not directly involved in emergency response operations. Unprotected emergency responders should not be allowed within the isolation area. Planning documents should include techniques to isolate the hazard area and deny entry to unauthorized persons at hazardous material incidents.

2. *Evacuate persons in the threatened area.* Evacuation is defined as a process to "move all people from the threatened area to a safer place."[7] To perform an evacuation, there must be enough time for people to be warned, to get ready, and to leave the area. Even after people are evacuated, they should not be allowed to congregate on the perimeter of the control zones. Evacuees should be sent upwind to a definite place, by a specific route, far enough away so that they will not have to be moved again if the conditions change.

3. *Protect persons who cannot be evacuated in place.* In-place protection is defined as a "means to direct people to quickly go inside a building and remain inside until the danger passes."[7] Certain protective actions must be taken inside the building. In-place protection is used when evacuating the public would cause greater risk than directing them to stay where they are or when an evacuation cannot be performed.

Establishing and Enforcing Scene-Control Procedures

Scene-control procedures must be implemented quickly. Control zones (Figure 13.8.15), decontamination (contamination reduction) activities, and communication must be established and maintained throughout the incident. Personnel should move between control zones through access control points.

Scene control is established through the use of control zones based on safety and the degree of hazard. The hot zone is the area surrounding a hazardous material incident. It extends far enough to prevent adverse effects from hazardous material releases to personnel outside the zone. The warm zone is the area where personnel and equipment decontamination (contamination reduction) takes place. The cold zone is the area containing the command post and other support functions. Access to various zones is determined by need and level of personal protection provided as specified in the plan of action.

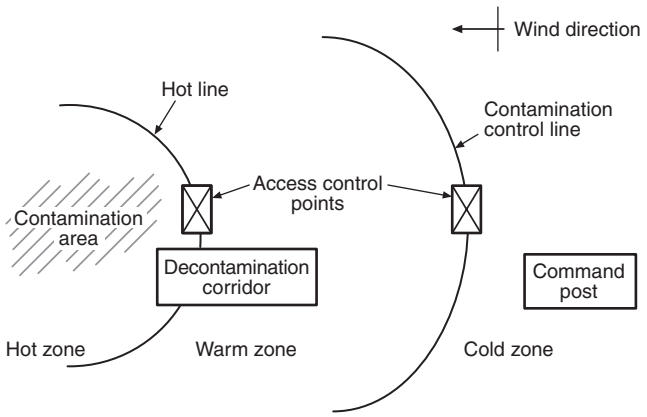

FIGURE 13.8.15 Control Zones

Extreme caution is necessary when providing emergency medical care to victims of hazardous material incidents.

Performing Control Functions

Responders are expected to perform control functions identified in the plan of action. They will have to select the tools, equipment, and materials for the tasks assigned. They should also understand the precautions for controlling releases from the containment systems involved.

In conjunction with their ability to use personal protective equipment, response personnel should be able to identify the symptoms of heat and cold stress. Response personnel should be aware of the physical and psychological stresses that can affect users of personal protective equipment. Personnel should be able to identify the signs and symptoms of exposure to any hazardous material involved. Response personnel should be able to record the use, repair, and testing of chemical protective clothing.

EVALUATING PROGRESS AND ADJUSTING ACCORDINGLY

The fourth and final duty in responding to hazardous material incidents is to evaluate the progress of the planned response—whether it stabilizes, intensifies, or otherwise changes. This duty evaluates the effectiveness of the following:

1. Personnel being used
2. Personal protective equipment
3. Established control zones
4. Decontamination process
5. Selected action options

A comparison of the actual behavior to that predicted indicates the effectiveness of the operations. Negative feedback initiates a re-evaluation of the situation, including another analysis of the problem, response objectives and options, and a modified plan of action. Positive feedback indicates successful operations; however, modification of the plan may still be necessary.

Termination

Termination of a hazardous material incident is that portion of incident management in which personnel are involved in documenting safety procedures, site operations, hazards faced, and lessons from the incident. Termination is divided into three phases: (1) debriefing the responders, (2) postincident analysis, and (3) critiquing the incident.[11]

Debriefing the responders is the process of reviewing a hazardous material incident focusing on the following factors:

1. Informing responders of any potential exposure to hazardous materials and the signs and symptoms associated with that exposure
2. Identifying equipment damage and unsafe conditions
3. Assigning information-gathering responsibilities for a critique
4. Summarizing the activities performed

Postincident analysis is the reconstruction of the incident to establish a clear picture of the events that took place during the incident. The postincident analysis focuses on four key topics: (1) command and control, (2) tactical operations, (3) resources, and (4) support services.

Critiquing the incident—emphasizing successful and unsuccessful operations—should be conducted with all response community members. The procedures for conducting a critique of a hazardous material incident should be in the local emergency response plan or the organization's standard operating procedures including written reports to management that suggest ways to improve future operations.

At the termination of the emergency phase, authority may be transferred to those responsible for the recovery activity in the incident. The local emergency response plan or the organization's standard operating procedures outline the steps for terminating the emergency phase of the incident.

Providing Reports and Subsequent Documentation

Responders to hazardous material incidents must comply with the reporting requirements of federal, state, and local agencies. All reports and other incident documents should be consistent with the local, state, and federal requirements.

Training records, exposure records, incident reports, and critique reports should become part of the file for the incident. An activity log and detailed exposure records should be maintained on each hazardous material incident. Typically, requirements for filing documents and maintaining records are found in the local emergency response plan and the organization's standard operating procedures.

SUMMARY

As with any emergency, favorably changing the outcomes requires a logical sequential process involving four duties: (1) analysis, (2) planning, (3) implementation, and (4) evaluation. Each of these duties is made up of tasks that need to be accomplished to complete that duty. Each task requires that

certain steps be performed to complete the task. The topics in this chapter describe the duties, tasks, and steps associated with managing the response to hazardous material incidents.

Fire Department's Role in EMS
EMS-Involved Organizations
EMS Organizational Models
System Performance Evaluation
Performance Evaluation Organizations
System Design Elements and Performance

Key Terms

advanced life support (ALS), ambulance service, basic life support (BLS), benchmarking, emergency medical responder, emergency medical services, emergency medical technician (advanced), emergency medical technician (basic), EMS coordinator, enhanced 9-1-1, medical control, medical director, medical first responder, paramedic, patient transport, process performance indicator index (PPII), response time performance

The fire service plays a significant role in the delivery of emergency medical services (EMS). During the past 50 years, fire service–based emergency medical services (EMS) has grown to be the principal operational delivery program in the majority of fire departments. In 2004, the 14.1 million EMS calls by local fire departments constituted 62 percent of total emergency responses, and the EMS share grows every year. In 2005, 67 percent of fire departments reported that they provide EMS response, up slightly from 65 percent in 2001. These departments protected 86 percent of the population, as most departments not providing EMS coverage were all-volunteer departments protecting rural communities. The term *cross-trained dual-role fire fighter* is generally being replaced by the recognition that fire fighters are the personnel who respond to the needs of their communities irrespective of the nature of the emergency.

As is the case with other fire department programs and responsibilities, the manner and degree of EMS system involvement is predicated to a great extent on the community being served. The recognition that "all EMS is local" is offset by the fact that common elements are applicable to all EMS systems. The core components of EMS systems were defined in legislation passed by Congress over 40 years ago. Since that time efforts by individual groups, including the American Ambulance Association (AAA), the International Association of Fire Chiefs (IAFC), the International Association of Fire Fighters (IAFF), the National Association of State EMS Directors (NAEMSD), the National Association of EMS Physicians (NAEMSP), the National Fire Protection Association (NFPA), and others, have expanded the understanding of EMS systems and the factors that define and influence the effectiveness and efficiency in the delivery of emergency medical services.

EMS is not a fast ride to an emergency room by ambulance nor is it singularly delivered by the fire department. It is a complex set of coordinated activities and responsibilities working in unison to deliver optimum service to a citizen in need of emergency medical care. NFPA 450, *Guide for Emergency Medical Services and Systems,* defines an EMS system as

> A comprehensive, coordinated arrangement of resources and functions which are organized to respond in a timely, staged manner to medical emergencies regardless of their cause.

Irrespective of the role of a fire department, from functioning as a first responder providing basic life support to one providing advanced life support critical care transport services, the adherence to accepted standards and measures of performance is essential to ensuring optimum patient care.

This chapter intends to provide the reader with an understanding of the role of emergency medical services delivery by fire departments. In addition, it identifies the various factors, standards, and performance measures that can be utilized by fire departments in their analysis and improvement of the emergency medical services program.

For related topics see also Section 12, Chapter 4, "Managing Fire-Rescue Departments"; Section 13, Chapter 2, "Organizing Rescue Operations"; and Section 13, Chapter 7, "Aircraft Rescue and Fire Fighting (ARFF)."

Jack J. Krakeel, MBA, is the chief of the Fayette County Department of Fire and Emergency Services, Georgia. During his 32 year career, he has been an advocate for fire-based EMS at the local, state, and national levels.

FIRE DEPARTMENT'S ROLE IN EMS

Historical Background

The delivery of emergency medical services by fire departments must be viewed within the historical and modern context of the fire service. Although the current nomenclature of prehospital or, if preferred, out-of-hospital emergency medical services was not defined until the genesis of modern EMS systems over 40 years ago, fire agencies across the country have routinely responded to rescues of all types since their founding with the delivery of first-aid services to those in need. The fire service's history in EMS is well documented within the history of departments such as Phoenix, Arizona, Chicago, Illinois, Columbus, Ohio, Miami, Florida, and others.

During the past 40 years, the evolution of the fire service to include EMS as an element of its core mission, "saving lives and property," has been the result of multiple factors, not singularly and simply the decline of fires. As early as 1976, communities across the country witnessed the lifesaving heroic actions of Squad 51 as the television series *Emergency* showcased the capabilities of trained Los Angeles County fire fighters delivering emergency medical care. The publication *EMS Agenda for the Future,* considered by many to be the second white paper in EMS, credits the show with being one of the influential factors of modern EMS system design.[1] The term *white paper* denotes the importance attached to the document in serving as a catalyst for change. The first white paper, published in 1967 and titled *Accidental Death and Disability: The Neglected Disease of Modern Society,*[2] functioned as the principal document from which modern EMS system improvements were generated.

Federal Funding. Whereas the period from the 1960s to the 1970s was known for the vast amount of federal funding committed to the development of EMS systems, the decade of the 1980s reversed that trend and placed the responsibility of supporting emergency medical services squarely on the shoulders of local government. Demand for service coupled with declining federal grant revenues resulted in many local governments turning to their fire departments for the delivery of EMS programs and services. Table 13.9.1 provides a summary of funding for the development of EMS systems.

Patient Transport. The consolidation of the patient transport industry during the decade of the 1990s resulted in further development of fire service–based systems as large corporate organizations shed nonprofitable transport service markets to focus attention on those environments conducive to corporate growth and consolidated market share.

The first few years of the new millennium have seen further strengthening of the fire department's role in EMS, specifi-

TABLE 13.9.1 Summary of Funding for EMS Systems

Legislation	*Time Period*	*Source*	*Amount*	*Explanation*
National Highway Safety Act of 1966 (Public Law 89-564, 23 U.S.C. 401)	1966–1973	Department of Transportation	Approx. $48 million	
National Highway Safety Act of 1966 (Public Law 89-564, 23 U.S.C. 401)	1966–1973	Department of Health, Education and Welfare (HEW)	Approx. $73 million	
Emergency Medical Services (EMS) Systems Act of 1973 (42 U.S.C. 300d)	1973–1976	Department of Health, Education and Welfare (HEW)	Approx. $50 million	
Emergency Medical Services (EMS) Systems Act of 1973 (42 U.S.C. 300d)	1973–1976	Health Resources Administration	Approx. $15 million	
	1974–1978	Robert Woods Johnson Foundation (private philanthropic foundation)	Approx. $14 million	Grants for the improvement of EMS systems
Omnibus Budget Reconciliation Act of 1981 (Public Law 97-35)	1981			Transferred federal funding of EMS to states through preventative health and health services block grants

cally through the absorption of third service municipal transport systems. Beginning during the mid-1990s, local governments' efforts to achieve cost savings through various economies of scale merged these agencies into their fire departments. Highly publicized mergers included those in New York, San Francisco, and St. Louis.

Development of 9-1-1 and E-9-1-1. Contributing to the multiple factors that influenced the widespread inclusion of emergency medical services within fire departments is the recognition of the development of 9-1-1 and enhanced 9-1-1 (E-9-1-1) systems throughout the country. As of late 2005, 98.5 percent of U.S. local fire departments, protecting 99.4 percent of the U.S. population, had some type of 9-1-1 service. What is more, 70.6 percent of U.S. local fire departments, protecting 86.7 percent of the U.S. population, had E-9-1-1 service. The growth of both 9-1-1 and E-9-1-1 since 1967 has resulted in this service being recognized as a fundamental and essential local government service. Responsibility for direct access to the EMS system through 9-1-1 has local governments and their elected leadership intrinsically involved in the EMS system design decision-making process.

The fire service has grown to be the largest provider of emergency medical care throughout the continuum of the EMS system from education and prevention, to system entry, through first response, and ultimately patient transport to a definitive care facility during the last 50 years. In light of the major demographic shifts (aging of the population) and new risks (terrorism, pandemics), there do not appear to be any major influences that will significantly alter the role of the fire service in responding to the emergency medical needs of their constituents.

Factors Influencing EMS Development

The emergence of modern prehospital emergency medical services and the widespread inclusion of fire departments in EMS can be traced to the middle of the twentieth century as a result of various factors that coalesced to define EMS as it is known today. These factors included (1) innovations and technological developments, (2) battlefield medical experience, (3) fire service attributes, (4) cardiac research, and (5) federal legislation and grant funding.

Innovations and Technological Developments. During the 1950s, Dr. Peter Safer, a noted physician trained in surgery and pathology, introduced the concept of airway control and artificial ventilation combined with external chest compressions that resulted in the lifesaving skill of cardiopulmonary resuscitation. In his groundbreaking work, Dr. Safer demonstrated that by training first responders and citizens in CPR, the opportunity for someone to survive cardiac arrest outside of traditional medical institutions could be improved. Dr. Safar authored the text *ABC of Resuscitation* in 1957.

Following the development of CPR and mass instruction to first responders and the lay community, researchers led by cardiologist Dr. Frank Pantridge from the Royal Victoria Hospital in Belfast, Ireland (1966), expanded on the work of researchers at Johns Hopkins Hospital in the development of portable cardiac defibrillators. Their innovation led to the institution of mobile coronary care units in Belfast. His efforts are generally considered to have led to the first mobile-based advanced life support (ALS) units to serve the general public.[3]

Battlefield Medical Experience. Concurrent with these innovations and technological developments were the experiences of military emergency physicians who served on the battlefields of Korea and Vietnam. They questioned why many of the lessons learned from the successes they witnessed in the combat theater, where early care was provided at the point of injury and forward medical bases (MASH) were used, could not be transferred to the civilian community. Drawing on their experiences, these physicians defined the country's failures for prompt and effective emergency care through a study conducted by the National Academy of Sciences, National Research Council's Committees on Trauma, Shock, and Anesthesia. Their publication was entitled *Accidental Death and Disability: The Neglected Disease of Modern Society.*[2] The first paragraph of the publication summed up the gravity of their findings:

> In 1965, 52 million accidental injuries killed 107,000, temporarily disabled over 10 million and permanently impaired 400,000 American citizens at a cost of $18 billion. This neglected epidemic of modern society is the nation's most important environmental health problem. It is the leading cause of death in the first half of life's span.[2]

Demonstrating the paucity of adequate ambulance services, the study stated:

> Adequate ambulance services are as much a municipal responsibility as firefighting and police services. . . . Very few communities provide sufficient financial support for adequate ambulance services. Where they are provided, they are usually maintained by the fire or police department. . . . First class ambulance service exists in few cities. Some such as the City of Baltimore employ highly trained full-time ambulance attendants with up-to-date vehicles and equipment as a separate mission of the fire department.[2]

Although many of the recommendations for improving care to the injured centered on hospital-based initiatives, some were specific to the out-of-hospital environment and applicable to the fire service community including the following:

- Extension of basic and advanced first aid training to greater numbers of lay population
- Preparation of nationally accepted texts, training aids, and courses of instruction for rescue squad personnel, police, fire fighters, and ambulance attendants
- Implementation of traffic safety legislation to ensure completely adequate standards for ambulance design and construction, for ambulance equipment and supplies, and for the qualifications and supervision of ambulance personnel
- Adoption at the state level of general policies and regulations pertaining to ambulance services

- Adoption at district, county, and municipal levels of ways and means of providing ambulance services applicable to local conditions, control and surveillance of ambulance services, and coordination of ambulance services with health departments, hospitals, traffic authorities, and communication services
- Delineation of radio frequency channels and of equipment suitable to provide voice communication between ambulances, emergency departments, and other health-related agencies at community, regional, and national levels
- Day-to-day use of voice communication facilities by the agencies serving emergency medical needs[2]

Fire Service Attributes. Individual fire agencies understood that they were uniquely positioned to embody many of the recommendations made by this pivotal study, recognizing that their organizations offered the following attributes in support of delivering emergency medical services:

- Dedicated and trained workforce
- Defined and practiced command/control functions
- Established communication systems
- Ability to function under emergency conditions
- Geographic deployment of assets and resources to respond in a time-sensitive manner
- Day-to-day involvement of responding to medical emergencies
- Public trust and confidence
- History of EMS service

Cardiac Research. Cardiac researchers in the United States, eager to expand the work of Pantridge, et al., engaged fire departments in their communities for the implementation of advanced mobile coronary care units. Cities and fire departments such as Seattle, Jacksonville, Los Angeles, Dayton, and others pioneered the concept of delivering advanced cardiac life support during this era. In 1966, the Columbus, Ohio, Fire Department introduced the concept of the "Heartmobile," considered to be one of the first advanced cardiac life support units (Figure 13.9.1). In their article on the evolution of prehospital care in the United States, the authors state: "Most of the early paramedic programs were based in fire departments."[4] In 1969, under the direction of Dr. Eugene Nagel, the Miami, Florida, Fire Department started the nation's first paramedic program.

Federal Legislation and Grant Funding. The publication of *Accidental Death and Disability: The Neglected Disease of Modern Society* served as the stimulus for the emergence of the federal government's role in EMS. Concurrently with the inclusion of payment for ambulance transport services in the Social Security Act of 1967, the focus on improving emergency medical care in the United States gained momentum, culminating with the passage of legislation designed to provide funding and guidance for the development of EMS systems across the country.

The first of the federal efforts to improve emergency care came about as a result of the passage of the National Highway Safety Act of 1966 (Public Law 89-564, 23 U.S.C. 401). Confronted with the reality that many of the injuries and deaths were directly attributable to automobile accidents, federal responsibility for EMS was placed within the Department of Transportation (DOT). Although there have been changes during the last 50 years, the principal federal agency charged with EMS responsibilities continues to reside within the agency responsible for roadway safety, the National Highway Transportation and Safety Administration (NHTSA). The National Highway Safety Act charged the DOT with the development of training texts and curriculum for basic emergency medical technicians (EMTs).

FIGURE 13.9.1 Heartmobile (Source: Courtesy of Columbus, Ohio, Fire Department)

Generally regarded as the most comprehensive EMS legislation passed was the Emergency Medical Services Act (EMS) Systems Act of 1973 (42 U.S.C. 300d). This landmark legislation promoted the development of regional EMS councils with specific responsibility for the coordination of EMS within their regions including ensuring adequate staffing, training, emergency facilities, communication, and transportation capabilities for persons in need of EMS services in their area. The 15 core elements or components of an EMS system were defined in the act. To receive federal block grant funding, the regional councils were required to meet the requirements of these 15 elements. The core components of EMS defined in 1973 continue to this day to serve as the basic building blocks of an effective and efficient EMS system design.

During the decade from 1966 to 1976, it is estimated that the federal government provided approximately $200 million for the improvement of EMS. The majority of this funding, administered by multiple federal agencies, was in the form of grants to states and local communities. Access to grant funds paved the way for the emergence of local government involvement in emergency medical services. Many local governments took advantage of the historic 75 percent federal and 25 percent local match grant program. This funding allowed for the acquisition of ambulances and equipment leading to a greater role of the fire service in delivering EMS within their communities. By 1976, morticians who prior to 1966 provided more than 50 percent of ambulance service in the country, had essentially been replaced by an array of public, private, and volunteer ambulance services.[4]

In addition to making grant funding available, the federal government developed the first series of ambulance design specifications. Currently known as KKK-1822E and administered through the Government Services Administration, the specifications and standards that continue to be used by the industry include vehicle style, design, and construction; performance characteristics; specifications for individual components such as the electrical system, oxygen delivery system, communication system; and optional and required medical equipment. The earliest units constructed in compliance with the first set of standards were marked with the distinctive "Omaha" orange stripe (Figure 13.9.2).

EMS-INVOLVED ORGANIZATIONS

During the 1980s, as the federal government's role in and funding for EMS systems waned, national organizations emerged to provide leadership for EMS systems and issues. Through collaboration and consensus-based processes, these and other organizations have essentially provided many of the standards and performance measures currently utilized by the industry.

International Association of Fire Chiefs (IAFC) and International Association of Fire Fighters (IAFF)

The International Association of Fire Chiefs (IAFC) was established in 1873 and has approximately 13,000 members. The organization provides leadership to chief officers and consists of both national and international membership. The association formed its first EMS committee in 1985; by 1991 the EMS committee had evolved as one of the largest sections within the organization. The International Association of Fire Fighters (IAFF) represents fire fighters in more than 3500 communities in the United States and Canada. Its membership of more than 274,000 members includes full-time professional fire fighters and paramedics who protect the lives and property of 85 percent of the nation's population. In 1991, the IAFC and the IAFF signed a joint memorandum of understanding (MOU) that defined the role of the fire service in the delivery of EMS.[5] The MOU initiated a series of collaborative efforts by both labor and management on emergency medical services issues of common concern to the fire service (Figure 13.9.3).

FIGURE 13.9.2 1970s Era Ambulance with Required Horizontal Orange Stripe (Source: Courtesy of Glenside Fire Protection District)

Commission on Fire Accreditation International

In 1995, the Commission on Fire Accreditation International was formed and included EMS as a core program that identified criteria and core competencies and performance indicators relative to EMS. Collaborative organizational fire service efforts with respect to EMS included transforming federal legislation that had the potential for inhibiting the role of fire departments in the delivery of emergency medical services. Of specific concern to the industry was the application of the 7K overtime exemption to medical services performed by fire departments. The Fair Labor Standards Act was amended in 1999 after joint efforts by the IAFC and the IAFF to reflect the role of fire fighters in the delivery of EMS. Historically, fire fighters were exempt from overtime compensation only in the performance of actual fire-fighting duties. Congress amended the act as a result of a redefinition of a fire fighter's duties by the Department of Labor that included emergency medical care. Known as Section 203(y), it states:

> "Employee in fire protection activities" means an employee, including a firefighter, paramedic, emergency medical technician, rescue worker, ambulance personnel, or hazardous material worker, who—
>
> (1) is trained in fire suppression, has the legal authority and responsibility to engage in fire suppression, and is employed by a fire department of a municipality, county, fire district, or State; and,
>
> (2) is engaged in the prevention, control and extinguishment of fires or response to emergency situations where life, property or the environment is at risk.[6]

In 2000, in a survey of its membership, the IAFC found that over 90 percent of fire departments participated in the delivery of emergency medical services.[7] This participation extended throughout the continuum of EMS care, including basic and advanced life support first responder services as well as over 50 percent of responding departments providing advanced life support transport services. These statistics are confirmed in the *Journal of Emergency Medical Services* (*JEMS*) publication in which its annual survey reflects that over 50 percent of the 200 most populated cities have fire department transport services and nearly all have either basic or advanced life support first responder services.[8]

National Association of State EMS Directors

In 2006, the National Association of State EMS Directors officially became the National Association of State EMS Officials, representing various state EMS agencies and their officials,

THE INTERNATIONAL ASSOCIATION OF FIRE CHIEFS
and
THE INTERNATIONAL ASSOCIATION OF FIRE FIGHTERS
JOINT RESOLUTION ON EMERGENCY MEDICAL SERVICES

WHEREAS, Pre-hospital emergency medical service is a major service provided by America's fire service, and;

WHEREAS, As first responders to most emergency situations, it is imperative that the fire service continue to provide pre-hospital medical care, and;

WHEREAS, The fire service has been hampered by lack of public recognition and support for its vital role in providing emergency medical care;

THEREFORE BE IT RESOLVED, That the leadership of the International Association of Fire Fighters and the International Association of Fire Chiefs agrees that America's fire service must continue to provide pre-hospital emergency medical care, and;

BE IT FURTHER RESOLVED, That the International Association of Fire Fighters and the International Association of Fire Chiefs urge all elected officials, professional associations and health care providers to recognize and support the provision of emergency medical care by the fire service.

Adopted by

Chief David W. Hilton, President
International Association of Fire Chiefs

Alfred K. Whitehead, President
International Association of Fire Fighters

FIGURE 13.9.3 IAFC/IAFF Joint Resolution on Emergency Medical Services

including state directors, medical directors, and training coordinators. It is considered a leading national organization for EMS, serving as an advocate for the development of effective, integrated, community-based, universal, and consistent EMS systems. In 2003, the National Association of State EMS Directors conducted a national EMS survey. The survey, completed by state EMS directors, reflected that with respect to EMS systems, approximately 48.6 percent are nonfire, non–hospital based, 44.9 percent are fire based, and 6.5 percent are hospital based.[9] Nonfire, non–hospital based services include private providers, volunteer agencies, and governmental services not affiliated with a fire department. State EMS agencies have fundamental responsibilities for the certification and recertification of EMS providers and the licensure of ambulance services.

EMS Standard-Developing Organizations

Between 1984 and 2005, the National Fire Protection Association (NFPA) developed and published various standards and guides for fire agencies specific to EMS. During this time period, other organizations made significant contributions to EMS. The American Ambulance Association developed the Commission on Accreditation of Ambulance Services. Its standards are utilized primarily by patient transport providers in an effort to be officially accredited by the agency. The National Association of EMS Physicians serves as the principal platform for the involvement of physicians certified in emergency medicine. Its initial efforts focused on the role, training, and certification of the medical director. The National Association of State EMS Directors and others took on a more visible role addressing the issues facing its constituencies, as examined earlier.

EMS ORGANIZATIONAL MODELS

Fire departments have generally been organized along functional lines of program and service delivery. The complexity of the organizational matrix depends on various factors, including agency size, community size, services being provided, and fiscal capability. Depending on these factors, an EMS organization within the fire department generally follows one of two matrices, which are delineated by the level of EMS being provided. A shared common element that exists between both transport and nontransport systems is that of medical direction. Service levels typically define the role of the agency within the system and represent either first response, transport, or both. Service levels are further defined based on level of care being provided, which generally parallels individual provider certification.

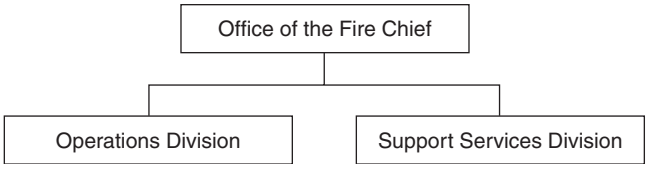

FIGURE 13.9.4 Typical EMS Organizational Model in Medical First Responder Fire Departments

Medical First Responder Fire Departments

In simple, less complex, and typically smaller organizations, such as those often found in rural and small municipal environments, duties and responsibilities for EMS administration and management are generally shared by existing personnel, both administratively and operationally (Figure 13.9.4).

Consistent with other operational programs, in this organizational model responsibility for EMS administration resides within the office of the fire chief. The fire chief has agency-wide responsibility for administrative functions, including planning, directing, controlling, and organizing the various aspects of EMS. In this model, the fire chief usually has a direct relationship with the medical director.

The operations division is generally responsible for the delivery of field programs such as fire suppression, hazmat, rescue services, and emergency medical services. Consistent with these duties are the day-to-day management of individual stations and companies.

The support services division includes all of the responsibilities to ensure that field programs have the essential resources and capabilities to fulfill their primary mission, including such functions as training, facility and fleet management, and supply and equipment management.

Patient Transport–Based Fire Department

The scope of responsibilities for EMS management and administration changes dramatically when the agency has responsibility for EMS transport services, irrespective of agency size. The complexities of patient transport require additional staff for the coordination of associated responsibilities, including medical direction and coordination, quality assurance, training and certification, billing, inventory control, equipment maintenance, and procurement. In smaller organizations that provide patient transport services, the position of an EMS coordinator is generally found within the support services division (Figure 13.9.5).

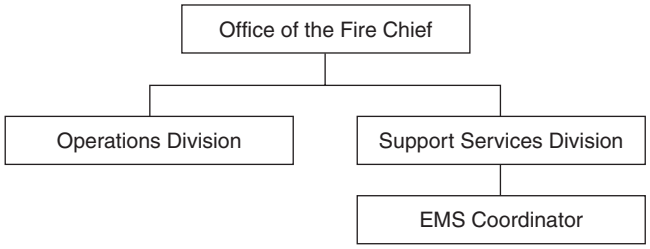

FIGURE 13.9.5 Typical EMS Organizational Model in Smaller Patient Transport–Based Fire Departments

Depending on agency size, the position of the EMS coordinator generally consists of a dedicated full-time position. In smaller organizations, it may be a shared position that includes EMS training in addition to coordinating the various aspects associated with patient transport activities. Organizations following this model are typically found in smaller communities and less densely populated environments.

In more complex organizations serving larger populations the organization typically reflects a divisional structure. These organizations are prevalent in urban and suburban environments (Figure 13.9.6).

The responsibilities for EMS administration and management are predicated on the recognition that certain functions must be carried in order for the system to be able to meet the demands of the population.

EMS Service Levels

The terms *service levels* and *level of care provided* are often used synonymously. Although there are parallels, service levels generally reflect the level of service being provided to a patient, which can consists of basic life support, advanced life support, or critical services. Service levels can be applied to both first responder as well as transport providing agencies.

Level of care can be defined as the provision of patient care services as determined by provider certification and licensure. Certification and licensure of personnel to perform within their specific scope of practice levels lie within the domain of

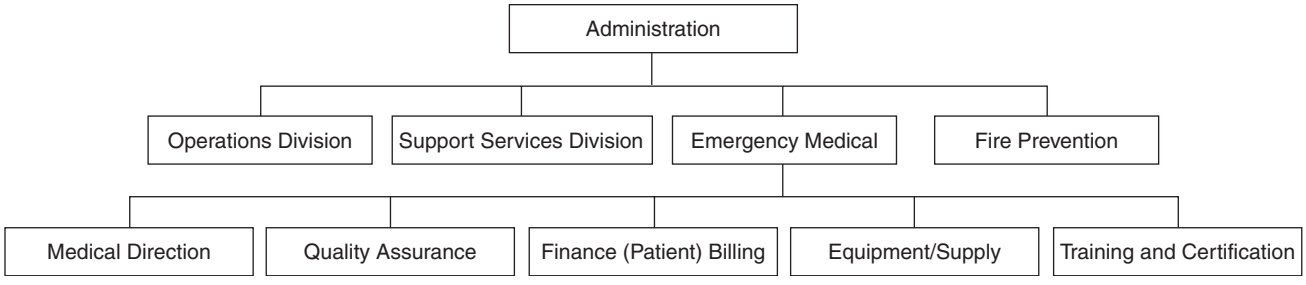

FIGURE 13.9.6 Typical EMS Organizational Model in Larger Patient Transport–Based Fire Departments

state and territory regulatory agencies. In addition, certification state and territorial agencies also govern the ability of agencies to provide services at a specified level and, depending on location, may include the authority to provide first response or patient transport services. These regulations and licensure requirements vary from state to state and are one of the reasons for the variation in EMS service delivery through the country. Although there are differences between the states and territories, certification levels include the following:

First responder
Basic emergency medical technician
Intermediate emergency medical technician
Paramedic

In addition to state and territorial rules and regulations, the Centers for Medicare Services also describe service levels for the purpose of patient transport reimbursement.[10] The establishment of the National Fee Schedule for Ambulances in 2002 defined CMS service levels as follows:

- *Basic Life Support Non-Emergency.* Scheduled transfer of patients from one facility to another requiring only basic life support services
- *Basic Life Support Emergency.* 9-1-1 call or equivalent response to a request for assistance requiring only basic life support services
- *Advanced Life Support Non-Emergency.* Scheduled transfer of patients from one facility to another requiring advanced life support services
- *Advanced Life Support Level 1.* 9-1-1 call or equivalent response to a request for assistance requiring advanced life support assessment services
- *Advanced Life Support Level 2.* Response to a request for assistance requiring advanced life support services that includes provision of at least one invasive procedure or administration of at least three separate medications
- *Critical Care Transport.* Provision of patient care services that exceed capabilities of a paramedic without additional training and certification

Within the fire service, there may be a single role such as that of a first responder or additional roles to include ambulance transportation. The level of care that certified fire fighters are capable of providing may encompass the entire spectrum from first responder certification to paramedic certification.

As of late 2005, 98 percent of U.S. local fire departments providing EMS service had all of their involved personnel certified to at least the first responder level. Also, 26 percent had all of their involved personnel certified to at least basic life support, and 87 percent had at least some involved personnel certified to that level. In addition, 3 percent had all their involved personnel certified to at least advanced life support, and 50 percent had at least some involved personnel certified to that level. Finally, no departments had all involved personnel certified to the level of paramedic, but 18 percent had at least some personnel certified to that level. For additional discussion and information on fire departments and organizational structures, refer to Section 12, Chapter 4, "Managing Fire-Rescue Departments."

SYSTEM PERFORMANCE EVALUATION

Performance Measures and Standards

The goal of any fire department should include a commitment to quality in its delivery of services. The quality process encompasses a number of activities, including the institution and use of various criteria by the department to measure its progress in achieving quality or modifying its program. These criteria may encompass performance measures, benchmarks, or standards.

Performance Measurement. According to the Joint Commission on Accreditation of Health Care Organizations (JCAHO):

> Performance measurement is used internally by health care organizations to support performance improvement and externally, to demonstrate accountability to the public and other interested stakeholders. Performance measurement benefits the health care organization by providing statistically valid, data-driven mechanisms that generate a continuous stream of performance information. This enables a health care organization to understand how well their organization is doing over time and have continuous access to objective data to support claims of quality. The organization can verify the effectiveness of corrective actions; identify areas of excellence within the organization; and compare their performance with that of peer organizations using the same measures. Similarly, performance data can be used by external stakeholders to make value-based decisions on where to seek quality health care.[11]

Benchmarking. Benchmarking is the process of emulating another agency's level of performance or excellence. Benchmarking can be valuable to an agency when comparative analysis reflects similar organizational attributes or service levels. Using benchmarking techniques reduces the time needed to implement best practices and reduces the potential for error in program implementation or modification.

Standard. A standard is generally defined as an accepted industry practice based on a consensus process that employs affected stakeholders in the development of the standard. Requirements may or may not be based on scientific research.

Efforts at developing performance measurements and standards within EMS that are designed to measure performance or serve as a basis for system improvement have been undertaken by various regulatory and nonregulatory agencies and organizations. The vast majority of these efforts have focused on consensus-based processes involving regulators, educators, practitioners, providers, and physicians.

System Performance Criteria

Efforts at developing system performance criteria have focused on how the system and the elements that define a system are functioning. EMS system evaluation can be conducted at the national, state, regional, and local levels.

EMS Performance Audit. The National Highway Transportation Safety Administration (NHTSA) routinely provides state EMS regulatory agencies with a process for evaluating their EMS system from a state perspective utilizing the core components of system design. Known as an EMS performance audit, the agency contracts with emergency medical service experts to conduct the audit of the state EMS administrative agency and through its efforts provide a blueprint for state EMS system improvement.

NFPA Standards and Guides. The National Fire Protection Association between 1984 and 2005 developed and published various standards and guides for fire agencies specific to EMS. These standards and documents include the following:

- NFPA 450, *Guide for Emergency Medical Services and Systems*
- NFPA 473, *Standard for Competencies for EMS Personnel Responding to Hazardous Materials Incidents*
- NFPA 1581, *Standard on Fire Department Infection Control Program*
- NFPA 1710, *Standard for the Organization and Deployment of Fire Suppression Operations, Emergency Medical Operations, and Special Operations to the Public by Career Fire Departments*
- NFPA 1999, *Standard on Protective Clothing for Emergency Medical Operations*

In 2001 the National Fire Protection Association established an EMS technical committee. As stated in NFPA 450, the committee's scope recognizes that it

> shall have primary responsibility for documents on the training and education requirements for personnel, personal protective equipment, health and safety programs, and quality assurance programs which incorporate physicians and the community in the planning process. It shall also be responsible for documents relating to emergency medical services, except those covered by other NFPA committees that have primary responsibility.

The committee's first effort resulted in the development of a comprehensive guide designed to assist individuals and agencies with a process for evaluating their EMS system. The application of NFPA 450 from a system's perspective can encompass local and regional systems. Although any analysis of an EMS system must recognize the core elements that have historically been defined to constitute an EMS system, other factors must be taken into consideration, including system design, finance, and medical direction.

NFPA 450 recognizes the following components as essential elements of an EMS system that are intrinsically linked and should therefore be coordinated:

- System regulation and policy
- Analysis and planning
- Finance
- Medical direction
- Quality management, clinical quality
- Public information, education, and relations
- Communications
- Equipment and facilities
- Human resources
- Operations

System Relationships

EMS organizations do not exist in a vacuum. Their success and ability to provide effective and efficient services are dependent on the various relationships the fire department has within the system's local domain. This system consists of multiple entities that impact the organization's ability to deliver quality services. Some of these relationships are reflected in Figure 13.9.7. As one can discern, these relationships are dependent on each other and any change in one can have an effect on the rest of the system. In order to quantify changes and their impacts, system analysis from both an historical as well as a prospective basis should be undertaken by the agency on a regular basis.

Response Time Performance. To illustrate the impact of the relationships that exist in a system when there is a lack of coordination, one can view the performance element of response time. Response time performance standards have existed for many years in the EMS industry, yet in many systems the ability to differentiate the contributions to response time from the various participants that make up a system's overall response time

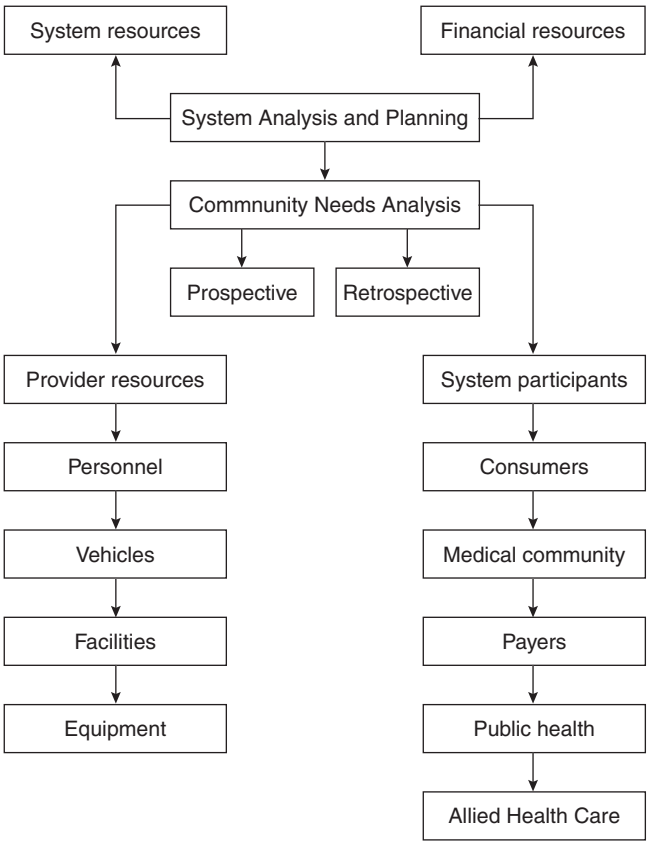

FIGURE 13.9.7 EMS System Relationships

do not exist or are not analyzed in the context of the contributing agencies. Without system coordination, analysis, and review, the time it takes a dispatch center to process a call, the turnout time of a first responder, the travel time to the scene of a transport unit, or the time it takes to turn a patient over to definitive care has little value in determining whether the system is performing consistent with expectations. Failure of any element of the agencies that contribute to response time performance can have a detrimental effect with respect to system performance.

Process Performance Indicator Index (PPII). Other efforts at developing a comprehensive identification of performance measures are ongoing. The Open Source EMS Initiative, an organization devoted to the collection of best practices and resource information for EMS agencies, has developed a draft of a comprehensive collection of areas for which EMS performance indicators should be established, including the following:[12]

- Administration/leadership
- Field operations
- Clinical care
- Medical direction
- Human resources
- Fleet management
- Supply management
- Dispatch and communications
- Information services
- Support services
- Prevention, community education, and access
- Special events and services
- Financial services
- Safety and risk management
- Research
- System measures

EMS Agenda for the Future

The *EMS Agenda for the Future,* a published federal document, consisted of a joint effort by the National Association of EMS Physicians and the National Association of EMS Directors to produce a vision for the future of EMS. The effort was funded through grants provided by NHTSA and the U.S. Department of Health and Human Services' Maternal Health Services Division. Utilizing experts from the industry, the *EMS Agenda for the Future* established a visionary blueprint for the progression and improvement of EMS in the United States. The document has been widely used by the federal government as its road map for providing a federal focus and improving EMS from a national perspective. Building on the efforts of the agenda, a companion document entitled *Emergency Medical Services Agenda for the Future Implementation Guide*[13] provides specific strategies, objectives, and responsibilities for implementing the vision. Other documents emanating from the agenda include the *Emergency Medical Services Education Agenda for the Future: A Systems Approach*[14] and the *National EMS Research Agenda.*[15] Both of these publications provide a blueprint for activities to improve EMS within their respective domains from a national perspective.

PERFORMANCE EVALUATION ORGANIZATIONS

During the last 20 years several accrediting bodies have been developed that wholly or partly have EMS-specific elements. Their efforts focus primarily on the individual agency. Generally included within their documents are requirements with respect to external relationships. The agency is required to demonstrate how they interact with organizations that impact their service delivery. Departments can voluntarily undertake accreditation as demonstration of compliance with accepted industry standards and performance and recognition of excellence.

Commission on Fire Accreditation International (CFAI)

Initiated by the International Association of Fire Chiefs and the International City-County Management Association, the Commission on Fire Accreditation International (CFAI) accredits fire departments internationally when they complete a self-assessment and peer review process of compliance with its criteria and performance standards. The accrediting body currently resides within the Center for Public Safety Excellence, Inc., an organization that also administers the Commission on Professional Credentialing. Provision of EMS as a core program of a fire department is included within the document. The Tempe, Arizona, Fire Department was the first agency to achieve CFAI accreditation. An essential component of the accreditation process is the development of a "Standard of Cover" document, which defines the agency's performance measurements for the various service delivery programs provided by the department.

Compliance with recognized performance measures can occur only when true system coordination exists and the individual participants in the system, from dispatch through definitive care, recognize their contribution and the critical role each plays to ensure the overall welfare of the patient needing emergency medical care. It should follow that the discussion of performance measures or standards for the various elements that constitute EMS should correlate to the progression of the medical event, the resources utilized to manage the critical care needs of the patient, and the contributors that provide resources and personnel in ensuring that the system is effective. Without ensuring that coordination exists in the various elements that make up an EMS system, ensuring quality or making improvements to the system would be difficult to achieve.

Commission on Accreditation of Ambulance Services (CAAS)

The first effort to accredit ambulance services was initiated by the American Ambulance Association. In May 1984, the AAA Board of Directors formed a committee on accreditation and standards. The standards developed by the committee represented a consensus-based process involving EMS officials from throughout the country. The efforts of the committee resulted in the formation of an independent Commission on Accreditation of Ambulance Services (CAAS) in 1990.

CAAS accreditation is based on the agency's seeking accreditation to demonstrate compliance with various standards and performance measures specific to the individual agency. The accreditation is focused on patient transport providers. In 1999, the Lubbock, Texas, Fire Department became the first fire-based transport provider to be accredited by CAAS. One of the most widely utilized performance measurements by the EMS industry identified in the document is 90 percent compliance with a response time performance of 8 minutes, 59 seconds (8:59) to life-threatening calls for service. This performance measurement is frequently used as a core requirement in contracts for patient transport services.

International Association of Fire Fighters (IAFF)

The International Association of Fire Fighters (IAFF) has developed a collection of performance measures specific to fire department–based EMS programs. Included are measures for call processing, turnout time, travel time, staffing, deployment, geographic coverage, protocol compliance, patient outcomes, availability of defibrillation, extrication capability, frequency of employee illness or injury, employee turnover rate, quality programs, and multicasualty response plans.

American Heart Association

According to its mission statement, the American Heart Association "is a national voluntary health agency whose mission is to reduce disability and death from cardiovascular diseases and stroke." Founded in 1924, the association has developed various programs specifically addressing cardiac care in the prehospital environment. The association, although not a standards-setting body, does publish peer-reviewed scientific journals and recommends changes to cardiac care based on scientific research. Within the prehospital environment, the American Heart Association offers specialty certification courses such as advanced cardiac life support, pediatric cardiac life support, as well as basic life support.

American Ambulance Association

The American Ambulance Association, founded in 1979, represents ambulance services across the United States. It is estimated that the association's membership serves over 75 percent of the U.S. population with emergency and nonemergency care and medical transportation services. The organization provides leadership services to its members and services as a voice and clearinghouse for ambulance services across the nation. The American Ambulance Association developed the "Contracting Guide for Ambulance Services," a document that contains various performance criteria for agencies involved in providing patient transport services. In addition, the document is designed to provide information on alternative system design and efficiencies.

American Society for Testing and Materials (ASTM) International

American Society for Testing and Materials (ASTM) International, one of the largest voluntary standards development organizations in the world, is a trusted source for technical standards for materials, products, systems, and services. The committee responsible for the development of these standards is known as the F30 Committee. ASTM has been developing EMS standards for the last 20 years, including the following:

- F1086-94(2002), *Standard Guide for Structures and Responsibilities of Emergency Medical Services Systems Organizations*
- F1149-93(2003), *Standard Practice for Qualifications, Responsibilities, and Authority of Individuals and Institutions Providing Medical Direction of Emergency Medical Services*
- F1224-89(2004)e1, *Standard Guide for Providing System Evaluation for Emergency Medical Services*
- F1268-90(2003), *Standard Guide for Establishing and Operating a Public Information, Education, and Relations Program for Emergency Medical Service Systems*
- F1286-90(2002), *Standard Guide for Development and Operation of Level 1 Pediatric Trauma Facilities*
- F1288-90(2003), *Standard Guide for Planning for and Response to a Multiple Casualty Incident*
- F1339-92(2003), *Standard Guide for Organization and Operation of Emergency Medical Services Systems*
- F1493-93(2003), *Standard Guide for Financing and Financial Accountability of Medical Transportation Systems*
- F1629-95(2007), *Standard Guide for Establishing Operating Emergency Medical Services and Management Information Systems, or Both*
- F1652-95(2007), *Standard Guide for Providing Essential Data Needed in Advance for Prehospital Emergency Medical Services*

SYSTEM DESIGN ELEMENTS AND PERFORMANCE

The Emergency Medical Services Systems Act of 1973 defined the essential elements of EMS system design. Although the core components have been modified, they stand largely intact as the fundamental elements of an EMS system. Performance measures and standards generally correlate to these elements. They include the following elements, some of which will be discussed here: public information and education, communications, human resources training, public safety, transportation, access to care, facilities, critical care, patient transfers, financial control, medical direction, quality management, resource deployment, record keeping, evaluation, disaster preparedness, mutual aid, and consumer participation.

Recognizing that there are multiple contributors to any EMS system, development of performance measures and standards has been predicated to a great extent on the contribution that each participant provides to the system and by the organizations that generally represent a specific professional constituency.

Public Information and Education

In the United States, the fire service has largely been successful in educating the general public and modifying the public's

behavior to reduce illness or injuries. Fire prevention efforts have been highly successful in reducing fire deaths and injuries. Similarly, efforts toward reducing injuries and death from non-fire-related causes have also been proven successful.

The role of the fire service in illness and injury prevention has progressed significantly in recent years. Although fire prevention continues to be a fundamental effort, programs such as NFPA's *Risk Watch*® that focus on injury prevention and reduction have been instituted in many communities, with the fire department often taking a leadership role.

Advances in technology, especially in the area of automatic external defibrillators, provide opportunities for departments to serve as the focal point for the institution of community automatic external defibrillator (AED) programs.

Benchmarking these and other similar programs provides the fire service with an excellent opportunity to expand its role in community education and prevention measures that focus on illnesses and injuries.

During the past five years, professional organizations such as the IAFC have expanded their role in providing leadership to fire departments by means of publications addressing preparedness for organizational and community health concerns. The impetus for the development of these documents varies, but the overall goal is to expand organizational awareness of the issues that departments and communities may face within the health care arena.

The first of these documents, published in 2001, is the *Fire Department Guide to Smallpox.*[16] The second document, published in 2005, is the *Fire Department Guide to Pandemics.*[17] Both of these documents provide organizational leaders with information and education to assist organizations in preparing for and managing health care crises in their communities.

Communications

The success of 9-1-1 to access public safety services and emergency medical care since the first system went into service in Haleyville, Alabama, in 1967[18] has been unparalleled from a public education perspective. The communication and dispatch centers serve as the primary access point for emergency medical care in most communities. Given this enormous responsibility, these centers and the personnel in their employ are recognized as being critical to ensuring that the appropriate resources and medical assistance are provided to constituents in need of EMS.

The *EMS Agenda for the Future,* a visionary document on how the future of emergency medical services may be constructed, utilizes the communication process diagram shown in Figure 13.9.8 to describe potential alternative decisions that could be made available in the future for EMS dispatch centers in order to optimize scarce response resources while simultaneously ensuring that callers' medical needs are appropriately met.

Dispatcher Certification. Various standards and performance criteria have been developed specific to the communication and dispatch function. In 1987, the NHTSA developed the curriculum for emergency medical dispatcher certification. The certification available through state training agencies provides the essential skills and knowledge base for individuals charged with the responsibilities of providing emergency medical care instructions prior to the arrival of response units.

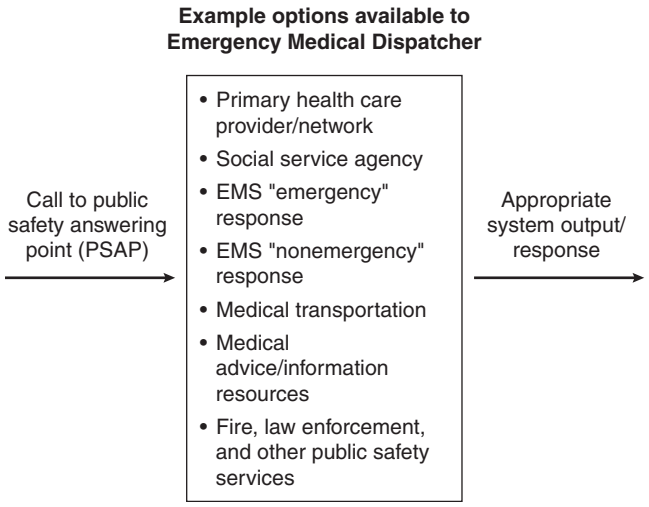

FIGURE 13.9.8 Sample Emergency Medical Dispatcher Options

Dispatching Protocols. Subsequent to the creation of the dispatcher curriculum, independent efforts have resulted in the development of standardized dispatching protocols designed to provide a hierarchical process for determining patient criticality and correlating prehospital care instructions. In 1987, Dr. Jeffrey Claussen developed a proprietary card system process that the dispatcher uses to ask specific questions. Based on the answers to the questions, the dispatcher is able to determine whether to dispatch basic or advanced life support units. The system also provides instructions in patient care for the dispatcher to relay to the patient or bystanders.

Using a process that allows for the identification of appropriate resource allocation is critical not only from a cost-containment perspective but also to ensure that the provider of transport services can recover revenues consistent with the dispatch of resources. The Centers for Medicare Services, through its modification of payment policies for Medicare patient transports in 2001, allows for the payment of advanced life support if the initial information provided to the dispatch agency indicated a need for an advanced life support response even though the patient may have needed only basic life support services.

Communication Standards and Performance Measures Resources. The principal organizations providing communication standards and performance measures include the following:

- *Association of Public-Safety Communications Officials (APCO).* The APCO Institute provides an Emergency Medical Dispatch program that is based on the *NHTSA National*

Standard Curriculum for EMD as well as ASTM International guidelines in a comprehensive EMD package. Emergency Medical Dispatch is a structured and sequential program that enables communication personnel to properly determine the nature and priority of an emergency medical call, dispatch the appropriate response, and provide the caller with specific medical self-help instructions to assist the patient until EMS personnel arrive.

- *National Fire Protection Association (NFPA).* NFPA 1221, *Standard for the Installation, Maintenance, and Use of Emergency Services Communications Systems,* is a standard for communication systems and facilities.
- *Commission on Accreditation of Law Enforcement Agencies* (*CALEA*). In 1996, CALEA and APCO collectively developed an accreditation program for public safety communications agencies. The CALEA *Accreditation Standards Manual* contains 216 standards designed to include the following categories: organization, direction and authority; human resources; recruitment and selection; training; and operations.
- *Commission on Fire Accreditation International* (*CFAI*). The CFAI, established in 1996, provides a voluntary accreditation program to fire departments encompassing 10 program categories that include performance indicators.

Response Time Performance Measurements

The ability to reach a victim of an accident or illness within time-sensitive parameters has long been a hallmark of the fire service. Strategically deployed resources throughout a community allow for rapid response to any emergency event. The single performance measurement most frequently utilized to measure an EMS system's performance is that of response time. The American Heart Association considers critical components of EMS systems to include appropriate access by citizens as well as timely dispatch of responders. According to the American Heart Association:

> Passage of time drives all aspects of emergency cardiac care and determines patient outcomes.[19]

Development of Response Time Standards. Initial efforts to establish response time standards were developed during the late 1970s by Dr. Michael Eisenberg. In his studies he found that patients who received CPR during the first 4 to 6 minutes followed by advanced emergency medical care in 8 minutes had a statistically higher probability of survival.[20] Since that time, the 8 minute standard for advanced life support has been universally adopted and reflected in community EMS system requirements and accreditation programs. In 1995, the Commission on Accreditation of Ambulance Services (CAAS) clarified its 8:00 minute standard to represent 8 minutes, 59 seconds.

NFPA 450 provides a comprehensive listing and definitions for response times including discrete time stamps, process intervals, and functional intervals. The identification of these measurements was established in an effort to create uniformity in how agencies define response time as well as the elements that constitute response time. In addition, acceptance and utilization of these values will facilitate system-to-system comparison and analysis.

Discrete Time Stamps. Discrete time stamps are identified as fixed points in time that can be captured electronically throughout the continuum of an EMS call. The value of these fixed points lies in the recognition that multiple system participants contribute to the overall lapse of time from the initial call to definitive care. These baseline points can then be aggregated and analyzed to determine system response time performance improvements as shown in Table 13.9.2.

Functional Intervals. Functional intervals represent the span of time during which specific functions are performed by system participants. The analysis of functional time intervals allows agencies and system administrators to determine whether any particular modification is necessary and designates the agency and personnel responsible for making improvements.

Process Intervals. Process intervals are designed to capture the time for the completion of specific elements within the system in accomplishing their objectives. The compilation and analysis of process intervals provide additional insight into overall system performance and whether there are unique circumstances or environments that have an impact on system performance.

Response Time Standards and Performance Measures Resources. The principal organizations providing response time standards and performance measures include the following:

- *Commission on Fire Accreditation International* (*CFAI*). CFAI's accreditation standard requires performance compliance of 60 seconds for turnout of personnel in urban and suburban communities to an emergency event.
- *National Fire Protection Association* (*NFPA*). NFPA 1710, *Standard for the Organization and Deployment of Fire Suppression Operations, Emergency Medical Operations, and Special Operations to the Public by Career Fire Departments,* establishes a 4 minute response time for the arrival of a unit with first-responder or higher capability to EMS calls and 8 minutes or less for an arrival of an advanced life support unit when such service is provided by the fire department. The standard further allows a 1 minute turnout time. Call processing time is covered by NFPA 1221, *Standard for the Installation, Maintenance, and Use of Emergency Services Communications Systems,* and requires that calls be handled in 60 seconds or less 95 percent of the time.
- *Commission on Accreditation of Ambulance Services* (*CAAS*). CAAS's accreditation standard allows 8 minutes, 59 seconds for arrival of advanced life support ambulance in urban and suburban communities from point of response unit notification of the event to life-threatening emergencies.
- *Centers for Medicare Services* (*CMS*). CMS provides a definition of an emergency response as one in which resources are mobilized and responding within the first 5 minutes from notification of the event. Definition is utilized to qualify for the payment of an emergency response versus a nonemergency request for Medicare-eligible patient transports.

TABLE 13.9.2 EMS Time Template

Column A *Discrete Time Stamps*	*Column B* *Function Intervals*	*Column C* *Process Intervals*
1. Event occurs	Recognition interval (1 to 2)	Call processing (4 to 11)
2. Discovery of event	System access interval (2 to 3)	System response (4 to 13)
3. Call for help	Switching interval (3 to 4)	Agency response (6 to 13)
4. Phone rings in 1st PSAP	Answer interval (4 to 5)	Unit response (11 to 13)
5. Phone "off hook" answered in 1st PSAP	Routing interval (5 to 6)	Patient contact (14 to 17)
6. Secondary dispatch phone rings (if appropriate)	Answer Interval (6 to 7)	Event to treatment (1 to 14)
7. Secondary dispatch phone "off hook" answered (if appropriate)	Interrogation interval (7 to 8)	On-scene management (13 to 15)
a. Interview begins	Resource selection interval (8 to 9)	Citizen reaction (1 to 3)
b. Pre-arrival instructions begin	Alert interval (9 to 10)	Unit cycle (11 to 18)
c. Pre-arrival instructions end	Acknowledgment interval (10 to 11)	Event elapsed (1 to 18)
8. Interview ends	Turn-out interval (11 to 12)	
9. Response resources identified	Travel interval (12 to 13)	
10. Dispatch time	Patient access interval (13 to 14)	
11. Unit acknowledgment	Scene management interval (14 to 15)	
12. Wheels turning (en route to scene)	Transport interval (15 to 16)	
13. Wheels stopped (arrived at scene)	Care transfer interval (16 to 17)	
14. Patient contact	Unit-ready interval (17 to 18)	
15. Wheels turning (en route to hospital)		
16. Wheels stopped (arrived at hospital)		
17. Transfer of care		
18. Available for service

Human Resources

The role of establishing educational criteria has largely been within the domain of the federal government through the National Highway Traffic Safety Administration (NHTSA). This statutory responsibility can be found in the Emergency Medical Services Systems Act of 1973.

Provider Level Skills and Knowledge. Since its initial development of the basic EMT curriculum, the NHTSA has undertaken various efforts to expand on the essential training and education for EMS personnel. In 1992, NHTSA developed the National Practice Blueprint designed to identify the essential skills and knowledge for each provider level:

- *First Responder.* Provision of care consistent with the guidelines prescribed in the *National Practice Blueprint for First Responder.* This certification level generally is limited to provision of basic first aid and CPR.
- *Basic EMT.* Provision of care consistent with the guidelines prescribed in the *National EMS Education and Practice Blueprint* for basic EMTs. This certification level is considered to be the minimum level of certification requirement to function on an ambulance. Many fire departments utilize this certification level as a requirement for their personnel in the same manner as NPQ FFI is required.
- *Intermediate EMT.* Provision of care consistent with the guidelines prescribed in the *National EMS Education and Practice Blueprint* for intermediate EMTs. This certification level serves to bridge the practice skills and capabilities of Basic EMTs and those of paramedics. Use of Intermediate EMTs is especially prevalent in areas where there is a lack of paramedics.
- *Paramedic.* Provision of care consistent with the guidelines prescribed in the *National EMS Education and Practice Blueprint.* The care and skills capability of this certification allows for the administration of various medications and invasive procedures such as intubation, pleural decompression, manual cardiac defibrillation, and other procedures as permitted under medical direction.

National Scope of Practice Model. In 2000, The National Highway Traffic Safety Administration convened a stakeholders' meeting to review EMS education comprehensively. Patterned after the highly successful *EMS Agenda for the Future,* the task force developed the *EMS Education Agenda for the Future.* Included in its findings and recommendations was the development of a *National EMS Scope of Practice Model.*[21] The work toward developing a National Scope of Practice Model was concluded in 2005. The model has recommended a new continuum of EMS providers that includes the following:

Emergency Medical Responder
Emergency Medical Technician
Paramedic
Advanced Practice Paramedic

The development of these new provider levels was based on a consensus process; thus the federal government does not have

any regulatory authority to require their adoption. Whether there will be widespread acceptance and adoption of the recommendations from the Scope of Practice task force will be determined by individual state regulatory agencies that generally have statutory authority over provider training, certification, and licensure.

Many states utilize testing and certification conducted by the National Registry of EMTs. The organization established in 1980 conducts comprehensive task analysis of provider skills. Through this analysis, the registry established testing materials and provides initial certification. Approximately 47 states and territories currently use the National Registry testing and certification process for personnel within their respective geographic areas.

Human Resource Standards and Performance Measurement Resources. The principal organizations providing human resource standards and performance measures include the following:

- International Association of Fire Fighters

  EMS Performance Measures
- State EMS Regulatory Agencies
- National Registry of Emergency Medical Technicians
- National Fire Protection Association

  NFPA 473, *Standard for Competencies for EMS Personnel Responding to Hazardous Materials Incidents*

Financial Control

Without appropriate financial controls and adherence to sound financial practices, EMS systems are subject to undue risk and potentially their demise. According to NFPA 450, EMS systems should have a comprehensive method for determining the cost of the EMS system. At a minimum the document recommends the establishment of an EMS financial plan that includes a cost analysis, short-term and long-term financial plans, and a financial reporting system.

Cost Analysis. A cost analysis should be conducted to study start-up costs, ongoing costs, and indirect costs:

Start-up costs. Generally include equipment, vehicles, supplies and materials, and personnel—including primary and support staff and training costs

Ongoing costs. Include equipment, vehicles, fuel, supplies and materials, communication systems, and personnel—including the cost of benefits, education/training, and certification costs

Indirect costs. Include insurance, legal services, medical oversight, contract services, regulatory compliance, billing services, and information management costs

Short-Term and Long-Term Financial Plans. Consistent with proper fiscal planning, the document identifies the development of a short-term financial plan, which consists of both an operating budget and a capital budget. A long-term financial plan should also be developed to insulate the agency from changes that can affect the organization fiscally. This plan should reflect new programs or services that are anticipated in the future, potential reimbursement changes, revenues, and cash flow projections. A contingency plan should be constructed if any of the analysis determines that the organization is at risk.

Financial Reporting System. Agencies that provide patient transport services should have a financial reporting system that provides the agency with information on the efficacy of revenue generation. Agencies should be able to identify and calculate gross billings, collection rate, payer mix, billing mix for advanced life support (ALS) and basic life support (BLS), scheduled and unscheduled transports, and miles per transport. The agency should be capable of determining bad debt expense, contractual allowances, write-offs, net revenue, revenues per transport, and accounts receivable turnover rate.

Finance Standards and Performance Measures Resources. The principal organizations providing finance standards and performance measures include the following:

- National Fire Protection Association

  NFPA 450, *Guide for Emergency Medical Services and Systems*
- American Ambulance Association

  Contracting Guide for Ambulance Services
  Medicare Compliance Manual
- Governmental Accounting Standards Board

Medical Direction

Medical direction is central to an agency's ability to provide patient services. Although there are exceptions, EMS personnel providing patient care are usually considered to be an extension of the physician and therefore require physician authority for the services they provide. Historically, physicians have provided their medical oversight services on a voluntary basis in the interest of patient care. However, with increasing demands on their time for the multitude of services being required of medical directors, the trend throughout the industry is to contract for and subsequently provide payment for medical director services.

The National Association of EMS Physicians (NAEMSP) and the American College of Emergency Physicians (ACEP) have been the principal agencies providing leadership and guidance for medical direction. In 2000, NHTSA in conjunction with NAEMSP and ACEP developed the National Standard Curriculum for Medical Direction.

Medical Oversight. Medical oversight provided by physicians encompasses the entire range of patient care activities provided by the EMS organization. The two principal functions of these services are online services and off-line services. Online services generally refer to medical control decisions affecting patient care at the time those services are provided. Off-line services refer to the additional services that the medical director

is engaged in, including protocol development, education and evaluation of personnel, administrative services, patient advocacy, medical community liaison, and participation in quality review and management processes.

Medical Direction Standards and Performance Measures Resources. The principal organizations providing medical direction standards and performance measures include the following:

- National Highway Transportation Safety Administration (NHTSA)
- National Association of EMS Physicians
- American College of Emergency Physicians
- National Fire Protection Association (see NFPA 450, *Guide for Emergency Medical Services and Systems*)

Quality Management

The process for ensuring that patient care services are delivered consistent with community expectations and organizational standards is known as quality management. The core component that drives the quality management program is the ability to generate meaningful data that can be analyzed, measured, and compared to established organizational expectations.

EMS Quality Management Elements. Elements of an effective EMS quality management program include conducting or measuring patient outcomes, effective review of clinical care, analysis and evaluation of system participant integration, human resource activities, data collection validation, and performance standard compliance. The process of quality management is ongoing, recognizing that changes based on the evaluation and analysis process require that change itself is monitored and evaluated to determine whether the desired results have been achieved.

Quality Management Standards and Performance Measures. The principal organizations providing quality management standards and performance measures include the following:

- National Fire Protection Association
  - NFPA 450, *Guide for Emergency Medical Services and Systems*
- National Highway Transportation Safety Administration (NHTSA)
  - *National EMS Information System*
  - *A Leadership Guide to Quality Improvement for EMS Systems*
  - *Uniform Pre-Hospital Data Elements and Definitions*
- National Institute of Standards and Technology
  - Malcolm Baldrige National Quality Award

Resource Deployment

The management of assets and resources in an EMS system is critical in ensuring effective and efficient delivery of services. In fire-based systems, resources are, with few exceptions, deployed from a fixed location. These locations are generally fire stations whose locations are routinely predicated on time and distance studies to meet specific response time objectives.

Deployment Models. In addition to fixed deployment models, variable deployment models are also used by the industry. These models are predicated on moving ambulance transport resources to various locations based on volume and location analysis. Time-of-day and computer-generated predictability patterns for call locations are also used to shift resources to predetermined points in the service area. This model of resource deployment, referred to as system status management, is routinely used by the private sector and by third-party service providers responsible for high-volume systems.

Tiered Response. The use of multiple agencies for the delivery of EMS is commonly referred to a tiered response. In a single-tier system, one organization has responsibility for response and care at a single level of care. Fire-based EMS transport systems fall into the single-tier category because they provide both the initial response as well as the patient transport at usually the advanced life support level of care. Multiple-tiered response systems are those in which an agency provides first response and initial care but delegates patient transport responsibilities to another entity. There are various types of multitiered systems; the most common is a fire-based first response system supported by a separate patient transport system provider, either public or private.

Resource Deployment Standards and Performance Measures. The principal organizations providing resource deployment standards and performance measures include the following:

- National Fire Protection Association
  - NFPA 450, *Guide for Emergency Medical Services and Systems*
  - NFPA 1500, *Standard on Fire Department Occupational Safety and Health Program*
  - NFPA 1710, *Standard for the Organization ad Deployment of Fire Suppression Operations, Emergency Medical Operations, and Special Operations to the Public by Career Fire Departments*
- American Ambulance Association
  - *Contracting Guide for Ambulance Services*
- International Association of Fire Fighters
  - *Effectiveness of Fire Based EMS*
  - *IAFF Performance Measures*
- American Society for Testing and Materials
  - ASTM F1224-89(2004)e1, *Standard Guide for Providing System Evaluation for Emergency Medical Services*
  - ASTM 1339-92(2003), *Standard Guide for Organization and Operation of Emergency Medical Services Systems*
  - ASTM F1517-94(2007), *Standard Guide for Scope of Performance of Emergency Medical Services Ambulance Operations*

SUMMARY

The evolution of EMS during the last 50 years has resulted in fire departments being the dominant provider of emergency medical care in their communities. The fire department's integration of EMS is not based singularly on a reduction in fire suppression activity but as a result of multiple factors. The factors responsible for the evolution of EMS and the fire service have been varied but are representative of local, state, and national issues. Fire departments have changed in concert with the environment in which they operate.

Successful delivery of EMS services by the fire department in the local community is dependent on the successful integration of multiple partners and a committed adherence to established standards and performance measures. As such, fire departments occupy a central role in responding to the emergency medical care needs of their constituents. Although changes are certain to occur in the industry, the delivery of EMS by fire departments is established and will continue to reflect a major operational program of the local fire department.

ACKNOWLEDGMENT

The late James O. Page is regarded as the "Father of Fire-Based EMS." His devotion and commitment to and advocacy of emergency medical services, particularly as a core service element of the fire department, are well known to those in the industry. He was a friend and mentor and his untimely passing will no doubt leave a great void in our profession.

Detection and Alarm

Shane M. Clary

14.1 Fire Alarm Systems
14.2 Automatic Fire Detectors
14.3 Notification Appliances
14.4 Fire Alarm System Interconnections
14.5 Inspection, Testing, and Maintenance of Fire Alarm Systems
14.6 Household Fire Warning Equipment
14.7 Fire Protection Surveillance and Security Services
14.8 Gas and Vapor Detection Systems and Monitors
14.9 Carbon Monoxide Detection in Residential Occupancies
14.10 Security and Intrusion Detection Systems

Historically, detection and alarm have been fire protection's first line of defense after an ignition has occurred. As technology has improved, fires and their by-products have been detected earlier and earlier. More recently, various forms of detection and alarm have become interconnected. At the same time, the fields of fire protection and security have grown closer together.

Section 14 of the *Fire Protection Handbook*® reflects the evolution of detection and alarm technologies. The 19th edition included the first chapter on carbon monoxide detection in residential occupancies. In this 20th edition, the section has been expanded to include a new chapter entitled "Security and Intrusion Detection Systems."

Chapter 1, "Fire Alarm Systems," describes types of signals and basic system components before explaining the basic types of systems: protected premises, central station, proprietary, remote station, and auxiliary. The chapter also discusses emergency voice/alarm communication systems and a new concept for the alerting of individuals, mass notification systems.

Chapter 2, "Automatic Fire Detectors," has been expanded to include video-based smoke and flame detection. After describing several types of detectors (heat, smoke, gas, radiant energy, and multisensor), the chapter discusses detector selection, installation, maintenance, and testing.

Chapter 3, "Notification Appliances," concentrates on notification devices that *NFPA 72*®*, National Fire Alarm Code*®*,* defines as fire alarm system components, such as bells, horns, speakers, and light or text displays that provide audible, tactile, or visible outputs (or any combination of those outputs). Mass notification systems and intelligibility are discussed.

Chapter 4, "Fire Alarm System Interconnections," presents the interface of process monitoring and building management systems (such as elevator control, door control, and heating, ventilating, and air-conditioning control) and fire protection systems.

Chapter 5, "Inspection, Testing, and Maintenance of Fire Alarm Systems," explains reliability analysis and prediction, as well as topics such as acceptance and reacceptance testing, a design lifetime, and sensitivity measurement. Schedules for system and component inspection, testing, and maintenance are presented.

Chapter 6, "Household Fire Warning Equipment," discusses why household fire warning systems are needed, the history of residential fire warning systems, research into system effectiveness, the importance of having a system in the home and how to make the best use of it, and the importance of an effective escape plan. Types of systems and detectors are covered, along with installation and testing guidelines.

The section considers the human element of detection and alarm in Chapter 7, "Fire Protection Surveillance and Security Services." This chapter discusses topics such as the management of security services, communications equipment, security service functions and supervision, security officers, and patrol routes and rounds.

Shane M. Clary, Ph.D., is vice-president of codes and standards compliance at Bay Alarm Company in Pacheco, California. He is the chair of the Technical Committee for the Fundamentals of Fire Alarm Systems, a member of the NFPA Standards Council, serves on a number of other NFPA technical committees, and is the author of the *NFPA Pocket Guide to Electronic Security System Installation.*

Chapter 8, "Gas and Vapor Detection Systems and Monitors," addresses the detection of flammable, combustible, or toxic gases and vapors that represent a hazard to the occupants or the facility.

The physical properties, sources, and hazards of CO are described in Chapter 9, "Carbon Monoxide Detection in Residential Occupancies." The chapter then outlines carbon monoxide standards and detection technologies and provides a discussion of fire service response to carbon monoxide alarms.

The section closes with a new subject in Chapter 10, "Security and Intrusion Detection Systems." This chapter provides a brief overview of premises security systems that are covered by two NFPA documents first approved in 2005: NFPA 730, *Guide for Premises Security,* and NFPA 731, *Standard for the Installation of Electronic Premises Security Systems.*

Chapter 1

Fire Alarm Systems

Wayne D. Moore

Chapter Contents

Selecting the System
Making the System Work
Types of Signals
Fire Alarm System Basics
Protected Premises System
Emergency Voice/Alarm Communication System
Central Station Fire Alarm System
Proprietary System
Remote Station System
Auxiliary System

Key Terms

auxiliary fire alarm system, central station fire alarm system, emergency voice/alarm communications, fire alarm control unit, fire alarm signal, fire alarm system, fire barrier, fire detection system, mass notification system, McCulloh system, proprietary supervising station fire alarm system, protected premises, remote supervising station fire alarm system, supervisory signal, trouble signal

A fire detection and alarm system is a key element among the fire protection features of any building. Because most fire deaths in the United States result from building fires, the use of fire detection and alarm systems in buildings can help to significantly reduce the loss of life from fire. Also, if properly specified, designed, manufactured, installed, maintained, tested, and used, a fire alarm system can help limit property fire losses in buildings, regardless of occupancy.

Strictly adhering to the requirements of *NFPA 72®*, *National Fire Alarm Code®*, is fundamental to maintaining an appropriate level of quality control through the steps that lead to the successful provision of a fire detection and alarm system. This document, working in concert with NFPA 70, *National Electrical Code®*, particularly Article 760 on wiring for fire alarm systems, forms the basis for requirements that have been created through the consensus standards-making process. These requirements represent the combined experience and professional judgment of the members of the eight technical committees that write the various chapters of *NFPA 72*.

This chapter discusses the philosophical basis for fire alarm system design, as well as the major operational characteristics of the various types of fire alarm systems currently in use.

For related topics see Section 14, Chapter 2, "Automatic Fire Detectors"; Section 14, Chapter 3, "Notification Appliances"; Section 14, Chapter 4, "Fire Alarm System Interconnections"; Section 14, Chapter 5, "Inspection, Testing, and Maintenance of Fire Alarm Systems."

SELECTING THE SYSTEM

In making the basic decision regarding what type of fire alarm system is needed for a particular building, certain questions must be answered. In answering these questions, one must bear in mind that the most successful approach to the overall protection of life and property is a holistic approach—an approach that relies on the fact that the protection provided by the sum of the individual components of the fire protection system will always be much greater than if one was to rely on each individual component alone. Thus, effective protection is a combination of interlocking, interrelated fire protection systems, designed to function in concert with each other to provide the desired level of protection.

It is not a matter of whether or not automatic sprinklers or a fire alarm system should be provided. Rather, automatic sprinklers, a fire alarm system, and proper building construction features such as fire barriers along with a host of other valuable prevention and protection features, all built on a foundation of management commitment to fire prevention and control, can assure a building owner or occupant that a facility is safe.

With this foundational truth in mind, fire alarm system selection must be based on answering the question: "What are the protection goals?" Is the building owner attempting to provide a level of life safety that will meet the needs of the people occupying the building and satisfy the requirements of the local building code and local authority having jurisdiction (AHJ)? Or is the building owner intent on providing a needed level of property protection? Or is the building owner trying to ensure that the mission of the facility is not interrupted by fire? Other protection goals include cultural/heritage preservation, environmental protection, and first responder safety. In most cases the development of the owner's fire protection goals will require a risk analysis of the property. A

Wayne D. Moore, P.E., is a principal and director of operations for the New England offices of Hughes Associates, Inc. He is chair of the Technical Correlating Committee on the *National Fire Alarm Code®* and is coeditor of the fire alarm newsletter *The Moore-Wilson Signaling Report.*

risk analysis involves identifying the most probable fire threats to the owner's property and then analyzing the impact of those fire threats on the building and operation.

The final answer may be "yes" to one or more of these questions. And, with each "yes" answer, the building owner will be guided to select the fire alarm system that will meet the needs of the facility.

MAKING THE SYSTEM WORK

Just as building fire protection is most effective when it consists of a series of interlocking, interrelated fire protection systems, ensuring the mission effectiveness or operational reliability of a fire alarm system is the result of specific attention given to a series of interlocking, interrelated steps:

- Specify
- Design
- Manufacture
- Install
- Maintain
- Test
- Use

Determining Goals

The user of the fire alarm system must define the reason why the system is being provided. This definition step will identify the protection goals of the user and also the external factors that may influence the fire alarm system installation. The user may determine that the protection goal is the preservation of the lives of the persons occupying the building. Such a *life safety goal* and the protection features it dictates will help determine the type of fire alarm system. Or the user may determine that the protection goal is the preservation of the physical building and its contents. Such a *property safety goal* and the protection features unique to this goal will also help determine the type of fire alarm system that can most effectively provide protection.

In analyzing the particular needs of a facility, the user may determine that the protection goal is the preservation of the ability to produce a product or provide a service. Such a *mission protection goal* will help determine the type of fire alarm system needed at the facility.

It may even be that the user determines that the protection goal actually embraces a combination of all three primary goals: (1) life safety, (2) property protection, and (3) mission protection. An analysis of how fire will affect the mission (business impact) involves identifying the critical business functions within the organization and determining the impact of a fire incident on that business function and whether or not the business can recover from the expected fire incident. Once the protection goals are clearly defined, the features of the fire alarm system can be determined. If the user simply wants to build his or her building to be compliant with the minimum requirements of the codes in force in the jurisdiction, the designer must still understand how the codes may combine to be able to properly design the fire alarm system to meet the user's needs.

Additionally the user may be a representative of the federal government and want a mass notification system (MNS) to be integrated with the fire alarm system. Care must be taken to ensure that the MNS and the fire alarm system operate as required. The MNS is the only system allowed to interrupt a fire alarm system to allow additional safety information to be announced to the occupants.

Generally speaking the user will not develop this information without consulting a fire protection engineer. The engineer will review the features selected to develop a clear and concise written set of specifications. These specifications will include the needed features and will include statements as to how the quality of the installation is to be ensured, including the initiating device, notification appliance, and signaling line circuit performance. This document will guide the system supplier in making recommendations regarding particular equipment, as well as guide the supplier by providing the required quality control measures.

Based on the specifications, a fire protection engineer working either as a consultant to the user or as an employee of, or consultant to, the system supplier can develop a detailed system design. *NFPA 72,* recognizes the need for trained designers and installers and provides guidance for both the owner and authority having jurisdiction to assist in determining if these individuals are qualified. Certification by a national organization is one of the recommendations of the code. By exercising care to ensure that the design meets both the specifications and the requirements of *NFPA 72,* the designer will greatly enhance the overall quality of the fire alarm system.

Meanwhile, the manufacturer of fire alarm system components has been studying the needs of fire alarm users and has developed products with a wide variety of features. The manufacturer will provide products of high quality that can meet the requirements of *NFPA 72* and pass the tests of the nationally recognized testing laboratories, such as Underwriters Laboratories Inc. (UL) and FM Global Research.

A qualified fire alarm system installer can now take the manufacturer's equipment that satisfies the user's specifications and the fire protection engineer's design and install a fire alarm system. The process of installation must also meet the requirements of *NFPA 72.* Quality assurance during installation is critical to the long-term usefulness and stability of the fire alarm system. There are several ways of ensuring installation quality and meeting the mission effectiveness goals.

Ensuring Installation Quality

To help ensure installation quality, UL has developed two fire alarm certificate programs. One certificate is for central station fire alarm systems. The other is for local, auxiliary, remote station, proprietary, and emergency voice alarm/communication systems. UL-listed contractors may apply to UL for a certificate covering the installation of a fire alarm system at a specific protected premises. The certificate describes the system, and states that the contractor has met the requirements of *NFPA 72* and the relevant UL standards. It further states that the contractor has a contract with the user for periodic testing and routine maintenance of the fire alarm system to ensure quality continuity. Periodically, UL representatives inspect a statistical sampling of certificated installations of each contractor to check on the accuracy of the information supplied on the certificate and to verify compliance with *NFPA 72* and relevant UL standards.

FM Global Research has developed a placard that the contractor may post at the fire alarm installation, stating that the

system has been installed to comply with the requirements of *NFPA 72* and the relevant FM requirements. When FM representatives visit facilities insured within the FM system, they look for this placard as an indication that standard fire alarm service has been provided.

Some AHJs require that installers demonstrate competency to install systems. Competency may be demonstrated by achieving certification through the National Institute for Certification in Engineering Technologies in fire protection, subfield fire alarms. The International Municipal Signaling Association also has an interior fire alarm certification program that has minimum competency requirements. Alternately, some AHJs may have developed an examination of their own that installers must pass. Many states, although not all, require that installers of fire alarm systems be licensed in that specialty in order to install these systems.

To ensure continuity of quality, a fire alarm system must be tested and maintained. *NFPA 72* sets forth the requirements for maintenance and testing in Chapter 10. Once again, the competency of the persons performing the testing and maintenance is critical to achieving an appropriate level of quality. (See Section 14, Chapter 5, "Inspection, Testing, and Maintenance of Fire Alarm Systems.")

Finally, just as the components of the fire alarm system must be listed by a nationally recognized testing laboratory for the specific use, the way the fire alarm system is used must conform to the requirements of *NFPA 72.* By carefully working through the steps (i.e., specify, design, manufacture, install, maintain, test, and use), the user of the fire alarm system will have a system that will serve the facility well for many years to come.

TYPES OF SIGNALS

Fire alarm systems may provide three types of signals: (1) alarm, (2) supervisory, and (3) trouble.

An *alarm signal* is a warning of fire danger that requires immediate action.

A *supervisory signal* indicates that action is needed in connection with the operation of other fire protection systems that are being monitored by the fire alarm system. Such systems may include extinguishing or suppression systems, such as automatic sprinkler systems, carbon dioxide systems, dry chemical systems, foam systems, and gaseous agent systems. They may also include the supervision of guards who make fire patrol tours throughout the protected premises. A supervisory signal may be either an "off-normal" signal, indicating a condition requiring attention; or a "restoration-to-normal" signal, indicating the condition that initiated the original off-normal signal has been resolved.

A *trouble signal* indicates a fault in a monitored circuit or component of the fire alarm system or the disarrangement of the primary or secondary power supply.

FIRE ALARM SYSTEM BASICS

Fire alarm systems are classified according to the functions they are expected to perform. Their installation, maintenance, and use are specified in *NFPA 72.*

The basic components of each system are:

1. A system control unit (Figure 14.1.1)
2. A primary, or main, power supply
3. A secondary, or standby, power supply
4. One or more initiating device circuits or signaling line circuits to which manual fire alarm boxes, sprinkler waterflow alarm initiating devices, automatic fire detectors, and other fire alarm initiating devices are connected
5. One or more fire alarm notification appliance circuits to which audible and visible fire alarm notification appliances, such as bells, horns, stroboscopic lamps, and speakers, are connected
6. Many systems also have an off-premises connection to a central station, proprietary supervising station, remote supervising station, or public fire service communication center by means of an auxiliary fire alarm system

FIGURE 14.1.1 Fire Alarm System Control Unit (Source: Mircom Ltd., Toronto, CN; Mammoth Fire Alarms, Lowell, MA)

Primary and Secondary Power Supplies

The primary and secondary power supplies at both the protected premises and at a subsidiary or supervising station must meet the requirements of *NFPA 72*. The primary power is usually supplied by a connection to utility-generated electric power. The connection must be from a branch circuit dedicated to the fire alarm system. The circuit and connections must be mechanically protected. The circuit disconnecting means must have a red marking, be accessible only to authorized personnel, and be identified as "Fire Alarm Circuit Control." Inside the fire alarm system control unit, a permanent legend must identify the location of the electrical panel board that contains the circuit disconnecting means.

Very remote areas may not have utility-generated power available. In these cases, electricity is usually supplied by generators on the site of the facility. Most often more than one generator is provided, each operated for a number of hours at a time to help ensure the reliability of the electric power. Primary power for fire alarm systems at geographically remote facilities is, therefore, supplied by generators.

Secondary power supply for a fire alarm system is required to automatically supply the energy to the system within 30 seconds whenever the primary power supply is not capable of providing the minimum voltage required for proper system operation.

The size of the secondary supply usually is measured in the amount of time that the secondary supply will operate the system, followed by a prescribed time period for the system to operate in an alarm condition. Local (protected premises), central station, remote station, proprietary, and auxiliary systems must have 24 hours of standby power, followed by 5 minutes of alarm. Emergency voice/alarm communication systems must have 24 hours of standby power, followed by 2 hours of emergency operation. To allow calculation of the power required for 2-hour emergency operation, *NFPA 72* specifies that the 2 hours of emergency operation are the equivalent of 15 minutes of operation under full load (i.e., with all input devices and output appliances operating).

The required capacity of the secondary power can be supplied by storage batteries; storage batteries with 4 hours of capacity in conjunction with an engine-driven generator; or multiple engine-driven generators, each of which must be capable of supplying the entire standby power load. This generator is considered "dedicated" to the fire alarm system. This means that the reason the generator was installed was to supply secondary power to the fire alarm system. Of course, if the generator has a greater capacity than is needed by the fire alarm system, it may also be used to supply loads related to the fire alarm system, such as lighting or air-conditioning equipment serving the room where the fire alarm system is located.

Engine-driven generators used to provide secondary power for a protected premises fire alarm system must comply with NFPA 110, *Standard for Emergency and Standby Power Systems,* Section 2.2, requirements for a Type 10, Class 24, Level 1 System. Installation must be in accordance with the *NEC,* Article 700. In addition, where survivability of circuits is required by Chapter 6, equal protection must be provided for power supply circuits.

Circuits

Fire alarm systems have three basic types of circuits: (1) initiating device circuits (IDC), (2) notification appliance circuits (NAC), and (3) signaling line circuits (SLC).

All fire alarm system cable and the wiring installation must conform to Article 760 of the *NEC* and the additional requirements of *NFPA 72*.

Initiating device circuits connect conventional (nonaddressable) fire alarm and supervising initiating devices to the system control unit. Notification appliance circuits connect notification appliances (audible and visible) to the system control unit. The term *signaling line circuits* is used to define circuits over which two-way data communications take place. This communication can take place between an addressable device and system control unit or the system control unit and the off-premises connection, such as a central station, a public fire service communications center, a remote station, or a proprietary supervising station.

There is at least one manufacturer that has the capability of using an SLC for the notification appliance circuit. The feature is software driven and permits selective area evacuation using the same SLC. When a Class B circuit is allowed, the notification appliances can be "T-Tapped" off the SLC and still meet the code requirements for monitoring of wiring and appliance integrity. The addressable controller for the appliances constantly polls the appliances to verify communications. Using short circuit fault isolators also helps to ensure survivability of the circuit.

NFPA 72 provides the fire alarm system designer with various circuit configurations that provide different levels of operation and integrity. The circuit configuration can only be defined when both the fire alarm control unit operation and the wiring configuration are known.

A typical circuit used in many fire alarm systems consists of a two-wire circuit with an end-of-line resistor. Initiating devices, with normally open contacts, are connected in parallel. A small amount of electrical current flows through the wire to monitor the wiring integrity. A break in the wire causes a trouble condition at the system control unit. Everything electrically beyond the break in the wiring is out of service until repairs are made to the circuit. Operation of an initiating device shunts the resistor, thus increasing the current, which causes the system control panel to respond in an alarm condition.

A two-wire circuit configuration that operates up to the single fault (open-circuit or ground-fault condition) is labeled a Class B circuit. A circuit configuration that requires the wiring to be returned to the system control unit, where the system control unit is configured to allow a device or appliance to operate on either side of a single open-circuit or ground-fault condition, is labeled a Class A circuit. Both of these designations can be applied to initiating device circuits, notification appliance circuits, and signaling line circuits.

Many fire alarm system control units have more than one initiating device circuit, so that the fire location can be indicated on an annunciator panel by floor, wing, subsection, or room. The annunciator can be built into the control unit or located in a lobby, maintenance area, telephone switchboard room, or some other location where it is accessible to building and fire service personnel.

Depending on the size of the building and the fire alarm system, addressable and addressable analog systems will have

one or two signaling line circuits. The code does not require more signaling line circuits than the number of connected devices dictates. However, it is prudent to "not put all of your eggs in one basket" and to use a minimum of two signaling line circuits for all except the smallest of systems.

Annunciation is principally designed to serve the fire department. Therefore, coordination with the fire department is important if the annunciation of alarms is to be effective. With the new liquid crystal display (LCD) annunciators and addressable technology, it is tempting to annunciate each point at a remote annunciator. This tactic results in too much information that will tend to confuse rather than help first responders.

NFPA 72 has Annex A material that details the guidelines for a standard fire service interface. Annunciators, information display systems, and controls for portions of the fire alarm system provided for use by the fire service should be designed, arranged, and located in accordance with the needs of the organizations intended to use the equipment.

Where annunciators, information display systems, and controls for portions of the fire alarm system are provided for use by the fire service, these should have a common design and operation to avoid confusion for users. The standard fire service interface uses an icon-based design that can be implemented in various manners on a range of system sizes and still maintain sufficient familiarity so that fire service personnel, with training, should be able to use effectively any variation that follows the guidelines presented in the Annex material.

NFPA 72®, National Fire Alarm Code®, Format

NFPA 72 comprises 11 chapters presented in the following format:

- Chapter 1 Administration
- Chapter 2 Referenced Publications
- Chapter 3 Definitions
- Chapter 4 Fundamentals of Fire Alarm Systems
- Chapter 5 Initiating Devices
- Chapter 6 Protected Premises Fire Alarm Systems
- Chapter 7 Notification Appliances for Fire Alarm Systems
- Chapter 8 Supervising Station Fire Alarm Systems
- Chapter 9 Public Fire Alarm Reporting Systems
- Chapter 10 Inspection, Testing, and Maintenance
- Chapter 11 Single- and Multiple-Station Alarms and Household Fire Alarm Systems

In *NFPA 72* the requirements for fire alarm systems that provide household fire warning have their own chapter (Chapter 11), and the requirements for fire alarm systems for all other occupancies are contained in Chapters 1 through 10.

In *NFPA 72* a fire alarm system that meets the requirements of Chapters 4 and 6 forms the basic fire alarm system "building block." A protected premises fire alarm system, whether it is used to notify the occupants so they may safely evacuate, used to actuate a fire suppression or extinguishing system, or used to oversee conditions at a facility and report status changes to a supervising station, must meet the requirements of these two chapters. The initiating devices and notification appliances connected to the protected premises fire alarm system must meet the requirements contained in Chapters 5 and 7, respectively. A supervising station fire alarm system must meet the requirements contained in Chapter 8. And a protected premises fire alarm system, its initiating devices and notification appliances, along with a supervising station fire alarm system, must all meet the testing and maintenance requirements contained in Chapter 10.

Because of the familiarity and wide usage of industry terms that have evolved over the years, *NFPA 72* has retained such terminology. One example of this terminology is the system designations: protected premises system, emergency voice/alarm communication system, central station system, proprietary system, remote station system, public fire reporting system, and auxiliary system.

PROTECTED PREMISES SYSTEM

The main purpose of a protected premises fire alarm system is to activate local audible and visible alarm notification appliances to notify the occupants that they must evacuate the protected building (Figure 14.1.2). Such a system could be limited to the basic features described earlier. The system could also interface with other protective systems that would help make the building safer in case of fire. Such features might include, for example, the operation of a fire-extinguishing or suppression system; the recall of elevators; the unlocking of doors; the closing of smoke barrier doors; the control of heating, ventilation, and air-conditioning (HVAC) equipment; or the operation of smoke control systems.

In a protected premises system, the alarm is not relayed automatically to a fire department. Instead, when the alarm sounds, someone must use some other means to notify the fire department. If the building is unoccupied at the time of the alarm, fire department response would depend on a neighbor or passerby hearing or seeing the audible and/or visible fire alarm notification appliances and telephoning the fire department.

Additionally a fire alarm system may be interfaced with a smoke control system. When such an interface occurs, the fire protection engineer and mechanical engineer must coordinate their efforts to ensure that the design and operation of the combined systems will work as expected by the authority having jurisdiction. Many jurisdictions now have a policy that the system design must be submitted with a narrative describing the system interface and operation of the systems, both individually and as combined systems.

EMERGENCY VOICE/ALARM COMMUNICATION SYSTEM

This system is used in occupancies, such as high-rise buildings and large assembly occupancies, where it is necessary to relocate occupants to areas of refuge rather than evacuate them (Figure 14.1.3). The voice/alarm system consists of a series of high-reliability speakers located throughout the building. They are connected to, and controlled from, the fire alarm communication console located in an area designated as a building fire command station. From the building fire command station, individual speaker zones or the entire building can be selected to receive an alert tone followed by a voice message that gives specific instructions to the occupants. Some systems have fire

warden telephone stations on each floor, or within each fire zone, to which a fire warden would report to assume local command and pass on specific evacuation instructions.

A trained building employee usually operates the fire command station until the fire department arrives, at which time the officer in charge takes over. The fire warden telephone stations may also be used during fire-fighting operations for communication with the fire fighters whose hand-portable two-way radios may not function properly in the high-rise building. *NFPA 72* recognizes that the installation of two-way, in-building radio communications enhancement systems will ensure that fire department radios will work in all areas of a high-rise building. A bidirectional amplifier is an example of such a system. The two-way, in-building radio communications enhancement system is permitted to be monitored by the building fire alarm system.

One important aspect of a voice/alarm communication system is that, since complete building evacuation is not always feasible, it can instruct occupants to relocate to areas of ref-

uge where they can safely wait for the fire to be brought under control. In such cases, communication with these relocated occupants must be maintained to keep occupants informed and, therefore, more comfortable with the soundness and safety of decisions that leave them still inside a burning building.

The most recent edition of the *National Fire Alarm Code* allows mass notification systems (MNS) to be integrated with emergency voice/alarm communication systems. The MNS can be a stand-alone system that interfaces with the fire alarm system to allow the MNS system to stop all alarm notification in the building while more specific instructions can be given. A typical example would be a terrorist event when occupants may be instructed to stay inside the building. The MNS can also be integrated with the fire alarm system using the same speakers as the fire alarm system. Annex material is provided in the *National Fire Alarm Code* to assist the designers, installers, and authorities having jurisdiction in understanding mass notification systems.

CENTRAL STATION FIRE ALARM SYSTEM

A central station fire alarm system is designed to receive signals from a protected premises at a constantly attended location operated by a company whose purpose is providing central station service. This operating company must be listed by either UL or FM Global Research. Central station installations must have either the UL certificate or FM Global Research placard; whichever means of verifying the character of the installation is required by the AHJ. It may be expected that central station service will be provided for only industrial and commercial facilities of relatively high value. In such cases, the central station fire alarm system is intended to enhance the property protection aspects of a facility in order to satisfy the recommendations submitted by a highly protected risk property insurance company acting in its role of AHJ for matters relating to property insurance.

In some cases, a central station operating company may collect signals from a specific geographic area at a subsidiary station and then transmit the signals to a central station for handling. Although the subsidiary station is not normally staffed, *NFPA 72* requires that it be capable of being staffed in an emergency. Such an emergency might include the failure of the communication channels between the subsidiary station and the central station.

There are eight elements of central station service: four at the protected premises and four at the central station. The four at the protected premises are installation, testing, maintenance, and runner service. The four at the central station are management or oversight of the system, monitoring of signals from the protected premises, retransmission of fire alarm signals to the public fire service communication center, and record keeping. Of course, a listed central station is allowed to contract for other services that do not include the eight points described previously. A central station may simply provide monitoring for alarm, supervisory, and trouble signals such as provided by a remote station.

Central station service may be provided entirely by a listed central station operating company, by a listed central station operating company that contracts one or more elements of central station service at the protected premises to a subcontractor, or by a listed local fire alarm installation company that will provide the four elements at the protected premises and subcontract the four elements at the central station to a listed central station operating company.

Signals may be transmitted from a protected premises using a variety of transmission technologies stated in *NFPA 72,* Chapter 8. Such technologies include active multiplex system encompassing leased line, optical fiber cable, private microwave radio system, and telephone-company-provided derived local channel system; digital alarm communicator system; digital alarm radio system; McCulloh system (the code now states that unless accepted by the authority having jurisdiction, McCulloh systems are not permitted to be installed after June 2003); two-way RF multiplex system; one-way private radio alarm system; or a directly connected noncoded system.

When they receive fire alarm, supervisory, or trouble signals, operators at the central station take actions prescribed by *NFPA 72.* In addition to notifying the public fire service communication center in the case of a fire alarm signal, the central station operators must notify designated persons either at the protected premises or at their homes. The operators must also dispatch a runner or service technician when equipment at the protected premises must be reset by someone from the central station. This runner must reach the premises within 1 hour.

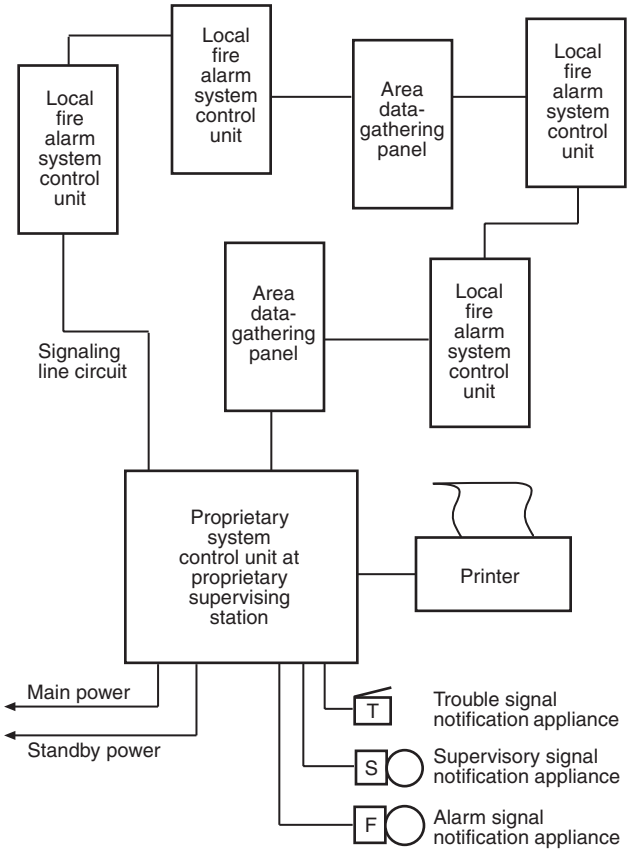
Similarly, supervisory signals and trouble signals also require a runner response. Unresolved guard tour signals require a runner response within one-half hour of the expiration of a 15-minute grace period. Other unresolved supervisory signals require a runner to reach the protected premises within 1 hour. In the case of a trouble signal, the service technician must arrive at the protected premises within 4 hours and begin making repairs to the fire alarm system.

PROPRIETARY SYSTEM

The proprietary fire alarm system is widely used in large commercial or industrial occupancies (Figure 14.1.4).

Signals transmitted over a proprietary system are received and automatically and permanently recorded at a constantly attended proprietary supervising station located either at the protected premises or at another location of the property owner. In very simplistic terms, a proprietary system is similar to a central station system but with the supervising station owned and operated by the property owner and located at the protected premises or another location of the property owner.

Many existing proprietary systems have separate initiating device circuits for each building zone or subsection, similar to local, auxiliary, and remote station systems. However, due to the increasing use of electronics, newer proprietary systems for larger buildings often have signal multiplexing and built-in minicomputer systems. These systems receive all signals from the protected building over one or more communication paths and determine the exact location of the fire by use of digitally coded information. Figure 14.1.5 shows the complexity and interrelationships among the many facets of a modern



(a)

(b)

FIGURE 14.1.4 (a) Typical Arrangement of a Proprietary Protective Signaling System; (b) Central Supervisory Station. An attendant constantly monitors the proprietary protective signaling system. The printer on the desk provides a permanent record of signaling traffic. (Source: SimplexGrinnell Company)

computer-controlled proprietary fire alarm system serving one large building. Proprietary systems can be used in one building as shown in Figure 14.1.5 or serve multiple campus-style such as shown in Figure 14.1.4(a).

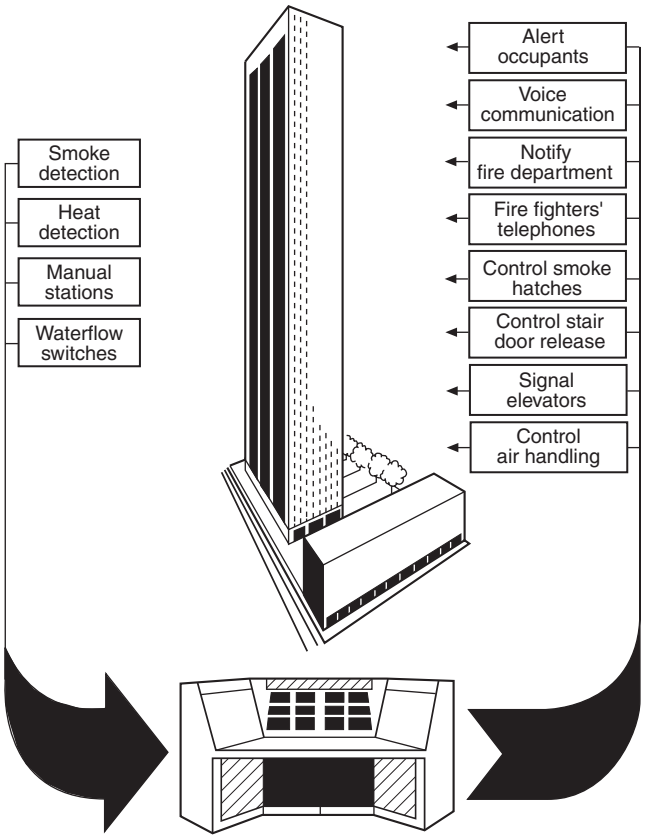


FIGURE 14.1.5 Modern Computer-Controlled Proprietary Fire Alarm System

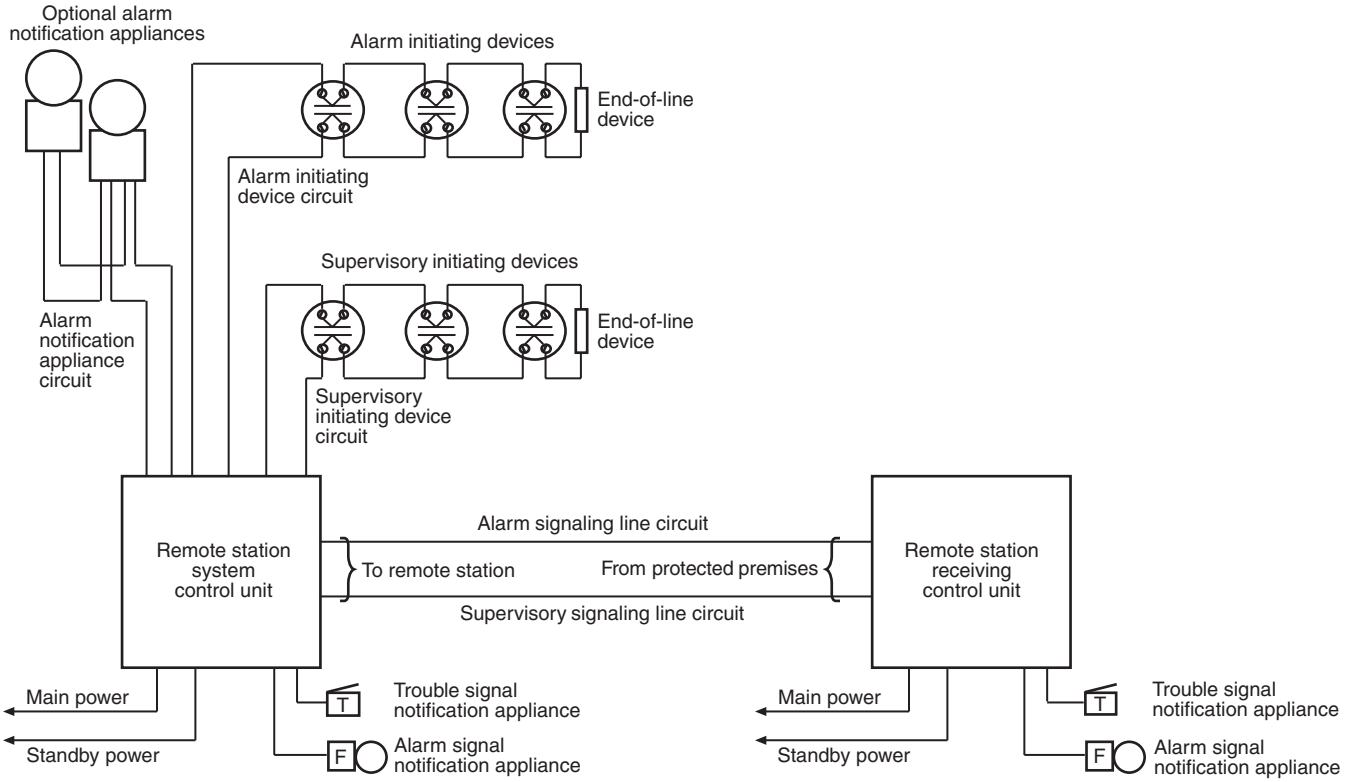
Proprietary control units are required to transmit alarm, supervisory, and trouble signals to the supervising station. Signals may be transmitted from a protected premises using a variety of transmission technologies as stated in *NFPA 72,* Chapter 8. Such technologies include active multiplex system encompassing leased line, optical fiber cable, private microwave radio system, and telephone-company-provided derived local channel system; digital alarm communicator system; digital alarm radio system; McCulloh system (the code now states that unless accepted by the authority having jurisdiction, McCulloh systems are not permitted to be installed after June 2003); two-way RF multiplex system; one-way private radio alarm system; or a directly connected noncoded system.

Upon receipt of fire alarm signals, supervisory signals, or trouble signals, a runner must be dispatched to investigate. Fire alarm signals must also be retransmitted to the public fire service communication center.

REMOTE STATION SYSTEM

A remote station fire alarm system connects the outputs from a building fire alarm control unit and transmits them to a remote location (Figure 14.1.6). *NFPA 72* specifies that fire alarm signals must be received at the public fire service communication center, at a fire station, or at the location of the public



(a)

(b)

FIGURE 14.1.6 (a) Typical Arrangement of a Remote Station Fire Alarm System. Note that, if a direct circuit connection is used, fire alarm and supervisory signals must be transmitted over separate signaling line circuits. (b) Remote Station Receiving Control Unit. Upon receipt of a remote station sprinkler waterflow alarm, the fire dispatcher prepares to retransmit the alarm to the fire companies that will respond.

agency that has the responsibility to receive fire alarms from the public.

If the public agency is unwilling to receive the remote station fire alarm signals, or if that agency is willing to allow another organization to receive those signals, then the signals may be received at a location acceptable to the AHJ that is attended by trained personnel 24 hours a day, such as a central station or monitoring company that will contract to provide the services required of a remote station. Upon receipt of fire alarm signals, the personnel retransmit the signals to the public fire service communication center.

In some cases, the public agency receiving fire alarm signals may also be willing to receive supervisory signals and trouble signals. In most cases, supervisory signals and trouble signals are transmitted to a constantly attended location acceptable to the AHJ, such as a monitoring company or a central station.

Signals may be transmitted from a protected premises using a variety of transmission technologies stated in *NFPA 72,* Chapter 8. Such technologies include active multiplex system encompassing leased line, optical fiber cable, private microwave radio system, and telephone-company-provided derived local channel system; digital alarm communicator system; digital alarm radio system; McCulloh system (the code now states that unless accepted by the authority having jurisdiction, McCulloh systems are not permitted to be installed after June 2003); two-way RF multiplex system; one-way private radio alarm system; or a directly connected noncoded system.

AUXILIARY SYSTEM

An auxiliary fire alarm system provides the interface between a protected premises fire alarm system and a public fire reporting system (Figure 14.1.7). *NFPA 72* states requirements for public fire reporting systems in Chapter 9. *NFPA 72* also states requirements for auxiliary fire alarm systems in Chapter 9. If a community does not have a public fire reporting system, then a protected premises within that community cannot have an auxiliary fire alarm system.

The transmission technology employed between the protected premises and the public fire service communication center is determined by the type of public fire reporting system (i.e., coded wired, coded radio, series telephone, or parallel telephone). The auxiliary fire alarm system interface may be a shunt-type or local energy-type connection to a coded wired, coded radio, or series telephone master fire alarm box (Figure 14.1.8). Or the auxiliary fire alarm system may be directly connected to a parallel telephone system circuit.

NFPA 72 states that only fire alarm signals may be transmitted by an auxiliary fire alarm system. In cases where the protected premises fire alarm system must also cover supervisory signals, these are usually transmitted by a remote station system or a central station contracted to receive supervisory signals as a remote station. Trouble signals are either received only at the protected premises, or they are transmitted by a remote station system or a central station contracted to receive trouble signals as a remote station.

SUMMARY

Fire alarm systems play an essential role in protecting property and lives from fire. An effective system is a combination of individual components designed to work together to provide the

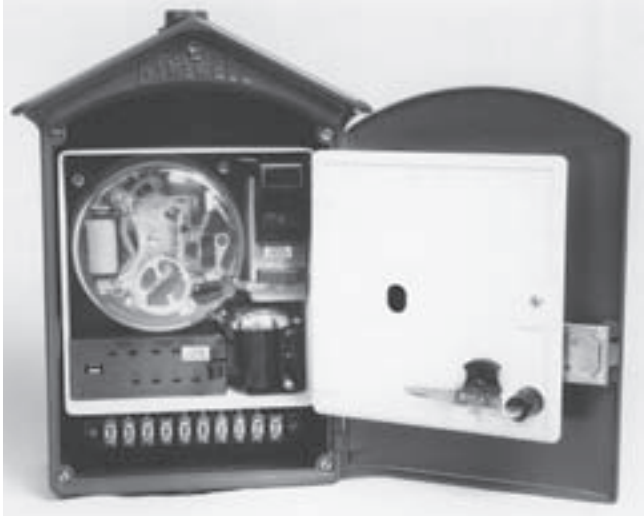

FIGURE 14.1.8 Local Energy-Type Masterbox That Connects the Protected Premises Fire Alarm System to the Public Fire Reporting System (Source: Gamewell-FCI, Div. Honeywell Inc.)

desired level of protection. The user of the fire alarm system must define the goal of the system, for example, whether the priority is life safety or property safety, in order to select the appropriate system. Once installed, the fire alarm system needs to be properly maintained and tested in order to ensure it will function as intended during an emergency.

Chapter 2

Automatic Fire Detectors

Revised by
Kenneth W. Dungan

Chapter Contents

Heat Detectors
Smoke Detectors
Gas-Sensing Fire Detectors
Multisensor and Multicriteria Detectors
Radiant Energy–Sensing Fire Detectors
Video-Based Flame Detection
Selection of Detectors
Detector Installation
Detector Maintenance and Testing

Key Terms

air sampling–type detector, combination fixed-temperature/rate-of-rise detector, electronic spot-type heat detector, fire signature, fixed temperature heat detector, flame detector, heat detector, infrared absorption detector, ionization smoke detector, multisensor detector, optical density, photoelectric smoke detector, rate compensation heat detector, rate-of-rise heat detector, smoke detector, spark/ember detector, thermal lag, video-based detection

Fire produces a variety of environmental changes called "fire signatures," which help make its presence known. Human beings are excellent fire detectors when able to effectively use the senses of smell, sight, and so on. However, human senses can be impaired by sleep, disability, illness, or distractions, so that timely, effective warning may not result. Beginning in the mid-nineteenth century, a number of mechanical, electrical, and electronic devices have been developed to substitute for human senses in detecting the environmental changes created by fire.

The fire signatures most often used as the basis for detection are heat, smoke (aerosol particulates), and radiant energy (IR, visible, UV). Several factors complicate the ability of any detector to sense fire reliably. (1) Different types of fires can have widely divergent fire signatures. For example, some materials burn intensely with little or no smoke, whereas smoldering fires have no visible flame and generally very low heat output. (2) The environmental change(s) being monitored must reach the fire detector and must exceed a threshold amplitude and/or rate of change before alarm can occur. (3) Nonfire conditions can produce ambient changes that mimic fire signatures and that may cause false (nuisance) alarms.

Most building codes require what amounts to partial coverage by detection systems, meaning some rooms or spaces do not have detectors in them. Designers must be aware that this can substantially delay detection and alarm because fire signatures become weaker as the distance from the fire to a detector increases, especially if there are any physical barriers between them. A minimum code design may not meet expectations.

The proper selection and location of automatic fire detectors are essential for achieving protection objectives. For example, the use of spot-type smoke detectors on a very high ceiling will delay detection of a fire until it grows very intense. In addition, detector access for testing, cleaning, or replacement may also be very difficult. In this particular application, the use of projected beam-type smoke detectors may be much more suitable.

Every application of detectors needs to be properly evaluated. This begins with a clear understanding of the protection objectives, likely fire scenarios, and the expected environment in each protected space. With that knowledge, the fire protection engineer can (1) evaluate the fire signatures expected from potential hostile fires at various times in their growth, (2) determine the effect of ambient conditions on various detector options, and (3) select the detector type(s) that will offer the best balance of fire response and discrimination (avoidance of nuisance alarms from nonfire ambient conditions). This chapter will help designers understand how the various types of automatic fire detectors operate, their performance capabilities, and how they are applied.

See also Section 2, Chapter 6, "Fundamentals of Fire Detection"; Section 14, Chapter 4, "Fire Alarm System Interconnections"; and Section 14, Chapter 5, "Inspection, Testing, and Maintenance of Fire Alarm Systems."

HEAT DETECTORS

Heat detectors are the oldest type of automatic fire detection device. They began with the development of automatic sprinklers in the 1860s and have continued to the present with a

Kenneth W. Dungan, P.E., is a principal of Risk Technologies in Knoxville, Tennessee. He is a fellow of the Society of Fire Protection Engineers.

proliferation of various types of devices. A sprinkler can be considered a combined heat-activated fire detector and extinguishing device when the sprinkler system is provided with waterflow indicators connected to the fire alarm control system. Waterflow indicators detect either the flow of water through the pipes or the subsequent pressure change upon actuation of the system.

Heat detectors are very reliable and have the lowest false alarm rate of all automatic fire detectors. They are best suited for fire detection in small confined spaces where rapidly building high-heat-output fires are expected, in areas where ambient conditions would not allow the use of other fire detection devices, or where very early warning of fire is not required.

Heat detectors are generally located on or near the ceiling and respond primarily to the convected thermal energy of a fire. They operate either when the detecting element reaches a predetermined fixed temperature or when a specified rate of temperature change occurs.

Operating Principles of Fixed-Temperature Heat Detectors

Fixed-temperature heat detectors are designed to alarm when the temperature of the operating element reaches a specified point. The air temperature at the time of alarm can be considerably higher than the rated temperature (depending on the fire growth rate), because it takes time for the air to raise the temperature of the operating element to its set point. This condition is called *thermal lag*. Fixed-temperature heat detectors are available to cover a wide range of operating temperatures—from about 135°F (58°C) on up. Higher temperature detectors are necessary so that detection can be provided in areas normally subjected to high ambient temperatures (i.e., boiler rooms, attics, etc.) or in special applications requiring detectors that operate only if close to the fire.

Fusible-Element Type. Eutectic metals—alloys of bismuth, lead, tin, and cadmium that melt rapidly at a predetermined temperature—can be used as operating elements for heat detection. The most common use is the fusible element in an automatic sprinkler. Fusing of the element allows the cover on the orifice to fall away, water to flow in the system, and the alarm to be initiated.

Eutectic metals may also be used to actuate electrical heat detectors. Often they are used as a solder to secure a spring under tension. When the element fuses, the spring action closes contacts and initiates an alarm (Figure 14.2.1). Devices using eutectic metals cannot be restored; either the device or its operating element must be replaced following operation.

Continuous Line Type. As alternatives to spot-type fixed-temperature detection, various methods of line-type detection have been developed. The detector shown in Figure 14.2.2 uses a pair of steel wires in a normally open circuit. The conductors are held apart by a heat-sensitive insulation. The wires, under tension, are enclosed in a braided sheath to form a single cable assembly. When the design temperature is reached, the insulation melts, the two wires contact, and an alarm is initiated. Following an alarm, the fused section of the cable must be replaced to restore the system.

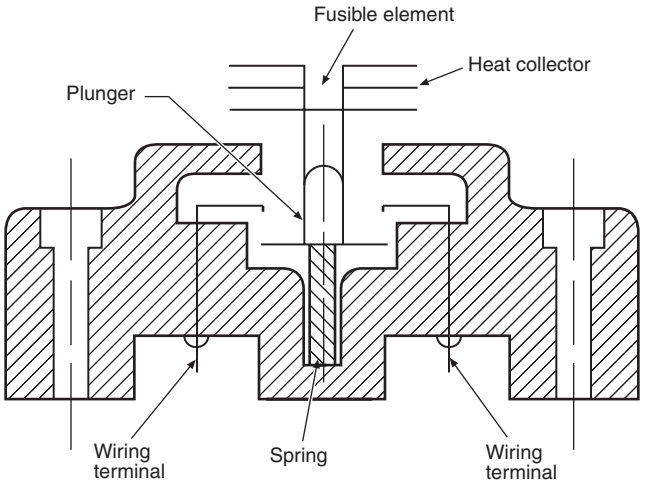

FIGURE 14.2.1 Fixed-Temperature Heat Detector, Spot-Type, Fusible Element

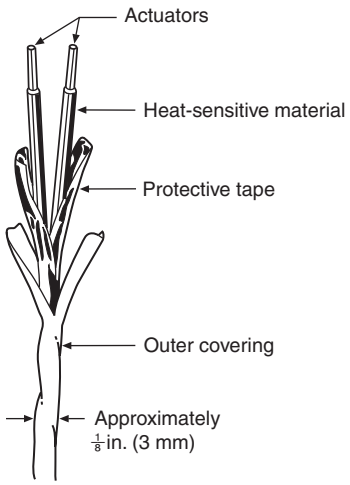

FIGURE 14.2.2 Line-Type Heat Detector

A similar alarm device utilizing a semiconductor material and a stainless steel capillary tube has been used where mechanical stability is also a factor (Figure 14.2.3). The capillary tube contains a coaxial center conductor separated from the tube wall by a temperature-sensitive glass semiconductor material. Under normal conditions, a small current (i.e., below alarm threshold) flows in the circuit. As the temperature rises, the resistance of the semiconductor decreases, allows more current flow, and initiates the alarm.

Bimetallic Type. When two metals with different coefficients of thermal expansion are bonded together and then heated, differential expansion causes bending or flexing toward the metal having the lower expansion rate. This action closes a normally

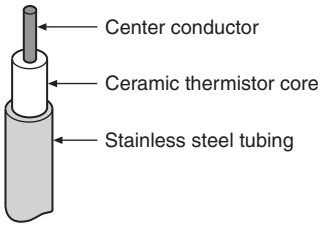

FIGURE 14.2.3 Construction of the Continuous Thermal Sensor Showing Outer Tubing, Ceramic Thermistor Core, and Center Wire

open circuit. The low-expansion metal commonly used is Invar™, an alloy of 36 percent nickel and 64 percent iron. Several alloys of manganese-copper-nickel, nickel-chromium-iron, or stainless steel may also be used for the high-expansion component of a bimetal assembly. Bimetals are used for the operating elements of a variety of fixed-temperature detectors. These detectors are generally of two types: (1) the bimetal strip and (2) the bimetal snap disc.

As it is heated, a bimetal strip deforms in the direction of the contact point. With a given bimetal, the width of the gap between the contacts determines the operating temperature: the wider the gap, the higher the operating point. The operating element of a snap disc device is a bimetal disc formed into a concave shape in its unstressed condition (Figure 14.2.4). Generally, a heat collector is attached to the detector frame to speed the transfer of heat from the room air to the bimetal. As the disc is heated, the stresses developed cause it to suddenly reverse curvature and become convex. This provides a rapid positive action that closes the alarm contacts. The disc itself usually is not part of the electrical circuit. All heat detectors using bimetal elements are automatically self-restoring after operation, when the ambient temperature drops sufficiently below the operating point.

Rate Compensation Detectors

A rate compensation detector is a device that responds when the temperature of the surrounding air reaches a predetermined level, with the rate of temperature rise having minimal effect on response (low thermal lag). This makes them rather sensitive fixed-temperature detectors (Figure 14.2.5).

A typical example is a spot-type detector with a tubular casing of metal that tends to expand lengthwise as it is heated, and an associated contact mechanism that will close at a certain point in the elongation. A second metallic element inside the tube exerts an opposing force on the contacts, tending to hold them open. The forces are balanced so that, with a slow rate of temperature rise, there is more time for heat to penetrate to the inner element. This inhibits contact closure until the total device has been heated to its rated temperature level. However, with a fast rate of temperature rise, there is less time for heat to penetrate to the inner element. The element, therefore, exerts less of an inhibiting effect, so contact closure is obtained when the total device has been heated to a lower level. This, in effect, compensates for thermal lag.

Thermal detectors using expanding metal elements are also automatically self-restoring after operation, when the ambient temperature drops to some point below the operating point.

Rate-of-Rise Detectors

One effect that a flaming fire has on the surrounding area is to rapidly increase air temperature in the space above the fire. Fixed-temperature heat detectors will not initiate an alarm until the air temperature near the ceiling exceeds the design operating point. The rate-of-rise detector, however, will function when the rate of temperature increase exceeds a predetermined value, typically around 12 to 15°F (7 to 8°C) per minute. Rate-of-rise detectors are designed to compensate for the normal changes in ambient temperature (less than 12°F [6.7°C] per minute) that are expected under nonfire conditions.

When applying rate-of-rise heat detectors, use care to avoid locating them in areas where temperatures might normally be expected to rise as much as 12 to 15°F (7 to 8°C) in 1 minute (or less) in order to avoid unwanted alarms. These include commercial kitchens, laundries, or dishwashing areas, truck or construction equipment repair facilities, in front of ceiling-mounted space heaters or air diffusers, near the outside doors of air-conditioned facilities, and in attics. Remember that these detectors will respond for the prescribed rate-of-rise in temperature, even if the current ambient temperature is frigid.

Rate-of-rise detectors that operate by pneumatic action have been manufactured for decades. In a pneumatic fire

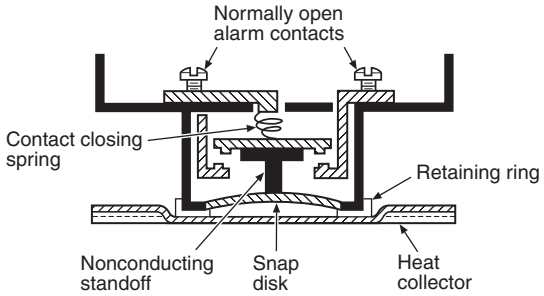

FIGURE 14.2.4 Spot-Type Fixed-Temperature Snap Disc Detector

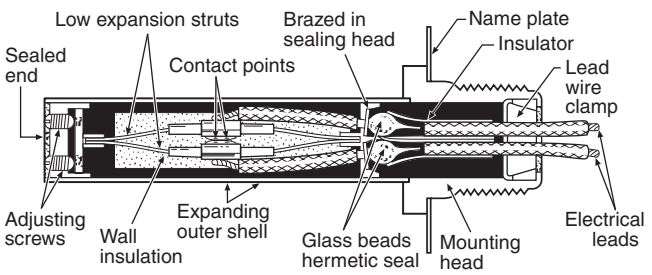

FIGURE 14.2.5 Section of Spot-Type Rate Compensation Detector

detector, air heated in a tube or chamber expands, increasing the pressure in the tube or chamber. This exerts a mechanical force on a diaphragm that closes the alarm contacts. If the tube or chamber were hermetically sealed, slow increases in ambient temperature, a drop in the barometric pressure, or both, would cause the detector to initiate an alarm regardless of the rate of temperature change. To overcome this, pneumatic detectors have a small orifice to vent the higher pressure that builds up during slow increases in temperature or during a drop in barometric pressure. The vents are sized so that when the temperature changes rapidly, as in a fire, the rate of expansion exceeds the venting rate and the pressure rises. When the temperature rise exceeds 12 to 15°F (7 to 8°C) per minute, the pressure is converted to mechanical action by a flexible diaphragm. Pneumatic heat detectors are available for both line- and spot-type detectors. A schematic of a spot-type pneumatic heat detector is shown in Figure 14.2.6, and a line type is shown in Figure 14.2.7.

Line Type. The line type consists of metal tubing, in a loop configuration, attached to the ceiling or side wall near the ceiling of the area to be protected (see Figure 14.2.7). Lines of tubing are normally spaced not more than 30 ft (9.1 m) apart, not more than 15 ft (4.5 m) from a wall, and with no more than 1000 ft (305 m) of tubing on each circuit. Also, a minimum of at least 5 percent of each tube circuit or 25 ft (7.6 m) of tube, whichever is greater, must be in each protected area. Without this minimum amount of tubing exposed to a fire condition, insufficient pressure would build up to achieve proper response.

In small areas where the line-type tube detectors might have insufficient tubing exposed to generate sufficient pressures to close the alarm contacts, air chambers or rosettes of tubing are often used. These units act like a spot-type detector by providing the volume of air required to meet the 5 percent or 25 ft (7.6 m) requirement. Since a line-type rate-of-rise detector is an integrating detector, it will actuate either when a rapid heat rise occurs in one area of exposed tubing or when a slightly less rapid heat rise takes place in several areas where tubing on the same loop is exposed.

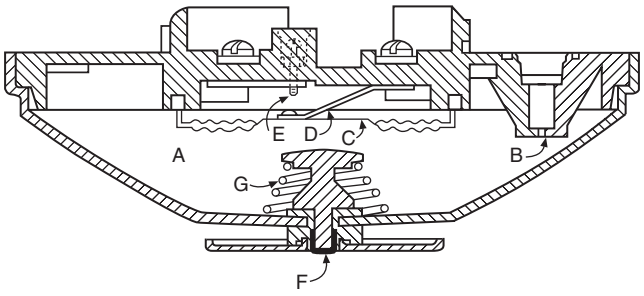

FIGURE 14.2.6 A Spot-Type Combination Rate-of-Rise, Fixed-Temperature Detector. The air in chamber A expands more rapidly than it can escape from vent B. This causes pressure to close electrical contact D between diaphragm C and contact screw E. Fixed-temperature operation occurs when fusible alloy F melts, releasing spring G, which depresses the diaphragm closing contact points.

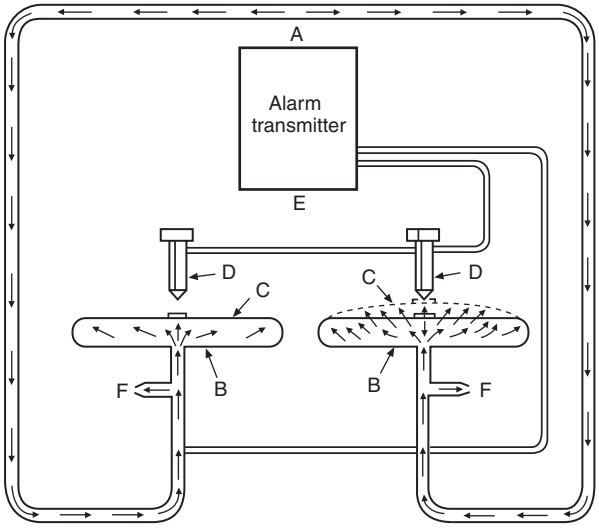

FIGURE 14.2.7 Line-Type Rate-of-Rise Heat Detector. The copper tubing A is fastened in a continuous loop to ceilings or walls and terminates at both ends in chambers B having flexible diaphragms C, which control electrical contacts D. When air in the tubing expands under the influence of heat, pressure builds within the chambers, causing the diaphragms to move and close a circuit to alarm transmitter E. Vents F compensate for small pressure changes in the tubing brought about by small changes in temperature in the protected spaces.

Spot Type. The pneumatic principle is also used to close contacts within spot detectors (see Figure 14.2.6). The difference between the line- and spot-type detectors is that the spot type contains all of the air in a single container rather than in a tube that extends from the detector assembly to the protected area(s).

Combination Fixed-Temperature/ Rate-of-Rise Detectors

Combination fixed-temperature/rate-of-rise detectors contain more than one element that responds to a fire. These detectors may be designed to respond from either element or from the combined partial or complete response of both elements. An example of the former is a heat detector that operates on both the rate-of-rise and fixed-temperature principles. Its advantage is that the rate-of-rise element will respond quickly to a rapidly developing fire, while the fixed-temperature element will respond to a slowly developing fire when the detecting element reaches its set point temperature. The most common combination heat detector uses a vented air chamber and a flexible diaphragm for the rate-of-rise function, while the fixed-temperature element is usually leaf-spring restrained by a eutectic metal (see Figure 14.2.6). When the fixed-temperature element reaches its design

operating temperature, the eutectic metal fuses and releases the spring, which closes the contacts.

Electronic Spot-Type Heat Detectors

A thermoelectric effect detector is a device that utilizes a sensing element consisting of one or more thermistors, which produce a change in electrical resistance in response to an increase in temperature (Figure 14.2.8). This resistance change is monitored by associated electronic circuitry, and the detector responds when the resistance changes at an abnormal rate (rate-of-rise type) or when the resistance reaches a specific value (fixed-temperature type).

The very low mass of the sensing elements used in electronic spot-type heat detectors gives them low thermal lag (for faster response), and their analog outputs can be analyzed by complex signal processing algorithms to further improve performance. This makes them the technology of choice for use in multisensor smoke detectors, discussed later in this chapter.

Rate-of-rise detectors of this type use two thermistors. One is exposed to changes in atmospheric temperature. When the temperature rapidly changes as in a fire situation, the temperature of the exposed thermistor increases faster than the temperature of the unexposed reference thermistor, generating a net change in resistance causing the detector to go into alarm condition. Most rate-of-rise detectors are designed with a fixed-temperature backup feature so that, should the temperature rise be slower than 15°F (8°C) per minute, the detector will operate when the exposed thermistor has reached a predetermined fixed temperature.

SMOKE DETECTORS

A smoke detector detects most fires much more rapidly than a heat detector. Smoke detectors are identified by their operating principle as being either (1) ionization, (2) photoelectric, or (3) video. As a class, ionization smoke detectors are spot-type detectors, which provide somewhat faster response to high-energy (flaming) fires, since they respond to the number density of smoke particles, and such fires produce large numbers of relatively small particles. Photoelectric smoke detectors, as a class, provide superior response to low-energy (smoldering) fires, since they respond to the optical density of smoke, and such fires produce a preponderance of visible size range smoke particles. Their performance advantage for detecting smoldering fires is substantial; this can result in much earlier warning when the fire growth rate is slow. They may equal or even surpass ionization detector response to flaming fires when the fire is not in close proximity, such as in duct smoke detector applications. For these reasons, photoelectric smoke detectors have captured an increasing share of the market in recent years. Photoelectric smoke detectors can be spot type, beam type, or air sampling type. Video-based smoke detection uses video cameras and computer software to analyze changes in the recorded images. Since this method of detection does not require transport of the smoke to a detector or a sampling port, it offers advantages in large open and high-ceiling spaces.

For decades, virtually all smoke detectors were nonanalog,* meaning they had only two operating states: normal and alarm. Typically they were not addressable devices, meaning they did not provide their specific identification or location information to the control unit, except as part of a zone (protected area) consisting of multiple detectors on a common fire alarm initiating circuit. Their ability to avoid false (nuisance) alarms was hampered by their fixed sensitivity and limited on-board signal processing ability. Some jurisdictions even required these smoke detectors to have a specified minimum sensitivity level in order to avoid excessive alarms from transient nonfire conditions such as smoking.

The advent of low-cost microprocessors and surface-mount electronics technology enabled detector manufacturers to utilize new smoke detector concepts, including the use of analog technology to monitor conditions in the protected space. Another advance was to make them addressable, meaning they individually communicate with the fire alarm control unit (FACU), so the specific device reporting is displayed. The data produced by these new technology smoke detectors are analyzed using complex signal-processing algorithms that are either on board the detectors or in the FACU. Some detectors offer a choice

*Nonanalog detectors have commonly been called "conventional" smoke detectors. However, because most new system installations now utilize analog-addressable smoke detectors, "nonaddressable" is the preferred term for those older technology devices.

of several field-selectable algorithms for specific applications (ambient conditions).

Microprocessors also make comprehensive self-diagnostics possible. The sensitivity of most analog-addressable smoke detectors can automatically be monitored by the control unit and adjusted over time as needed to hold a constant sensitivity, despite the effects of dust buildup, component drift, or gradual changes in ambient conditions. The FACU can also arrange individual detectors to have different sensitivity settings for day and night or weekend to take advantage of different ambient conditions when the business is closed. Some detector models use distributed intelligence so that several capabilities like this reside within the detector itself to reduce communication traffic on the signaling line circuit. This may permit less stringent wiring methods to be used.

Addressable devices are constantly polled by the control unit, typically every few seconds, and immediate notice is given if a detector fails to report or needs servicing. Some multisensor smoke detectors are able to report as many as 20 to 30 specific trouble conditions to the FACU. The substantial performance advantages and unique features offered by analog-addressable smoke detectors make them the sensor of choice for most smoke detection applications. Nonaddressable smoke detectors are now primarily used for replacement purposes in existing or very small systems.

Ionization Smoke Detectors

As stated, smoke detectors utilizing the ionization principle are usually of the spot type. An ionization smoke detector has a very small amount of radioactive material (an alpha emitter) that ionizes the air in the sensing chamber, rendering the air conductive and permitting a minute current flow through the air between two charged electrodes. This gives the sensing chamber an effective electrical conductance. When smoke particles enter the ionization area, they decrease the conductance of the air by attaching themselves to the ions, causing a reduction in ion mobility. The current flow is monitored and when conductance is below a predetermined level, the detector is in alarm (Figure 14.2.9). With analog-addressable detectors, this alarm threshold can be varied to compensate for ambient conditions.

Photoelectric Smoke Detectors

The presence of suspended smoke particles generated during the combustion process affects the propagation of a light beam

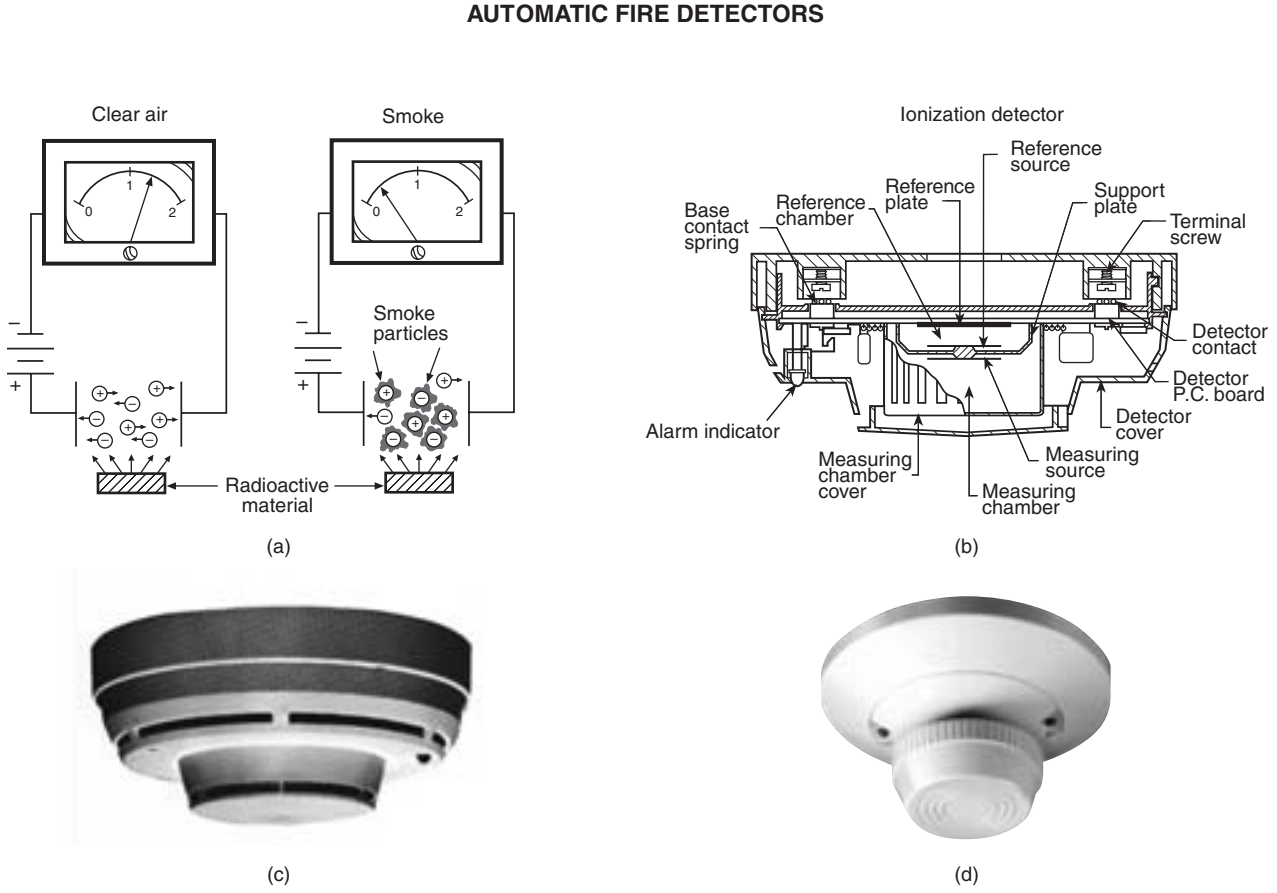

FIGURE 14.2.9 (a) Principle of Operation for Ionization Smoke Detector; (b) Cross-Sectional View of an Ionization Smoke Detector; (c) Ionization Smoke Detector (Source: Siemens Building Technologies, Fire Safety Division); (d) Ionization Smoke Detector (Courtesy of Gamewell-FCI)

passing through the air. The effect can be utilized to detect the presence of a fire in two ways: (1) obscuration of light intensity over the beam path or (2) scattering of the light beam.

Light Obscuration Principle. Smoke detectors that operate on the principle of light obscuration consist of a light source, a light beam collimating system, and a photosensitive device. When dense smoke obscures part of the light beam, or less dense smoke obscures more of the beam, the light reaching the photosensitive device is reduced, and this initiates the alarm (Figure 14.2.10).

Most light obscuration smoke detectors are the beam type and are used to protect rather large spaces such as atriums, auditoriums, manufacturing areas, and so on. Each projected beam smoke detector is equivalent to a row of spot-type smoke detectors along the beam path. They are installed with the transmitter (pulsed IR light source) at one end of the area to be protected and the receiver (photosensitive device) at the opposite end.

The transmitter and receiver must have a completely unobstructed view of each other that cannot normally be blocked. In the event of any sudden accidental blockage, the detector generates a trouble signal rather than an alarm, since smoke buildup from a fire would not cause a sudden, complete blockage of the beam. If multiple parallel sets of these smoke detectors are installed, it may be prudent to alternate the transmitter and receiver locations to avoid possible cross-talk between adjacent units. Some models may also be sensitive to intense flashing lights, such as on large machinery or vehicles, if the source is close to their optical axis.

Projected beam smoke detectors have a permitted operating range, for example, 33 to 330 ft (10 to 100 m). This range varies from model to model, as does the permitted minimum mounting distance below the ceiling, and so on. They require very stable mounting surfaces, so that alignment of the IR light beam can be maintained. This becomes more important at longer ranges and less so when the beam's throw distance is shorter. In all cases the manufacturer's detailed instructions for installation and beam alignment must be followed.

Light-Scattering Principle. When smoke particles enter a light path, scattering results. Smoke detectors utilizing the photoelectric light-scattering principle are usually of the spot type. They contain a light source and a photosensitive device arranged so the light rays normally do not fall onto the device. When smoke particles enter the light path, light strikes the particles and is scattered onto the photosensitive device, causing the detector to respond (Figure 14.2.11).

(b)

(c)

FIGURE 14.2.11 (a) Cross-Sectional View of a Photoelectric Scattering Smoke Detector; (b) Photoelectric Smoke Detector (Source: System Sensor®); (c) Photoelectronic Smoke Detector (Courtesy of GE Security)

The photosensitive device used in scattering detectors usually is a photodiode or a phototransistor. The light source is typically an infrared light-emitting diode (LED), pulsed to reduce power drain. However, several manufacturers recently introduced a photoelectric spot-type smoke detector utilizing a very sharp laser beam. Because the laser beam is so intense, more light is reflected into the sensing chamber than with a standard LED. A signal-processing algorithm is used to discriminate between airborne dust particles and smoke particles entering the sensing chamber. These attributes enable it to have up to 100 times the sensitivity of LED units and still be very stable. It's intended for special applications, like cleanrooms, telecommunications hubs, archives, and computer rooms, where very early warning of incipient fires is essential.

Air Sampling–Type Smoke Detectors

As the name implies, air sampling–type smoke detectors draw in air from the protected space and analyze it for smoke particles. The fact that air is mechanically transported to the sensor permits the use of filters to remove most dust particles, a common source of false alarms for ordinary nonaspirating smoke detectors. Almost all air sampling–type smoke detectors utilize the photoelectric light-scattering principle, enhanced by various means to give it the capability for very high sensitivity. However, there are at least three rather different design approaches.

Continuous Air-Sampling Smoke Detection. These devices use a network of tubing or piping (with spaced intake ports) and an aspirating fan to draw a sample of air from the protected area. Their photoelectric detector has an intense light source, either a pulsed laser or a xenon strobe, to increase the amount of light that any smoke particles will forward scatter toward a photosensitive element. This makes these units capable of very high sensitivity, surpassing all spot-type smoke detectors, except the laser source design previously discussed.

The use of a tubular network to draw air back to the detector permits the sensor to be located out of harm's way, for applications such as prisons and mental hospital isolation rooms. Typically, these devices also have several user-definable alert and alarm levels to take advantage of their capability for high sensitivity and, for special applications like computer room fire suppression system control, to initiate various actions, including gaseous agent release.

There are limitations imposed on the application of these devices as a result of the method of sampling air and transporting it back for analysis. (1) Transport time limits the length of the sampling network and, therefore, the size of the area covered by the detector. (2) Smoke dilution reduces their inherent high sensitivity, proportional to the number of sampling ports in the network, and this fact must be considered in design. (3) The piping network is supervised for breakage or blockage but the airflow condition of an individual sampling port usually cannot be sensed. (4) The ability to zone these systems is limited, but some models can monitor several different piping networks, on a rotating basis (using air valves), as long as each network is within the permitted length.

Cloud Chamber Principle Air-Sampling Smoke Detection. These devices also use a network of tubing or piping (with spaced intake ports) and an aspirating fan to draw individual samples of air from the protected area. After being filtered to remove dust particles, it enters a humidifier where distilled water is used to raise the relative humidity to approximately 100 percent. Then the sample of air is subject to some reduction in air pressure, using a vacuum pump, so that it becomes supersaturated. If any smoke particles are present, they act as condensation nuclei for water droplets, triggering formation of a cloud in the sensing chamber. The density of the cloud is measured by a photoelectric light-scattering detector, which will respond if a threshold alert or alarm value is exceeded.

This phenomenon is effective for detecting the submicron particles that are produced in abundance by thermal decomposition during the pyrolysis or precombustion phase of incipient fires. For example, an electric motor that is "cooking out" releases large numbers of decomposing molecules from insulation on the winding, long before there is any visible smoke or flame. This gives cloud chamber principle smoke detectors unsurpassed ability to provide very early warning of incipient fire.

The need to transport the sampled air back to the unit through a piping network imposes the same limitations on these devices as previously discussed. In addition, they require more frequent servicing than other types of smoke detectors, including replenishment of the distilled water supply. They are most often used where the protected space has very high value or mission-critical contents that demand very early warning of incipient fires and justify the expense.

Spot-Type Aspirating Smoke Detection. This design combines the technology of spot-type photoelectric smoke detection with filtered, periodic aspiration. The objective is to detect smoke reliably in very dusty environments where regular spot-type detectors cannot be used.

Air is sampled by a small on-board fan, which cycles on and off to reduce power drain. The time between samples is less than a minute, and airflow (filter status) is verified every few hours. The filter is replaceable and the time between filter clogs can vary from a few months up to several years, depending on ambient conditions. Typical applications are heated stables, paper plants, cotton and textile mills, commercial laundries, food processing areas, and so on. A separate power supply is required for fan power. They are not intended for outdoor use, nor for locations with potential explosion hazard.

Video-Based Smoke Detectors

Video-based smoke detectors operate on the principle of identifying changes in the digitized video image from a camera or series of cameras. Closed-circuit TV (CCTV) cameras view an area and the images that are within the field of view of the cameras are transmitted to a computer. The computer looks for areas of change as it digitizes the images. Only those pixels that show a change are further processed to discriminate the particular characteristics of smoke. These cameras work in the visible light range and therefore need an illuminated space. The use of video cameras also provides a visual image to an operator monitoring

the system, which can provide very useful input to emergency management decisions. The software allows masking of portions of the field of view to minimize unwanted alarms from ambient sources of smoke or dust. As previously stated, these devices can offer significant advantages in large open facilities, where transport of smoke to other means of smoke detection can cause delays in identifying and locating a fire condition. Examples of such applications include the turbine hall of electrical generating facilities, large assembly plants, or aircraft hangars.

GAS-SENSING FIRE DETECTORS

Many changes occur in the gas content of the environment during a fire. It has been observed that detectable levels of gases are reached after detectable smoke levels and before detectable heat levels. One of three operating principles, that is, semiconductor, catalytic element, or infrared absorption, may be used in a gas-sensing fire detector or in a combination (multisensor) detector.

Semiconductor Principle

Fire-gas detectors of the semiconductor type respond to either oxidizing or reducing gases by creating electrical changes in the semiconductor. The subsequent conductivity change of the semiconductor causes actuation of the detector.

Catalytic Element Principle

Fire-gas detectors of the catalytic element type contain a material that, in itself, remains unchanged, but that accelerates the oxidation of combustible gases. The resulting temperature rise of the element causes detector actuation.

Infrared Absorption Principle

Carbon dioxide, carbon monoxide, water vapor, and hydrocarbons absorb different frequencies of infrared light. This principle can be used to measure the presence of and concentration of one or more of these gases from a fire.

MULTISENSOR AND MULTICRITERIA DETECTORS

The combination of sensors placed in a single spot-type detector has been a common practice for decades. The early devices were combinations of a heat detector with a smoke detector. *NFPA 72®*, *National Fire Alarm Code®*, required that any heat detector combined with a smoke detector should have a listed spacing of 50 ft (15.25 m). For these devices both sensors act independently, carry independent listings, and require independent testing of each element.

With the development of analog-addressable or "intelligent" detectors, the use of multicriteria detectors was introduced. These devices are typically smoke detectors that integrate the response of two or more sensors to achieve greater sensitivity (early response) without sacrificing stability (increasing unwanted alarms). These devices can incorporate a thermal sensor with a smoke sensor or multiple smoke sensors (e.g., ion and photo). The signal from each sensor is analyzed and combined using proprietary algorithms to establish alarm thresholds. Development is under way by some manufacturers to incorporate gas sensors such as CO or CO_2 to improve the performance of smoke detectors.

RADIANT ENERGY–SENSING FIRE DETECTORS

Radiant energy–sensing devices sense the radiant energy (electromagnetic radiation) emitted as a by-product of the combustion reaction, which obeys the laws of optics. This includes radiation in the ultraviolet, visible, and infrared portions of the spectrum, emitted by flames or glowing embers. They are categorized as flame detectors and spark/ember detectors.

The selection of the radiant energy–sensing detector requires that the device's spectral response be matched to the spectral emissions of the potential fire to be detected. The fire protection engineer must also evaluate any nonfire radiant energy sources in the area to be protected to determine if they could cause nuisance alarms in the detector being considered.

All flame and spark/ember detectors respond in accordance with the inverse square law, which defines the fire size versus distance curve for the detector. Therefore, if the distance from the detector to the fire is doubled, the signal received drops to $(½)^2 = ¼$ of what it previously was. Sensitivity also drops off as the source of radiant energy being detected is displaced from the optical axis of the detector. Each detector model will have manufacturer's data on its effective (normalized) sensitivity versus angular displacement (Figure 14.2.12)

Because these detectors are line-of-sight devices, they must be positioned so that no point requiring detection in the hazard

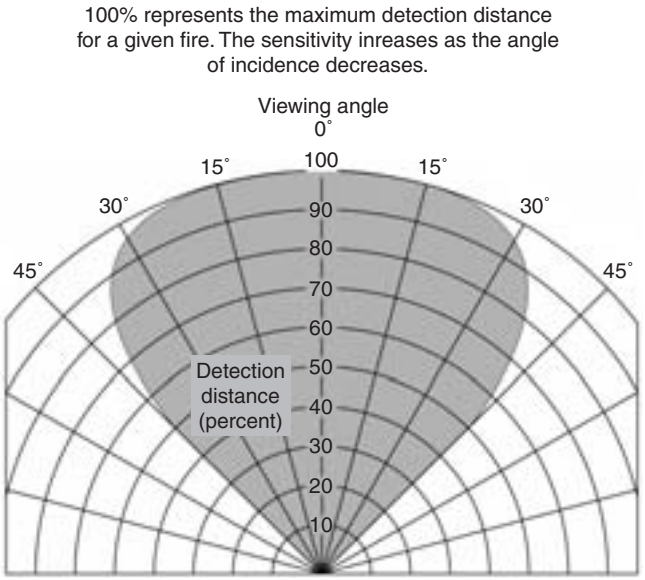

FIGURE 14.2.12 UV Fire Detector Cone of Vision (Courtesy of Detector Electronics Corporation)

area is obstructed or outside the field of view of at least one detector. Spacing will depend on the overall protection objectives of the system, including the minimum size of flaming fire or spark/ember that must be detected and the response time required.

An additional consideration for all applications of radiant energy–sensing fire detectors is the effect of the medium between the anticipated fire and the sensor. Different wavelengths of radiant energy are absorbed with varying degrees of efficiency by materials suspended in the air or that may accumulate on the optical surfaces of the detector. Some examples include atmospheric humidity, smoke, dust, aerosol film, fog, rain, and snow. Detector lens clarity must be assured between maintenance intervals by electronic monitoring or inspection, possibly augmented by a lens air purge device. Protective housings (behind glass, plastic, etc.) should not be used unless listed for the purpose, because some optical materials are absorptive at the wavelength(s) used by these detectors.

FIGURE 14.2.13 Typical UV Detector Assembly (Courtesy of Detector Electronics Corporation)

Flame Detectors

Other than video-based flame detectors, discussed later in the chapter, flame detectors operate in the UV and/or IR portion of the spectrum. Most such flame detectors exhibit some kind of fuel specificity and are qualified based on a defined fire under specific conditions. When employing these detectors for fuels other than the defined fire, the designer should make appropriate adjustments to the maximum distance between the detector and the fire. The various types of UV/IR flame detectors and their principles of operation follow.

Ultraviolet Flame Detectors. The ultraviolet spectrum comprises wavelengths ranging from approximately 0.1 μm to 0.35 μm. UV detectors typically use a vacuum photodiode Geiger-Muller tube to detect the ultraviolet radiation that is produced by a flame. The photodiode allows a burst of current to flow for each UV photon that hits the active area of the tube. When the number of current bursts per unit time reaches a set level, the detector initiates an alarm. A special control unit is required to monitor the count rates from UV detectors and initiate alarm (Figure 14.2.13).

UV detectors are sensitive to most fires, including hydrocarbons (liquids, gases, and solids), ammonia, sulfur, hydrogen, hydrazine, and metals such as magnesium. However, the smoke produced by combustion of middle and heavy fraction petroleum distillates is highly absorptive in the UV end of the spectrum, and this must be compensated for in system design if UV detectors are used.

Potential sources of UV detector nuisance alarms include lightning, arc welding, X rays (used in industrial nondestructive testing of metals), and radioactive materials.

Infrared Flame Detectors. The total infrared spectrum comprises wavelengths ranging from approximately 0.76μm to 220 μm. IR detectors basically comprises a filter and lens system used to screen out unwanted wavelengths and focus those remaining on a photovoltaic or photoresistive cell sensitive to IR energy. They can respond just to the resulting net IR component of the flame or in combination with a flame flicker sensor (typically looking for a flicker rate of 5 to 30 Hz).

Although almost all materials that participate in flaming combustion emit UV radiation to some degree during such combustion, only carbon-containing fuels emit significant radiation in the 4.35 μm (carbon dioxide) band used by many IR detectors to sense flame (Figure 14.2.14). This means that IR flame detectors are not responsive to carbon-free fuels, such as hydrogen and sulfur.

Potential sources of nuisance alarms from infrared flame detectors include gas (oxy-acetylene) welding in their field of view and solar radiation from sunlight (a strong IR source). Several measures are available to prevent sunlight from being a problem, including the use of multiple wavelength technology. This design (commonly referred to as an IR/IR detector) employs filters to pass radiation from different portions of the infrared spectrum to separate IR sensors. The two outputs are

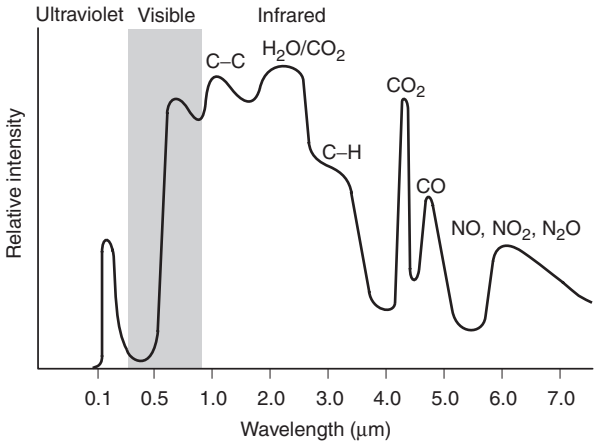

FIGURE 14.2.14 Spectrum of a Typical Flame (free-burning gasoline)

continuously compared and an alarm is initiated when the relationship between them indicates a fire.

Ultraviolet/Infrared Flame Detectors. Combination UV/IR devices sense radiation from portions of both spectrums and use the resulting signal to indicate a fire. They typically require both UV and IR sensor response to cause an alarm, resulting in better false alarm rejection than either UV or IR detectors alone. (In circuit design this is called an "AND" circuit because it requires condition A and condition B to exist before declaring that an alarm should sound. If either the UV or the IR sensor could trigger an alarm, that would invoke an "OR" circuit.) An AND circuit makes the system subject to the combined limitations of both technologies.

Spark/Ember Detectors

Spark/ember detectors are primarily installed to detect sparks and embers that could, if allowed to continue to burn, precipitate a much larger fire or even an explosion. They are typically mounted on a duct or conveyor to monitor the fuel as it passes by. Usually it is necessary to enclose the portion of a conveyor where the spark/ember detectors are located, because they normally require a dark environment to operate properly.

Radiant energy from an ember is primarily of infrared and, to a lesser degree, visible wavelengths. In general, embers do not emit significant ultraviolet energy until their temperature reaches approximately 3240°F (1727°C).

Spark/ember detectors are often used to control in-duct fire-extinguishing systems for woodworking plant dust collectors or textile plant ventilation. For example, sawdust or textile fiber embers may be traveling past the unit at 328 ft/sec (100 m/sec), and their detection triggers a very brief burst from a downstream water spray nozzle. Typically, a subsequent detector further downstream verifies extinguishment and, if necessary, repeats the spray burst at another point in the duct. For applications such as this, spark/ember detectors are required to have a very fast response time.

Common sources of nuisance alarms include incident light, electrostatic discharge in the fuel stream, and electromagnetic interference (EMI/RFI).

VIDEO-BASED FLAME DETECTION

Operating Principles and Applications

Video-based flame detection operates in the visible light range and as with video-based smoke detection previously described uses video cameras. The images from one or more cameras are processed by computer software to look for and identify the characteristics of a flame. The cameras also provide a video image of the area to assist the operators in managing the emergency. The detectors/cameras are enclosed in explosionproof electrical enclosures. Since they view visible light, they are not affected by UV or IR sources and can be enclosed behind a glass or plastic view port. As with video-based smoke detectors, portions of the camera field of view can be masked to eliminate ambient sources of unwanted alarms. Commercially available models are capable of detecting a 10 kW flaming fire (one ft^2 [0.093 m^2] gasoline pan fire) at a distance of 65 ft (20 m) and can operate in temperatures ranging from –40°F (–40°C) to 158°F (70°C). Examples of applications of video-based flame detection include offshore petroleum facilities (e.g., platforms and vessels) and land-based petrochemical facilities (Figure 14.2.15).

Combination Video Technologies

The combination of smoke and flame video technologies is also being applied. As the software matures and field experience grows, the advantages of video camera technology will broaden their application.

SELECTION OF DETECTORS

When a fire detection system is being planned, the choice of detectors is critical for ensuring proper performance. Numerous factors must be considered in order to make the right choice. This is true whether the design is prescriptive (per a regulatory formula), is performance based (the usual case for flame or spark/ember detection systems), or uses some elements of both. Regardless of the design method, the following basic steps should normally be included in the selection of automatic fire detectors:

1. Determine the specific fire protection goals for the system, such as life safety, property protection, continuity of operations, and compliance with building codes, statutes, and criteria of the authority having jurisdiction (AHJ).

FIGURE 14.2.15 Video-Based Flame Detector (Source: Micropack Detection (Americas) Inc.)

2. Obtain stakeholder input to quantify these goals as explicitly as possible.
3. Develop general design objectives that outline how the preceding goals will be met.*
4. Evaluate the fire threat, including possible ignition sources, the type and quantity of fuels available, their expected growth rate, whether a fire suppression system is present, and so on. For example, very different threats would be posed by a petrochemical processing area, a hotel, and a woodworking shop.
5. Determine what fire signature(s) would be presented by potential fires at various points in their growth and what the area's normal ambient conditions would be (without fire present).
6. Weighing the foregoing factors, select fire detectors on the basis of their sensitivity to the fire signatures, response time (signal processing time), and relative immunity to false alarms in the anticipated ambient conditions (or their discrimination ability).

There is normally an inverse relationship between the sensitivity/speed of detection and the detector's ability to discriminate between fire and nonfire conditions. In general, heat detectors have the lowest false alarm rate but the slowest response time. Because the heat generated by small fires tends to dissipate fairly rapidly, heat detectors are best used to protect confined spaces or installed directly over hazards where flaming fires could be expected. They are typically installed in a grid pattern at their listed spacing or at reduced spacing for faster response. The operating temperature of a fixed temperature heat detector should be at least 25°F (14°C) above the maximum expected ambient temperature in the area protected. (For application information on rate-of-rise–type heat detectors, see previous comments in the corresponding portion of this chapter.)

Smoke detectors normally have much faster response times than heat detectors. The fire plume (buoyancy effects), air currents from HVAC, and diffusion may all be involved in transporting smoke. The response time advantage of smoke detectors becomes larger as the size of the space increases. Although frequently installed in a grid pattern, at a uniform recommended spacing, they are more properly located by considering the sources of potential fires and how the smoke would be transported. (For application information on the various types of smoke detectors, see previous comments in the corresponding portion of this chapter.)

Radiant energy–sensing detectors generally offer extremely fast response to any source of radiation within the spectrum they monitor. However, this can result in high false alarm rates if they are applied improperly. Since most are listed for NFPA 70, *National Electrical Code®*, Class I or II locations, they are well suited to protecting areas where potentially explosive or flammable vapors or dusts may be present. (For application information on the various types of radiant energy–sensing detectors, see previous comments in the corresponding portion of this chapter.)

*For performance-based design these design objectives are explicitly stated and quantified and then are used to develop specific performance criteria for the system, stated in fire protection engineering terms. See *NFPA 72®*, *National Fire Alarm Code®*, Annex B, for a more thorough description of the performance-based design process.

DETECTOR INSTALLATION

After selection of the most suitable detectors to use, the next step is to determine where to locate them within the space to be protected. Video-based smoke and flame detection offer distinct advantages in large open spaces. The potential to detect fires before the transport of smoke to a high ceiling and the ability to view and record the visual images of the area can provide additional benefits over spot-type or beam-type smoke detectors. Likewise the visual image provided with the video flame detectors provides an additional emergency management tool.

Detector Placement

Spot-type detectors are usually installed on the ceiling, not less than 4 in. (0.1 m) from the wall. If their listing permits, they are also permitted to be installed on the wall, with their highest edge no less than 4 in. (0.1 m) and no more than 12 in. (0.3 m) from the ceiling (Figure 14.2.16).

Where subject to mechanical damage, detectors must be protected. Any mechanical guard used with a smoke or heat detector must be listed for use with the detector. Otherwise, sensor performance may be degraded. Smoke detectors are often required to be set at higher sensitivity when used with plastic or perforated metal guards due to their effect on smoke entry. One manufacturer has a unique metal guard that looks like the series of smoke detectors it protects and that is engineered not to affect detector sensitivity.

Smoke detectors should not be installed in an air stream from an HVAC supply grill, because that will inhibit smoke from a fire in the protected space from reaching the detector. (The smoke detector would be bathed in a clean air stream when the HVAC supply fan is running.) This can also affect heat detector performance, usually to a lesser degree. Locations adjacent to a return air grill should also be avoided, because returns can affect air circulation patterns in the room so as to inhibit the detection of smoke from low-energy fires.

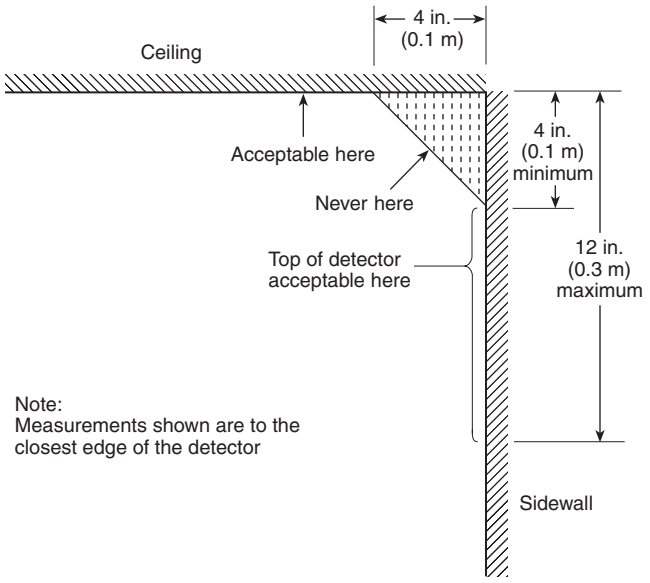

FIGURE 14.2.16 Mounting of Spot-Type Detectors

Where ceilings are high or ceiling construction is not smooth, the spacing of smoke or heat detectors should be reduced appropriately. Specific information on the treatment of joisted, beamed, and sloped ceilings can be found in *NFPA 72*.

When heat detectors are installed at their listed spacing, detection times will approximately equal the operating times of standard 165°F (74°C) sprinklers. If a faster response is desired, detector spacing should be reduced.

Spacing of Heat Detectors on High Ceilings

The hot air in a fire plume is diluted by entrainment with cooler air as it rises. Therefore, it had generally been assumed that heat detectors should be spaced more closely together on a high ceiling to achieve the same response time that they would provide on a standard 8 ft to 10 ft (2.5 to 3.0 m) high ceiling. To determine how much closer the detectors should be, a series of full-scale fire tests was funded by the Fire Detection Institute. These tests explored different ceiling heights in addition to several other design parameters. The data clearly showed that heat detectors must be spaced more closely together on a high ceiling to achieve the same response time that they would have on a 10 ft (3 m) ceiling (Table 14.2.1).[1]

Annex B of *NFPA 72* was developed from these tests and presents a performance-based design approach that can be used to determine the effect of changes in various design parameters on heat detectors in a flaming fire scenario only (plume-dependent response). The formulas it contains take into account the detector's listed spacing and temperature rating, the ceiling height, the design fire size, the fire growth rate, the normal ambient temperature, and the response time index (RTI) of the device. The thermal response characteristics of a heat detector describe how fast heat is transferred to the sensor. The plunge test used characterizes this as a response time index. The RTI allows the calculation of the time it takes for the heat-sensing element to reach its alarm threshold, based on the temperature and velocity of the fire plume or ceiling jet passing by the device.[2]

TABLE 14.2.1 Heat Detector Spacing Reduction Based on Ceiling Height

Ceiling Height Above		Up to and Including		*Multiply Listed Spacing By*
ft	*m*	*ft*	*m*	
0	0.00	10	3.05	1.00
10	3.05	12	3.66	0.91
12	3.66	14	4.27	0.84
14	4.27	16	4.88	0.77
16	4.88	18	5.49	0.71
18	5.49	20	6.10	0.64
20	6.10	22	6.71	0.58
22	6.71	24	7.32	0.52
24	7.32	26	7.93	0.46
26	7.93	28	8.54	0.40
28	8.54	30	9.14	0.34

The formulas can be used by entering a set of known values and design objectives and then calculating for one unknown, such as the required detector spacing in a given situation.

Spacing of Smoke Detectors

Nationally recognized testing laboratory approval (listing) tests for smoke detectors do not yield a listed spacing as they do for heat detectors. However, because the largest spacing evaluated in the fire test room used for these tests is 30 ft (9.1 m), manufacturers use that figure as the normal recommended spacing when smoke detectors are installed on a flat, smooth ceiling. Reductions in spacing may be required to address factors that can affect response, including ceiling height, beamed or joisted ceilings, and high rates of air movement (such as in a computer room). Room size, corridor width, and beam pocket size must also be considered. Calculations have demonstrated that in corridors and in small rooms, reduced spacing for nonsmooth ceilings may not be required.[3]

In design applications where predicting the response of smoke detectors is not critical, the prescriptive criteria in the body of *NFPA 72* should provide sufficient information to design a basic smoke detection system. The performance-based design methodology of Annex B can also be used for smoke detector design calculations. Again, this applies only to the flaming fire scenario, where fire plume and ceiling jet flows are major factors in smoke transport to the sensor. Thus, it cannot be used for low-energy (smoldering) fires. There are other limitations resulting from the fact that smoke detector response varies for different burning materials, and the properties of smoke itself change as it ages. These limitations will continue to affect the ability of fire protection engineers to more accurately predict smoke detector response until such time that testing laboratories are able to determine (and publish) meaningful performance metrics for all smoke detectors.

Special Applications

Duct smoke detectors are installed in the return and/or supply ducts of HVAC systems in buildings to prevent smoke from a fire being spread throughout the building by its recirculating HVAC system. Return duct smoke detectors, where required, are permitted to be replaced by total coverage smoke detection in the area served by the HVAC system or by spot-type smoke detectors located in each return air opening. Upon the detection of smoke, the HVAC system either shuts down or transitions to a smoke control mode such as 100 percent exhaust and/or 100 percent outside fresh air. The detection of duct smoke is made difficult by its dilution with return air from other spaces (away from the fire) and possibly with outside fresh air. Also, when the HVAC system fan is not running, smoke may not reach the duct detector. For these reasons, air duct smoke detectors must never be considered as a substitute for open area protection.

Smoke detectors are also used to initiate the closure of smoke doors in buildings to limit the spread of combustion products in the event of fire. This can be accomplished with detectors located near each controlled door or by door frame mounted hold-open devices with integral smoke detectors.

Smoke and/or heat detectors are often used for control of fire suppression systems such as gaseous (clean agent) and

preaction or deluge sprinkler installations. The design of these special systems should be undertaken only by fire protection engineers or other qualified individuals.

DETECTOR MAINTENANCE AND TESTING

A systematic program of preventive maintenance and regular testing is essential to ensure the continuous, proper performance of detectors. Analog-addressable detectors have an inherent advantage in this regard due to their on-board diagnostics and constant reporting for each roll call. Whereas a nonaddressable detector could be dead for months and not found until the next scheduled test, failure of an analog-addressable detector would be known in seconds. However, it is still necessary to periodically inspect smoke detectors and test them with smoke or equivalent aerosol to ensure that their smoke entry remains unaffected by such possibilities as conduit stack effect, HVAC air streams (supply diffuser changes), or even the detector being painted, taped up, or bagged. (See Section 14, Chapter 5, "Inspection, Testing, and Maintenance of Fire Alarm Systems" and *NFPA 72* chapter on inspection, testing, and maintenance.)

SUMMARY

Automatic fire detectors are activated by environmental changes known as fire signatures, principally heat, smoke, and radiation. Various types of systems have been developed to detect these divergent fire signatures, including heat detectors, smoke detectors, gas-sensing fire detectors, and radiant energy–sensing fire detectors. The type of fire detection system installed depends on several factors, including reliability, sensitivity, and environmental characteristics. The detectors must be properly installed, positioned, maintained, and tested to ensure dependable fire protection.

Chapter 3

Notification Appliances

Robert P. Schifiliti

Chapter Contents

Operating Modes for Notification Appliances
Audible Signaling
Visible Signaling
Combination Audible/Visible Units

Key Terms

audible appliance, fire alarm system, household fire-warning equipment, notification appliance, temporal code-three signal, visible signal

Fire alarm systems and household fire-warning equipment protect life by automatically indicating the need for the occupants to evacuate or relocate to a safe area. They may also notify emergency forces or other responsible persons who may then assist the occupants or assist in controlling and extinguishing the fire. Emergency communication systems (ECS) and mass notification systems (MNS) are used to provide information to occupants of a building or area for a variety of threats and emergencies. Audible and visible notification appliances alert the occupants, and, in some cases, emergency forces, and convey information to them.

A fire alarm system that simply sounds an audible signal and flashes strobe lights in a space is conveying a single bit of information—fire alarm. Systems that send voice announcements or that use text or graphic annunciators typically convey multiple bits of information. They may signal a fire alarm or other threat and give a specific location and information on how and where to evacuate or relocate. As the cost of emergency voice/alarm systems (EVAC) comes down closer to conventional systems, they are being used more and more by designers. They are almost always required by codes in high-rise buildings but can also be effectively used in smaller buildings. When provided with detailed information about a fire or other emergency, people tend to evacuate or respond to the information more quickly and effectively than to alarms that merely produce an audible signal or flash. The audibility requirements for voice systems are the same as for conventional systems except that it is only an alert tone, not the actual voice that is measured for proper audibility. In addition to audibility, the intelligibility of the signal content becomes important.

Audible and visible appliances may also be used to indicate a trouble condition in the fire alarm system or they may be used as supervisory signals to indicate the condition or status of other protection systems, for example, automatic sprinklers.

For related topics see Section 12, Chapter 15, "Public Emergency Services Alarm, Dispatch, and Communications Systems"; Section 14, Chapter 1, "Fire Alarm Systems"; and Section 14, Chapter 5, "Inspection, Testing, and Maintenance of Fire Alarm Systems."

OPERATING MODES FOR NOTIFICATION APPLIANCES

There are two operating modes for alarm notification appliances: (1) public operating mode and (2) private operating mode. In the public operating mode, audible and visible signaling is intended for the occupants or inhabitants of the area protected by the fire alarm system, emergency voice/alarm systems (EVAC), emergency communication systems (ECS), or mass notification systems (MNS). In the private operating mode, audible and visible signaling is intended only for persons directly concerned with implementation and direction of emergency actions in the area protected by the system. For example, in a bank or shopping mall, the fire alarm is intended to alert all occupants and convey the need for them to evacuate. This scenario describes a public mode system. If an EVAC or ECS system is used, it may be used to convey information to all occupants or to some subset of the occupants, but would still be considered to be in the public mode. In a prison or

Robert P. Schifiliti, P.E., is president of R. P. Schifiliti Associates, Inc., a fire protection engineering and consulting firm located in Reading, Massachusetts. He chairs NFPA's Technical Correlating Committee on *Signaling Systems for the Protection of Life and Property* and is a member and past chair of the *NFPA 72®* Notification Appliances for Fire Alarm Systems Technical Committee. Mr. Schifiliti is the vice-chair of the NFPA Fire Protection Research Foundation's Detection and Alarm Research Council and chair of the Council's Research Planning Committee.

hospital, the system may be designed to notify only the trained staff. They will then initiate emergency procedures, including assisting occupants who might not otherwise be able to evacuate or relocate. This scenario describes a private mode system. Similarly, a supervisory signal at a guard's station indicating an off-normal status of a fire pump is considered to be private mode signaling.

The operating mode of the system affects the selection and placement of notification appliances. In general, the requirements for private mode signaling are less stringent, because they are intended for a professional staff that has been trained to look and listen for that signal and to immediately take certain actions when it is seen or heard.

AUDIBLE SIGNALING

Audible notification appliances are the most common method for signaling a fire alarm or other emergency condition in a building or area. There are two factors that affect the performance of audible notification systems. Here performance is defined as the ability to alert and convey information. The first is the rating of the audible appliance. Typically, audible appliances are rated by measuring the sound pressure level (SPL) at a fixed distance in a special room.

Rating of Audible Appliances

Without giving the exact mathematical definition, sound pressure level is a measurement of how loud something is. The measurement is expressed in decibels (dB). For almost all emergency alarm applications, the sound pressure level is expressed in dBA (i.e., decibels, A-weighted). A sound pressure level expressed in dBA has been adjusted to account for the way the human ear perceives different frequencies. Typically, high-pitched sounds (high frequency) are heard better than low frequency, bass, sounds. The A-weighting adjustment corrects for this so that the loudness of sounds that are composed of different frequencies can be compared.

Audible appliance ratings are usually stated as a certain sound pressure level (SPL) at a distance of 10 ft (3.05 m). This is a starting point for the design or analysis of audible signaling systems. Because the rating is measured in a room with certain reverberation characteristics, the actual performance will vary depending on the field conditions. In a room or hallway with concrete block walls, a sheetrock ceiling, and a tile floor, the actual SPL at 10 ft (3.05 m) will probably be greater than the rating of the audible appliance. However, in an acoustically soft situation, such as a room with wood walls, carpet on the floors, and an acoustical tile ceiling, the SPL may be less than the appliance's rating.

The second factor affecting the performance of audible notification systems is the net sound pressure level produced throughout all of the building or area served by the system. As one moves away from an audible appliance, the SPL decreases. As one gets closer, the SPL increases. In a wide-open space where the sound does not reflect off any surfaces (no reverberation), the SPL decreases by roughly 6 dB every time the distance from the source is doubled. This condition is called the free-field condition. An anechoic chamber, designed to absorb all sound waves, simulates a free-field condition. In almost all other situations there is some reverberation. Nevertheless, the 6 dB rule can be used when designing a system or analyzing the expected performance of a system. Note that dBA is used when expressing an absolute SPL that has been adjusted using the A-weighting scale. However differences are always expressed as dB.

For example, if an appliance has a rating of 90 dBA at 10 ft (3.05 m) and the distance is doubled to 20 ft (6.1 m), one would expect to measure an SPL of approximately 84 dBA (Figure 14.3.1). At a distance of 40 ft (12.2 m), one would expect an SPL of 78 dBA. At 80 ft (24.4 m), the SPL would be approximately 72 dBA.

When there are multiple audible appliances in a space, their combined SPL is greater than any one, but the individual SPLs are not simply added together to get the result. For example, consider two appliances rated 90 dBA at 10 ft (3.05 m) that are spaced 40 ft (12.2 m) apart. Alone, each unit would produce about 84 dBA (90 – 6) in the center (20 ft [6.1 m] from each). With both units operating, a measurement taken between the two at 20 ft (6.1 m) from each would be about 87 dBA (3 dB greater than a single unit). Fire alarm designers usually ignore this effect so that their designs are conservative.

This type of analysis works well in open spaces. However, sound loss through walls and doors requires more complex calculation methods. Of course, in an existing building a temporary audible appliance can be used to study sound transmission and attenuation throughout the space and through the walls and doors. By measuring sound loss from one side of a door/wall assembly, designers can obtain representative values for a structure to be used in later design and analysis of the fire alerting system. The *SFPE Handbook of Fire Protection Engineering*[1] contains calculation methods that can be used in design and analysis of audible alerting systems.

Fire Alarm Audibility Design Goals

How loud should an alerting system be? Obviously, the audible signals must be louder than the ambient noise in a space. So, the first step is to measure the ambient noise. When designing new systems, tables of ambient noise levels may be used as an estimate. Annex A of *NFPA 72®, National Fire Alarm Code®*, contains such a table. Two different ambient noise levels are required to complete a system design: (1) the average SPL dur-

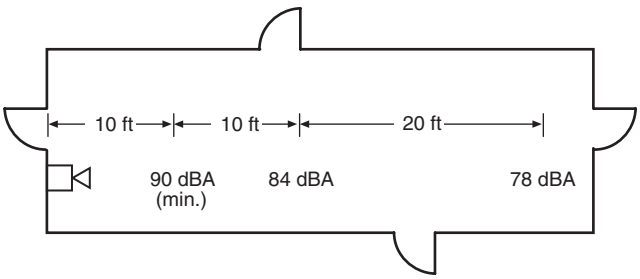

FIGURE 14.3.1 Example of 6 dBA Rule (1 ft = 0.305 m)

ing the time the area is occupied, and (2) the maximum SPL that lasts 60 seconds or more.

Fire alarm audibility goals are dependent on the mode of operation. In the public operating mode, the fire alarm system must produce a sound pressure level that is 5 dB above any ambient noise that lasts 60 seconds or more, or 15 dB above the 24 hour average, whichever is greater. In the private operating mode, the fire alarm system must produce a sound pressure level that is 5 dB above any ambient noise that lasts 60 seconds or more, or 10 dB above the average, whichever is greater. In either case, if the area will be used for sleeping, the minimum SPL required of the fire alarm system is 75 dBA. When designing an EVAC or MNS system, the same goals should be used for the audibility of the system's alert tone.

A fire alarm or other emergency tone signal may have the same SPL or less, measured in dBA, than the ambient noise and still be clearly heard. This occurs when the two signals (ambient and alarm) operate at different frequencies. In high noise occupancies such as manufacturing plants, it might be more effective to conduct a frequency analysis of the ambient noise and then design a fire alarm signal at frequency bands not occupied by noise. See Figure 14.3.2 for an example. The figure shows a one-third octave band analysis of noise and an alarm signal in a compressor room. The loudness of each frequency band is measured in dB (*Y* axis). The *X* axis shows the center frequency for each band measured in Hertz (Hz = cycles per second). The frequency bands range from low, bass-level frequencies on the left through midrange tones and up through very high-frequency tones. (Middle C on a piano is approximately 262 Hz.) On the far right, L_P represents the logarithmic sum of all the frequency bands while L_A is the logarithmic sum adjusted using the A-weighting scale to correct for how the human ear hears different frequencies. The noise can be thought of as a picket fence. To hear a fire alarm signal above the background noise, it does not have to be louder than all the component frequencies added together; it just has to be louder than one. As long as one of the alarm signal's frequency bands (pickets) is taller than the corresponding noise picket, you will hear the signal, even if the total broadband sound pressure level of the noise is greater than the total broadband sound pressure level of the signal. Consult *NFPA 72,* ISO, or an audio design text for more information.

Because building codes require residential and other sleeping-type occupancies to have a minimum degree of soundproofing, they represent the most challenging scenarios for fire alarm system design. Given the high SPL that must be achieved to alert a sleeping person, it has been shown that audible appliances are almost always needed in each sleeping room.[1] In other occupancies, such as offices and schools, it may be sufficient to place audible appliances in the corridors only. In any case, careful design is needed to ensure that audibility requirements are met.

Audibility Requirements. Once the system is installed, a complete test, including SPL measurements, must be done to prove that the system meets the signaling requirements. Various types of sound level meters are available for use in testing system audibility. Some are very expensive and have many features for special system analysis, and others are very inexpensive, yet serve the purpose. It is important that the meter have an A-weighting scale for measurement of the ambient and fire alarm SPLs.

In addition to the minimum sound pressure levels that a fire alarm must produce, there is a maximum allowable SPL of 100 dBA. This is below the threshold of pain, which occurs at about 130 dBA, and is intended to reduce the chances of damaging someone's hearing. It is possible to achieve fire alarm audibility requirements by using a few very loud appliances or a larger

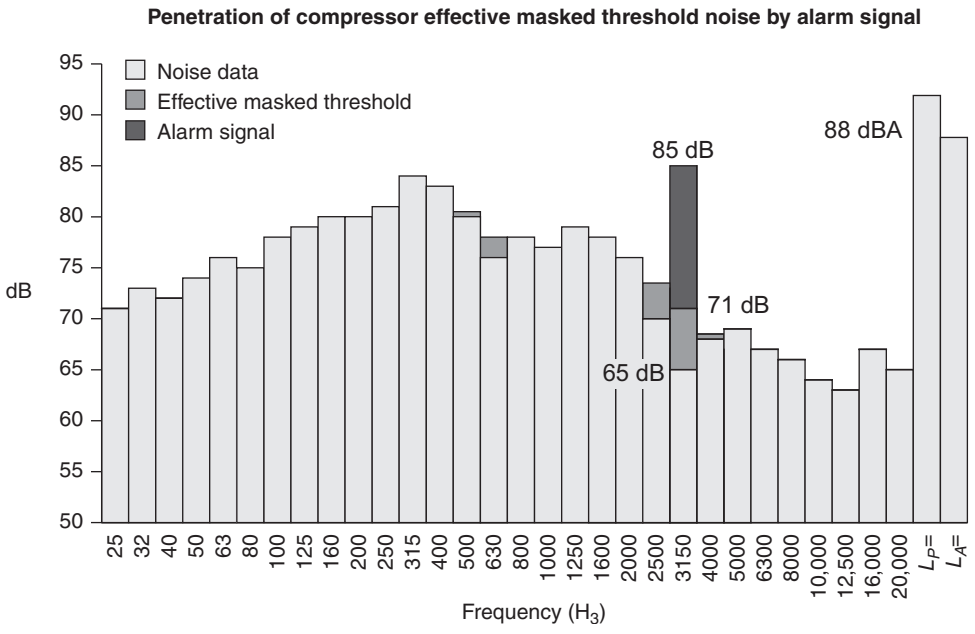

FIGURE 14.3.2 One-Third Octave Band Analysis

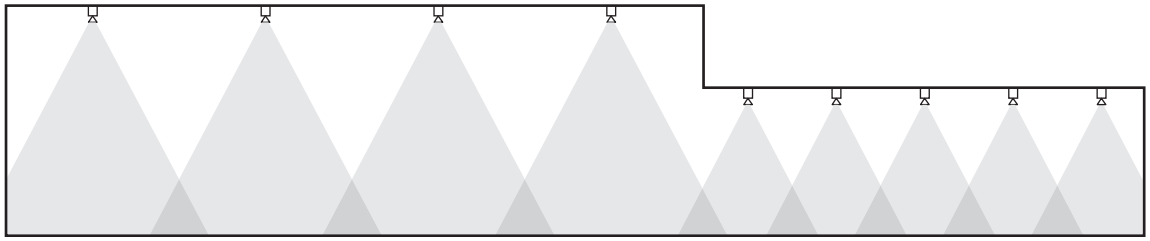

FIGURE 14.3.3 Spacing Between Textual Audible Appliances for Direct Field Coverage

number of units at a lower SPL rating. In general, system reliability is better with a larger number of lower SPL units. Also, the cost may be lower using a larger number of lower SPL units.

Intelligibility Requirements. If the system is being designed to transmit voice messages, the design should use a larger number of low-power units so that the voice message is intelligible. If only a few high-power speakers are used, reverberation or echoes of the sound may make it difficult to understand the message.

For voice communication, a sufficient audible level does not guarantee that the message will be intelligible. There are many factors affecting speech intelligibility in addition to the audible level. Some of the factors are a part of the audio system design and installation; others are a part of the architectural/acoustical environment. In addition, the talker and the listener are also a part of intelligibility, although they are generally taken to be "average" or slightly below "average."

For systems used to reproduce voice, specifying a louder system may result in degradation of the intelligibility of the message. One of the basic concepts in the design of intelligible voice systems is to have all listeners in the direct field of a single speaker, and to avoid having the system so loud that sound reverberates from other locations to the listener. If a person is in the direct field of two speakers, the sound from the farther one arrives some time after the sound from the closer speaker. The same effect occurs when the sound bounces off a wall and comes back to the listener (reverberation). The degree of impact on intelligibility depends on the time difference between the first arrival of the word or sound and the arrival from the second source. Distributing the speakers to reduce or eliminate the overlap of the direct field sound is the best design practice. Though at first counterintuitive to many fire alarm system designers, the lower ceiling height requires a smaller spacing between the speakers (see Figure 14.3.3). For additional information about the factors affecting speech intelligibility and their effects on system design, consult *NFPA 72* and "Understanding Speech Intelligibility and the Fire Alarm Code," by Kenneth Jacob.[2]

Audible Emergency Evacuation Signal. *NFPA 72* requires all audible evacuation signals to comply with ANSI S3.41, *Audible Emergency Evacuation Signal.*[3] (Note: *NFPA 72* does not itself require existing systems to comply with current requirements.) That signal is commonly referred to as a temporal code-three signal. The pattern consists of an "on" phase (a) lasting 0.5 seconds ± 10 percent, followed by an "off" phase (b) lasting 0.5 seconds ± 10 percent, for three successive "on" periods, which is then followed by an "off" phase (c) lasting 1.5 seconds ± 10 percent. The signal should be repeated for a period appropriate for the building, but not less than 180 seconds. A single-stroke bell or chime sounded at "on" intervals lasting 1 second ± 10 percent, with a 2 seconds ± 10 percent "off" interval after each third "on" stroke, is acceptable (Figures 14.3.4, 14.3.5, and 14.3.6.). The

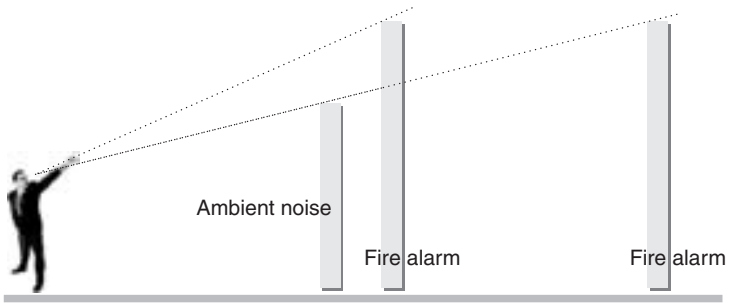

FIGURE 14.3.7 Effect of Ambient Noise on Ability to Perceive an Alarm

type of signal is not important; it may be a bell, horn, chime, whoop, or any other sound, provided it is not used for any purpose other than fire alarm. The intent is that the pattern of the sound will be standard from system to system. Systems intended to relocate people or to simply alert them of a nonfire emergency must not use the standard evacuation signal.

Importance of Location

The farther your ear or sound meter is from a sound source, the less loud it will be. Basic design practice is to analyze or estimate the ambient noise and then select and place alarm appliances to overcome that background noise. The picket fence analogy is useful here again (Figures 14.3.7 and 14.3.8). It is possible to hide a larger object that is farther away with a smaller object close by. Similarly, when you are at a certain location and the noise is at a certain level, there is a distance at which an alarm signal will be clearly heard, and there is a distance at which it will not be heard. Also, for set levels of noise and alarm and for set distance between their sources, there is a point where you can be so close to the noise that it will mask the alarm, as shown in Figure 14.3.8.

VISIBLE SIGNALING

Visible fire alarm notification appliances are often intended only to augment audible appliances. However, when it is expected that hearing-impaired persons may be in the protected area or when ambient noise levels are high, visible appliances may be the primary means of occupant notification that a fire emergency exists. Increasingly, visible appliances are being used as an integral part of occupant notification systems. For MNS or EVAC systems, simple visible appliances, such as strobes, are used to signal the need to "get additional information." Other types of visible appliances, such as scrolling signs, annunciators, and displays may be used to convey visible information during an emergency.

Building codes, NFPA *101*®, *Life Safety Code*®, and *NFPA 72,* as well as state and federal laws, all contain requirements for the use of visible notification appliances under certain circumstances. At present, only the use of strobe lights is addressed by *NFPA 72*. Other appliances and systems, such as revolving beacons or the flashing of building lights, have also been shown to be effective under certain circumstances. However, requirements necessary to ensure their availability and effectiveness are not addressed by the code at this time.

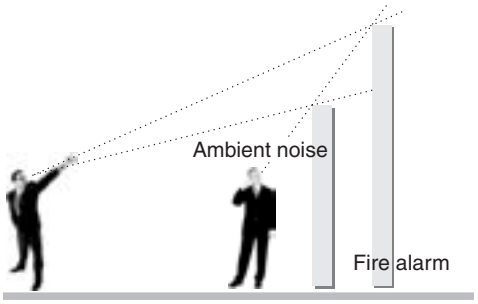

FIGURE 14.3.8 Effect of Proximity on Ability to Perceive an Alarm

Factors Affecting Performance of Visible Appliances

Visual signaling and notification using strobe lights involve a large number of complex variables. For this reason, *NFPA 72* uses prescriptive code language to provide simple, preengineered solutions. As with audible appliances, *NFPA 72* addresses two factors affecting the performance of visible notification appliances: (1) source intensity and (2) illumination at some distance from the source.

Source intensity is a measure of the light output of the appliance. The unit of measure is the candela (cd). (This unit was formerly called "candlepower." There is a one-to-one relationship between candela and candlepower.) As one moves away from any light source, the illumination it provides decreases. Illumination is measured in units of lumens (lm) per ft^2, or lumens per m^2 (also called "lux"). Formerly, the unit used to describe illumination was the "footcandle." One footcandle equals one lumen per ft^2. One lumen per m^2 equals 0.926 footcandles. Figure 14.3.9 shows the relationship between source intensity and illumination.

The inverse square law is used to determine the illumination, E, at some distance, d, from a source of intensity, I (i.e., $E = I/d^2$).

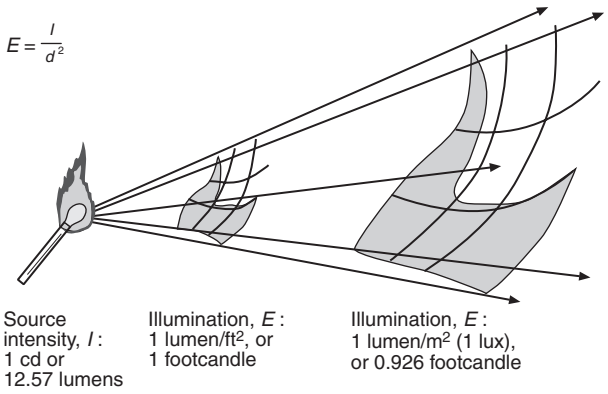

FIGURE 14.3.9 Visible Intensity Versus Illumination

Because strobe lights flash for a very brief period of time, the perceived brightness can vary depending on the actual peak source strength and duration of the flash (Figure 14.3.10). One appliance might reach a peak intensity of 1000 candelas in 0.1 second, while another might reach 750 candelas in 0.2 second. Nevertheless, the human eye might perceive both as being equally bright. A complex mathematical relationship is used to relate the perceived brightness of a strobe light to that of a constantly burning light. The result is called the "effective intensity" (candela effective [cd eff]).

The design of visible notification systems involves many additional factors beyond those discussed herein. Many other factors, such as how much light is absorbed versus how much is reflected by a surface, the angle that the light strikes a surface, and the color of the surface, affect the performance of the notification system. For instance, as light strikes a surface at some angle, only a portion of that light is reflected back to the human eye. The term used to describe the reflected light is "luminance." Thus, a certain intensity appliance produces a certain illumination at some distance on a surface, but a person looking at that surface sees a certain luminance.

To simplify the process of designing and evaluating visible notification systems, *NFPA 72* contains prescriptive requirements for the intensity and spacing of visible appliances that are sufficient in almost all applications to alert persons. In essence, *NFPA 72* provides preset designs that can be used for a variety of actual field conditions.

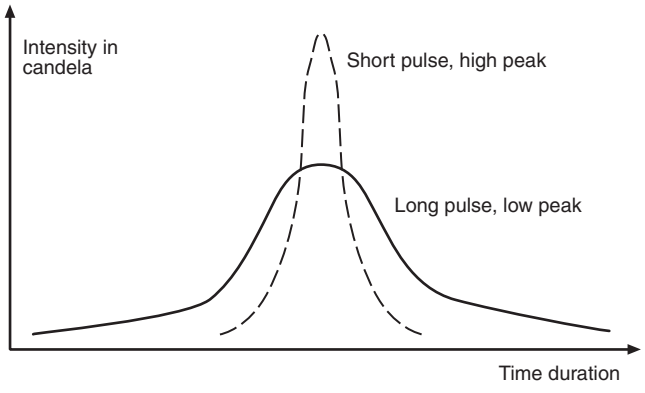

FIGURE 14.3.10 Visible Peak Versus Effective Intensity

The prescriptive requirements contained in *NFPA 72* are based, in part, on tests performed by Underwriters Laboratories Inc. (UL).[4] The tests were conducted in real classrooms and test facilities with similar size characteristics. Use of *NFPA 72* methods for larger spaces may not be valid. For example, in large stores or warehouses, it is not known if these methods will be conservative or ineffective.

Fire Alarm Visibility Design Goals

NFPA 72 contains tables listing the minimum intensity strobe required in certain size rooms to alert the occupants. For instance, a single 15 cd eff strobe can be used when centered on one wall of a 20 ft × 20 ft (6.1 m × 6.1 m) room. There are also listings for use of multiple units in a single room. Using the 20 ft × 20 ft (6.1 m × 6.1 m) room as an example, the illumination on the opposite wall would be $15/20^2 = 0.0375$ lumens per ft^2. *NFPA 72* permits a performance-based design approach using this level of illumination as the requirement. See *NFPA 72* and the *SFPE Handbook of Fire Protection Engineering* for examples.

Occupancies where hearing-impaired persons may sleep must have higher strobe intensities than for nonsleeping areas to ensure that the hearing-impaired person can be awakened. A 110 cd eff strobe no more than 16 ft (4.9 m) from the pillow was sufficient to awaken hearing-impaired persons. Other methods, such as bed shakers or fans, may be used to supplement visible signaling. In practice, a bedroom strobe light is often combined with a smoke detector. In that case, the strobe light must have an even higher intensity (177 cd eff) to overcome potential obscuration by a smoke layer at the ceiling.

Some spaces, such as corridors, can be treated differently from those rooms where a person may have his or her face turned away from a strobe light. In corridors, a person's view path is more concentrated, and the person is usually moving. Recognizing this, *NFPA 72* allows the use of 15 cd eff strobes at longer distances than what would be required for rooms. The luminous intensity required is actually less, given that a person is likely to directly see the appliance or to see more surfaces illuminated by the strobe.

When designing the audible part of an occupant-notification system, it is best to use a greater number of lower-power SPL units. The opposite is true for visible appliances. The use of a lower number of higher-intensity units will usually be more cost-effective. Furthermore, with fewer appliances, the distance between them is greater, and the chances of a person directly viewing more than two units at a time is reduced or eliminated. That, in turn, reduces the likelihood of triggering a seizure in a person who has photosensitive epilepsy.

When choosing and placing visible appliances, every effort should be made to place the unit in the concentrated viewing path of the target audience. For example, in a meeting room or classroom, the appliance should be on the wall that the majority of people face. This, however, is not a requirement of the code, since the entire methodology for signaling in rooms is based on having sufficient illumination for indirect alerting. Further-

more, a mounting height of 6.5 to 8 ft (2.03 to 2.44 m) ensures that the visible appliance is unlikely to be blocked by common furnishings.

In spaces such as large auditoriums the use of high-intensity indirect signaling may be warranted. This method of indirect signaling uses much higher-intensity strobes that must be located so that they cannot be directly viewed by the human eye (they could temporarily or permanently impair vision). The light from the strobes is used to illuminate large areas of walls and ceilings. The UL research used indirect illumination. However, the illumination was on a wall in front of the test subjects, and the maximum intensity was low enough to allow direct viewing of the appliance's element. Another possible method of visible signaling in such high-challenge spaces is to flash some or all of the building lights. Although these methods may prove effective, at this time there are few test data to support specific performance requirements for these notification methods. It should be noted that the authority having jurisdiction (AHJ) must approve any type of alternate arrangement that is not directly covered by code requirements.

In the past, guidelines for meeting the visible signaling requirements of the Americans with Disabilities Act (ADA)[5] have cited strobe intensities and distances different from those specified in *NFPA 72*. However, through a process called "equivalent facilitation," the requirements of *NFPA 72* have been shown to meet or exceed the original ADA "Accessibility Guidelines" (ADAAG). The ADAAG have been revised to follow *NFPA 72* requirements.

Visible Signaling in Warehouse Stores

In large warehouse spaces and large distribution spaces such as superstores, it is possible to provide visible signaling using strobe appliances. However, mounting strobe lights at a height of 2.0 to 2.4 m (80 to 96 in.) along aisles with rack storage subjects the lights to frequent mechanical damage by forklift trucks and stock.

Tests of systems in large warehouse/superstores designed using ceiling-mounted strobes, and the prescriptive approach of *NFPA 72*, showed that the systems worked because of both indirect and direct signaling effects.[6] The signal-to-noise ratio produced by the operating strobes was low in many locations due to high ambient light. However, with strobes located over the aisles or unobstructed by stock, indirect and some direct notification was sometimes achieved. Direct notification can occur even when occupants do not look up toward the ceiling-mounted strobes due to the extended cone of vision shown in Figure 14.3.11.

Tests showed that the strobe intensity and spacing resulting from the prescriptive design were generally sufficient for occupant notification by a combination of direct and indirect signaling. The best performance was achieved where strobes were directly over aisles or where strobes in adjacent aisles were not obstructed by stock. The performance-based design method will almost always result in aisles not having a line of strobes in them, since the spacing of strobes can be greater than the spacing of aisles. Also, it is recognized that aisles may be relocated after installation of the system. Good design practice is to place strobes over aisles, especially those that are likely to remain unchanged such as main aisles and over checkout areas. Where reorganization of aisles results in strobes not in or over an aisle, or where that is the base design, it is important to have a clear view from that aisle to a nearby strobe (Figure 14.3.12). Some spaces may have marginal strobe effect (direct or indirect). However, occupants in these large stores and storage occupancies move frequently and place themselves in a position where they receive notification via the strobes.

COMBINATION AUDIBLE/VISIBLE UNITS

To meet the requirements of ANSI S3.41, *Audible Emergency Evacuation Signal,*[3] some systems will require separate circuits for audible and visible appliances. Some combination audible/visible appliances may be available that can be installed on a common circuit. In any case, it will be important to size the circuit to handle the expected load. Greatest flexibility is obtained by putting fewer than the maximum number of units on a circuit when the system is first designed or installed. In this way, if the acceptance test shows deficiencies in some areas, additional units can be added without overloading the circuits or the system.

Most codes do not require audible and visible appliances to be on separately controlled circuits. However, if they are, the audible circuits can be silenced after a building has been completely evacuated, and the visible appliances can be left

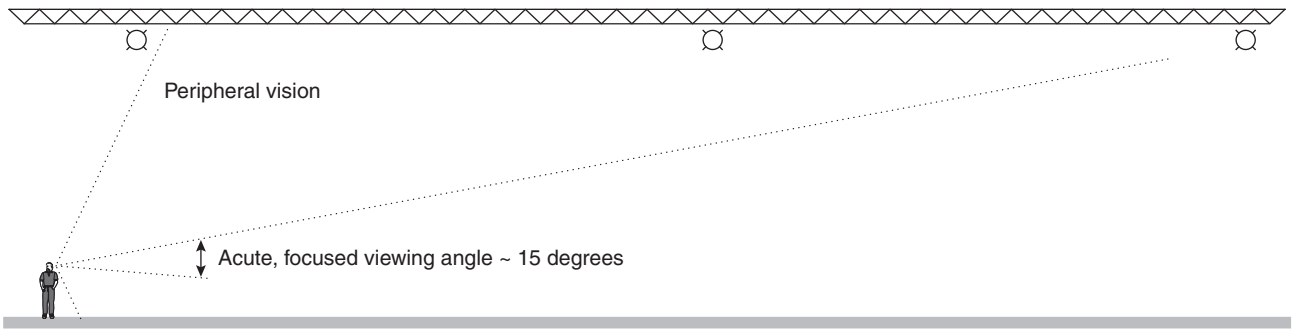

FIGURE 14.3.11 Occupant Perception of Notification Through Extended Cone of Vision

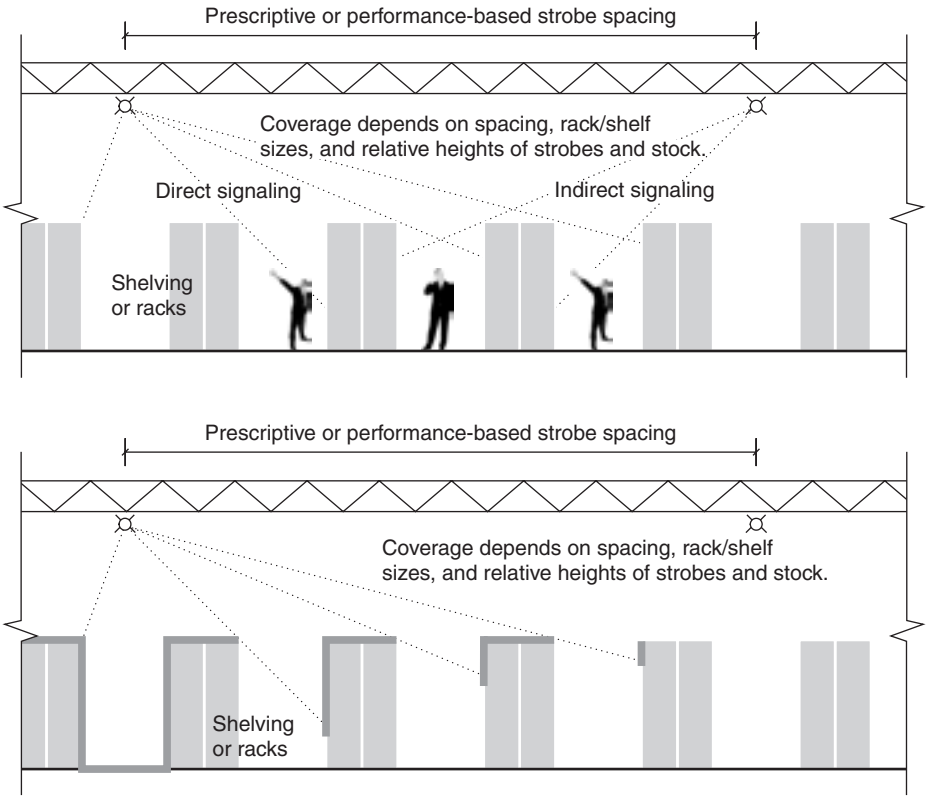

FIGURE 14.3.12 View of Strobe from Aisle

in operation. This is a way of telling people not to reenter the building or space. Similarly, good design practice is to include an audible and a visible appliance on the outside of the building to assist arriving fire fighters in locating the building or building entrance. Placing appliances on each side of a building or at each entrance also helps inform persons that they should not enter the building or space.

When designing or installing occupant notification systems utilizing both audible and visible appliances, it is best to determine the locations of the visible units first. This is because their location is more dependent on viewing angles, intersections of corridors, and blockage by furnishings. Once the visible appliances have been placed, audible appliances can be located so that some or all of the units can be combination audible and visible appliances. The use of combination units may reduce installation costs slightly. Figure 14.3.13 shows examples of both visible and combination audible/visible notification appliances.

FIGURE 14.3.13 Typical Visible and Combination Audible/Visible Notification Appliances (Source: Gentex Corp.)

SUMMARY

Audible and visible notification appliances are used to alert occupants of a building that they need to evacuate or relocate to a safe area. In addition, they may alert emergency personnel or indicate a problem in the fire alarm system or other protection system, such as automatic sprinklers. When used in the public operating mode, the notification appliance will alert the occupants of an area, such as a shopping mall, that they need to evacuate. In the private operating mode, the notification appliance is intended for trained staff responsible for undertaking emergency actions in locations such as hospitals or prisons.

Audible notification appliances are the type most commonly implemented, and their placement, decibel setting, frequency, and length of signal are calculated according to numerous factors, including the physical parameters of the area being protected. Visible notification appliances are usually used to supplement the audible alarm system, but in certain cases

(such as loud ambient noise) they may be the primary alarm system. As with audible systems, the design of visual notification appliances must use many calculations based on a variety of factors, including the physical properties of light.

Key Terms

automatic sprinkler system, building automation system, fire alarm control unit, fire alarm system, interconnection, protected premises, waterflow alarm

Many fire protection systems, fire safety control functions, process monitoring systems, and building operation and control systems can contribute to life safety in a building. A significant benefit can be obtained if these systems are interfaced with the building fire alarm system. *NFPA 72®*, *National Fire Alarm Code®*, requires that all fire protection systems in a protected property be connected to the protected premises (local) fire alarm system. Many interface strategies are now also required by building codes and (other) relevant standards.

The integration of commercial fire and nonfire protection systems has existed for many years. In addition to the benefits to life safety, the combination of systems was an attempt to conserve valuable construction dollars through systems integration. In other cases, systems integration was seen as a necessity for ease of building management—for example, combination security/access control and fire alarm systems or building automation and fire alarm systems.

There are some commercially available combination systems that are tested, listed, and manufactured to serve as combination systems. However, many systems provide some form of protection or management of a building, such as elevator control, door control, and heating, ventilating, and air-conditioning (HVAC) control, which can benefit by being integrated or interfaced with the fire alarm system. These systems are not necessarily manufactured, tested, or listed as a single integrated system. Their interface with fire protection systems will be presented in this chapter.

See also Section 2, Chapter 6, "Fundamentals of Fire Detection"; Section 14, Chapter 1, "Fire Alarm Systems"; Section 14, Chapter 10, "Security and Intrusion Detection Systems"; and Section 16, Chapter 3, "Automatic Sprinkler Systems."

AUTOMATIC SPRINKLER SYSTEMS

The fire protection system that will provide the most obvious benefit by interfacing to a fire alarm system is the automatic sprinkler system, which can be monitored both for waterflow alarms and for disablement of system components or water supply. Fire and building codes as well as other relevant standards identify the specific system functions that must initiate alarm and supervisory signals. In addition, "good engineering practice" may conclude that certain functions or devices should be supervised.

The value of installing an automatic sprinkler system for life safety and property protection has been well documented over many years of service in a variety of specific applications. It is obviously necessary to ensure that the automatic sprinkler system is maintained in such a condition that it is always ready to discharge water on a hostile fire, holding the fire to its area of origin, and helping to control smoke development.

One way of making certain that an automatic sprinkler system remains fully in service is to supervise its operational features as well as the availability of water supplies. At the same time, it is necessary to initiate an alarm signal whenever the sprinkler system does operate so that personnel

A. M. (Fred) Leber is CEO of Leber/Rubes, Inc., a fire protection and building code consulting engineering firm in Toronto. A member of the NFPA Standards Council and a fellow of the Society of Fire Protection Engineers, he is chair of Subcommittee 2 of Underwriters Laboratories of Canada. Mr. Leber also chairs two ISO committees.

may respond promptly and take whatever action is needed. Thus, these two functions—waterflow alarm and automatic sprinkler system supervision—are vital elements of an overall fire protection program.

AUTOMATIC SPRINKLER SYSTEM WATERFLOW ALARMS

Notification Functions

Notification of a waterflow alarm may be as simple as a hydraulically operated water motor gong serving a single sprinkler riser (see Section 16) or as complex as a multiplex proprietary fire alarm system monitoring several hundred sprinkler risers at a very large industrial facility. In either case, there are certain basic functions that must be provided by whatever waterflow alarm equipment is installed, including the following:

1. The prompt detection of the discharge of a certain number of gallons per minute (L/min) at nominal pressure that would be equivalent to the amount of water discharged from a single operating sprinkler having the smallest orifice of those sprinklers installed in that particular system
2. The reliable operation of a suitable audible alarm notification appliance; the exact nature of the particular appliance will depend on the purpose of the specific waterflow alarm system
3. The provision of suitable facilities to test the operation of the waterflow alarm device, preferably by an actual flow of water equivalent to the discharge from a single automatic sprinkler having the smallest orifice of those sprinklers installed in the system

Notification of waterflow alarms can be categorized according to their purpose and according to their method of operation. For example, the notification of a waterflow may be an alarm signal to alert someone either outside the building or in the immediate area protected by the sprinkler system riser. Such a signal would normally be produced by the operation of either a hydraulically operated or electrically operated bell. The waterflow alarm system also may be installed to provide an alarm signal that will sound throughout the protected building. This will normally be achieved by connecting the waterflow alarm initiating device to a protected premises (local) fire alarm system.

The waterflow alarm signal may transmit the signal off-premises to a constantly attended location by means of a signaling system for central station service, an auxiliary fire alarm system, or a remote station fire alarm system. The waterflow alarm signal may provide a signal that will be transmitted to a constantly attended location on the protected premises or to another location of the same owner. This will normally be accomplished by connecting the waterflow alarm initiating device to a proprietary fire alarm system.

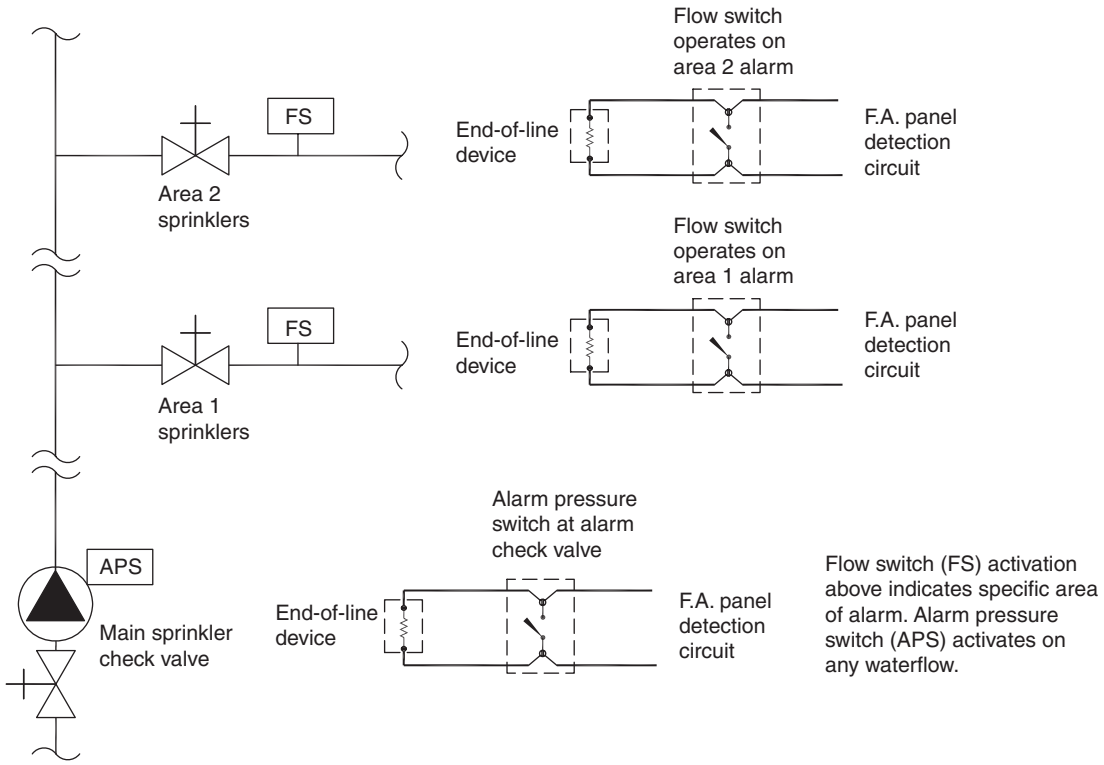

FIGURE 14.4.1 Alarm Pressure Switch Connection

Electrically Operated Waterflow Alarms

Waterflow alarms may be signaled using electrically operated fire alarm notification appliances, such as vibrating bells, horns, sirens, chimes, and several varieties of flashing lights. Such signals usually are initiated by electrical switches incorporated into some type of pressure- or flow-operated device.

Waterflow Alarms for Wet Pipe Automatic Sprinkler Systems

For wet pipe automatic sprinkler systems, the flow of water is generally detected hydraulically by an alarm check valve or by a vane-type waterflow alarm initiating device. The alarm check valve and waterflow alarm initiating device cause an electrical contact closure when waterflow is detected. This contact is connected to the fire alarm system. Either of these would be installed at the point the water supply piping enters the building from the underground. Supplementary vane-type devices could also be installed at various points in the piping system, for example, on each floor of a high-rise building. This allows a more precise determination of the location where water is flowing and subsequently aids in obtaining a timely response to the emergency.

Alarm Check Valves

Depending on the specific design, alarm check valves are generally referred to as being either "plain type" or "differential type." (See Section 16, Chapter 3, "Automatic Sprinkler Systems," for more information on alarm check valves.) The basic design of most alarm check valves incorporates a clapper that lifts from its seat when water is discharged from sprinkler system piping above the valve. The movement of the clapper is used to allow waterflow into an "alarm port." This port can be connected to electrical or mechanical devices that initiate an alarm at the fire alarm system. Since the clapper may be subject to movement as a result of sudden changes in water pressure, a retard mechanism is installed that takes up the water surge and prevents clapper movement and subsequent false alarms.

Pressure-Operated Switch Waterflow Alarm Initiating Devices

A pressure-operated switch could be mounted on a fitting connected to the alarm port of the alarm check valve, as long as there is no shutoff valve in the connection. In such a case, it would normally be necessary to provide an electronic or electropneumatic retard mechanism, either built into the pressure-operated switch or installed at the fire alarm system control unit, if one exists. A pressure-operated switch so located could be used to initiate a fire alarm signal on a central station, local, auxiliary, remote station, or proprietary fire alarm system (Figure 14.4.1).

Vane-Type Waterflow Alarm Initiating Devices

Far and away the most common electrically operated waterflow alarm initiating device is the vane-type waterflow switch

FIGURE 14.4.2 Vane-Type Waterflow Alarm Switch

(Figure 14.4.2), which is designed to be inserted into the riser just above the point at which the water supply piping enters the building from underground. Even if the wet pipe system has been equipped with an alarm check valve, a vane-type waterflow alarm initiating device may still be used. In this case, it normally would be installed just above the alarm check valve.

A small hole approximately 1 in. (25 mm) in diameter is drilled into the riser. The drill bit has a special piece of spring steel wire that captures the metal center of the hole, which is called the "coupon." Once the coupon is removed from the drill bit, it is usually attached to one of the mounting bolts of the waterflow alarm initiating device to show future inspectors that it was not left inside the pipe where it might possibly move upward into the sprinkler system and become an obstruction to the proper operation of the sprinkler system. The plastic or thin metal vane is rolled up and inserted into the riser. Once it resumes its original shape, it forms a thin barrier that covers almost all of the interior of the riser. When a sprinkler fuses, water flowing past the vane will push the vane upward, actuating a switch. When the switch contacts close, they initiate an alarm by activating the fire alarm system.

Two problems that may occur occasionally with vane-type waterflow alarm initiating devices are leaks around the point of entrance into the riser and detached vanes. The laboratories that test and list such devices require that each vane have a supplementary means of attaching the vane to the device so that, even if the vane breaks off, it will be retained near its original point of connection.

Waterflow Alarms for Dry Pipe, Preaction, and Deluge Automatic Sprinkler Systems

Automatic sprinkler systems equipped with dry pipe valves, preaction valves, or deluge valves also must have appropriate waterflow alarms. Each of these types of valves has a passageway that is uncovered when the clapper of the valve trips into the open position. Since these three types of valves are not affected generally by surges in the water system, no retard chamber is necessary. Piping connected to the outlet from the alarm passageway of these valves may be attached to a water motor gong or to a pressure-operated switch.

Vane-type waterflow alarm initiating devices are not permitted to be used for dry pipe valve, preaction, or deluge sprinkler systems. This prohibition comes from concern that the hydraulic shock occurring when these valves trip would increase the possibility that the vane might become detached.

Drop-in-Pressure Waterflow Alarms

An alternative arrangement designed to initiate a waterflow alarm, even if the main automatic sprinkler system control valve is shut, is the drop-in-pressure waterflow alarm. The supervision of all fire protective system control valves 2½ in. (63.5 mm) nominal size or larger is considered very important, especially when a fire alarm system is used to supplement or supplant standard guard service. Occasionally, it is simply not possible to obtain this valuable supervision. In such cases, it is essential that some method of detecting sprinkler system waterflow be used that will initiate an alarm even if the sprinkler control valve is shut. One method of accomplishing this is to use a waterflow alarm initiating device that detects a drop in sprinkler system pressure as a means of detecting the discharge of water from the system.

Such devices may use an ancillary storage chamber connected to the sprinkler system through a restricted orifice. Under normal conditions, the pressure in the ancillary chamber is the same as that in the sprinkler system. When system pressure drops, the pressure stored in the chamber acts on a diaphragm to activate an alarm initiating switch. Other such devices may employ a pressure-sensing transducer and associated electronic circuitry to detect the rate of pressure change in the system. A slow rate of change is reported as a trouble signal, whereas a rapid rate of change is reported as an alarm.

The most common drop-in-pressure waterflow alarm initiating device uses a pressure switch to sense the pressure in the system and, for wet pipe systems, employs a small riser-mounted excess pressure pump (Figure 14.4.3). (An excess pressure pump is not needed for dry pipe systems.) When the water pressure in a wet pipe system or the air pressure in a dry pipe system drops to a predetermined pressure setting, the pressure switch initiates an alarm signal. The automatic excess pressure pump maintains a pressure of 29 to 47 psi (200 to 325 kPa) in excess of the water supply pressure above an alarm check valve. A continuous white pilot light, controlled by a differential switch, indicates when the pressure in the sprinkler system is more than 29 psi (200 kPa) above the supply pressure. Should the water supply fail, a low-pressure switch shuts off the current

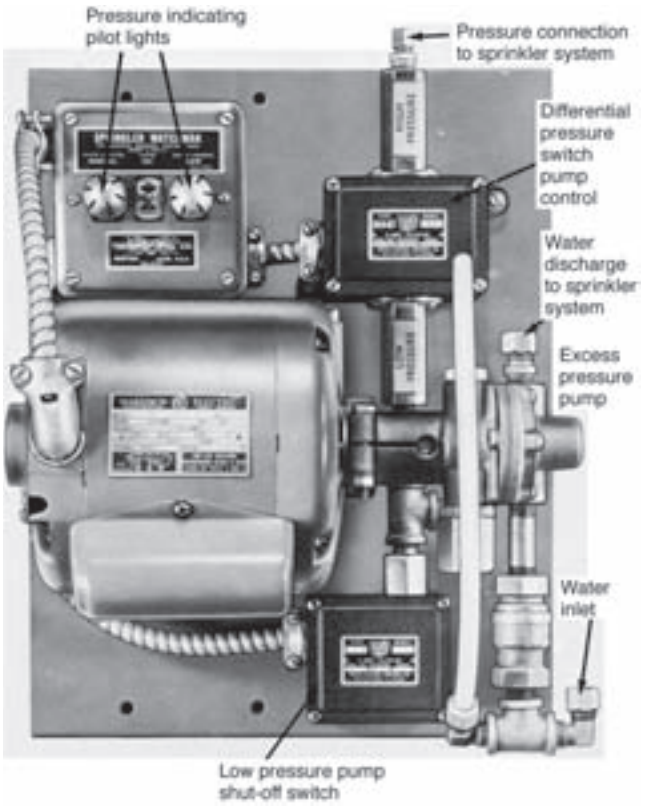

FIGURE 14.4.3 Excess Pressure Pump for Installation on a Wet Pipe Sprinkler System (Source: The Gamewell Co.)

to the pump so that it will not run without water. This switch also controls a red pilot light to show when the supply pressure drops below 29 psi (200 kPa). A second pressure switch on the sprinkler system (not a part of the pump unit) is connected into the sprinkler system alarm circuit and gives an alarm if system pressure fails completely (e.g., a closed water control valve) when a sprinkler operates. A third pressure switch gives a warning by a local bell or other means in the event the pressure pump fails to maintain system pressure within the established excess pressure range.

Drop-in-pressure-type waterflow alarm initiating devices should be connected to the sprinkler system through an automatic stop-and-waste valve. Such a valve automatically "wastes" the pressure trapped between the valve and the device to the atmosphere. Thus, a signal is initiated whenever the valve is closed. This eliminates the possibility of tampering with the device without producing a signal.

Testing Waterflow Alarm Initiating Devices

The piping connected to the alarm outlet from alarm check valves, dry pipe valves, preaction valves, or deluge valves usually is connected also through a normally closed valve to a point of water supply below the alarm check valve, dry pipe valve, preaction valve, or deluge valve. Opening this test bypass valve will allow water to flow into the alarm piping, actuating the water motor gong or pressure-operated switch. Unless

the dry pipe valve, preaction valve, or deluge valve is going to be performance tested with a full actuation of the system, opening the alarm test bypass valve is the only way to test the alarms.

In the case of a dry pipe valve, care must be taken to be certain that the automatic velocity drain from the intermediate chamber of the dry pipe valve is not stuck in the closed position and that the check valve at the alarm outlet from the dry pipe valve intermediate chamber is not stuck in the open position. The combination of these two faults will most likely cause the dry pipe valve to trip when the alarm test bypass valve is opened. This tripping occurs when water from the test bypass valve flows back into the intermediate chamber of the dry pipe valve, destroying the differential between the air seat and the water seat inside the valve.

For wet pipe automatic sprinkler systems, the only proper way to test the operation of a vane-type waterflow alarm initiating device, and the preferable way to test all other types of waterflow alarm initiating devices, is to open the valve at the inspector's test connection. This valve, installed on a 1 in. (25 mm) piece of pipe—for older installations, it is often located at the most remote point of the sprinkler system, and, for more modern installations, it is often located at the top of the riser—terminates outside the building in an orifice that can simulate the discharge from a single sprinkler having the smallest orifice used by those sprinklers installed on the system. Thus, opening the inspector's test connection will simulate the fusing of a single sprinkler.

Last but not least, it is important to consider the consequences of a test when systems are interfaced. The testing of a sprinkler system could, for example, cause an unnecessary building evacuation. This could lead to injury as well as disruption of building operations. In addition, other interfaced systems such as heating and cooling equipment and elevators may be actuated or de-energized inadvertently, again creating potential risk to building occupants. Where testing is conducted and interfaced systems are disconnected temporarily, it is absolutely necessary to reconnect any bypassed functions on completion of the test. Interfaced system functions must also be tested but this should be done deliberately, with full knowledge of consequences, and not by negligence.

AUTOMATIC SPRINKLER SYSTEM SUPERVISION

Supervisory Initiating Devices

To ensure that an automatic sprinkler system is ready to discharge water on a hostile fire and hold the fire to its area of origin, a central station, local, remote station, or proprietary fire alarm system may be connected to supervisory initiating devices that will supervise critical operating features of the sprinkler system. Fire and building codes as well as other relevant standards identify the specific equipment required to be supervised and must be considered when assessing an existing system or designing a new one. As well, good engineering practice may conclude that certain functions or devices should be supervised.

Functions or Devices to Be Supervised

Supervision may include the following devices or functions:

1. *The position of sprinkler water shutoff valves.* Normally, only those valves that are 2½ in. (63.5 mm) or larger are supervised. This supervision is provided by mounting a supervisory initiating device on the valve that will initiate an off-normal signal whenever the valve is operated into a closed position and that will initiate a restoration-to-normal signal whenever the valve is returned to a fully open position.

When mounting an initiating device where it will come in contact with the threaded shaft of the valve, care must be taken that the device is adjusted so that it will not falsely initiate a restoration signal if the shaft stops turning with the sensing portion of the device between two of the threads. This is a particularly troubling problem with larger sizes of control valves (Figures 14.4.4 and 14.4.5).

FIGURE 14.4.4 Valve Supervisory Switch for an Outside Screw and Yoke (OS&Y) Valve

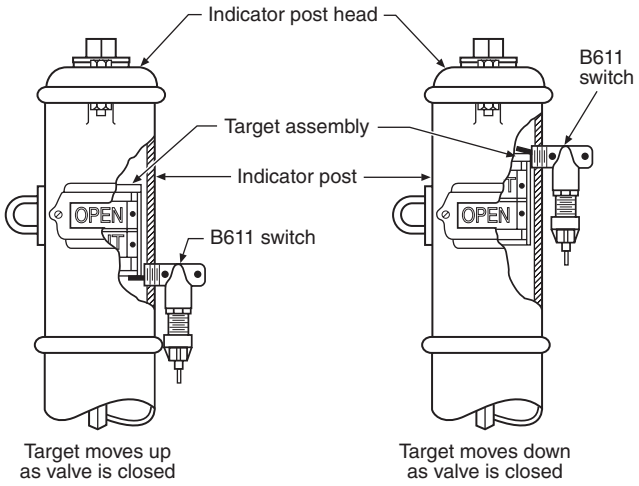

FIGURE 14.4.5 Valve Supervisory Switch for a Postindicator Valve (PIV)

FIGURE 14.4.6 Low-Temperature Switches for a Water Storage Tank

Some systems employ a metal or other loop attached to the water shutoff valve. One end of the loop plugs into an electrical switch mechanism such that a turn of the valve requires removal of the loop from the switch mechanism. These are not generally allowed in new systems because they can be plugged into the switch once the valve is closed, thereby allowing the fire alarm system supervisory circuit to return to normal unless latching circuitry is used in the monitor circuit.

2. *The air pressure in a dry pipe sprinkler system or water pressure tank and the supervisory air pressure in a preaction sprinkler system.* Connecting an air pressure supervisory initiating device to the system being supervised allows it to be monitored. Such a device is designed to initiate a supervisory off-normal signal whenever the air pressure climbs above or drops below a designated set point. Conversely, the device will initiate a restoration-to-normal signal whenever the air pressure is restored to the valve at which the device is set.

During installation, it is important that provision be made to allow testing of the device by simulating its operation during abnormal conditions. One method of accomplishing this is to connect the device to the sprinkler system through a stop-and-waste valve. When operated, such a valve automatically "wastes" the pressure trapped between the valve and the device to the atmosphere. Thus, whenever the valve is closed, a signal is initiated. This eliminates the possibility of tampering with the device without producing a signal.

3. *Low temperature in a building equipped with a wet pipe automatic sprinkler system, in a closet protecting a dry pipe valve, preaction valve, or deluge valve from freezing, or of the water inside a storage tank.* Mounting a temperature supervisory initiating device at the location to be supervised allows it to be monitored. Such a device is designed to initiate a supervisory off-normal signal whenever the temperature drops below a designated set point. Conversely, the device will initiate a restoration-to-normal signal whenever the temperature is restored to the value at which the device is set (Figure 14.4.6).

4. *The level of the water in a storage tank.* Mounting a water-level supervisory initiating device in a storage tank allows the water level to be supervised. Such a device is designed to initiate a supervisory off-normal signal whenever the water level rises above or drops below a designated set point. Conversely, the device will initiate a restoration-to-normal signal whenever the water level is restored to the value at which the device is set. During installation, it is important that provision be made to allow testing of the device by simulating its operation during abnormal conditions (Figure 14.4.7).

5. *The operation and integrity of a fire pump.* Connecting supervisory initiating device circuits to the "remote signal" contacts inside the fire pump controller allows it to be monitored. When an electric motor–driven fire pump operates into a running condition or when the power to the motor is interrupted, distinct supervisory signals are initiated. Similarly, when an engine-driven fire pump operates into a running condition—that is, its main switch is placed in a position other than "automatic start"—the battery charger fails, the engine experiences an abnormal condition or fails to start, or the controller fails, distinct supervisory signals are initiated. Conversely, a restoration-to-

FIGURE 14.4.7 Low-Water-Level Switch for a Water Storage Tank

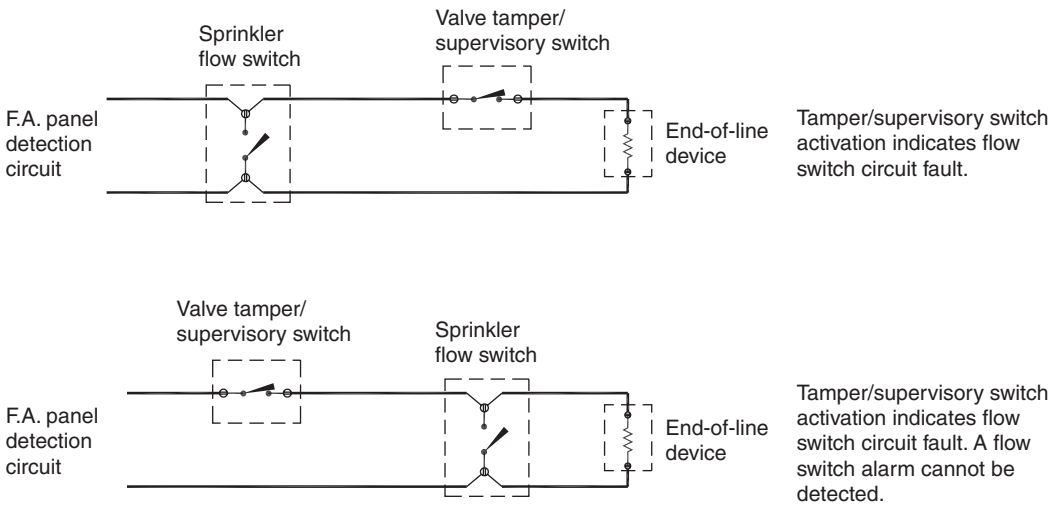

FIGURE 14.4.8 Incorrect Wiring of a Flow Tamper Switch

normal signal will be initiated whenever the particular feature of the fire pump that is off-normal is restored to normal.

6. *Tampering with a waterflow switch cover.* The switch cover may be monitored for removal (tampering that could affect the switch's ability to activate an alarm) by a supervisory switch connected to activate when the cover is removed.

NFPA 72 requires that three signals be identified at the fire alarm control unit: (1) alarm, (2) supervisory, and (3) trouble. In order to comply with that requirement, supervisory initiating devices must not be on the same initiating device circuit as alarm initiating devices. A common wiring configuration has been to install the waterflow alarm initiating device on the same circuit with the supervisory initiating device, for example, an OS&Y supervisory switch (as shown in Figure 14.4.4).

Although electrically this configuration may work, the wiring configuration with both devices on the same circuit will not provide the differentiation between a broken connection (trouble condition) and a closed valve (supervisory condition). If the wiring configuration and panel operation (such as with addressable devices) can provide the signal differentiation required by *NFPA 72,* then the devices can be wired on the same electrical circuit. Refer to Figures 14.4.8 and 14.4.9 for descriptions of incorrect and correct means of connecting these devices to a fire alarm system.

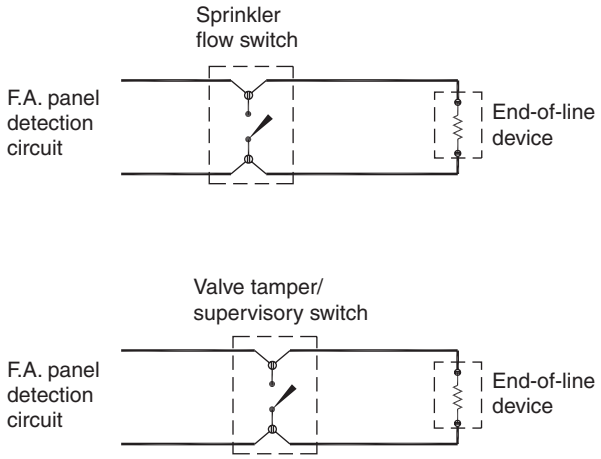

FIGURE 14.4.9 Correct Wiring of a Flow and Tamper Switch

OTHER AUTOMATIC FIRE SUPPRESSION SYSTEMS

There are many other types of fire suppression systems found at protected premises, such as a kitchen hood/duct suppression system or a carbon dioxide or other gaseous suppression system. Each of these fire suppression systems must be connected to the protected premises fire alarm system to initiate an alarm. Each of these systems must also be supervised for proper operation. In most cases, there is an NFPA or other relevant standard describing the respective fire suppression system, and that standard provides information as to interfacing requirements with the fire alarm system. The supervisory devices must be listed for the intended application and installed in accordance with *NFPA 72*.

Automatic fire pumps and special service pumps must be supervised in accordance with the requirements of NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection,* and the authority having jurisdiction (AHJ). Examples of other standards include NFPA 14, *Standard for the Installation of Standpipe and Hose Systems,* NFPA 22, *Standard for Water Tanks for Private Fire Protection,* and NFPA 24, *Standard for the Installation of Private Fire Service Mains and Their Appurtenances.*

FIRE SAFETY FUNCTION INTERFACES

NFPA 72 also provides guidance for installation requirements of fire safety control functions that will be interfaced with fire

alarm systems. These fire safety control functions can include elevator control, door control, building automation system control, and process monitoring and control systems.

General

Fire safety control functions are those functions that contribute in some way to life safety in a building. In many cases these functions are required to be implemented by law. As such and in recognition that they contribute to life safety, it is reasonable to connect these functions to their respective devices with circuits that are monitored for integrity per *NFPA 72* to ensure that someone is notified if they are disabled. Supervised circuits may be provided in a number of ways as illustrated below (Figures 14.4.10 and 14.4.11).

Elevator Control

Fire alarm systems are interfaced to elevator control systems to initiate an elevator recall sequence or to initiate a power shutdown. The interface is generally accomplished by connection from the fire alarm system to a relay that is in turn connected to the elevator controller.

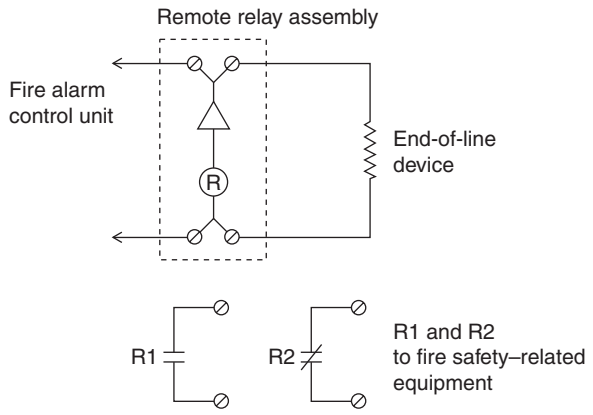

FIGURE 14.4.10 Polarity Reversing Circuit. Note: The remote relay assembly will be mounted within 3 ft (0.9 m) of the controlled fire safety–related equipment.

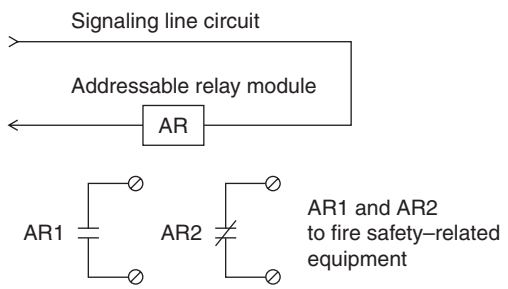

FIGURE 14.4.11 Addressable Circuit. Note: The addressable relay module will be mounted within 3 ft (0.9 m) of the controlled fire safety–related equipment.

Elevator Recall. Fire alarm systems are interfaced to elevator control systems to actuate the elevator recall sequence. The recall sequence and initiation requirements are found in Chapter 3 of *NFPA 72*. In most jurisdictions, only the elevator lobby and machine room smoke detectors are required to initiate recall of the elevators. The standard that originally provided the smoke detector placement requirements and requires the elevators to be recalled is ANSI/ASME A17.1, *Safety Code for Elevators and Escalators.* The ANSI/ASME A17.1 committee has now developed a liaison relationship with the *NFPA 72,* Chapter 3 committee, and all detection and interface requirements are contained in *NFPA 72,* Chapter 3. Additional requirements may be found in local building and fire codes or other elevator codes and standards.

Elevator Shutdown. When the elevator machine room or hoistway is protected with automatic sprinklers, ANSI/ASME A17.1 requires that the power to the elevators be shut down prior to or on discharge of water from the sprinklers. The power shutdown or shunt trip can be accomplished in either of two ways. When heat detectors are used, they must be installed within 2 ft (0.6 m) of each sprinkler, have both a lower temperature rating and a higher sensitivity than the sprinkler head, and be installed in accordance with *NFPA 72,* Chapter 6. When pressure or waterflow switches are used to shut down the elevator power, they must not have a time delay associated with their operation. In either case, it is assumed that elevator recall will have already taken place through the operation of the smoke detectors required for the elevator recall function.

Door Control

Doors may be connected to a fire alarm system for either of two reasons: to release a door normally held open such that it closes automatically or to unlock a door that is normally locked to allow unrestricted egress from a building. The interface is generally accomplished by connection from the fire alarm system to a relay that is in turn connected to either the hold open or locking device mechanism or to a security system that provides door control functions. In each case, the circuit should be arranged to provide a fail-safe operation. In other words, the circuit design must allow release of the door in case of circuit failure, security system failure, or power failure.

Door Release Service. When smoke and fire doors are held in the open position to allow free movement in corridors of buildings, it is required that the doors be released when a fire alarm system is activated. These hold-open devices are commonly magnetic units that are normally powered from a 24- or 120-V ac supply that is interconnected through a relay in a smoke detector or in the fire alarm control unit. *NFPA 72* does not require the door hold-open devices to be connected to the standby power because the units operate in a fail-safe fashion. When power is lost, the hold-open units deactivate and the doors close.

Alternatively, an unnecessary release of the doors (even during a nonemergency power failure) may not be desirable, and in this case the door hold-open devices should be powered from a separate "no-break," battery-supported power supply. The standby time should be equivalent to fire alarm system standby duration if practical.

If it is necessary to use the fire alarm system power supply (which is not encouraged and may not be allowed by the AHJ), then the fire alarm system power supply must not be disabled by any fault in the door hold-open device or related circuit, and the standby battery calculations for the fire alarm system must include the full load power required by the door hold-open devices during the required fire alarm supervisory and alarm periods (Figure 14.4.12).

Door Unlocking Devices. The life safety objectives of NFPA *101, Life Safety Code*®, and local building codes are achieved, in part, by establishing prescriptive requirements intended to ensure that building occupants can freely and promptly evacuate buildings during an emergency. The objective and scope of a security system may differ from the primary occupant life safety objective of the codes. Subjects of security protection may include persons, building assets, or contents. Threats may originate from within the building or from outside. It may therefore be desirable to control movement of persons into, through, and out of buildings. Conflict arises when security systems attempt to control occupant movement in buildings in contravention of the principle of the codes to permit freedom of movement for self-preservation during an emergency. The security system cannot override the code requirements established to provide life safety.

NFPA *101*®, *Life Safety Code*®, requires all stairway exit locked doors be unlocked when an alarm occurs in the building. This is based on the danger of fire deaths occurring in smoke-filled stairways where occupants are trapped after discovering that they have entered an unsafe area and cannot return to the corridor. The proper way to interconnect these unlocking devices (including electromagnetic locks and electric strikes) is so that when power is lost, they unlock. This is a fail-safe operation, and when the unlocking devices are wired in this fashion, the interconnecting wiring does not require monitoring for integrity. This is generally achieved by connecting locking devices through a normally closed contact that opens on fire detection. This contact may be part of a relay controlled by the fire alarm system or a contact within a manual pull box near the locking device.

Sometimes a locking device is connected to a security system that monitors, powers, locks, and unlocks the doors. Even in this case it is prudent to connect the fire-alarm-controlled, normally closed relay contact directly to the locking device by a method allowing fail-safe operation. The security system may fail to respond as required or the connection between the security system and fire alarm system may be lost. In all cases the locking device must release on loss of power to the device (Figure 14.4.13).

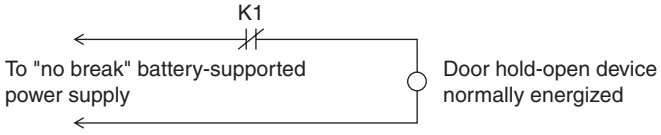

FIGURE 14.4.12 Door Release Control Circuit. Note: K1 is typically operated by fire alarm system activation. This may be supervised conventional relay or addressable relay module.

Building Automation Systems

It has become necessary in many cases to connect building control systems, such as heating and ventilation systems, to the fire alarm system. This has come from recognition that smoke spread can be controlled by use of the building environmental systems and by use of dedicated fans and dampers designed for the purpose. The control of smoke movement and the ability to exhaust smoke aid in providing the time necessary for occupants to leave a building.

Practically speaking, there are many pitfalls in implementing a smoke control strategy. The fire alarm system is generally implemented by a separate contractor with a different skill set than that needed for the mechanical systems employed in smoke control. Also, the systems are generally completed at different times and are commissioned by different people at different times. The fact that there are numerous ways to interface the fire alarm system with building automation and control systems equipment just confirms that this is one of the most difficult systems interface challenges.

The fire alarm system and heating, ventilation, and air-conditioning (HVAC) system may be interfaced by appropriate electrical contacts, digital data interfaces, and other methods listed for the purpose. Appropriate testing of the final interconnected equipment is critical to achieving the building design objectives.

Non-Computer-Controlled Building Systems. Many building HVAC systems are controlled during an emergency by direct connection from the building fire alarm system to the respective fan and/or damper that is to be controlled. Power is generally switched on or off via a relay contact in the fire alarm system or located near the controlled equipment or controlling motor control center (MCC). The wiring for these controls must be monitored for integrity in accordance with *NFPA 72*. In addition, it may be required or desirable to monitor the controlled device to confirm activation or initiate interlocks to prevent undesirable events. Please refer to NFPA 96, *Standard for Ventilation Control and Fire Protection of Commercial Cooking Operations,* for examples. See Figures 14.4.14 and 14.4.15 for examples of appropriate connections.

Computer-Controlled Building Systems. The computerization of building control systems has led to the integration of these systems with the fire alarm system control unit. Because the fire

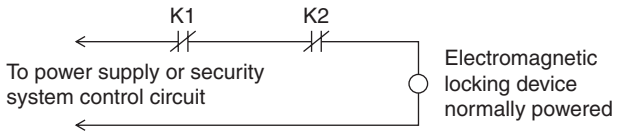

FIGURE 14.4.13 Electromagnetic Lock Control Circuit. Note: K1 is typically operated by fire alarm system activation. This may be by supervised by conventional relay or addressable relay module. K2 is contact operated when manual station at the controlled door is activated.

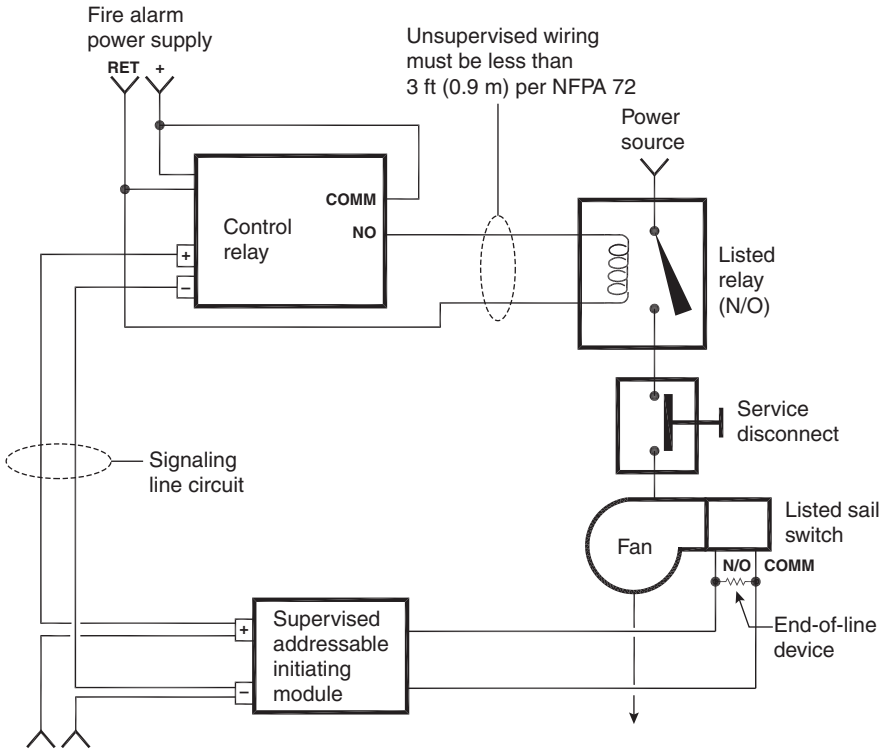

FIGURE 14.4.14 Direct Fan Control with Feedback (Courtesy of SimplexGrinnell, Westminster, MA)

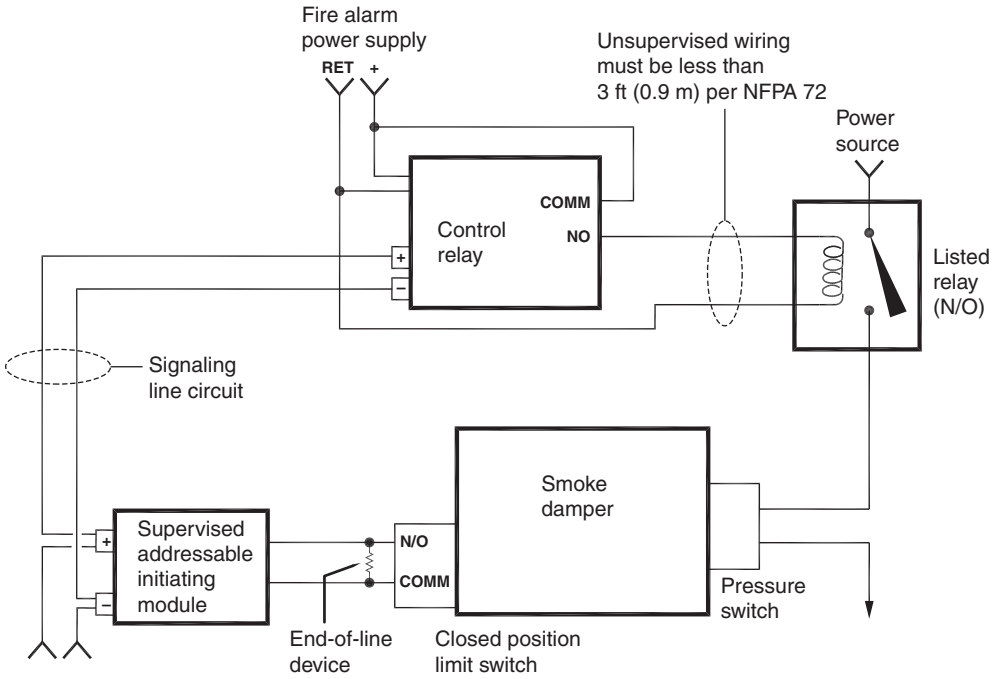

FIGURE 14.4.15 Direct Damper Control with Feedback (Courtesy of SimplexGrinnell, Westminster, MA)

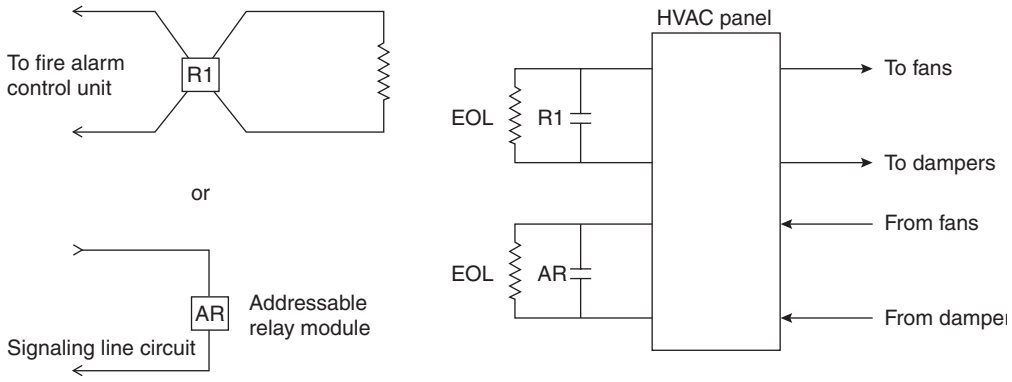

FIGURE 14.4.16 Computer-Controlled Building Systems Relay Interface

safety control function devices must be listed for compatibility with the fire alarm system control unit, so as not to interfere with the fire alarm system's operation, the system designer and the installer must be careful not to interconnect computerized devices together that have not been listed for compatibility. One of the areas that presents this problem is the interconnection of the fire alarm system to the HVAC system direct digital control (DDC) devices used to control fire/smoke dampers. In many cases, the fire alarm system is connected directly to the fire/smoke damper and not to the HVAC system DDC device. This is done instead of connecting the fire alarm system directly to the damper control. This is due to the compatibility requirement and also due to technician/programmers who lack expertise in fire alarm systems working on the interface, the DDC type of interconnections should be approached very carefully.

A computer-controlled HVAC or other building system may be interconnected to the fire alarm system via electrical contacts. These are actuated by the fire alarm system to advise the HVAC system of the fire location such that appropriate HVAC equipment functions can take place. In this case, the relay contact may either activate the fans and dampers directly as described earlier, or the contact may activate an HVAC system–monitored input circuit at an HVAC system control unit.

A computer-controlled HVAC or other building system may be interconnected to the fire alarm system via a digital data interface or via a network connection. Where a fire alarm system is connected to other equipment via a network to share data, this communication must be implemented by means listed for the purpose by a recognized laboratory. The network interconnection must be monitored for integrity and may not interfere in any way with the required operation of the fire alarm system. Data received by the fire alarm system from other equipment may not alter or affect the fire alarm system operation in any way other than to display information for operator use (Figures 14.4.16 and 14.4.17).

INTERCONNECTED FIRE ALARM CONTROL UNITS

There are numerous occasions where it is necessary or required by design to interconnect fire alarm control units. This function may occur during an addition to a building, such as a new wing to a hospital, or during a renovation to an existing building. In the past, there was no guidance as to the proper way to interconnect different manufacturers' control equipment. This created the potential for makeshift interconnections that were improper, unreliable, and unmonitored. *NFPA 72* requires that the interconnected fire alarm control units be connected by listed methods and the interconnection must be monitored for integrity. In addition to monitoring the interconnected system for alarm conditions, the interconnected control must be monitored for conditions that are essential for the proper operation of the interconnected system.

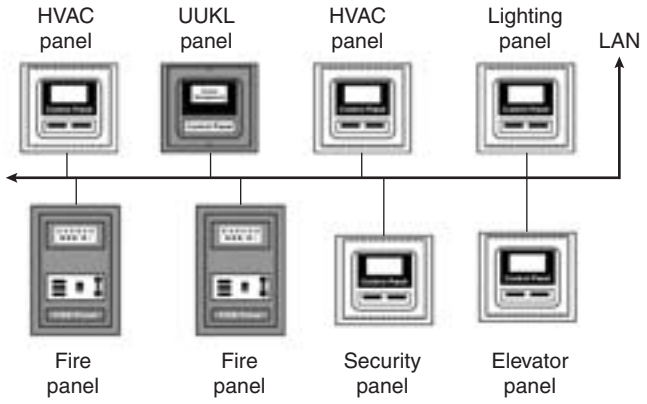

FIGURE 14.4.17 Computer-Controlled Building Systems Interface via LAN (Courtesy of SimplexGrinnell, Westminster, MA)

When an owner or designer suggests that two different manufacturers' control units be interconnected, the AHJ would be wise to ask each manufacturer for a letter indicating the approved interconnection method or drawing showing the approved interconnection method. If the interconnection is being made using relay configurations, the relays used must be listed and compatible with the control units being interconnected.

The objective of the interconnection and its consequences must be carefully considered. Many times it is desirable for one

system to actuate the other. One example is where the systems provide protection and audible signaling for adjacent spaces. When the first system actuates it may cause an alarm condition in the second system. The second system may then actuate the first system in return. Special measures must be taken to allow a reset condition since both control panels must be reset simultaneously or they will continue to actuate each other.

Another example of room for error is the possibility of shared control of fire safety systems by two interconnected fire alarm systems. It may be that the first fire alarm system or one of its components is in close proximity to an exhaust fan for a smoke shaft whereas the second fire alarm system is in close proximity to dampers in the exhaust shaft. If the fan and dampers are connected to different fire alarm systems and the interface between them is compromised, then it is possible for the exhaust fan to start based on an alarm initiation on the first system. Since the second system may not be aware of the alarm, there may not be an open damper in the shaft, which could lead to collapse of the shaft.

Fire alarm system interconnections must be carefully considered and designed to ensure only desirable operations. Where the connection between two fire alarm systems is deemed necessary, the design of the resulting system should emulate the operation and control of a single system. Consideration must also be given to the final commissioning and annual testing protocols that will be used. System failure can almost be guaranteed if, over time, different service companies work on the interconnected systems.

INTERFACED EQUIPMENT

Nonfire Alarm Interfaced Equipment

There are times when an owner may wish to interconnect a process monitoring system or some other type of nonfire alarm system to the fire alarm system. Caution should be exercised, and the AHJ should be consulted. If the system being interfaced is monitoring conditions affecting the life safety of occupants or protection of the property, then it may be required to have that system initiate an alarm condition on the fire alarm system. Otherwise, these nonfire signals must be considered supervisory in nature.

Interface Areas of Concern

The most important areas of concern when interfacing the fire alarm control unit with a fire safety function control device are that (1) the relay used to initiate control must be located within 3 ft (0.9 m) of the controlled circuit or device; (2) the relay, digital data interface, or other interface method must be listed for the intended purpose; (3) the relay, digital data interface, or other interface method must be compatible with the fire alarm control unit; (4) the wiring between the fire alarm control unit and the relay, digital data interface, or other interface method must be monitored for integrity, unless the control device is connected in a fail-safe manner; and (5) the relays, digital data interfaces, or other listed means of providing fire safety functions must not interfere with other operations of the fire alarm system.

TESTING INTERFACED SYSTEMS

Whether the interfaced system is a security system or a special hazard suppression system, care must be taken when performing acceptance and periodic testing of the fire alarm system. The technicians performing the tests must be totally familiar with all of the systems interfaced to the fire alarm system or must have other technicians present for the test who are familiar with the interfaced systems.

Interfaced systems equipment connections must be tested by operating or simulating the operation of the equipment being supervised. Signals required to be transmitted must be verified at the control panel. The test frequency for the interfaced equipment is governed by the applicable NFPA standard(s) for the equipment being supervised by the fire alarm system.

The system's test protocol, required sequence of operation, and test results must be documented to assure appropriate ongoing testing and system reliability. The testing protocol must recognize that the interconnected systems are designed and installed by different disciplines. Action must be taken to ensure that results are consistent with performance requirements and that connections present during testing remain in place following final commissioning or annual testing.

SUMMARY

The purpose of this section is to make the reader aware of the need to address interface requirements early in the design stage to ensure the reliable operation of both the fire alarm system and the systems being interfaced to the fire alarm system. Ensuring compatibility and correct operation during the acceptance tests is required to achieve reliable operation.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on fire alarm system interconnections discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

Chapter 5

Inspection, Testing, and Maintenance of Fire Alarm Systems

John M. Cholin

Chapter Contents

Reliability
Electronic Components
Inspection, Testing, and Maintenance Requirements for Signaling Systems and Components
Inspection, Testing, and Maintenance Scheduling for Systems and Components
Household Fire-Warning Equipment
Criticality of Inspection, Testing, and Maintenance on the Effectiveness of the System

Key Terms

acceptance test, design lifetime, failure, fire alarm control unit, fire alarm system, household fire-warning equipment, inspection, maintenance, notification appliance, protected premises, reacceptance test, reliability, reliability prediction, semiconductor, sensitivity measurement, supervising station

With each passing year, improvement in the understanding of fire and its behavior enables designers to better design fire alarm systems to achieve specific objectives and levels of performance rather than compliance with a minimum prescriptive standard. Yet, when designers employ performance-based design, the whole fire protection strategy becomes far more dependent on the fire detection portion of the protection system. This increased reliance on the fire detection and alarm system places a greater importance on maintaining the predictability of the fire detection system response, necessitating an effective inspection testing and maintenance program. Furthermore, no performance-based or objective-oriented design is complete without an explicit quantitative assessment of the level of confidence one can have that the fire alarm system will perform as intended. All computational methods that have been developed to assess this parameter are predicated upon an inspection, testing, and maintenance program at specified regular and predictable times throughout the life of the system. Consequently, without a thorough understanding of the impact the inspection, testing, and maintenance program has on the mission effectiveness of the fire alarm system, one cannot use a performance-based, objective-oriented design approach.

This chapter first develops the concepts of reliability analysis and prediction that form the foundation on which all inspection, testing, and maintenance programs should be based. It then reviews the types of electronic components from which fire alarm systems are constructed. These two background areas form the basis for inspection, testing, and maintenance requirements for fire alarm systems, components, and scheduling. Further, design concepts are applied to the household fire alarm system. Finally, this chapter addresses criticality of inspection, testing, and maintenance on the mission-effectiveness of the system.

This chapter is specifically limited to inspection, testing, and maintenance of fire alarm systems. These are the electronic and electrical systems that are designed (1) to sense a fire, transmit that information to a control unit of some type, and activate personnel warnings, whether for persons occupying the site or at a remote location; and (2) for remedial response, such as the discharge of extinguishing systems and activation of devices designed to enhance the compartmentation of the fire.

This chapter does not cover maintenance of specific remedial response systems. Inspection, testing, and maintenance of these systems are addressed in NFPA 11, *Standard for Low-, Medium-, and High-Expansion Foam;* NFPA 12, *Standard on Carbon Dioxide Extinguishing Systems;* NFPA 12A, *Standard on Halon 1301 Fire Extinguishing Systems;* NFPA 13, *Standard for the Installation of Sprinkler Systems;* NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection;* NFPA 16, *Standard for the Installation of Foam-Water Sprinkler and Foam-Water Spray Systems;* NFPA 17, *Standard for Dry Chemical Extinguishing Systems;* NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection;* NFPA 25, *Standard for the Inspection, Testing, and*

RELIABILITY

Murphy's law is familiar. Anything that can go wrong will go wrong. From this truism we can then conclude that any "system" will suffer a failure of one of its constituent components at some moment during its design lifetime. A fire alarm system is a "system" as used in this context. It is also a system on which people rely for life safety, property preservation, and mission continuity. Yet we are assured by Murphy's law that every fire alarm system will experience a failure of some component over the lifetime of the system. This establishes a compelling justification for a regimen of inspection, testing, and maintenance to be employed with every fire alarm system.

Reliability Defined

The reliability of a system includes both the ability to (1) detect and correctly respond to every occurrence of fire and (2) not render a fire alarm indication except when the legitimate fire alarm stimulus actually occurs. For a system to be deemed reliable, alarm signals will occur if, and only if, there is a fire. For the purposes of this chapter, reliability is defined as the measure of the certainty that the system will provide the appropriate response to the conditions that occur, as they occur, during the defined lifetime of the system.

Fire Alarm System Objectives

The driving force behind every inspection, testing, and maintenance program is the need to make system reliability as high as possible. Reliability is essential for fire alarm systems, simply due to mission objectives for these systems. Fire alarm systems are intended to fulfill three essential objectives: (1) ensure life safety, (2) conserve property, and (3) ensure continuity of the mission of the site. The life safety objective is achieved through timely warning of occupants. This is usually the highest priority. Mitigation of property damage is achieved through the timely actuation of automatic fire-extinguishing systems and transmission of fire alarm signals to the fire service. This is generally the second priority. After the first two objectives are met, the third objective, that is, continuity of the mission of the site, becomes attainable. In many cases, the mission objective places greater demands on the fire alarm system. The objectives cannot be attained if the system is unstable, nor can they be attained if the system allows too large a fire to develop prior to the actuation of fire-extinguishing systems. The three objectives can only be achieved when the fire alarm system operates reliably.

System Elements

Experience has shown that reliability of a system is the result of contributions from four system elements: (1) design, (2) installation, (3) equipment, and (4) maintenance. Each of these elements contributes to the overall reliability of the system. Often some "problems" are designed into the system. For example, a smoke detector located above a normally occurring source of aerosols that are not indicative of a fire is a problem that is designed into the system. This represents a reduction of the system reliability that was present during the design process. Other examples of design problems are rate-of-rise heat detectors in an area where rapid and wide fluctuations in temperature are expected, control panels mounted on surfaces that are vibrating, or smoke and heat detectors improperly mounted relative to the ceiling plane. Initial inspection and testing of the system should identify any problems that are designed into the system, so they can be corrected before the system is accepted.

Other problems are introduced during installation. These also deduct from the attainable system reliability. For example, installation problems include substandard wiring, general-purpose conduit and boxes where weathertight materials are needed, insufficient torque on screw terminals, abraded wire insulation, and so on. The initial inspection and test of the system should uncover these types of problems. If they are not corrected prior to acceptance, they will create problems over the operational lifetime of the installation. Furthermore, design and installation problems may not always be apparent during initial inspection. These errors are most likely discovered as a result of a system failure or in the context of the regularly scheduled maintenance program. These examples illustrate the necessity of an initial inspection and test program to uncover problems that are literally designed or installed into the system.

Another source of failures is the equipment itself. Most of today's electronic fire alarm system devices are extremely reliable. They are mature technologies, produced under stringent quality assurance programs that are audited by nationally recognized testing laboratories, such as Underwriters Laboratories Inc. (UL) and FM Global. However, all electronic components manifest a statistical failure rate that results in failures of these devices over time. These failures occur after the system has been accepted and consequently can only be uncovered through a program of regular maintenance and testing.

A program of inspection, testing, and maintenance of fire alarm systems is critical to achieving the design objectives of the system. This is the final element affecting the reliability of every system. It is through the inspection, testing, and maintenance program that errors in product manufacture, system design, and system installation are discovered and corrected. A fire alarm system without an inspection, testing, and maintenance program is every bit as incomplete as a car with only three wheels.

Although inspection, testing, and maintenance schedules have traditionally been developed based on the qualitative judgment of technical committee members, the emergence of performance-based and objective-oriented designs demands a more rigorous method of assessing the reliability of a system. Performance-based design requires that the inspection, testing, and maintenance schedules provide the reliability necessary to

achieve the performance objectives of the design. If reliable performance is to be achieved from a fire alarm system, a rigorous inspection, testing, and maintenance program on a schedule that is derived from the computed reliability of the system and its components is crucial.

Reliability Prediction Techniques for Fire Alarm Systems

The reliability of a fire alarm system, like any electronic system, can be computed using a method developed during World War II by a German rocket scientist named Lusser, who discovered that the reliability of a system was the product of the reliabilities of the individual components. According to the Lusser product law, as the number of components increases, the reliability of each individual component has to be improved commensurately to maintain the reliability of the overall system. The Lusser product law is expressed mathematically by

$$P_T = P_1 \times P_2 \times P_3 \times \cdots \times P_n$$

where

P_T = Probability of successful operation for the system, or reliability

P_n = Probability of successful operation of the nth component

n = The number of constituent components

This equation applies to systems in which the failure of any one component will mean the failure of the system. The probability of successful operation of a system is not directly computable. It is computed from failure rate data for each of the constituent components of that system. Failure rate, that is, the probability of failure, is related to the probability of successful operation by

$$\Lambda_T = 1 - P_T$$

where

Λ_T = Failure rate of the total system

P_T = Probability of successful operation for the system, or reliability

The failure rate, Λ, of a system assembled from components having exponential failure rates, is computed from the sum of the failure rates of each of the components, Λ_n, from

$$\Lambda = q_1\lambda_1 + q_2\lambda_2 + q_3\lambda_3 + \cdots + q_n\lambda_n$$

where

Λ = Failure rate of the total system

q_n = Quantity of the nth component in the system

λ_n = Failure rate of the nth component in the system

The component failure rates are usually expressed as failures per million device operating hours (f/mdoh), and the system failure rate is expressed as failures per million operating hours (f/moh). The previous equation enables one to calculate the reliability of a system based on the failure rates of the constituent components. Each fire alarm system component, that is, a control panel, detector, or notification appliance, has a calculable failure rate and, hence, the system failure rate can be computed. The failure rate of each of these major components is computed from the failure rates of the individual electronic components from which it is made.

Bathtub Curve. Research into the reliability of systems and components has shown that, for most physical systems, when the failure rate is plotted versus time, a curve of familiar shape results from the empirical data.[1,2] This curve is termed the *bathtub curve.* The bathtub curve can be modeled as the sum of two bell-shaped, Gaussian curves, one centered at the time the product is made and called the *turn-on curve,* and the other centered at the design lifetime and termed the *lifetime curve.*[3]

The first, the turn-on curve, shown in Figure 14.5.1(a), describes the rate at which failures can be expected to occur from the date of manufacture, forward over time, due to inherent defects in both constituent components and manufacturing technique. It illustrates the phenomenon known as "infant mortality" in the components and finished product. The second curve, shown in Figure 14.5.1(b), is also a Gaussian distribution, but it is centered at the design lifetime. It describes the distribution of failure rates due to long-term aging.

When the failure rates from the initial turn-on and the lifetime curves are added together (having adjusted the standard

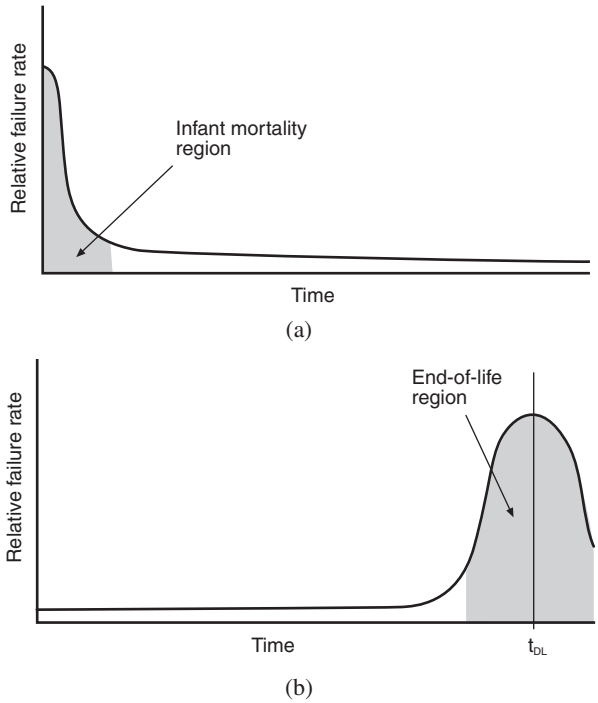

FIGURE 14.5.1 (a) Initial Turn-On Curve Showing Failure Rate of a Component or System at Turn-On; (b) Lifetime Curve Plotting the Failure Rate due to Long-Term Aging of Components and Establishing the Design Lifetime, t_{DL}

deviations for each of the distributions to match the experimentally measured failure rates for each failure mechanism), their sum yields a bathtub curve as shown in Figure 14.5.2.

The bathtub curve is divided into three regions. The leftmost is the "infant mortality" region. This is the initial turn-on phase where failures due to inherent defects in constituent components and manufacturing techniques usually appear. In order to ensure that these failures occur before the product is shipped to a customer, most manufacturers "burn-in" their products for time periods sufficient to allow inherently defective products to fail prior to shipment.

The right-hand portion of the bathtub curve is the "end of useful life" portion. This portion of the curve is used to establish the *design lifetime* of the assembly. The design lifetime of a product is that age at which the probability of operability at the end of the recommended service interval is less than 0.5, due to the acceleration in the frequency of failures resulting from long-term deterioration of constituent components. As the failure rate of the constituent components continues to escalate, it becomes increasingly difficult to maintain the operability of the assembly.

The region of the bathtub curve between the infant mortality region and the design lifetime region is the statistical region, where failures are entirely random. The statistical failure rate region of the curve is very long compared to the infant mortality region and end-of-life region. Over the statistical failure rate region, failures are randomly unpredictable. This region is essentially flat, indicating a fairly uniform failure rate per unit time over this region. Although the actual failure rate may be low, it is always a finite, positive number. Regardless of the time (distance along the x axis) between and the failure rate in the statistical failure region will, to the limits of precision available from the actual data, approach a horizontal line indicating a constant, evenly distributed failure rate. Because this region is flat, one can use the concept of the mean time between failures (MTBF), a quantification of failure rate, to predict the length of time the system can be expected to remain operational. It is a statistical average that is valid over a population of systems, but does not provide any guidance on what will happen with any specific system at any specific time.

Failure Rates. Since the failure rate is essentially constant over the statistical failure rate region of the bathtub curve, the failure rate of any electronic component and, hence, any electronic system assembled from electronic components can be derived from the failure rate data established in *Military Handbook: Reliability Prediction of Electronic Equipment.*[2] This handbook, known as *MIL Handbook 217,* provides experimentally derived failure rate data on electronic components commonly found in electronic assemblies, including fire alarm system components. *MIL Handbook 217* allows the engineer to compute the failure rates of the detectors, notification appliances, control panels, relay panels, interfaces, and other system components. From these failure rates the engineer can then compute the inherent failure rate (IFR) for the system. It is derived from the failure rates of the components from which the system has been assembled. It is important to keep in mind that this inherent failure rate does not include failures due to improper design or installation. Failures caused by design errors or installation errors must be added to the inherent failure rate computed from *MIL Handbook 217* before one can calculate the failure rate of a device or system.

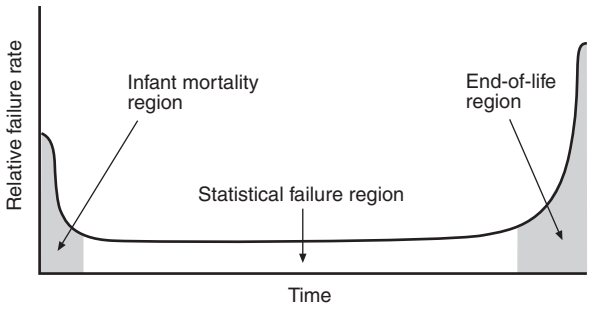

FIGURE 14.5.2 Bathtub Curve, the Sum of the Turn-On and Lifetime Curves

Once the inherent failure rate has been computed, the reliability of the system can be calculated:

$$R = e^{-\Lambda t}$$

where

R = Reliability of the system

e = Napierian logarithm base, 2.71828

Λ = Inherent failure rate of the system

t = Time period for which reliability has been computed[4,5]

This relation allows one to determine the maintenance interval based on the inherent failure rate of the system and the reliability level sought. The factor t is the interval of time between each execution of the inspection, testing, and maintenance procedures for the system. Assuming maintenance restores the entire system to complete operability, the required maintenance interval is computed from

$$t_R = \ln R_R/(-\Lambda)$$

where

$\ln R_R$ = Napierian log of the required reliability, R_R

Λ = Inherent failure rate of the system

t_R = Required maintenance interval to achieve the required reliability

The mathematical relations shown give the engineer the ability to calculate a recommended maintenance interval on a totally new product. It allows the engineer to calculate a maintenance interval that is specifically intended to produce a system with a predetermined reliability. Indeed, most high-technology systems and products have maintenance regimens developed from these relations rather than the consensus committee method used for fire alarms.

An Example Analysis

To illustrate the usefulness of the above computational method, consider the fire alarm system shown in Figure 14.5.3. It consists of 10 smoke detectors, a horn/strobe notification appliance,

and a control panel. Its design objective is to alert the occupants of a fire, enabling them to make safe egress from the facility, with a reliability of 90 percent (0.9). For the purposes of this example only, and with the understanding that these failure rates are not derived from any specific device but are intended to be of the same order of magnitude as commercially available products, use the failure rates in Table 14.5.1.

The inherent failure rate of the system as described is 43.65 f/moh:

$$43.65 \text{ f/moh} = 0.00004365 \text{ failures per hour (f/h)}$$

$$\Lambda = 0.3824 \text{ failures per year}$$

Using the required interval equation

$$t_R = \ln R_R/(-\Lambda)$$

where

$$\ln R_R = \ln 0.90 = -0.11$$

$$\Lambda = 0.3824$$

$$t_R = -0.11/-0.3824$$

$$t_R = 0.288 \text{ yr}$$

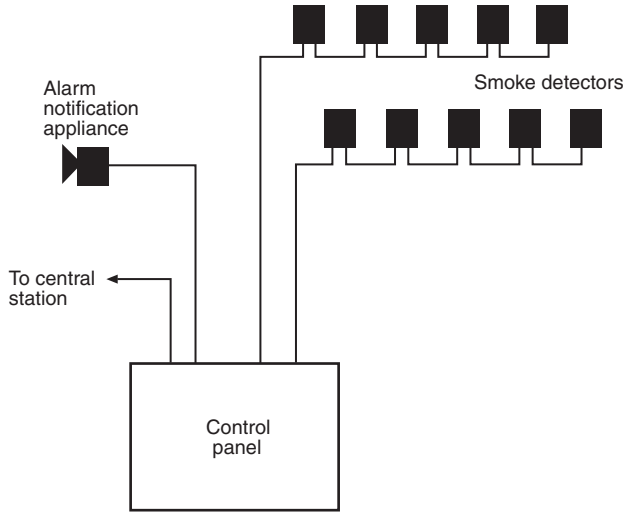

FIGURE 14.5.3 Simplified Example Fire Alarm System

TABLE 14.5.1 Compilation of Computed Failure Rates Providing the Basis for the Reliability Calculation

System Component	*Quantity (q)*	*Failure Rate (λ) (f/mdoh)*	*($q_x\lambda_x$) (f/moh)*
Smoke detectors	10	1.00	10.00
Horn/strobe	1	2.50	2.50
Control panel	1	25.00	25.00
Screw terminals	49	0.10	4.90
Wire segments	25	0.05	1.25
Inherent failure rate, Λ			43.65

This indicates that this system, with the component failure rates used, will require a complete inspection, test, and maintenance routine every 0.288 years in order to maintain at least a 90 percent reliability in achieving its design objectives. As performance-based, objective-oriented designs become more prevalent, reliability predictions for those systems similar to this example will be required to determine the maintenance frequency necessary to achieve the performance criteria. A reliability of 0.9 is a very high reliability, well above that of most systems. It means that there is only a 10 percent chance that there will be any form of failure during the time periods between inspection, testing, and maintenance routines.

The concept of failure is very broad here. Failures include trouble conditions resulting from supervised conditions; spurious alarms; failure to alarm within the design sensitivity or time frame for the design fire; and failures of electronic components, even if the component failure does not cause a system performance malfunction. A reliability of 0.9 (90 percent) is much higher than most owners need. This same system (see Figure 14.5.3 and Table 14.5.1) could achieve a 50 percent reliability with a maintenance schedule of 1.8 years. A maintenance program predicated on an inspection and testing regimen performed every 1.8 years will surely be less expensive than one based on a time interval of every 0.288 years. So how would one determine what target reliability one should use? Clearly, a balance must be achieved between the cost of the service/maintenance program and the inherent reliability of the system. Ideally, the reliability to be achieved should reflect analysis of the cost of failure, which will in turn need to distinguish among different types of failures, as listed above.

The inspection, testing, and maintenance schedules required by *NFPA 72®*, *National Fire Alarm Code®*, are prescriptive in nature and are based on a consensus opinion of what an average system requires. They are not the result of actual reliability calculations. The facility owner/operator must keep in mind that the prescriptive requirements represent the minimum acceptance criteria. There are often circumstances that demand that these minimum criteria be exceeded. It is obvious from the preceding that the larger or more complex the system is, the more frequently it must be inspected and tested if the design performance is to be achieved.

The implications of reliability cannot be overstated. The failure to maintain a system virtually assures the owner/operator of the protected site that the fire alarm system will *not* achieve the design objective.

ELECTRONIC COMPONENTS

The anticipated reliability of an electronic system such as a fire alarm system can be computed because the reliability of the individual electronic components has been thoroughly studied and documented, primarily under the auspices of the U.S. Department of Defense. This prior research has shown that each general type of electronic component exhibits particular and predictable failure modes. Understanding these failure modes leads to understanding the impact such a failure may have on a

fire alarm system component (detector, notification appliance, control unit, or other such system component). It is important for the owner/operator or responsible party to be aware of these failure modes, as the test methods prescribed by *NFPA 72* are intended to uncover those system components that have suffered a component failure.

Semiconductors

Semiconductor devices fail either to a short or open circuit. The semiconductors in use in modern fire alarm systems often include integrated circuits (IC) consisting of hundreds of thousands of simple semiconductor diodes and transistors. This is especially true of the microcomputers at the operational core of the control unit. Regardless of the complexity of the component, most semiconductor failures are catastrophic in nature, meaning that they fail completely and precipitously, often with a little puff of white smoke curling up from the circuit board.

Semiconductor failures are the result of one of three causes: (1) internal flaw, (2) overcurrent, or (3) overvoltage. Internal flaws are becoming less common as semiconductor manufacturing science continues to advance. Nevertheless, occasionally thermal ion migration or die-bond failure, typical internal flaws, cause a semiconductor to fail.

Since microcomputer memory consists of large integrated circuit arrays of transistor memory cells, there is the possibility of a memory failure. Usually, memory failures are catastrophic in nature and the entire device fails. It is rare that a single memory cell (location) or group of cells fails to retain data. Often, control units have diagnostic programs that are executed during the regularly scheduled maintenance to detect memory location failures. Additionally, regular thorough functional tests provide a measure of assurance that there are no memory location failures where the executable programs are stored.

The probability of this type of event is addressed in the reliability calculations presented earlier. Given enough time, a failure of this type is likely to occur, even with the highest-quality electronic equipment. The testing frequency and methods stipulated by the manufacturer and *NFPA 72* are intended to identify these types of failures with a minimum elapsed time period between the occurrence of the failure and its discovery. In other words, the time between failure and its discovery is as short as possible.

Overcurrent and overvoltage failures are usually associated with some other event that places an unintended stress on the system. Occasionally the event is the failure of some other electronic component subjecting adjacent components to the overvoltage or overcurrent. More frequently, overvoltages and overcurrents are the result of wiring and interconnection errors. Regardless, both overvoltages and overcurrents cause severe overheating of the semiconductor die, and the current-carrying portion of the die melts and/or vaporizes. Obviously, this type of damage is irreversible. Usually, these types of failures result in trouble signals and unwarranted activations of parts of the system and generally do not go unnoticed. It is important to correctly identify the source of the failure quickly. Otherwise, it is likely to occur again. Electrical transients caused by lightning, power supply spikes and surges, operation of highly inductive or capacitive equipment in close proximity to the fire alarm system, and even radio frequency interference have been known to cause these types of failures. Generally, the reliability computations presented earlier do not explicitly address the contribution of these external events to the failure rate of the system.

Resistors, Capacitors, and Inductors

These components are classified as "passive" components. They are less likely to fail than semiconductor devices because their structure is much simpler. Usually, these components fail to an open circuit. This generally causes some type of inexplicable action by the system, such as a trouble signal or the unwarranted actuation of some control system function. Rarely do these failures occur, and on those occasions when they do, they are immediately noticed. These failures are included in the reliability computations presented earlier.

Circuit Board Solder Bonds

A major source of electronic system failures occurs in the solder bonds between the electronic components and the circuit board. Solder bonds are occasionally broken during shipping and installation, rendering the unit "dead on arrival." Unfortunately, broken solder bonds do not always show up immediately. Broken solder bonds can behave as either an intermittent or high-resistance connection. Both of these cause spurious operation of portions of the system or intermittent trouble signals. There is no guarantee that these failures will be noticed when they occur. Broken solder bonds are just as likely to allow the unit to "fail silent."

As a system ages, the lead and tin atoms in the solder begin to migrate, allowing the solder to crystallize and become brittle. Variations in temperature, vibrations, and excessive moisture also contribute to the premature failure of solder bonds. A significant percentage of the computed failure rate for a fire alarm system component is derived from the failure rate assigned to each of the hundreds of solder bonds in that component.[2]

Transformers

Transformers are generally very reliable. Furthermore, since most transformers are used in the power supply section of a control unit, their failure will cause obvious indications, making timely repair likely.

Relays

Those switching functions that cannot be accomplished with solid-state (transistor) switches are accomplished with relays. Relays are electromechanical switches that are activated by causing current to flow through an electromagnetic coil situated such that the magnetic attraction developed by the coil pulls a switch from one pole to another. Often several switches are connected together so that the energization of the coil causes all of the switches (poles) to transfer at the same time.

As in any other mechanical component with moving parts, there is a possibility of a mechanical impediment to operation

from dust, corrosion, or wear. There is also the possibility that, even though the electromagnet has mechanically closed the contacts, electrical current fails to flow due to contact contamination by oxide, dirt, or some other material. The continuity of the electromagnetic coil can be lost, rendering the relay inoperative.

With all of these potential failure modes, relays do not provide the level of reliability of solid-state components. Nevertheless, most fire alarm system control units are equipped with relays, because they are very useful for providing a general-purpose switching function, especially for circuits that operate at higher voltages, such as 115 V ac. Although some relays are available in sealed versions, most relays are constructed with simple dust covers. This is usually adequate for normal indoor installations, but extra care must be exercised when testing a unit that is installed where it is exposed to a wide variation in ambient temperature, dust, excessive humidity, or corrosive aerosols. All of these environmental factors have been implicated in relay failures.

When "operation-critical" functions are performed by a fire alarm system with relays, the failure rate of the relay must be included in the reliability computation for the fire alarm control unit. The testing regimen for a fire alarm control unit must test the operability of all of the relays to verify that they are still operable.

Switches

Switches enable an operator to introduce electronic signals into the fire alarm system. The least reliable part of any switching system is the human operator. Nevertheless, once the operator is taken out of the picture, there are two general failure modes for switches: (1) failing to operate when they should and (2) operating when they should not. Since switches are usually mechanical components with moving parts, they suffer relatively high failure rates. The exception to this rule are some of the newer capacitive and membrane switch technologies where the parts do not actually move.

The first failure mode is of lesser concern, because an operator is present and the failure is immediately apparent. It is extremely rare that a fire alarm system is designed requiring that an operator activate a switch in order to secure the life safety and property conservation objectives of the system. Usually, system switches are used to interrupt the automatic functions of the control unit. In this scenario, failure of the switch should result in a safe condition.

The second failure mode usually takes the form of intermittence and generally causes trouble signals. The listing criteria for the nationally recognized testing laboratories require that the off-normal position of any switch result in a trouble signal. This requirement came from years of experience with failures of switches.

Screw Terminals

The least reliable part of a screw terminal is the person with the wire stripper and screwdriver. However, screw terminals do occasionally vibrate loose. *NFPA 72* requires that the wiring to initiating devices and notification appliances be monitored for integrity. However, wiring within the control unit enclosure is not required to be, and is often not, monitored for integrity. Consequently, the failure rate of the screw terminals must be factored into the reliability calculations.

Fuses

Fuses demonstrate one principal failure mode: they fail to an open circuit. This failure mode led nationally recognized testing laboratories to establish a listing criterion requiring that all fuses be monitored for integrity. The failure of any fuse should result in a trouble signal. It is required that monitoring fuses for integrity be done during testing.

Indicator Lamps

The invention of light-emitting diodes (LEDs) ended the reliability problems with indicator lamps. Although it is possible for an LED to fail, it is not a common occurrence. When LEDs fail, they cease making light. LED indicators are generally deemed inherently reliable and are not always monitored for integrity. Their failure rate is included in the reliability prediction for the control unit.

Batteries

Batteries are the most commonly used source of secondary power for fire alarm systems. It is important to understand how batteries fail in order to understand the importance of proper testing. Batteries are designed to provide a specified current for a specified time at a specified voltage. The specified current for a specified time is called capacity. Batteries undergo failure modes where they lose their capacity. Batteries can also lose their output voltage. These two failure modes are separate and distinct, occurring independently of each other.

The loss of capacity cannot be discovered by simply measuring open terminal potential, nor does the loss of terminal potential necessarily imply a loss of capacity. When a totally "dead" battery, that is, one that cannot provide any current at any voltage, is measured with a voltmeter under "open terminal conditions," the meter will usually show very close to nominal potential (voltage). That is because the mechanism of failure which results in the loss of capacity does not necessarily change the open terminal potential of the battery. When a battery is measured with a voltmeter and shows less than nominal open terminal potential, it may still have the ability to provide very large currents in spite of its lower terminal voltage. Consequently, the testing regimen for battery systems must test the ability of the battery to perform its intended function: to store and supply, as needed, electrical energy. A measurement of terminal potential and whether the battery "holds charge" does not provide an adequate assessment of the battery set.

Wires

Wiring is subject to two general classes of failure: (1) breakage of the conductor and (2) loss of insulation. The continuity of wiring conductors used in signaling line circuits, initiating device circuits, and notification appliance circuits is required to be monitored for integrity per *NFPA 72*. When fire alarm control

units are used to actuate extinguishing systems, the wiring to the actuating mechanism and other critical functions should be monitored for integrity also. However, the monitoring circuitry in most fire alarm system control units does not have the ability to distinguish between a normal conductor and one that is damaged. Close visual inspection is necessary on initial acceptance and whenever revisions are made.

The insulation on wiring conductors represents a different problem. Thermoplastic wire insulation behaves much like a supercooled liquid, in that it can flow over time away from a point of compression. This is particularly common when conductors are pulled taut against the edge of a metal enclosure or when pinched between an electrical box and its cover (both indicative of substandard installation practice). Under these conditions, the insulation will slowly flow away from the stress point, eventually allowing the conductor to make electrical contact with the enclosure. This creates a "ground fault."

The nationally recognized testing laboratories require that fire alarm system control units operate completely isolated from earth ground and provide ground-fault detection. These requirements ensure that a single ground fault will be detected, yet will not impair the operation of the system. It is imperative that the first ground fault be corrected before a second one occurs, as the second ground fault introduces a circuit via ground between two separate circuits in the system.

We can see that there is a direct mathematical connection between the reliability of a system and the failure rates of the constituent components. We have also reviewed the types of failures that occur with the types of electronic components that are used in the detectors, notification appliances, and control units in a fire alarm system. If an engineer were given a target reliability level to be achieved, the quantities of each fire alarm system component in the system, complete parts lists for each and every system component, and the failure rate data of each of those electronic components, she/he could, conceptually, calculate a maintenance interval for the system. In actual practice, this is rarely done. Instead, minimum-compliance prescriptive maintenance intervals are used.

INSPECTION, TESTING, AND MAINTENANCE REQUIREMENTS FOR SIGNALING SYSTEMS AND COMPONENTS

The reliability analysis presented earlier establishes the demand that fire alarm systems be maintained. *NFPA 72* establishes this requirement and places the responsibility for the regular inspection, testing, and maintenance on the owner/operator of the site. *NFPA 72* references the manufacturer's instructions, effectively making the manufacturer's instructions part of *NFPA 72* by reference and thus enforceable by the local authorities having jurisdiction (AHJ).

Definitions

To discuss the inspection, testing, and maintenance of fire alarm systems, one must define several terms that are not explicitly defined in *NFPA 72,* but are important in establishing the expected course of conduct.

Inspection. An *inspection* is a close visual observation of the item being inspected without causing the item to perform its intended function. There is said to be a facility manager who insists that the inspector's nose be less than 12 in. (305 mm) from the object to qualify as an inspection. This rule differentiates between a casual glance at a device and an inspection. It works for the manager. An inspection does not require the operation of the device being inspected, but it does require that a written record be made of the observed status of the device. Is it clean? Dirty? Bent? Covered with paint? In "as installed" condition?

Test. A *test* is a process where the device under test is provided a stimulus to determine if it is functional, and a written record of the response of the device under test is made. The term *test* does not necessarily imply that the stimulus is of a similar magnitude to that expected from the fire the unit is intended to detect. However, it does imply that the device has also been inspected while the test was conducted. Many tests require that the system be intentionally impaired to determine if the system properly responds to the impairment. *It is critical that all conditions created in the context of a test be returned to the normal state before the test is deemed completed.* The written record should include both the observed status of the unit and whether it was found to be functional.

Sensitivity Measurement. *Sensitivity measurement* is the quantitative measurement and recording of the stimulus necessary to achieve an alarm signal from an initiating device. This is very different from a test. A test does not imply that the stimulus is of a similar magnitude to that obtained from the design fire. A sensitivity measurement determines how large a stimulus is necessary to cause an alarm response. This measurement is to be compared to the value for the unit as shipped to quantify any change in the performance one can anticipate from the unit. Thus, the sensitivity measurement is intended to assess the ability of the detector to perform its intended function when the design fire occurs. It is understood that initiating devices are also inspected and tested when the sensitivity is measured. The written record should contain the observed status, the sensitivity measurement, and the verification of the functionality of the unit.

Bear in mind that many "intelligent/analog" detectors are actually addressable sensors where the alarm set point is stored in a memory location at the control panel. These systems continuously measure the sensor output and compare it to the value stored in memory for that particular device. These systems often can provide a printout of the current measured values for the initiating devices and their alarm points, thus satisfying the requirements of *NFPA 72*. Observations of physical status and verification of operability are normally associated with measurement of sensitivity, and these must be separately performed when "intelligent/analog" detection is encountered.

Acceptance Test. An *acceptance test* of a system is the process wherein every initiating device is provided an appropriate stimulus that simulates the existence of the design fire, and the

design sequence of operations of each system component in the entire system is verified and recorded in written form. This is usually achieved with a sensitivity measurement, including the functional test to initiate an alarm. Once the alarm is initiated, the technician verifies that all system functions, including interconnections to other building systems, operate as designed. It is preferable to repetitively operate all interconnections for each initiating device rather than verify their operation once and assume that all other initiating device alarms will cause the same operations. Often, problems show up after several operational cycles that would otherwise be missed. Programming errors in some software architectures can lead to problems that can only be uncovered with complete function verifications.

Reacceptance Test. A *reacceptance test* is an acceptance test performed after modifications have been made to the system. Modifications include any change, repair, adjustment to hardware or wiring, or any change in system software. The scope of a reacceptance test can be limited. All components, circuits, system operations, or software functions that are known to be affected by the change in the system must be tested, in addition to 10 percent of the initiating devices (up to a maximum of 50) known to not be directly affected by the change. A reacceptance test does not necessarily imply a complete acceptance test in all cases. However, there are times when a reacceptance test is equivalent to an acceptance test because of the nature of the modifications or repairs performed.

Documentation

Every form of evaluation of a fire alarm system must be completely documented. This includes inspections, tests, sensitivity measurements, acceptance tests, and reacceptance tests. This documentation should be retained in a secure location for future reference. The lack of complete documentation is often viewed by the courts and regulatory authorities as presumptive evidence that the required testing and inspection have not been done. A minimum compliance form for documenting the inspection and testing of a fire alarm system is provided in *NFPA 72*. However, many AHJs require a more complete form as part of a test plan.

Personnel

NFPA 72 establishes qualifications criteria for individuals inspecting and testing fire alarm systems. The facility owner is responsible for making certain that the people performing these functions are qualified. Many fire alarm systems are connected to supervising stations and automatic extinguishing systems. The personnel testing a fire alarm system must be sufficiently familiar with these interconnections to take the appropriate steps to prevent accidental discharge of an extinguishing system or reporting of a fire alarm to the municipal fire service during testing of the system.

Preparation and Coordination of Inspection, Testing, and Maintenance Activities

Many fire alarm systems are connected to off-premises monitoring services, fire pump controllers, special agent extinguishing systems, and building management systems. There are times when the functional testing of a fire alarm system will cause serious interruptions in site operations due to these interconnections. By the same token, it is critical to verify that the interconnections are operative and that the fire management plan for the entire site is achieved when a fire alarm signal occurs.

This presents a dilemma to the facility manager. Should a shutdown be endured, a major problem if the facility is the hub of an online computer network, or should the shutdowns be bypassed, thereby failing to verify complete system operability? Usually the question is not an all or nothing situation, and reasoned decisions must be made regarding which automatic interconnections to bypass and which to allow to operate. The facility manager must recognize that some interconnections actuate extinguishing systems that represent a significant cleanup and/or recharge expense if they are actuated. Understandably, these types of systems must be disabled for routine inspection, testing, and maintenance. However, the portion of the system that is disabled should be as small as possible. For example, many extinguishing system actuators are removable from the extinguishing agent containers, allowing all of the electrical components to be tested. This is a very desirable feature. However, since the electrical supervision cannot recognize this type of impairment, there is the danger that the system will be left with the actuators removed from the agent storage containers. Extra care must be taken to ensure that all of the actuators are properly reinstalled at the conclusion of the inspection, testing, and maintenance program.

Some interconnections, such as smoke management systems, automated process controls, and data processing systems, will interrupt site productivity to the point that the cost of an unwarranted actuation is too high to allow during routine inspection, testing, and maintenance. Systems with these types of interconnections can be designed with built-in disconnect switches that are supervised when in the off-normal state. However, remember that when these functions are disabled, their operability is not verified. It may be reasonable to permit the inspection, testing, and maintenance program to be performed with these types of functions disabled during normal operations time in a site that has experienced no modifications since the initial acceptance tests; however, it is not appropriate if revisions or modifications have been made. If it is critical for a function to occur in order to achieve the design objectives of a fire protection system, then it is equally critical that those functions be inspected and tested.

Finally, off-site reporting and resulting responses must be addressed. These can be effectively managed with prior notification. All impairments must be monitored. Usually, at the beginning of a service visit, the technician places a telephone call to the monitoring entity to advise them that the system is being tested and to disregard alarm and trouble signals. The monitoring entity should be under strict instructions that, when such a call is received, the following are addressed:

1. Call back the facility manager to verify that testing is about to commence.

2. Verify that an alternative procedure to report a fire is in place.
3. Require verification when testing will be completed and deem any signal occurring after that time as a real signal, unless a second call is received rescheduling the estimated completion time.
4. Require a follow-up call on completion of the maintenance visit that confirms the system has been restored to fully automatic status.

System impairments that facilitate inspection, testing, and maintenance should not be granted casually. A system impairment can permit an inconsequential fire to become a large-loss fire. It is also possible for fires to grow to serious proportions because the monitoring entity failed to report the fire. Fire alarm systems should be designed and serviced with these considerations in mind. Every system must be serviced, and often the service activities necessitate disabling portions of the fire alarm system or interconnections. However, the disabling should be limited to the smallest possible portion of the building fire protection assets. Furthermore, if at all possible, those portions that are directly affected by the testing should be disabled individually, thereby keeping operative as many building fire protection assets as possible.

The Test Plan

The inspection, testing, and maintenance regimen for a fire alarm system must stipulate the following:

1. What procedure is to be performed?
2. How it is to be performed?
3. What data are to be recorded in the documentation?
4. How frequently is the specific procedure to be performed?

These four criteria are usually organized into a test plan. A formal test plan is often a very good investment. It establishes a formal procedure to ensure the complete inspection and testing of the system and a record of the results for future reference. Once a test plan has been developed, it is used each time the inspection and test program are performed. Consistency of the presentation of results facilitates identifying problem areas.

NFPA 72, Chapter 10, "Inspection, Testing, and Maintenance," is organized to facilitate the development of a formal test plan. It establishes test methods and then stipulates an inspection and testing frequency. The test methods outline what procedures are to be performed. They are intended to be used in conjunction with the manufacturer's instructions for the specific make and model of equipment involved. Thus the manufacturer's instructions provide the specific "how to" information. The issue of documentation is addressed by *NFPA 72,* Chapter 10, in the section on records.

The frequency of each procedure varies, depending on the general class of device. For example, batteries are inspected more frequently than initiating devices. The frequency of visual inspections is different (i.e., more frequent) than testing. The frequencies provided by *NFPA 72* have been based primarily on experience developed over the recent past rather than reliability data for the fire alarm system components.

Supervising Station Systems

Supervising station systems monitor a number of protected premises fire alarm systems via one or more types of communication paths. The principal concerns during the inspection and testing of these systems is that each communication path is intact and operable and that the supervising station fire alarm control unit is fully operational.

The inspection, testing, and maintenance procedures for specific models of a control unit for a supervising station fire alarm control system are established by the manufacturer. Since supervising station fire alarm systems include many of the same components that make up a protected premises system but organized in a manner that fulfills the design requirements for a supervising station system, the inspection and testing requirements for these components are the same, regardless of the type of system in which they are used.

Protected Premises Systems

There are two general objectives in the testing and inspection of a protected premises fire alarm system. The first is to verify the operability of the system and identify any failures in system components that have failed to a "silent" state. Any failures identified during the course of the inspection and testing must be repaired to restore the system to a fully operational state. The second is to identify changes in the occupancy that render a formerly appropriate system inappropriate, based on the hazard area to be protected. Both objectives affect proper response to a fire.

Fire Alarm Control Unit

The manufacturer for each make and model of fire alarm control unit (FACU) provides a recommended service procedure for the control unit. These procedures are included in *NFPA 72* by reference. However, the fire alarm control unit is one building block in a much larger system, and the manufacturer rarely knows how the overall system is designed. Consequently, there are at least two layers of functions that must be tested. The first layer comprises those functions that are an integral part of the FACU, irrespective of the particular system in which it is used. These functions include supervision of relays, fuses, main power supply, batteries, wiring integrity, alarm indications, trouble indications, supervisory indications, and isolation from ground. The second layer is specific to the facility or system. These are usually in a "sequence of operations" format, establishing the response functions that occur as a result of each input (initiating or supervisory device) signal.

Functions. All functions of the system should be tested. The supervision of all signaling line circuits, initiating device circuits, notification appliance circuits, and signal transmission circuits must be tested. Furthermore, when the FACU is used for the actuation of extinguishing systems, all circuits activating equipment whose operation is critical to successful extinguishment must also be supervised. The testing of these functions consists of creating breaks and ground faults on each circuit

and verifying that the appropriate trouble signal is rendered by the FACU.

The sequence of operations must then be tested to verify the operability of all those functions the control unit is intended to implement specifically for the hazard area it protects. These functions are application specific and vary from one site to another.

Annex C of *NFPA 72* provides specific tests for each type (style) of circuit. Trouble signals can be introduced on signaling line circuits and initiating device circuits by temporarily removing detectors (from their mounting bases) or wiring conductors from detectors. Similar techniques are used for notification appliance circuits. Signaling line circuits are usually interrupted at the FACU screw terminals, with a verification that the trouble signal is received. Alarm signals must be generated on each initiating device circuit or zone by causing a detector to alarm with heat, smoke, or radiant energy, as appropriate, to verify that the design alarm response occurs. The alarm response will include actuation of the notification appliances, alarm indication at the control unit, actuation of interconnected equipment, and signal transmission to the off-premises receiving station.

Conductors on each initiating device, notification appliance, and signaling line circuit must be temporarily grounded to verify that the ground detection circuitry and associated trouble indications are operative. The applications manual for most FACUs stipulates the amount of resistance between conductors and ground that should be detected. A fixed resistor reflecting that criterion should be used to test ground-fault detection.

Special hazards extinguishing systems employ specialized equipment to address the unique needs of the various extinguishing system equipment designs and agent limitations. Each manufacturer is required to provide an engineering manual that addresses the inspection, testing, and maintenance needs of the control unit and ancillary equipment necessary to operate the special hazards extinguishing system. These functions include cross-zone detection, matrix detection, verified detection, sequential detection, detector counting detection, abort switches, solenoid activation (release), and squib actuation (release). When these functions are implemented by the FACU, the specific inspection and testing requirements established by the manufacturer must be observed.

The functional test serves to verify that all of the system interconnects are energized when appropriate and that the system achieves the basic functions it was designed to achieve. However, this type of general "macroscopic" test does not fully evaluate all the system components. There are specific tests to evaluate these components.

Fuses. The listing standards of the nationally recognized testing laboratories require that all fuses be supervised. However, it is possible that the supervisory circuitry could fail and not provide an indication that such a critical component was inoperative. Furthermore, it is conceivable that the fuse may have been replaced with another of the wrong value. Consequently, all fuses must be checked for supervision and correct value. Keep in mind that a fuse cannot be properly checked visually. The only way to check a fuse for continuity is with a volt-ohm meter (VOM) or multimeter.

Indicating Lamps. All indicating lamps must be operated to verify that they are still functional. Modern fire alarm control panels use LEDs for indicator lamps. LEDs are much more reliable than the old incandescent lamps but can still fail. Most fire alarm control units are equipped with a lamp-test switch specifically for this purpose, while others have a key-pad code that performs the lamp-test function.

Main Power Supply. There are electronic component failures that could render the main power supply incapable of supporting the design current load on the system during fires yet not appear under normal, quiescent conditions. The main power supply test entails temporarily disconnecting the secondary supply and applying the maximum design current load to the system while monitoring the output voltage of the system power supply. If the power supply voltage drops below that stipulated in the manufacturer's applications manual, remedial action must be taken.

Engine-Driven Generators. In those instances where an engine-driven generator is used as a required power source, either as a primary or a secondary supply, it must be tested according to the procedures outlined in NFPA 110, *Standard for Emergency and Standby Power Systems.*

Uninterruptable Power Supply (UPS). In those cases where a UPS system is dedicated to the fire alarm system, it must be tested per NFPA 111, *Standard on Stored Electrical Energy Emergency and Standby Power Systems.* Note that a UPS is used for a number of purposes, one of which is the fire alarm system. UPS is treated by *NFPA 72* as being no different than public utility power, and the requirement for a secondary power supply for the fire alarm system is still enforceable.

Secondary Power Supply. The secondary power supply must be able to support the full current load of the fire alarm system when the primary supply is lost. Primary power is often lost during a fire. Testing of the secondary power supply entails temporarily disconnecting the primary power supply and applying the maximum design current load to the system while monitoring the output voltage of the secondary system power supply. If the secondary power supply voltage drops below that stipulated in the manufacturer's applications manual, remedial action must be taken. Additional and more specific testing is required when the secondary power supply consists of a battery set.

Batteries. The lead/acid battery chemistry is the most commonly used type in fire alarm system service. These batteries are typically found as unsealed lead/acid batteries, unsealed calcium grid (lead-calcium) batteries, sealed lead/acid batteries, and gelled electrolyte lead/acid batteries. All of these batteries use a solution of sulfuric acid in water as the electrolyte. These various types require slightly different charging potentials and maintenance. It is imperative that the battery charger be properly matched to the battery, consistent with the listing.

Battery Testing. The testing of a battery set consists of general tests that are performed regardless of battery chemistry and

specific tests for specific types of batteries. A visual inspection is required for all types to discover any terminal corrosion, looseness in terminal connections, or electrolyte leakage. All of these are serious conditions that can cause an increase in the series resistance of the battery set, thus depriving the fire alarm system of the necessary operating potential under large current load conditions.

Batteries exhibit a number of failure modes that result in either a loss of operating potential or a loss of capacity. The exact mechanism of each class of failure mode is dependent on the battery chemistry; nickel/cadmium batteries behave somewhat differently than lead/lead peroxide batteries.

Battery Test Regimens. In general, the test regimen for all batteries includes the following:

1. Battery charger test
2. Discharge test, in which the batteries must support a design current load
3. Load voltage test, in which the voltage is measured while the batteries support a design current load
4. Open circuit test, in which the open-circuit potential of the battery is measured

Battery Discharge Rates. There is a relationship between the output potential of a battery, measured in volts, and the output capacity of the battery, measured in ampere hours (Ah). This relationship is illustrated with a "family" of potential versus discharge time curves for a number of discharge currents, as shown in Figure 14.5.4. When the terminal potential reaches 85 percent of original value, the battery is generally considered effectively depleted. The discharge current multiplied by the length of time it takes to deplete the battery is its capacity (C), measured in Ah (ampere hours). Typically, batteries exhibit smaller capacities when the discharge rates are higher. The battery industry usually uses a 20 hour discharge rate for their specifications. A 10 Ah battery will support a 0.5 A load for 20 hours and be at 85 percent of its fully charged potential after having been discharged at that rate for that time period.

The capacity of the battery is a function of the number of charge carriers stored in the unit. Unfortunately, there are chemical reactions that occur within a battery that "lock up" charge carriers into precipitates, thus removing them from the electrochemical reservoir of available charge carriers. This results in the battery becoming depleted far sooner than expected.

Battery Deterioration. Two symptoms indicate a deterioration of the battery: (1) loss of capacity (Ah) and (2) loss of potential (voltage). These symptoms can usually be traced to the stresses inherent in recharging and maintaining charge. When the battery is being charged, lead sulfate is converted to lead and lead dioxide. As charging continues, hydrogen and oxygen gas are formed from the electrolysis of the water in the electrolyte solution. In the sealed and gelled electrolyte batteries, the hydrogen and oxygen are contained within the battery until sufficient pressure is achieved to cause the battery to vent. In the unsealed type, these gases are allowed to escape. The loss of hydrogen and oxygen represents a loss of water from the electrolyte. This increases the concentration of the acid in the electrolyte. As a result, a lead sulfate and lead sulfite precipitate begins to form, "locking up" the lead in an insoluble and unusable form. This process is called sulfation. Since the capacity of the battery is directly proportional to the quantity of lead available, a sulfated battery cannot support the current load it could before the sulfation occurred.

With unsealed lead/acid batteries the acid concentration is determined by measuring the specific gravity of the electrolyte. As water is lost, the specific gravity of the electrolyte increases. When the specific gravity reaches the upper allowable limit, reagent-grade distilled water is added, restoring the acid con-

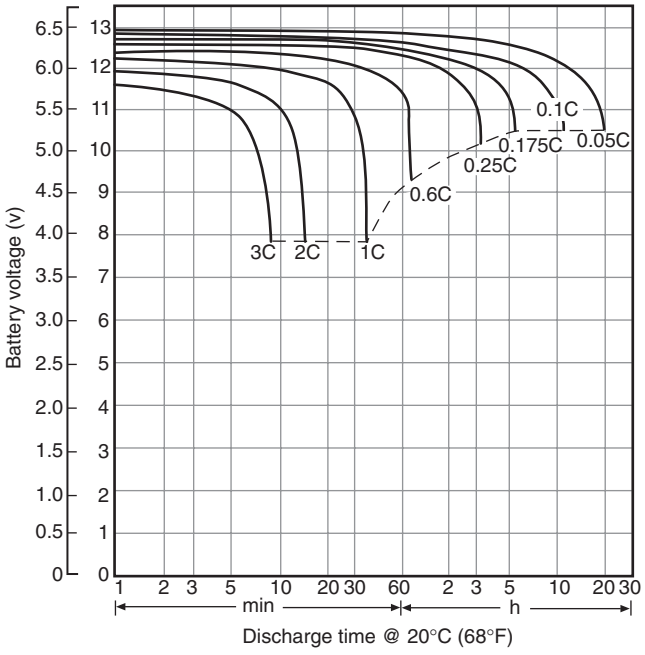

FIGURE 14.5.4 Capacity (C) of a Battery as a Function of Discharge Rate, Time, and Voltage

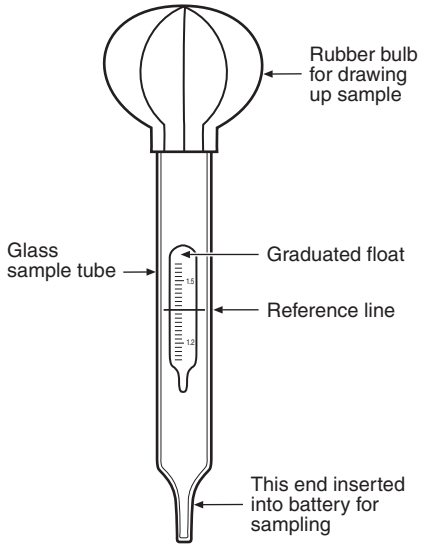

FIGURE 14.5.5 Hydrometer

centration to the design value. The measurement of electrolyte specific gravity is done with a hydrometer, similar to that shown in Figure 14.5.5. Always use one that has a float and a graduated scale.

The sealed lead/acid and gelled electrolyte lead/acid batteries have no provision for returning the electrolyte to the design specific gravity range. These batteries are designed to minimize the loss of hydrogen and oxygen and include design features to offset the effect of the slow leakage that often accompanies continuous float charge. Eventually, the loss of water allows sulfation to occur, with the resultant loss of capacity. If the recharging current is properly matched to the batteries, these types of batteries usually provide reliable service over a time period generally between 3 and 5 years, after which they must be replaced. Figure 14.5.6 shows a typical capacity versus time curve for a sealed or gelled electrolyte lead/acid battery.

Loss of potential failure in batteries comes from either the shorting of a cell or internal deterioration that causes an increase in the internal resistance of the battery. Both of these failure mechanisms result in a battery set that cannot provide sufficient potential for the fire alarm system to operate as intended.

Shorted Battery Cells. Shorted cells usually result from the recharging and maintenance of charge over a period of time. During the recharging of the battery, lead ions move between the lead-dioxide plate and the lead plate. Occasionally a needlelike crystal forms. As it continues to grow, it eventually extends from one plate to an adjacent plate, making an electrically conductive contact between the two. This shorts out the cell, resulting in a battery with a terminal potential 2.2 V lower than originally designed.

When a cell becomes shorted, two serious problems arise. The first is that the battery charger, sensing an inordinately low battery potential, forces a greater charging current into the battery. The increased current overcharges the remaining cells, dehydrating the electrolyte, ultimately causing catastrophic failure. Second, if the fire alarm system loses primary power supply while connected to a battery with a shorted cell, it will not receive an adequate operating potential and will very likely not be able to support the design output load.

Increase of Resistance Within Batteries. Batteries can also lose the ability to maintain output potential due to increases in internal resistance within the battery. During the discharge and recharge of the battery, lead ions migrate through the electrolyte between the plates within the battery. Eventually, electrical resistance within portions of the plate, interconnecting conductor bars, and electrolyte begins increasing. This causes the internal resistance of the battery to increase. This condition only shows up when the battery is required to supply current to a load (the fire alarm system). The larger the current load placed on the battery, the larger the drop in voltage due to internal resistance, and, hence, the easier it is to detect.

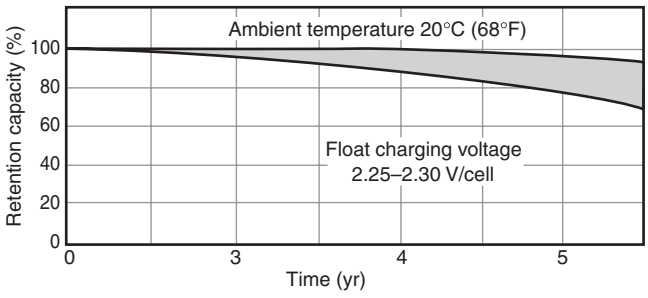

FIGURE 14.5.6 Capacity Versus Time Curve of a Sealed or Gelled Electrolyte Lead/Acid Battery

The likelihood of a shorted cell failure and increased resistance failures increases as the length of time under recharging conditions increases. This fact underscores the importance of using the battery that has been listed for use with the battery charger and of performing the maintenance as prescribed by *NFPA 72*.

Nickel/Cadmium Batteries. Nickel/cadmium battery secondary power supplies are rarely encountered in connection with fire alarm systems, but when they are, it is only as sealed batteries. Sealed nickel/cadmium batteries manifest similar failure modes to the lead/acid units. However, there is an additional failure mechanism called the "memory effect" associated with some nickel/cadmium batteries that is unique to that chemistry. Fire alarm systems are "float-charge" applications. These are applications where the battery is maintained at full charge by a battery charger over long periods of time and, occasionally, are partially discharged, only to be restored to full charge when the primary power is restored. Some nickel/cadmium batteries exhibit a "memory effect," where the usable capacity of the battery declines to that quantity that has been recurrently used.[6] Thus, a 20 Ah battery discharged several times by 2 or 3 Ah will lose the ability to supply more than the 2 or 3 Ah. Nickel/cadmium batteries are much better adapted to cycle charge applications where the unit is completely discharged prior to recharging. This is an additional loss of capacity failure mode that must be addressed in the test program.

Battery Charger and Load Tests. Because the failure modes of batteries are so complex, battery secondary power supplies represent a challenge for any testing program. NFPA 72 provides specific tests for each type of battery. Each type requires a charger test, where the recharge potential of the battery charger is measured with a multimeter to verify that the recharge potential is within acceptable limits. Since most battery failure mechanisms are related to recharging and overcharging, the charger test is essential.

For each type of battery there is a load test. A current load is placed on the batteries and the battery potential is measured. This test is intended to identify batteries that have excessive internal resistances. Consequently, the larger the load, the better. The ideal load is one that is equivalent to the fire alarm system in full alarm with all notification appliances operating, the emergency voice evacuation system operating, and extinguishing system solenoid valves energized. A bank of power resistors can be used to simulate the system load for the battery load test (Figure 14.5.7). One 24 ohm (Ω), 100 W resistor allows 1.0 A to flow at 24 V. Current increases for parallel-connected resistors.

Where the battery is being used for a public fire alarm reporting system, the load tests must be modified and the potential between each side of the battery and earth-ground must be

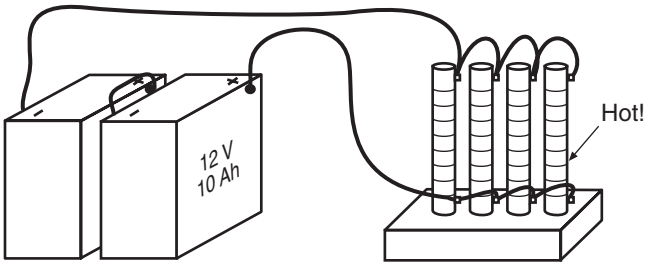

FIGURE 14.5.7 Bank of Power Resistors

included. The standard multimeter cannot be used for testing public fire alarm reporting system power supplies due to the possible erroneous readings caused by voltage differentials in the ground potential. A standard 10-M input impedance meter can be converted to read battery potentials for a public reporting system power supply, with the addition of a properly sized ballast resistor (Figure 14.5.8).

$$R = 100\ \Omega/\text{V} \times \text{Battery voltage}$$

For a 12-V battery

$$100\ \Omega/\text{V} \times 12\ \text{V} = 1200\ \Omega$$

It is important to note that none of these tests actually tests for battery capacity. The load test is used to infer that no serious loss of capacity has occurred. This inference is supported by the observation that loss of capacity is almost always accompanied by an increase in internal resistance. A better inference can be drawn from a timed discharge/recharge test. In this test, a fraction of the battery capacity is discharged and then the battery is returned to the battery charger, while the current is monitored over time. A curve similar to Figure 14.5.9 results. If the capacity returned to the battery, measured in Ah, is no more than 110 percent of the capacity removed, then the battery has retained its design efficiency and one can be more certain that no loss of capacity has occurred. The only sure way to completely verify

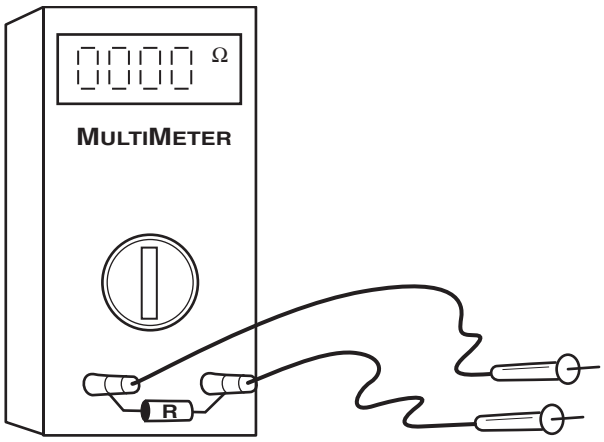

FIGURE 14.5.8 Multimeter

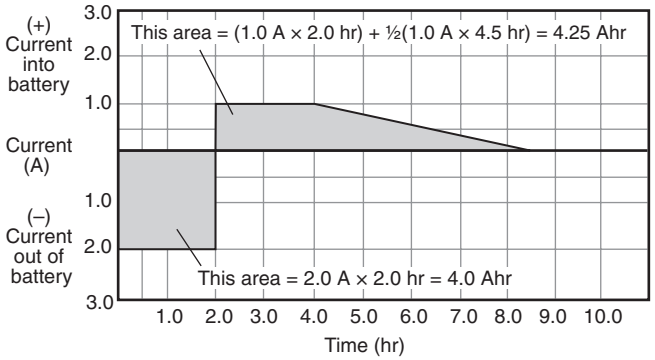

FIGURE 14.5.9 Partial Discharge/Recharge Integration Used to Infer Battery Capacity

design battery capacity is a full, measured discharge of the battery set at the design discharge rates with subsequent monitored recharge.[6]

Recently, meters have become available that purport to measure battery capacity by measuring the dynamic impedance of the battery. While some of the manufacturers of these meters proffer "research reports" supporting the ability of the meter to distinguish batteries with compromised capacity from those with full rated capacity, none of these meters has been listed by UL or FM for this purpose, as of the time this chapter was written.

Transient Suppressors. Since fire alarm systems must maintain isolation from ground and monitor that isolation, they are vulnerable to damage from the electromagnetic pulse (EMP) that occurs during a lightning strike. Transient suppressors are designed to absorb a finite quantity of energy before they overheat and fail, melting to a short circuit or vaporizing to an open circuit. These devices must be tested with a multimeter to verify that they are still intact.

Remote Annunciators. Many fire alarm systems include a remote annunciator to provide information regarding the status of the control unit and the identity of alarm signals at a remote location. Representative signals must be generated at the fire alarm control unit, and correct annunciation verified. Remember that most remote annunciators serve to provide the first responding fire service members with critical information relating to the nature and location of the fire alarm. The presentation of this information must be clear and understandable.

Interface Equipment. Commonly, fire alarm control units are interconnected with other control systems in the protected site. These interfaces must be inspected and tested in a manner consistent with the requirements established by the manufacturer and the expected operation of the interfaced systems.

Off-Premises Signal Transmitters. Fire alarm systems often transmit signals to monitoring stations that are off the immediate premises. The transmitter and the signaling line circuit from the protected premises to the supervising station must be in-

spected and tested as part of the inspection and testing program for the protected premises fire alarm system.

The oldest type of off-premises signaling is the McCulloh system. Where this type of signaling is used, the fire alarm control unit terminals must be regularly inspected for corrosion, and the function must be tested for successful signal transmission, in spite of each of the following four fault conditions:

1. Open circuit in one conductor
2. Ground fault on one conductor
3. Short circuit between the two signal conductors
4. A concurrent open circuit and ground fault

Currently, digital alarm communicator systems are the most commonly provided method for communication to a remote supervising station. Since it is impossible to supervise the entire signal path from protected premises to supervising station, two "numbers" (lines) are used: (1) primary and (2) secondary.

Digital alarm communicator transmitters are tested by verifying that they transmit the appropriate signal to the remote supervising station receiver. When an alarm signal is created in the fire alarm system, it must be verified that the DACT seizes the line and transmits the alarm signal to the supervising station. Similarly, the line seizure and trouble signal transmission must result from a trouble signal on the fire alarm control unit. When either of the signaling lines (numbers) is disconnected, the DACT must transmit a trouble signal on the alternative line within 4 minutes.

Systems similar to the digital alarm communicator are now available using radio communication. These are referred to as digital alarm radio transmitters and receivers (DART and DARR, respectively). These systems must also have provisions for secondary communications paths and must be tested in a similar manner as the DACT/DACR system.

Emergency Voice Communication Equipment. The inspection of the emergency voice communication equipment includes the remote phone jacks, handsets, phone hooks, control panel interface, and amplifiers. These components must be inspected for damage or deterioration due to ambient conditions. The testing includes a verification of the operability of both the primary and backup amplifiers, as well as the switching between them. A verification that the call-in silence, off-hook indication, and the operability of the communication from remote jacks to the base station must be achieved in the testing. Each phone set must be tested and determined to be operable. Finally, system operability with a simulated fire condition communications load, involving the concurrent operation of at least five phone sets, should be conducted to assess the voice quality and clarity of the system.

Guard Tour Monitoring Equipment. When guard tour monitoring equipment is integrated into the fire alarm control unit, it must be added to the inspection and testing schedule for the system. The inspection and testing procedures for this equipment prescribed by the manufacturer should be followed.

Metallic Conductors. Metallic conductors installed in a building are subject to damage and gradual deterioration. The inspection and testing of a fire alarm system must include an evaluation of the wiring. Stray potentials can be introduced into the fire alarm system from a number of sources. These are most often related to leakage currents and electromagnetic interference from high-voltage ac conductors that have been installed in close proximity to the fire alarm system conductors. However, sources of dc leakage currents have also been encountered. The multimeter is used to measure the conductor-to-conductor and conductor-to-ground potentials, both ac and dc, for each fire alarm system circuit. Where the potential differs from that stipulated in the manufacturer's installation manual by more than 1.0 V (ac or dc), the source of the potential must be identified and the problem corrected.

Fire alarm system conductors can also become shorted. There are many circumstances where a shorted circuit will not result in a "trouble" signal at the control panel, because the control unit circuitry does not monitor for short-circuit conditions. Consequently, fire alarm circuits should also be tested with the multimeter to verify the proper impedance on circuits that are not connected to normally closed contacts of other intentionally closed circuits.

Finally, damage to conductors can cause an increase in conductor resistance that will prevent successful operation of the devices served by the circuit. One method to test for this condition is to short the circuit at the end and measure the loop resistance to verify it is within the limits established by the equipment manufacturer. If this method is elected, particular care must be exercised to ensure that no shorting devices can accidentally be allowed to remain in place at the conclusion of the testing. An alternative method requires that detailed records be kept of the loop resistance as installed, including (1) the end-of-line supervisory component and (2) comparing subsequent tests to the as-installed values to identify circuits where the resistance has changed. This method may not be available when testing addressable detector fire alarm systems.

Initiating Devices

Initiating devices sense a fire or a change in the state of some other monitored condition that has an effect on the fire safety of the protected site. These initiating devices, listed in the same order as in *NFPA 72,* include the following:

1. Heat detectors
2. Smoke detectors
3. Radiant energy sensing detectors
4. Sprinkler system waterflow alarms
5. Extinguishing system operation initiating devices
6. Manually activated alarm initiating devices (manual fire alarm boxes)
7. Supervisory signal initiating devices

Each of these devices must be tested to verify that its ability to sense the condition for which it was designed has not deteriorated. The specific test is dependent on the type of device and how it senses the condition it is intended to monitor.

Heat Detectors. A source of failure for heat detection devices is a layer of insulating material between the detector and the fire which retards or prevents response. This can be found in

the form of paint or some other coating. Physical damage can also be found to be a source of problems, causing both spurious alarms as well as failure to alarm.

There is a wide variety of heat sensor designs in common use. *NFPA 72* categorizes heat detectors into various classes based on their general operating characteristics and physical form. Each type has unique features and, hence, specific requirements regarding the inspection, testing, and maintenance of detectors of that type. The method of testing is established by the manufacturer of the detector, and it is reviewed by nationally recognized testing laboratories as part of the listing evaluation. Consequently, it must be followed meticulously for the results to be credible.

Most methods involve the use of a heat source to simulate the flow of heated air and smoke beneath the ceiling across the detector surface. *NFPA 72* requires that restorable, spot-type, and line-type heat detectors be tested by heating them in the manner required by the manufacturer and verifying an alarm within 1 minute. Nonrestorable, spot-type, and line-type detectors, such as those that use a eutectic alloy of specific melting point, are not tested until they are 15 years old, at which time they are either all replaced or a sample is removed and tested by a nationally recognized testing laboratory to substantiate their continued operability. The actuation of nonrestorable heat detectors is simulated by shorting the circuit conductors for verification of the circuit operability.

Smoke Detectors. As with heat detectors, there is a wide variety of smoke detectors using a number of different design concepts. Since smoke detectors exist as spot-type, line-type, and air-sampling-type devices, specific methods must be employed that are appropriate to the detector type. However, all inspection, testing, and maintenance methods relating to smoke detectors are designed to ensure three general criteria:

1. Smoke can enter the sensing "chamber" of the detector.
2. The detector attains the alarm state at the smoke concentration for which the detector was listed.
3. The detector alarm signal is received and processed by the fire alarm system control panel.

Spot-type smoke detectors are available using the ionization technology and the photoelectric technology. In ionization detectors, the accumulation of dust within the sensing chamber over time can interfere with the flow of electrical current through the sensing chamber in a manner similar to the effect of smoke. This tends to render the affected detector more sensitive and, hence, more prone to spurious alarms. The same effect is seen in the photoelectric detectors. The accumulation of dust increases the internal reflectance within the sensing chamber, making it more sensitive and prone to render a spurious alarm. A sensitivity measurement is critical in order to identify units that have suffered a change in sensitivity due to dirt accumulation that is not apparent from an external inspection.

Spot-type detectors are also subject to clogging from airborne dust or, worse yet, paint. The application of paint to the exterior of a spot-type smoke detector permanently changes the smoke entry characteristics of a detector and is prohibited by *NFPA 72*. Detectors must be carefully inspected to ensure that smoke entry is uninhibited. Room air-handling equipment can create airflows of such magnitude that it is impossible for the smoke from the design fire to reach the detectors. Consequently, an "in place" test is required to ensure the continued ability for smoke to reach the detector. Usually, an aerosol can of surrogate smoke or some other method outlined in the manufacturer's instructions is used to simulate the flow of the ceiling jet and access to the detector to verify this criterion.

Line-type smoke detectors are usually of the projected beam, light-obscuration type, which use the protected room as a sampling chamber. These detectors respond when the optical transmission of light across the room is reduced due to the presence of smoke. The accumulation of dust and dirt on the optical surfaces of these units can cause an increase in detector sensitivity. Consequently, they must also be inspected. Since the alarm threshold of the projected beam-type detectors must be adjustable to accommodate different room dimensions, the manufacturers of this type of detector provide a test method that was evaluated during the listing evaluation. The sensitivity of the unit must be measurable. Often, neutral density filters or test screens are placed between the emitter and receiver units of the projected beam detector to simulate the optical effect of a smoke accumulation in the protected space.

Air-sampling smoke detectors use a set of sampling tubes and a fan to convey air from the protected space to the detector unit. Detailed inspection and testing methods for these units are stipulated by the manufacturers. The test methods must verify that all of the air-sampling ports and tubes are operative at their design flow rates and that the detector unit, including the sampling fan, is operating within the parameters established by the listing. This implies a sensitivity measurement similar to that required of all of the other detector types.

Smoke detectors are also often used to monitor the air in heating, ventilating, and air-conditioning (HVAC) ducts. Generally, spot-type detectors are used for this type of service, installed in specially listed housings equipped with sampling tubes that allow air to be sampled from the duct. The inspection, testing, and maintenance for these units include the inspection and testing of the spot-type detector within the housing and the testing of the airflow through the sampling tubes, similar to that required for air-sampling-type units.

Traditionally, smoke detectors were designed with fixed alarm thresholds. However, recently "analog/addressable" detectors have been introduced where the alarm threshold for each detector is a numerical value stored in the fire alarm control panel memory. The control panel sequentially addresses each detector, and the unit responds with a voltage or current that is the analog of stimulus its sensing element is sensing at that moment. The analog voltage or current is compared to the value in memory, and the "alarm" decision is made in the control panel. The sensitivity of this type of detector is determined by the difference between the sensed analog value and the stored threshold value. This type of detector and control panel design minimizes the need for individual detector sensitivity measurements, but does not change the need for regular inspections and maintenance.

Radiant Energy–Sensing Detectors. This category includes flame detectors and spark/ember detectors. These detectors de-

pend on the optical clarity of their lenses and windows, as well as a clear, unobstructed line of sight to the fire. The inspection of these detectors must verify these two critical parameters. The inspection must include a review of the location of the detector and any opaque objects that may have been introduced into the hazard area since the last inspection to verify that the ability of the detector to respond to the design fire has not been impaired.

A close inspection of the detector window/lens must be made to determine if any opaque materials have adhered to the optical surfaces, reducing the sensitivity of the unit. Keep in mind that many materials are transparent in the visible portion of the spectrum but opaque in either the ultraviolet or infrared portions of the spectrum, where the detectors may operate. Many radiant energy–sensing detectors are available with a lens clarity monitoring feature. This feature is often associated with flame detectors using ultraviolet sensing as all or part of the detection method, since very small levels of contamination can have a very significant effect on the effective sensitivity of the unit.

Window clarity monitoring is not a sensitivity measurement. Sensitivity measurement for radiant energy–sensing detectors requires a means by which a radiant emitter, listed for the purpose, is used to provide emissions of the specific wavelengths and intensities representative of the fire the unit is designed to detect. The response of the detector is measured to determine whether a variation in the calibration has occurred.

The measurement of the sensitivity of a radiant energy–sensing detector, whether a flame detector or a spark/ember detector, is a required part of the inspection and testing regimen required by *NFPA 72*. A flame detector equipped with a built-in sensitivity checking and test lamp that performs both functions is shown in Figure 14.5.10. Sensitivity measurements are used to identify which detectors have suffered a loss of sensitivity due to aging of internal electronic components or deterioration of the optical clarity of the detector window or lens. In the author's experience, a common source of performance deterioration in radiant energy–sensing detectors is a loss of clarity in the detector's optical surfaces. Particular attention must be paid to this fact when maintaining these detectors.

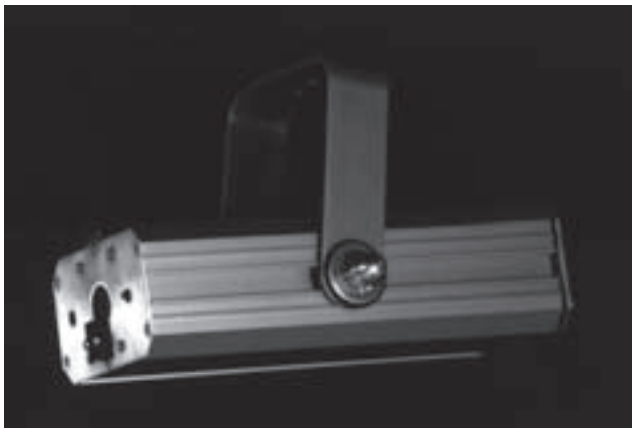

FIGURE 14.5.10 Flame Detector (Source: J. M. Cholin Consultants)

Sprinkler System Waterflow Alarms. Sprinkler system waterflow alarm initiation devices are often the only form of automatic fire detection in the protected site which can render a fire alarm signal during those periods when the building is unoccupied. The flow of water through the sprinkler system is an indication that a serious condition exists. Consequently, failure to render a signal when waterflow occurs is a doubly serious concern. This establishes the background for the aggressive inspection, testing, and maintenance schedules for these devices.

Sprinkler system waterflow alarm initiating devices are tested by operating the valve controlling flow through the inspector's test connection on the sprinkler system. If the waterflow initiating device is monitoring dry-pipe, preaction, or deluge systems, the alarm bypass connection, specifically installed for this purpose, is used for testing of waterflow initiating devices. Operation of the appropriate test connection causes a flow equivalent to the smallest orifice sprinkler head installed in the system. The waterflow alarm initiating device must transmit a signal to the fire alarm control panel within 90 seconds of the start of the waterflow. The delay between the time that flow begins and the time the alarm is transmitted to the fire alarm control panel is necessary to accommodate the oscillatory flows that often occur in large sprinkler systems and, as a result, surges in the public water supply pressure.

Extinguishing System Operation Initiating Devices. These initiating devices usually take the form of discharge switches specifically designed for the particular model of extinguishing system involved. Some of these discharge switches have a means to simulate the pressure of the extinguishing agent and, thus, test the operability of the initiating device. Others do not, and the testing can only be performed by shorting the contacts at their wiring terminations. In either case, each extinguishing system discharge initiating device must be tested as specified by the manufacturer and appropriate system functions verified.

Manually Activated Alarm Initiating Devices. Manually activated alarm initiating devices, commonly called manual fire alarm boxes, have traditionally consisted of a mechanical means to cause an electrical switch to transfer from open to closed, thereby shorting the conductors of the fire alarm initiating device circuit. Two aspects of these devices should be inspected and tested. First, the mechanical portion of the unit should be inspected and the operability should be verified. Recent legislation establishes maximum allowable forces for the operation of manual fire alarm boxes. Any unit that appears to have suffered corrosion, damage, or some other potentially adverse effect should be tested to verify that the operation force is within the limits for the make and model device in question. This is especially important in hazard areas where the walls have been painted subsequent to the installation of the manual station. Second, the manually actuated alarm initiating devices should be actuated to verify that the internal switch contact is electrically operative. Furthermore, many fire alarm systems actuate different responses due to the operation of manual stations in different

areas of the building or facility. The proper sequence of operation must be verified for each area.

Publicly accessible fire alarm boxes, commonly known as street boxes, are addressed in *NFPA 72*. These devices exist in a wide variety of types, connected to a variety of municipal signaling systems. The maintenance of these units is a municipal function, and the appropriate means of inspection and testing is established by the municipality.

Supervisory Signal Initiating Devices. Supervisory signal initiating devices monitor the status of critical fire protection assets. These include sprinkler system control valve status, water pressure status, water level, air pressure, and temperature. It is imperative to recognize that the failure mode and probability of the electrical supervisory initiating device is not related to the probability of failure of the monitored condition. Any coincidence in the frequency and scheduling of the inspection and testing of a supervisory signal initiating device with the supervised device is just that, a coincidence. Control valves do not fail on the same timetable as valve status supervisory signal initiating devices. The failures of valves are due to the compression welding of bronze components, tuberculation of the piping, galvanic corrosion, and the polymerization of seat grease. Failure of status switches is related to the corrosion of electronic contacts and the fatigue of copper wiring conductors and mounting brackets. The inspection and testing of the supervisory signal initiating devices are necessary to ensure that these devices are providing an accurate indication of the status of the supervised equipment and a reliable indication of the change in status of the equipment if and when it occurs.

Inspection and testing of the supervisory signal initiating devices usually involve a close inspection of each device to verify that the ambient conditions have not caused any deterioration in the device, followed by a temporary simulation of a change in status to verify that the supervisory signal initiating device transmits the indication of the change in status to the fire alarm control unit. Once the receipt of the change-in-status signal at the fire alarm system control unit has been verified, the simulated change in status is restored to normal and the receipt of the return-to-normal signal at the control unit is verified. Transmission of a change in status to the fire alarm system control unit should occur without any undue delay. If delays are encountered, the cause should be identified and corrected.

Notification Appliances

The principal objective of every fire alarm system is to ensure timely notification to all building occupants, enabling them to make safe egress from the fire location; therefore, the inspection and testing of the alarm notification appliances are crucial.

The three general types of notification appliances referenced in *NFPA 72* are (1) audible notification appliances, (2) visible notification appliances, and (3) speakers for emergency voice communication. Each type of notification appliance has a test method that verifies that the unit is providing the notification signal at a level consistent with the design objective.

Audible Notification Appliances. These include bells, horns, sirens, chimes, speakers, buzzers, and any other device designed to make a sound other than human speech. They all have a means of converting electrical energy into sound, often involving the making and breaking of an electrical switch contact connected to a bell clapper or a diaphragm and an electromagnet, thus producing a mechanical oscillation and sound. Corrosion, metal fatigue, paint clogging, mechanical damage, electrical contact erosion, and electrical conductor fatigue all can cause a deterioration in the quantity of sound a device produces. Each audible notification appliance must be inspected for signs of deterioration.

The audibility must also be tested to verify that the audibility criteria for the hazard area are still being achieved by the system. Audibility is verified through the measurement of the sound pressure produced by the audible notification appliance. Sound pressure is measured in units of decibels, dBA (the A signifies the A-scale which is designed to weigh sound pressure versus frequency in a manner that approximates human hearing). The sound pressure measurement is made with a sound meter. Only sound meters that comply with ANSI S1.42, *Design Response of Weighting Networks for Acoustical Measurements,*[7] should be used for the assessment of fire alarm systems. Care must also be taken that the sound pressure meter is used as directed by the operating manual to minimize measurement errors (Figure 14.5.11).

Two criteria must be met by the audible notification appliances. First, the system is required to produce a sound pressure level of 15 dBA above the average ambient and 5 dBA above the maximum sound pressure level having a duration of at least 60 seconds, measured 5.0 ft (1.5 m) above the floor in the occupiable area. Because sound intensity usually varies inversely with the distance from the audible appliance, the sound pressure readings are taken at a location furthest from the audible appliance. Generally, if the minimum compliance sound level is achieved at that location, it can be safely assumed that closer locations will also be above the minimum compliance sound level. However, "usually" does not mean always. Occasionally, buildings have unexpected acoustics that affect the sound intensities at various locations within the building. This should be noted when assessing audibility and additional measurements should be taken wherever the audibility seems lower than "normal."

The second criterion is the maximum allowed sound pressure level at the closest occupiable location to the audible

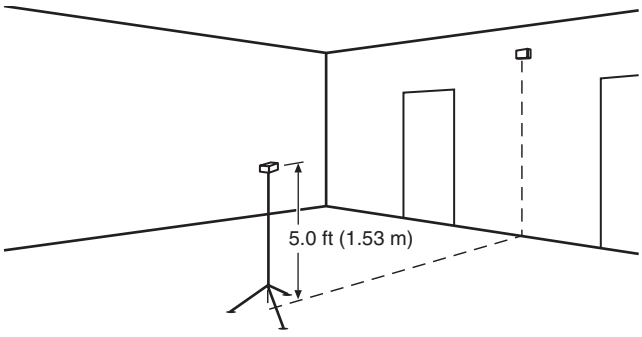

FIGURE 14.5.11 Sound Pressure Meter Mounted on a Tripod for an Audibility Measurement

appliance. This sound level cannot exceed 110 dBA without subjecting the occupant to potential hearing injury, according to the U.S. Occupational Safety and Health Administration (OSHA). System component failures rarely result in higher sound output from audible notification appliances. However, changes in the occupancy, such as installation of catwalks, stairs, mezzanines, and so on, can render a formerly unoccupiable location occupiable. This is consistent with the inspection of all other system components, in that the role of the inspection includes identifying changes in the protected space that may have an impact on the fire alarm system.

Speakers. Emergency voice communication speakers are also audible notification appliances, and they are required to achieve sound levels equivalent to audible notification appliances. The inspection should identify any form of damage, for example, mechanical deformation, corrosion, metal fatiguing, and paint clogging. The testing is similar to that for audible notification appliances. The sound level is measured with an ANSI S1.42–compliant sound level meter.[7] The minimum compliance sound level must be verified throughout the hazard area, and the test must verify that the maximum allowable sound level is not exceeded at any occupiable location.

An additional test criterion, one that is not relevant to other audible notification appliances, is included when emergency voice communication speakers are evaluated. This criterion is the intelligibility or clarity of the voice communication. In the testing of emergency voice communication speakers, the intelligibility of the speech message must be assessed. For existing systems, installed prior to 1999, the intelligibility assessment is essentially qualitative—can the speech message be understood by the intended recipients? Generally, intelligibility is maximized by using more audible notification appliances, so that each dissipates less power rather than using fewer higher-power audible notification appliances.

More recently, the trend has been toward using more quantitative intelligibility assessment methods, especially in acoustically challenging spaces where highly reflective wall, floor, and ceiling surfaces dominate or where very large power levels are needed to attain the requisite sound pressure levels. These challenging spaces include arenas, museums, atria, airport concourses, rail stations, and similar "special-purpose" spaces. An assessment method has been referenced in Annex A of *NFPA 72* and is outlined in Annex A of IEC 60849, *Sound Systems for Emergency Purposes.*[8] The method relies on the measurement of the common intelligibility scale (CIS) for the system. The objective means of determining intelligibility, and hence calculating the CIS, are found in IEC 60268, *The Objective Rating of Speech Intelligibility by Speech Transmission Index.*[9] Subjective techniques are also available, as found in ANSI S3.2-1999, *Method for Measuring the Intelligibility of Speech over Communications Systems.*[10] These methods are generally employed by sound engineers in the design of commercial sound systems and can be applied equally well to fire alarm emergency voice systems.

Visible Notification Appliances. Visible notification appliances are inspected and tested to verify that they are still capable of achieving the design objectives of the fire alarm system. A light meter analogous to the sound-level meter is not in common usage as of this writing. This limits the inspection and testing to those procedures recommended by the manufacturer of the specific visible notification appliance used.

During the inspection and operational testing of the visible notification appliances, particular attention must be paid to any furnishings such as shelves, ornamental plants, lamps, banners, sculptures, and so on, or added construction features, for example, stairs, catwalks, ladders, lighting fixtures, and partitions, that interfere with a clear line of sight to the visible notification appliances. Furthermore, many systems rely on synchronization to ensure that the combined effective light pulse rate does not exceed 4 Hz, a frequency at which there is concern over the effect on those persons prone to seizures. Synchronization is achieved by different means from manufacturer to manufacturer; most manufacturers produce both synchronized and unsynchronized product. Consequently, where the design relies on synchronized visible notification, the inspection must verify that all of the visible notification appliances visible from any single viewing location are still synchronized or are separated by at least 55 ft (16.8 m).

INSPECTION, TESTING, AND MAINTENANCE SCHEDULING FOR SYSTEMS AND COMPONENTS

The requirements regarding the inspection, testing, and maintenance of fire alarm signaling systems must also be scheduled. Since different components have different failure rates, those with the higher failure rates require more frequent inspections and testing if the overall system reliability is to be kept at an acceptable level. Inspection, testing, and maintenance interval recommendations come from both the predicted reliability derived from failure rate analyses and from experience data derived over time. Manufacturers provide specific schedules for the service requirements for their products, and these must be observed where they establish a more frequent regimen of inspection, testing, and maintenance.

The objectives of an inspection program are to identify cases where the hazard area has changed, rendering the existing fire alarm system inappropriate for the hazard area, or some episode of physical abuse has occurred that has damaged the component, rendering it incapable of performing in a manner consistent with the system design. The frequency of these types of conditions is a function of the hazard area, not the inherent reliability of the system components. Consequently, some sites will require more frequent inspections due to the unique nature of the particular site. *NFPA 72* provides the required visual inspection frequencies, reproduced here as Table 14.5.2.

Testing of fire alarm system components occurs on a schedule that is less frequent than the inspections. The testing uncovers failures that are not apparent from a visual inspection and are generally attributable to the combined effect of the ambient conditions and the inherent failure rates of the components. There are applications where the testing frequency established in *NFPA 72* as a minimum compliance criterion is not adequate to achieve the required level of reliability. The effective reliability

of such a fire alarm system can be improved by implementing a more frequent testing program. *NFPA 72* provides the required testing frequencies, reproduced here as Table 14.5.3.

HOUSEHOLD FIRE WARNING EQUIPMENT

Household fire alarm systems have been implemented in a number of different ways. More recent design concepts correct the performance shortcomings of older design philosophies and reflect the improved performance of modern equipment.

NFPA 72 requires the monthly inspection and testing, per the manufacturer's instructions, of all smoke detectors in a household fire alarm application, regardless of whether those detectors are single-station units, interconnected multiple-station units, or detectors integrated into a complete household fire alarm system. This monthly testing should include a verification that all audible and visible notification appliances are operative. Furthermore, *NFPA 72* requires that household fire alarm systems, that is, systems consisting of detectors, notification appliances, and a control panel, be inspected and tested at least every three years by a qualified alarm technician with a procedure in compliance with the manufacturer's instructions.

UL 217, *Standard for Safety Single and Multiple Station Smoke Detectors,* allows a maximum failure rate of 4.0 f/mdoh for the detector circuitry.[11] This failure rate can be expressed as 1.0 failure per 250,000 device operating hours, or 1.0 failure per 8760 hr/yr × 28.5 yr, or 0.035 failures per year. The battery for the smoke detector can only operate the unit for one and a half years before it is depleted. The depletion of the battery is not included in the failure rate assigned to the battery. The failure rate for the household fire alarm is the failure rate per detector and the depletion rate for the battery multiplied by the number of units in the household. Assuming six detectors in the average house and a failure rate of $1 - (1 - 0.667)(1 - 0.035) = 0.679$, one obtains $6 \times 0.679 = 4.074$ failures per year for Λ. Using the equation developed earlier, that is,

$$R = e^{-\Lambda t}$$

where

R = Reliability of the system

e = Napierian logarithm base, 2.71828

Λ = Inherent failure rate of the system

t = Time period between performing recommended inspection and testing, 1/12 of a year or 0.0833 yr

$$R = e^{-4.074 \times 0.0833}$$

$$= 0.712 \text{ or } 71.2 \text{ percent}$$

Source: *NFPA 72®, National Fire Alarm Code®,* 2007 ed., Table 10.3.1, pp. 72-106–72-108.

Thus, generally available residential smoke detectors when installed, inspected, and tested monthly per the manufacturer's instructions and *NFPA 72* can be expected to provide a functional reliability of a nominal 71.2 percent.

CRITICALITY OF INSPECTION, TESTING, AND MAINTENANCE ON THE EFFECTIVENESS OF THE SYSTEM

Electronic systems are, at this time, the only systems on which solid reliability data exist in the quantity and quality that allow one to develop a predictive computational method to assess various design alternatives. All physical systems have failure modes, and each system component demonstrates failure at a finite rate over the majority of its operational lifetime. Nonelectrical fire alarm systems are not necessarily more reliable than electronic systems. It is possible to compute the reliability of electrical systems only because good failure rate data exist.

The one concept to be gained from reliability analysis and prediction computations is that all systems are destined to fail, given enough time. It is a probability so high as to approach a *certainty.* A performance-based design cannot be deemed complete until it includes a quantitative assessment of the likelihood that the system will perform as designed. This assessment is dependent on the service and maintenance interval for the system. With long time intervals between inspection and testing procedures, the probability increases that the system will be operating with some type of unnoticed impairment during the intervening time periods. Obviously, the time during which the system is partially and perhaps even completely impaired increases with the increase in the time interval between each exercise of the required inspection and testing. Consequently, no performance- or objective-oriented design is complete without a preventive maintenance program that includes inspection and testing on an interval that is predicated upon the size and complexity of the system itself.

Consider the example fire alarm system presented earlier. A system consisting of 10 smoke detectors, a notification appliance, and a control panel produced a predicted failure rate of 0.3824 failures per year. Table 14.5.4 shows the effect of varying inspection and testing intervals on the reliability of this system. The reliability of the system and, hence, the needed maintenance interval are dependent on the size and complexity of the system. Table 14.5.5 demonstrates the impact that increasing system size has on the needed inspection and testing interval in order to maintain a uniform design reliability of 71.2 percent (0.712). Clearly, as the size or complexity of the system increases, the frequency of the inspection and testing program must be increased to retain a constant reliability. If the inspection and testing frequency is held constant, then the reliability of the system decreases each time the size and complexity of the system are increased.

TABLE 14.5.4 System Reliability Dependent on the Inspection and Testing Interval System (actual values based on the reliability data used in the example)

Inspection and Testing Interval	*Reliability*
Quarterly	0.904
Semiannually	0.826
Annually	0.682
Biannually	0.465

TABLE 14.5.5 Inspection and Testing Interval Necessary to Maintain a 71.2 Percent Reliability as System Size Is Increased (values based on the reliability data used in the example)

System Size	Λ	*Inspection and Testing Interval (yr)*
10 detectors, 1 notification appliance	0.3824	0.93
20 detectors, 2 notification appliances	0.5278	0.68
40 detectors, 4 notification appliances	0.8554	0.42
80 detectors, 8 notification appliances	1.4860	0.24

Tables 14.5.3, 14.5.4, and 14.5.5 demonstrate the importance of the inspection, testing, and maintenance program. A system cannot be expected to achieve the design objectives if the inspection, testing, and maintenance program does not reflect the reliability objectives of the design. The failure to maintain a system in a manner consistent with the design assures the owner/operator of the protected site that the fire alarm system will *not* achieve the design objective.

SUMMARY

The essential objectives of a fire alarm system—life safety, property protection, and continuity of the site's mission—will be achievable in the event of a fire only if the alarm system functions properly. An inspection, testing, and maintenance regimen employed at regular intervals is essential for ensuring the reliable performance of the fire alarm system. Because at some point in its lifetime any system will suffer a failure, a schedule of inspection, testing, and maintenance must be developed based on the size and complexity of the system. The four main system elements—design, equipment, installation, and maintenance—are critical to the reliability of the system and should be the focus of the regimen.

Key Terms

heat detector, household fire alarm, Indiana Dunes Report, interconnected smoke alarm, intrusion detection, multiple-station alarm, notification appliance, Operation School Burning, single-station alarm, smoke alarm

America's fire death rate is dominated by fires in U.S. homes. Household warning systems, specifically smoke alarms, provide a rare combination of effectiveness and affordability in reducing the risk of death in home fires. The dominance of U.S. homes in fire deaths is demonstrated each year. In recent years, four of every five deaths have occurred in U.S. homes, as have over 90 percent of fire deaths in structures. Analyses by the National Fire Protection Association (NFPA) indicate that when a fire occurs, having detectors present cuts the chances of dying nearly in half. If every home had an operable smoke alarm, home fire deaths would be reduced by an estimated 36 percent, approximately 1100 lives saved per year.[1]

Although heat detectors for residential use have been available since 1921, field tests have shown that they are not as effective as smoke alarms in detecting fires in the home. Fire tests in residential occupancies have shown that measurable amounts of smoke have preceded measurable amounts of heat in almost all cases. In the other cases, the smoke and heat appeared almost simultaneously. Consequently, codes and standards have mandated the use of smoke alarms because they provide a greater level of protection.

Residential smoke alarms were relatively expensive when they began to appear in the marketplace in the late 1960s. In 1970, however, the introduction of a battery-operated smoke alarm, along with line-powered (AC-powered) smoke alarms, initiated a period of public acceptance of single-station residential smoke alarms. In 2004, 96 percent of U.S. homes had at least one smoke alarm.[2]

This chapter discusses the reasons household fire-warning systems are needed, the history of residential fire-warning systems, research into system effectiveness, the importance of having a system in the home and how to make the best use of it, and the importance of an effective escape plan. The types of systems and detectors will also be covered, along with guidelines for installing and testing household fire warning equipment.

For related topics see the following chapters in Section 14: Chapter 1, "Fire Alarm Systems"; Chapter 2, "Automatic Fire Detectors"; Chapter 3, "Notification Appliances"; and Chapter 9, "Carbon Monoxide Detection in Residential Occupancies."

RESIDENTIAL FIRE DETECTOR RESEARCH

Early Test Programs

Current performance requirements and installation practices for residential fire detectors are the result of knowledge and experience gained from several test programs. The first major test programs using heat and smoke detectors were Operation School Burning and Operation School Burning No. 2, conducted by the Los Angeles (California) City Fire Department in 1959 and 1961, respectively. These tests had a major impact on fire protection and proved two significant points:

Daniel T. Gottuk, Ph.D., is a senior engineer at Hughes Associates, Inc., and is a project manager for a variety of fire-related forensic, research, testing, and development programs. He is chair of the NFPA Technical Committee on Single- and Multiple-Station Alarms and Household Fire Warning Systems.

(1) smoke alarms could provide a high level of life safety due to their fast response to a fire, and (2) detectable quantities of smoke usually precede detectable levels of heat.

The next significant test series was conducted by the Bloomington (Minnesota) Fire Department in May 1969. Although all detectors employed in the Bloomington tests were system-connected units, the results of these tests—such as time of detector response, order of response as a function of detector and fire type, and conditions at time of response—correlated well with subsequent tests.

Four Levels of Protection Concept

In 1974 NFPA members adopted a major change to NFPA 74, *Household Fire Warning Equipment.* Prior to this, NFPA 74 required that, in addition to a smoke alarm, a home be protected with a heat detector in every major room of the dwelling. The 1974 edition recognized two facts: (1) the mandatory total system approach was impractical for the majority of the population, and (2) heat detectors were not the most effective detectors for the home. Therefore, an NFPA committee developed a matrix of four "levels of protection" from which the homeowner could choose. The four levels of protection concept was finally adopted by the NFPA membership, but not without a fight. The opposition (principally some fire chiefs and fire marshals) felt that they could not recommend anything less than complete protection, and that effectiveness of Level 4, which provided for one or two smoke alarms in the home, had not been proved by test data.

Indiana Dunes Report and Minneapolis Fire Department Study

Based on this latter argument, the National Bureau of Standards (NBS) (now the National Institute of Standards and Technology [NIST]) contracted with IIT Research Institute and Underwriters Laboratories Inc. (UL) to provide just such test data. The results of the first phase of this test program were published in August 1975 under the title "Detector Sensitivity and Siting Requirements for Dwellings." The study, more commonly known as the Indiana Dunes Report, showed, in fact, that Level 4 coverage was inadequate under certain conditions. The report recommended that at least one smoke alarm on each story of the residence be used as a minimum requirement. This system was referred to as the "every level" smoke detection system. Based primarily on the results of this report, NFPA 74 was revised again in 1978 by dropping the four levels of protection and adopting a minimum required system of one smoke alarm on each story (floor level) of a home. Also, because of the slow response of heat detectors when compared to smoke alarms, NFPA 74 no longer permitted the use of heat detectors as the prime method of fire detection.

Shortly after publication of the first phase of the Indiana Dunes Report, the Minneapolis Fire Department conducted a similar independent study on smoke alarm performance. The Minneapolis and Dunes tests were very similar in that each was conducted in a two-story house with basement, with detectors installed on each floor. Likewise, the conclusions of the Minneapolis and Dunes tests were essentially identical; thus, the Minneapolis tests provided an independent verification of many of the conclusions of the Dunes tests. Over the next quarter century, a number of additional studies would be conducted on the performance of home smoke alarms and all confirmed the earlier studies.[2–4]

CODES AND STANDARDS

It is well known that compliance with strong smoke detection laws offers the potential of significant reduction in loss of life and property from fire. For uniformity, laws adopted statewide are preferable to local ordinances. Most states and communities now require residential occupancies from single-family dwellings to hotels and motels to be equipped with smoke alarms. Although most model building codes and life safety codes include specific requirements for smoke alarms in residential occupancies, the development of these requirements has generally originated from what is now known as *NFPA 72®*, *National Fire Alarm Code®*.

In 1993, NFPA 74 was combined with the other fire alarm system standards and now appears as Chapter 11 of *NFPA 72*. In the latest editions of the code, Chapter 11 was changed to address equipment requirements rather than occupancy-specific requirements; this is reflected in the current technical committee and chapter name, Single- and Multiple-Station Alarms and Household Fire Alarm Systems. Chapter 3 of *NFPA 72* provides definitions for these different types of fire alarm equipment. A single-station alarm is a device that includes a sensor and notification appliance in one unit and a power source that is typically a self-contained battery and/or connection to an AC circuit in the dwelling. A multiple-station alarm is a single-station alarm that has the means to be interconnected to other alarms (that is, when one sounds an alarm signal, all connected devices will sound). A household fire alarm system is different in that it incorporates a fire alarm control panel to power and monitor smoke detectors and often to provide alarm notification through separate appliances. Smoke detectors are different from smoke alarms in that they require a panel to operate, whereas a smoke alarm is a stand-alone device.

In 1989, NFPA 74 added requirements for interconnected smoke alarms in new construction, and in the 1993 conversion of NFPA 74, the requirement for a smoke alarm in each sleeping room in new construction was introduced in *NFPA 72*. This change specifically addressed the protection of the occupant of the sleeping room. Detection of smoke from a fire within the sleeping room by an alarm outside the sleeping room, especially with the door closed, has been a problem. The interconnection of devices located in bedrooms also provided better distribution of the alarm signal, particularly for fires detected by alarms remote from the sleeping area. In 2007, *NFPA 72* was changed to require a uniform set of installation requirements regardless of occupancy age (i.e., new or existing). These changes are partly enabled by several new wireless technologies that permit smoke alarms to be interconnected.

ELEMENTS OF RESIDENTIAL FIRE PROTECTION

The many elements of fire safety and fire protection can be grouped into six elements that need to work together in an integrated system for best results:

1. Fire prevention
2. Prevention of unusually rapid early growth or spread
3. Automatic detection
4. Automatic suppression
5. Compartmentation or containment
6. Evacuation or escape

Each is important individually, and all are interdependent in any successful residential fire protection scheme. From the perspective of household early warning systems, these six elements need to be examined in terms of the essential steps that make the automatic detection element successful and the other fire elements that can render detector protection unsuccessful. Taking them in order, one may focus on prevention of ignition and of rapid early growth or spread under a generic title of minimizing fire hazards.

Although automatic residential sprinkler systems are gaining acceptance for new home construction and are mandated in several jurisdictions, the general consensus among fire safety professionals is also to recommend automatic smoke detection in accordance with *NFPA 72,* Chapter 11, "Single- and Multiple-Station Alarms and Household Fire Alarm Systems," providing a minimum level of life safety protection.

Minimization of Fire Hazards

Preventing a fire before it occurs is always easier than detecting it once it has occurred; therefore, minimizing fire hazards in and around the home is the first key element to minimizing hazards. This prevention includes care in the selection and use of all potential heat sources (e.g., tobacco products, heating and cooking equipment, the electrical system, appliances, lighting appliances) and fuel sources (e.g., furnishings and contents, interior finishes). Preventing rapid early growth or spread implies special attention to removing all unessential flammable liquids and other highly combustible items from the home. Further, it should also mean strict adherence to and enforcement of building and fire codes in the construction of residential occupancies, use of only low-flame-spread materials for interior finish, and use of low-flammability or fire-retardant-treated materials in residential furnishings. Proper compartmentation is also essential to slow the fire as it moves from zone to zone, extending the time to hazardous exposure for most occupants.

It must be realized that, if a fire develops rapidly enough, residential smoke alarms may not provide enough time for the occupants of a dwelling to escape before their exit routes are cut off. Therefore, it is highly dangerous for people to be careless, thinking smoke alarms will protect them from their carelessness.

Installation of Smoke Alarms

Full effectiveness for household warning systems means the right number of smoke alarms, located in the right places and operating properly. As required by *NFPA 72,* Chapter 11, "Single- and Multiple-Station Alarms and Household Fire Alarm Systems," the acceptable minimum consists of one smoke alarm in each bedroom, outside each sleeping area and one on each habitable story, including the basement of the home. It is also recommended that the minimum package be supplemented by additional smoke alarms in other areas as needed. For example, a smoke alarm could be located in living and family rooms, and smoke or heat alarms could be located in the kitchen, attached garage, attic, and furnace room. Each additional alarm could provide more time for the family to escape. When more than one smoke alarm is installed, the alarms should be arranged so all of the devices sound when any one device detects smoke. This chain of alarms can be done by installing either multiple-station smoke alarms or a complete household fire alarm system with smoke detectors, panel, and notification appliances.

Equally as important as the installation are proper care and maintenance of the equipment. Each residential smoke alarm comes with an owner's booklet describing the necessary maintenance procedures. A smoke alarm with a dead or missing battery will be useless in a fire. In fact, NFPA analysis of reported fires has shown roughly one-third of U.S. home smoke alarms are not working when fires occur, typically because of dead or missing batteries. This is a major obstacle to achieving full success with home smoke alarms. Because of the battery problem, *NFPA 72* and many local building codes mandate use of both primary AC and secondary battery power, with an exception in some cases that allows an alarm with a nonrechargeable, nonreplaceable 10 year life battery.

Development of Escape Plan

The last key element in residential fire protection is the development and practice of a family escape plan. Remember, residential smoke alarms can do no more than warn occupants of a fire in the home; they will not extinguish the fire. Also, depending on the speed at which the fire is developing, the amount of time available for escape may be limited. It is critical that all occupants leave the home immediately and *call the fire department once outside the home.* Delay can be fatal if people take extra time, for example, to get dressed, gather valuables, or look for pets. Also, it is important that everyone have an alternative way out of each room in case the primary exit is blocked by fire. There must be a prearranged outside meeting place so everyone will know that the entire family has escaped the fire. Any delay can be fatal, including reluctance to climb out of windows. Any actions that increase the risk of death can be fatal, such as reentering a burning home to look for people who may very well have already escaped.

Information on how to formulate a family escape plan is contained in the homeowner's booklet provided with each residential smoke alarm and by NFPA in its EDITH (Exit Drills in the Home) materials.

TYPES OF SYSTEMS

Residential fire detection may range in size from one single-station smoke alarm in an apartment, manufactured home, or recreational vehicle to a centrally wired system containing numerous detectors and separate alarm notification appliances. The fire detection system may be combined with a burglar alarm system and an emergency medical alert system. It may be connected to an alarm monitoring company by leased telephone lines or by a digital alarm communication transmitter. The number of devices and the complexity of the system are determined, on the low

end, by the minimum acceptable for a given dwelling, and, on the high end, by the extent of the occupant's needs and finances. *NFPA 72* states that the minimum requirements for detection can be met either by the installation of smoke alarms or with a fire alarm system using smoke detectors.

Single- and Multiple-Station Smoke Alarms

A single-station alarm (Figures 14.6.1, 14.6.2, 14.6.3, and 14.6.4) is a self-contained device that consists of a detecting element, electrical control components, an alarm-sounding appliance, and a provision for connection to a separate power supply source (such as the direct AC wiring of a home) or an integral power source or both.

A direct-wired type, when provided with one or more additional wires for interconnection with other similar smoke alarms, is referred to as a multiple-station smoke alarm (Figure 14.6.5). When interconnected according to the instructions provided, an alarm from any one of the interconnected smoke alarms activates the alarm in all the devices. This is important because the smoke alarm near the bedrooms should sound when a smoke alarm located in another area senses smoke. New technologies now allow for wireless interconnected battery-powered smoke alarms, as well as AC-powered ones (Figure 14.6.6). These wire-

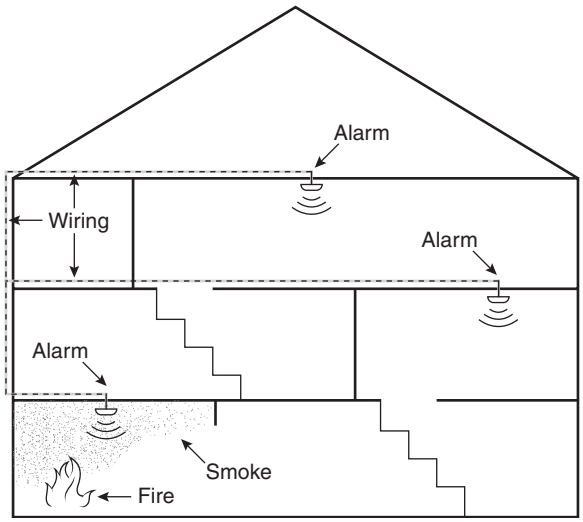

FIGURE 14.6.5 Multiple-Station Smoke Alarms with Hardwired Interconnection (Source: Hughes Associates, Inc.)

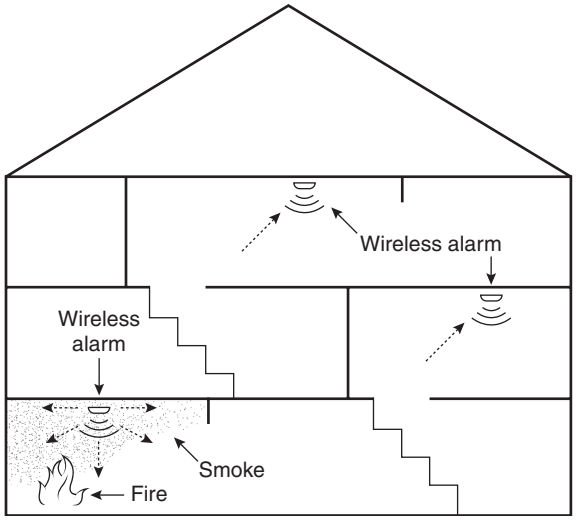

FIGURE 14.6.7 Wireless Interconnected Smoke Alarms (Source: Hughes Associates, Inc.)

FIGURE 14.6.6 Wireless Interconnected Battery-Powered Smoke Alarm (Source: Kidde: A UTC Fire and Security Company)

less interconnected alarms can be easily used in existing homes (Figure 14.6.7), whereas previously to convert to interconnected alarms generally required expensive rewiring of the house. The number of smoke alarms that are permitted to be interconnected is limited to 12 by *NFPA 72,* Chapter 11. Additional multiple-station alarms, other than smoke alarms, are permitted with limitations as specified in Chapter 11 of *NFPA 72.*

NFPA 72, Chapter 11, "Single- and Multiple-Station Alarms and Household Fire Alarm Systems," requires that low-power wireless systems comply with all of the requirements given in *NFPA 72,* Chapter 6, "Protected Premises Fire Alarm Systems."

Wireless systems are composed of smoke alarms with built-in low-power radio transmitters. System operability, including battery condition, is verified by periodic transmission via repeaters, when necessary, to a central receiver. Both repeaters and the central receiver operate from AC power with standby battery, thus providing a reliable system.

Household Fire-Warning System

In addition to single- and multiple-station alarms, there are household fire-warning systems similar in makeup and operation to the local fire alarm systems described in *NFPA 72,* Chapter 6, "Protected Premises Fire Alarm Systems." Such a system typically consists of a fire alarm control unit (panel) that derives main power from the AC house wiring and contains a rechargeable standby battery capable of operating the system for at least 24 hours (Figure 14.6.8). In addition, this system uses smoke detectors and heat detectors of the system-connected type. Some detectors include a self-contained sounder for alarm.

The fire alarm system can also have separate alarm notification appliances, such as bells, horns, or electronic sirens. The control unit also might have provision for connection to an automatic digital dialer, central station, or television cable to transmit the alarm to a point beyond the household. Where the system is connected to a supervising station, *NFPA 72,* Chapter 11, permits the station to verify alarm signals prior to reporting them to the fire service provided that the verification process does not delay the reporting by more than 90 seconds.

The most popular method for such a connection is digital communication. *NFPA 72* permits (1) operation with only one telephone line and (2) programming to call only one digital alarm control receiver (DACR) number.

Combination Systems

Both wired and wireless household fire alarm systems often include intrusion detection in addition to fire alarm functions.

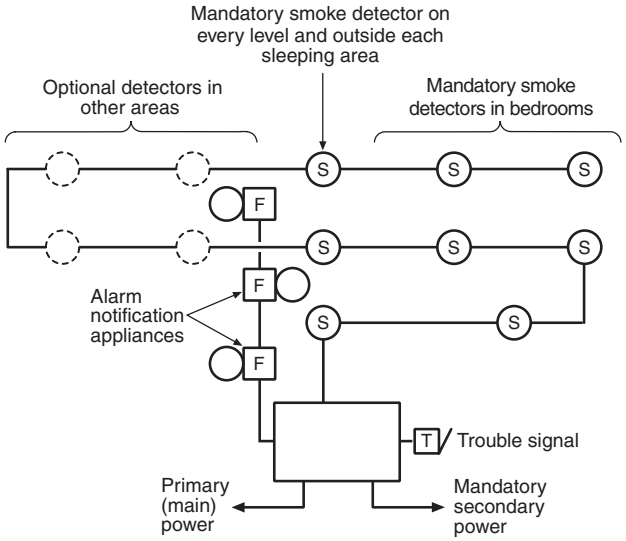

FIGURE 14.6.8 Typical Household Fire Alarm System, with Separate Control Panel

This could make the system more cost effective. In combined systems, the fire alarm signal must take precedence over the intrusion detection alarm signal. The audible alarms are required to be distinctive so the homeowner can immediately discern the difference between a fire and an intrusion. In addition, a system that provides for transmission of alarms to a point beyond the household by means of a digital dialer will sometimes have a medical alert feature that can be used to summon medical help.

DETECTION SYSTEM COMPONENTS

Smoke Alarms

Single- and multiple-station alarms may be of either the ionization or photoelectric type. Tests have shown that listed smoke alarms of either the ionization or photoelectric type should provide adequate warning to the occupants for most residential fires. It might be noted that, as a class, ionization alarms generally respond faster to open flaming fires than photoelectric alarms. Conversely, the photoelectric alarms generally respond faster to smoldering fires. Because residential occupancies experience both flaming and smoldering fires, an extra margin of occupant safety might be achieved if the home were equipped with one alarm of each type. However, the number of potential nuisance alarms may increase. Both types of smoke alarms are subjected to, and must pass, the same test fires for listing by a testing laboratory. Typical test fires are described in UL 217, *Standard for Safety Single- and Multiple-Station Smoke Detectors,* and ANSI/UL 268, *Standard for Safety Smoke Detectors for Fire Protective Signaling Systems.*

Alarm Notification Appliances

A smoke alarm sounds an audible alarm at the device itself. *NFPA 72* requires that a device should provide at least 15 dBA above the maximum ambient sound level at the ear of the sleeping person or at least 75 dBA, whichever is greater. Per the design and listing requirements, the sound level output of an alarm must be at least 85 dBA at a distance of 10 ft (3.05 m). This should be sufficient to meet the *NFPA 72* requirements and to alert most sleeping people as long as the alarms are located per the current code requirements.[5,6]

If alarms are not installed per the current codes (i.e., interconnected and located on every floor and in every bedroom), occupants should be aware of the factors that may impact the effectiveness of alarms to wake people. Long distances between the alarm and the bedroom, closed bedroom doors, a noisy appliance in the bedroom such as an air conditioner or humidifier, or impaired hearing could prevent an occupant from being awakened by the alarm. This possibility is why it is important for alarms to be interconnected and to sound in the bedroom.

A wired or wireless household fire alarm system normally has an alarm-notification appliance circuit for connection of various appliances, such as fire alarm bells, horns, or electronic sirens. These devices can produce higher sound levels and can be located independently of the detectors. They can be clearly audible throughout the house or even outside, where neighbors might hear the alarm. Regardless of the type of devices installed in the home, alarm signals should be measured in each bedroom.

Several studies have examined the response of adult occupants to the smoke alarm signals; Bruck[7] provides a summary of these. In general, an unimpaired sleeping adult will awake quickly to a smoke alarm signal that reaches the occupants at a sound level of 55 to 60 dBA. Recent studies have also shown that most older adults, who as a population group generally experience hearing loss compared to the general population, will wake to smoke alarms installed per the current codes.[6,8] Other studies[9,10] have specifically investigated the waking effectiveness of smoke alarms with children. These studies have shown that a 55 to 60 dBA signal will not reliably wake children between the ages of 6 and 15 years. Even at a sound level of 89 dBA at the pillow, 71 percent of 6- to 10-year-olds and 29 percent of 11- to 15-year-olds slept through alarms. Children under 6 years old would be even less likely to awaken than the 6-year-olds.[11] Due to the deep sleep behavior of children, many simply will not awaken to smoke alarms, even at extremely loud levels of 123 dBA[12] that can be painful to individuals. The key point to understand: children will likely sleep through an alarm and will need assistance to escape from a fire. Though parents typically realize that they have difficulty in waking their children at times, many parents seem quite surprised when presented with these findings. Occupants must plan to help both young children and people with disabilities that will impede waking or escape.

INSTALLATION PRACTICES

Smoke Alarm Location Guidelines

Alarms should be located on the ceiling, at least 4 in. (102 mm) from the wall, or on the side wall, 4 to 12 in. (102 to 305 mm) from the ceiling to the top of the device (Figure 14.6.9). On floors containing bedrooms, the ceiling of the hallway serving

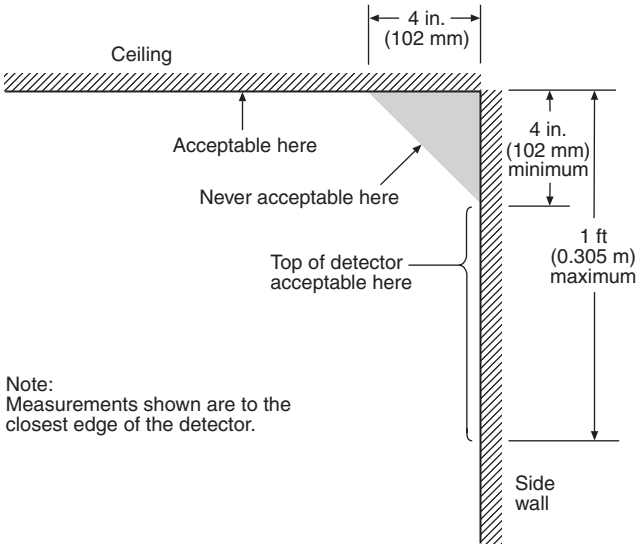

FIGURE 14.6.9 Proper Mounting of Smoke Alarms

the bedrooms is the usual alarm location. On other floors, alarms should be located near the stairways to intercept smoke rising from lower floors. Smoke alarms (indicated by a backward "S" in the figures) must be located on each story (Figure 14.6.10) as well as between the sleeping area and the rest of the family living unit (Figure 14.6.11). A smoke alarm should be provided to protect each sleeping area in addition to smoke alarms required in bedrooms (Figure 14.6.12).

Alarms should be located no closer than 3 ft (0.9 m) from heating vents so that air issuing from the vent will not blow the

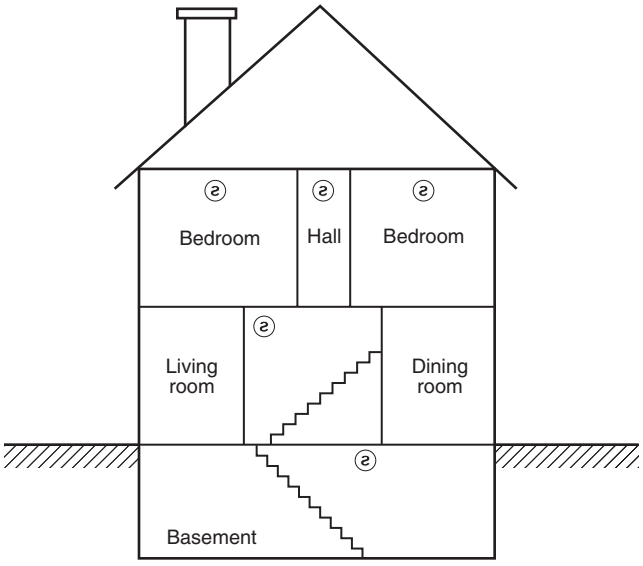

FIGURE 14.6.10 Smoke Alarm to Be Located on Each Story (Source: *NFPA 72®, National Fire Alarm Code®,* 2007 ed., Figure A11.5.1[d])

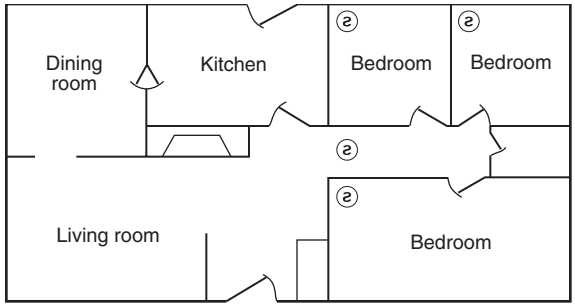

FIGURE 14.6.11 Smoke Alarm to Be Located in Each Bedroom and Between Sleeping Area and Rest of Family Living Unit (Source: *NFPA 72®, National Fire Alarm Code®,* 2007 ed., Figure A11.5.1[b])

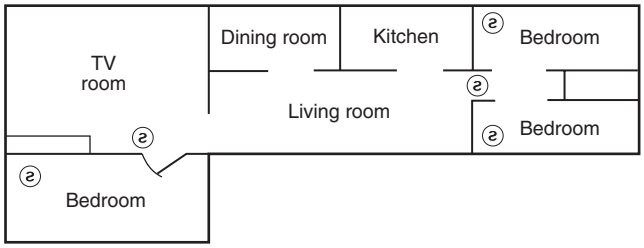

FIGURE 14.6.12 Smoke Alarm to Be Located in Each Sleeping Area as Well as in Each Bedroom (Source: *NFPA 72®, National Fire Alarm Code®,* 2007 ed., Figure A11.5.1[c])

smoke away from the alarm. Some smoke alarms are not suitable for location within kitchens, because of false alarms from cooking vapors. Chapter 11 of *NFPA 72* requires that smoke alarms located within 20 ft (6.1 m) (horizontally) of cooking appliances incorporate temporary silencing (hush) features or be of the photoelectric type. Also, some smoke alarms are not permitted in garages, where automobile exhaust might cause alarms, or in attics or other unheated spaces where extremes of temperature or humidity might affect their operation. Before a smoke alarm is installed in any of these locations, its specifications should be checked to ensure it is appropriate for the intended area.

Another consideration is the temperature of the mounting surface. If a smoke alarm is installed on a surface that can be even a few degrees warmer or cooler than the room temperature, its response may be delayed by the cold or warm air layer at the mounting surface. Smoke alarms should not be installed on uninsulated exterior walls, ceilings below uninsulated attics, or ceilings containing radiant heating coils. If the alarm is colder than the air temperature and if the relative humidity is high, condensation of water vapor may occur in the alarm and either produce a false alarm or disable the alarm. Condensation, dust, and insects are three of the most common things that lead to alarm malfunction.

Special Considerations for the Disabled

In general, households with disabled or elderly occupants need a higher level of protection to provide additional escape time. If the disabled person could not escape without assistance, provisions should be made for someone to provide help. Alarms that signal to remote receivers could be used, for instance, to sound the alarm in a neighbor's home. For hearing-impaired occupants, some alarms can be connected to bed vibrators, flashing strobes (see *NFPA 72,* Chapter 4, "Notification Appliances for Fire Alarm Systems"), or fans to provide tactile or visual as well as aural stimulation (Figure 14.6.13).

MAINTENANCE AND TESTING

Maintenance

Household fire-warning equipment should be maintained in accordance with the recommendations of the equipment manufacturer. In general, this means little more than keeping the equipment clean and free of dust and replacing the batteries when needed. Alarms should never be disconnected due to nuisance alarms. If a smoke alarm sounds a nuisance alarm caused by cooking, the problem can typically be corrected either by moving the alarm to another location, farther from the cooking source, or by replacing it with a smoke alarm that is not as sensitive to cooking smoke.

Testing

The importance of testing smoke alarms cannot be emphasized too strongly. Smoke alarms are basically electronic devices, and, because all devices will fail at some time, the failure rate projection of a smoke alarm can be estimated. From these projections, the life expectancy or the average failure rate of the smoke alarm can be determined. *NFPA 72* requires that smoke alarms in one- and two-family dwellings be replaced when they fail to respond to the operability test (i.e., pushing the test button) or after 10 years from the date of manufacture. This recommendation was developed in part on the estimate that after 10 years there will be a 30 percent chance that a unit will fail.

FIGURE 14.6.13 Combination Photoelectric Smoke Alarm/Strobe Light (Source: Gentex Corporation)

To reduce the period of time that a smoke alarm could be out of service because of failure, the alarm that has failed can best be identified by periodic testing and then replaced. The following example is merely illustrative and is not indicative of currently available units, but it demonstrates the importance of periodic testing of smoke alarms. Assuming a 10-year life of a smoke alarm and a predicted failure rate of 4 failures per million hours of operation (which is the minimum listed design requirement for alarms), if the alarm is never tested, the residents could be unprotected for 276 weeks, or over 5 years. On the other hand, with an alarm that is tested monthly, residents will be unprotected only for at most 5 weeks. This example has a built-in factor of 2 weeks, so a defective alarm can be removed and a replacement can be obtained and installed. However, a defective alarm should be replaced immediately. This example dramatically shows how important it is to test a smoke alarm frequently.

Guidelines for testing smoke alarms can be found in *NFPA 72,* Chapter 10, "Inspection, Testing, and Maintenance," and in the manufacturers' instructions.

SUMMARY

In the United States, fire deaths occur predominantly in the home, and thus household fire-warning equipment is essential for life safety. The types of systems and smoke alarms vary according to minimum standards and the occupants' specific needs. Installation of an adequate fire-warning system and ongoing maintenance and testing ensure that the system will work effectively. Fire protection in the home also involves formulating an escape plan and minimizing fire hazards.

Security Officers
Evaluating Fire Security Service

Key Terms

fire alarm system, patrol, security, security officer, security tour, surveillance, watchclock

Effective fire protection at a commercial or industrial facility depends on the degree to which the management of the facility is committed to providing an appropriate level of fire loss prevention and fire control. Once the hazards of the facility have been identified and evaluated, and built-in fire protection systems have been provided to offset the impact of those hazards, the protection features must be consistently managed.

A fire alarm system is a management tool that oversees fire protection surveillance. The fire alarm system can monitor the availability of other fire suppression systems. It may also monitor the activities of guards making fire patrol tours.

The fire alarm system should monitor all fire alarm initiating devices. Examples are manual fire alarm boxes; heat, smoke, radiant energy, fire-gas, or other fire detection devices; and the discharge and supervisory device connections for automatic sprinkler systems and other fire suppression or extinguishing systems, such as dry chemical, foam, foam-water, water mist, carbon dioxide, and other gaseous agents.

The fire alarm system should also monitor pertinent supervisory initiating devices for both "off-normal" and "restoration to normal" conditions. These include the following:

- Any automatic sprinkler control valve 2½ in. (63.5 mm) or larger
- Dry pipe or preaction valve high and low air pressure
- Fire protection water tank or reservoir level
- Fire protection water-pressure tank high and low air pressure
- Electric-driven fire pump operation, power failure, loss of phase, and phase reversal
- Diesel-engine-driven fire pump operation, controller switch in a position other than "automatic," engine or controller problems, and failure of the battery charger
- Steam-driven fire pump operation and steam availability
- Low public water system pressure when fire protection systems are fed from a dead-end public water main, or when the public water system is deemed unreliable

In addition, for those geographic areas subject to freezing winter temperatures, the fire alarm system should monitor low temperature for the following:

- Buildings protected by wet pipe automatic sprinklers
- Dry pipe, deluge, or preaction valve closets
- Fire pump rooms
- Fire protection water tanks

Section 14, Chapter 4, "Fire Alarm System Interconnections," discusses these interfaces into the fire alarm system in detail. In order to ensure immediate attention to signals generated by the protected premises fire alarm system, to ensure that management is promptly notified of the nature of these signals, and to keep proper records of signals received, it may be wise to connect the fire alarm system to a central station, proprietary, remote station, or combination auxiliary and remote station fire alarm system. This will ensure that signals receive attention at all times.

Lawrence J. Wenzel, P.E., is a senior fire protection engineer with Hughes Associates, Inc., Oakdale, Connecticut.

For those facilities where some type of security service is included, and intended to be part of the overall fire protection surveillance, the protected premises fire alarm system can also monitor the patrol tours made by security officers.

For related topics, see the following chapters in Section 14: Chapter 1, "Fire Alarm Systems"; Chapter 4, "Fire Alarm System Interconnections"; Chapter 5, "Inspection, Testing, and Maintenance of Fire Alarm Systems"; and Chapter 10, "Security and Intrusion Detection Systems."

FIRE AND SECURITY SERVICES

Containment of fire to its area of origin involves several factors, one of the most important of which is early detection. During normal business hours, most occupiable areas (i.e., areas other than concealed spaces, exterior surfaces) are continuously or routinely occupied or observed by the people in the areas. (Intermittent occupation might apply to areas such as lavatories, hallways, or closets.) By their presence, the occupants provide fire protection surveillance because they are able to detect a fire when it occurs. A carelessly discarded cigarette, for example, may ignite the contents of a wastebasket; that fire may spread until the entire building is involved. However, someone who discovers the fire while it is still in its incipient stage may be able to extinguish it with a portable fire extinguisher. In some cases, the occupants can also detect conditions, such as a malfunctioning machine, that might lead to a fire. Similarly, increased security surveillance is vital in guarding against fires of incendiary origin.

Security officers generally serve three purposes in helping to protect a property against fire loss: (1) watch the property at times when the management is not present; (2) facilitate and control the movement of persons into, out of, and within the property; and (3) carry out procedures for the orderly conduct of some operations on the property, such as the shipping and receiving functions. Security officers may be facility employees or employees of outside firms that provide these services on a contract basis, or a combination of both. The duties of these individuals may be supplemented or, in some cases, replaced in part by various approved fire and security protective signaling systems.

MANAGEMENT OF SECURITY SERVICES

In conjunction with fire and explosion suppression systems and various other management programs for loss prevention and control, a comprehensive program of fire protection and security surveillance provides a means of (1) continually monitoring the facility for conditions that might lead to a fire or explosion, (2) promptly notifying the public fire department or private fire brigade that a fire or explosion has occurred, and (3) effectively inhibiting unauthorized access to the facility. Management must determine how this surveillance can be best achieved.

In concept, security officers should patrol thoroughly all unoccupied areas of a facility often enough to be able to detect conditions likely to result in a fire or other emergency. These patrols should be supervised in some way so management can verify that the security officer is indeed making the patrol tours.

The highly protected risk (HPR) property insurance carriers generally recommend that the first patrol tour begin within 30 minutes of vacancy and that subsequent patrol tours be made every hour at night and every other hour (bihourly) during the day. Each tour should not exceed 45 minutes in actual length, allowing the security officer at least 15 minutes of rest.

Management Roles

Management should develop a written surveillance plan for both fire protection and security in the facility. To do this, the property manager should determine which areas of the facility are unoccupied during both working and nonworking hours. The property manager should also designate a management representative who will be responsible for overseeing the surveillance program. It is very important that management retain supervisory control of surveillance to maintain program integrity. This representative should review surveillance reports daily and evaluate changes in the facility that might require modification of the surveillance plan.

The facility's fire loss prevention and control manager should be consulted during the establishment of procedures to be followed by security officers. Procedures and instructions to security officers should be geared to the specific actions required. General instructions or superficial training are of little value. Meaningful, specific instructions cannot be prepared, however, without an investment of both time and thought by those who manage the property. Management should also establish a clear line of succession in the event of absences. Even when there are only two security officers employed, one should be designated as the leader.

Supervision of security officers provided under contract with outside firms should be through the designated representatives of the company providing the security service. In the contract for services or supplementary documents, the company should be given details as specific and complete as possible regarding the services expected.

Security Officer Equipment

Management is responsible for providing security officers assigned to patrol a property with adequate equipment and information with which to safeguard their own health and safety. Potential situations that must be considered include the following:

- Sudden illness or injury while the security officer is alone at the property
- Possibility of a security officer being overpowered by an intruder
- Development of a situation requiring management decisions

The first situation can be addressed by equipping security officers with devices for prompt, efficient communication, such as portable two-way radios, which would allow them to summon aid.

In the second situation, an intruder may prevent the security officer from using any communications equipment. It then becomes necessary to have a system or procedure whereby the security officer's failure to transmit a signal or meet a predetermined schedule will be investigated promptly.

Third, situations that require management decisions may arise at times when the property is attended by security officers only. Such decisions may involve conditions ranging from the unscheduled arrival of merchandise or supplies to anonymous bomb threats. Security officers must have instructions and the means for contacting management personnel.

COMMUNICATIONS EQUIPMENT

Security officers should be provided with facilities for communication within and outside the property. A control center should provide a point with which officers may communicate, and the center should have communications facilities to points outside the property. Such a center is needed even when there is very limited security service. For example, in a facility with only one or two officers, this control center might simply be a room with a telephone. Even with a complete fire alarm and security system covering all areas of the property, a control center on the property is necessary.

If an emergency voice/alarm communication fire alarm system is provided, security officers may communicate with the building fire command station by using the fire warden telephones.

Where the equipment for security officer communications, including officers on watch patrol, requires that signals from officers be monitored, the control center should be provided with an operator. Additional operators needed to staff a 24 hour operator service should be provided at the control center, according to the character of security service provided. For some services, runners, or security officers who can be dispatched to investigate signals, should also be provided.

A directory of names and telephone numbers (including any other information to assist in making emergency calls to the outside) should be kept at the control center in a visible index or other quickly accessible form. This directory should give information about the public fire and police departments, key management personnel, and other outside agencies that may have to be contacted in an emergency.

SECURITY PATROL TOUR SUPERVISION

Off-premises security officer supervisory service designed to report the performance of a security officer may be provided by central station, proprietary, or remote station fire alarm systems. Portable watchclocks may also be used to supervise the security officer if centralized, immediate supervision is not required.

Tour supervisory systems generally consist of security officer patrol tour supervisory initiating devices of some type and a means of recording signals initiated from these devices. Many companies refer to this equipment as "guard tour supervisory" devices. Two types of supervisory service systems are (1) compulsory and (2) noncompulsory, based on whether the guard follows a compulsory preset pattern or not.

Compulsory Tour Supervisory Systems

This system involves one or more "active" security patrol tour supervisory initiating devices that are installed in conjunction with several "passive" security patrol tour supervisory initiating devices. These devices are arranged so that the security officer must progress in a fixed route from one station to another. Ordinarily, the officer carries some type of device called a "key," which can be a "wand" that serves as a handheld computer with a memory function. The initiating devices can be arranged so that the passive devices condition the key so that it may operate the next device, whether that device is active or passive. In addition to conditioning the key for the next device, active initiating devices also either transmit a signal to an on- or off-premises central recording location or cause a signal to be recorded inside the key, which indicates the date and time that the active initiating device was operated. This system is particularly useful when, because of the nature of the facility, it is essential that the security officer follow a carefully prescribed route. One disadvantage to this system from a security standpoint is that the tour may not be varied. This is sometimes felt undesirable because a potential intruder who is observing the movement of the security officer might be able to readily discern a pattern to the officer's movement.

In many compulsory tour systems, the security officer initiates a starting signal at the beginning of a round and initiates a finishing or completion signal at the end of the round. All of the other stations in between would be passive initiating devices. A fixed schedule of starting and finishing times is arranged in advance when a compulsory tour is monitored by an off-premises facility. If the security officer fails to either begin or end a round within the prescribed times, on the expiration of a "grace" period of usually no more than 10 or 15 minutes in length, the off-premises monitoring facility will initiate action. Normally, an attempt will be made to contact the security officer by telephone. On failure to reach the officer, the off-premises monitoring facility will normally dispatch the police department and notify the management of the facility that the security officer has failed to respond.

When a compulsory tour system is used in conjunction with a proprietary fire alarm system, the process works much the same, except that, since the receiving location is normally located on the protected premises, the operator at the receiving location will be more readily able to determine why the guard has not begun or ended a round.

Noncompulsory Tour Supervisory Systems

In this system, all of the initiating devices are active. The security officer progresses from station to station, with each initiating device indicating the date and time of the officer operating the station. By following the progression of signals, the off-premises or on-premises monitoring station can follow the progress of the security officer during the course of the round. In some cases, combination manual fire alarm boxes/officer patrol tour

supervisory initiating stations are grouped in the same physical housing. These stations are arranged so that they may be actuated by any person to indicate a fire, but may also be operated by a security officer to indicate the progress of a tour.

Delinquency Reporting Systems

Some compulsory or noncompulsory tour supervisory systems are arranged so that, rather than reporting every time the security officer operates an active initiating device, the system only transmits a signal when the officer has failed to operate the device within a prescribed time period. Such delinquency reporting systems are utilized when it is desired to reduce the amount of signal traffic associated with the officer patrol tour supervisory system. Many remote station fire alarm systems that supervise security officer patrol tours are arranged in this fashion.

Telephone, Radio, and Other Voice Reporting Systems

Occasionally, a security officer patrol tour is supervised by means of the guard reporting from a specific location by means of a voice reporting system. Probably the most common system uses a telephone system equipped with calling subset identification. When the security officer initiates voice communication over such a system, the system indicates and records the specific location from which the officer is calling. Other systems employing means of voice communication, including radio systems, can also be used. In some radio systems, a tour supervisory initiating device must be inserted into the radio before the security officer establishes patrol tour contact. This device transmits a digital code that gives a specific location, thus indicating that the officer is at the prescribed tour station.

Portable Watchclocks

In many cases, management determines that it is not necessary to provide immediate supervision of the security officer patrol tours, and elects to provide retrospective security officer patrol tour supervision by means of a stationary or portable watchclock. Figure 14.7.1 shows a portable watchclock. This clock provides an embossed record tape, made directly from type on the recording key. The tape has 24 ruled segments and is synchronized with the clock mechanism. If a security officer fails to punch in, the omission is indicated by a prominent white space on the tape. This clock indicates when it was opened. The records from these devices must be reviewed the following day to determine that the officer has indeed made the prescribed tours and operated all of the tour supervisory initiating devices. Although this method lacks the immediacy of the other tour supervisory methods, it is sufficiently cost-effective to be the most common tour supervisory method employed. Traditionally, a spring-wound clock mechanism—either at a single location in the case of a stationary watchclock or in a portable case that the guard can carry from location to location—is used to drive some type of recording medium. The most common recording medium is a paper disk or a paper tape. In this case, the tour supervisory initiating devices are embossing keys that must be inserted into the portable watchclock and turned, making their impression on the paper tape. The tour supervisory initiating devices for the stationary clock are usually some type of electric switch or, in at least one design, a magneto that must be operated by the officer, causing the stationary clock to record the specific location.

(a)

(b)

FIGURE 14.7.1 Portable Watchclock: (a) Front view; (b) Interior view (Source: Detex Corp.)

The portable watchclock can be an effective supervisory tool if access to the clock is carefully controlled so that the security officer cannot have access to the internal mechanism of the watchclock. This means that someone in management should actually open the clock and retrieve the record each day. To safeguard against premature opening of the clock, a telltale device places a mark on the paper disk or tape whenever the clock is opened. Even when a security service company provides the security officer patrol tour service, it is advisable to have management supervise the retrieval of records from the watchclock to prevent any collusion between upper-level officers, such as sergeants or lieutenants, and the guards themselves.

Another type of portable watchclock uses computer-based equipment to supervise the route and timing, if desired, of the security officer. As shown in Figure 14.7.2, manufacturers have developed scanners that read the station and store the station's information in the handheld unit carried by the officer. The equipment shown in Figure 14.7.2 is typical of the hardware available for use by security officers, who carries the handheld "wand" unit or a similar device and passes it over data strips or

FIGURE 14.7.2 Computer-Based Equipment for Route Supervision (Source: ProxiGuard)

similar points installed throughout the premises (Figure 14.7.3 and 14.7.4). The use of handheld wands or similar readers is very much the norm for security officers to register their rounds. The handheld unit is then attached to some type of download device for computer storage of the report (Figure 14.7.5).

The security officer can then download the information from the handheld unit to a data-gathering unit designed specifically for this equipment, or in some cases to a computer outfitted with the corresponding program information. Other designs allow the handheld unit to be placed on a base unit that will produce a printed report. Components may be as simple as a bar code strip fixed to a piece of equipment to more sophisticated electronic stations. This type of equipment gives management a number of options to help detail the activities of the security officer.

FIGURE 14.7.3 Security Officer Registering Rounds (Source: ProxiGuard)

FIGURE 14.7.4 Handheld Wand (Source: ProxiGuard)

SECURITY SERVICE FUNCTIONS

A sufficient number of security officers should be provided to accomplish the needed services. If officers are assigned to other part-time duties in addition to their regular security officer services, these duties should be arranged so they will not interfere with regular officer duties.

Control of Pedestrians and Vehicles

Fireguard service can facilitate and control the movement of persons within a property when the property requires such service. Duties in this category include the following:

- Preventing the entry of unauthorized persons who might set a fire or do damage to the facility
- Controlling the activities of people authorized to be on the property, but who may not be aware of procedures established for the prevention of fire
- Controlling pedestrian and vehicular traffic during exit drills, and evacuating the property or parts of it during emergencies
- Controlling gates and vehicular traffic to facilitate access to the property by the public fire department, members of a private fire brigade, and off-duty management personnel in case of fire or emergency

Control of Operations

Security service should be established to carry out certain procedures for the orderly conduct of operations on the property, including procedures for fire loss prevention and control, both by personnel associated with the property and outside contractors. Duties in this category include the following:

- Promptly discovering a fire and calling the public fire department (also the fire brigade of the property, where there is such a brigade)
- Operating equipment provided for fire control and extinguishment *after* giving the alarm and before the response of other persons to the alarm
- Monitoring signals of fire alarm systems
- Patrolling routes chosen by management to ensure surveillance of all the property at appropriate intervals

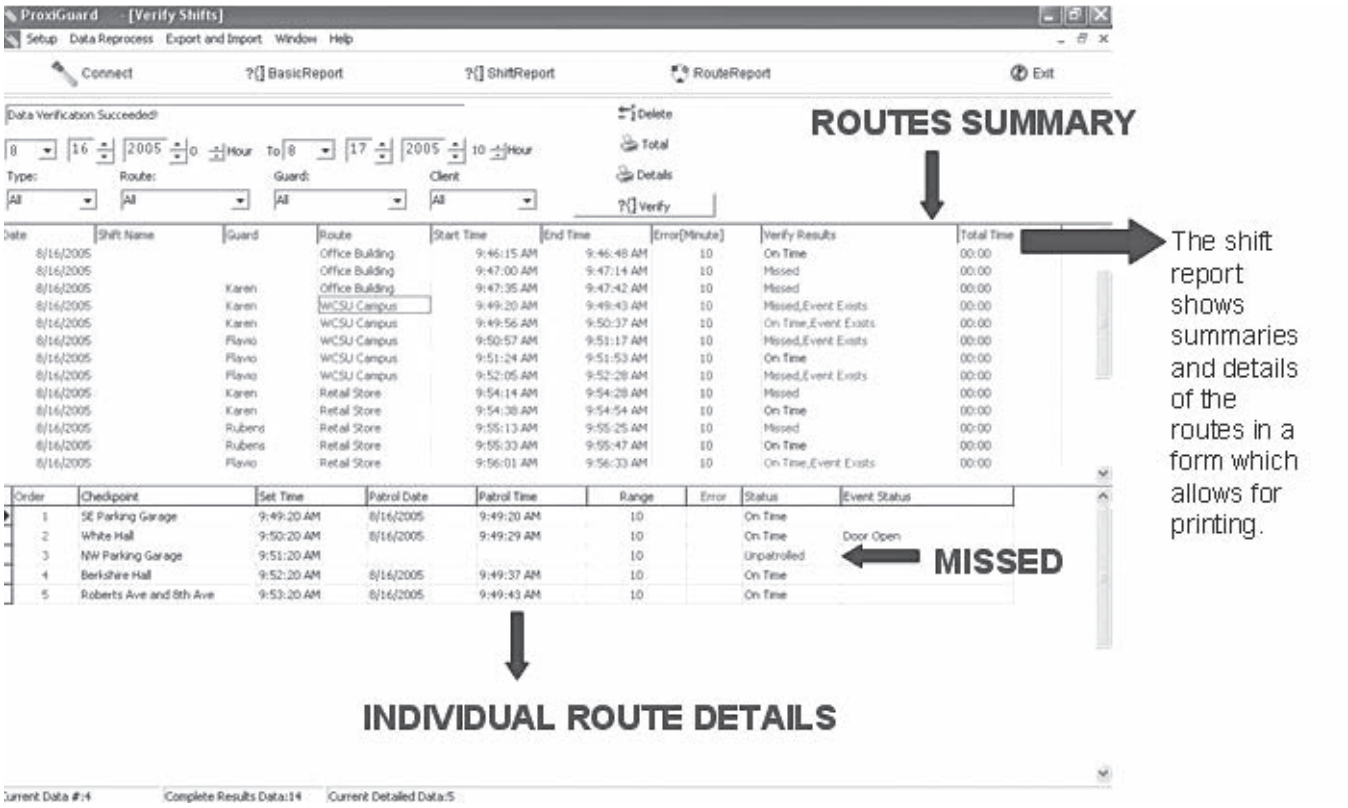

FIGURE 14.7.5 Report Generated from Information Downloaded from Handheld Wand

- Starting up and shutting down certain equipment when no other personnel are provided for this purpose
- Checking permits for "hotwork," including cutting and welding, and standing by to operate fire-extinguishing equipment when necessary
- Detecting conditions likely to cause a fire, such as leaks, spills, and faulty equipment
- Detecting conditions likely to reduce the effectiveness with which a fire may be controlled, such as portable fire extinguishers not in place, sprinkler valves not open, and water supplies impaired
- Performing operations to ensure that fire equipment will function effectively including, for example, testing automatic sprinkler and other fixed fire protection systems, including fire pumps, and other equipment related to these systems and assisting in the maintenance of this equipment; checking portable fire extinguishers and fire hose and assisting in pressure tests and maintenance service on these items; testing fire alarm systems; and checking equipment provided on any fire apparatus and carrying out the periodic tests and maintenance operations required for the apparatus

PATROL ROUTES AND ROUNDS

Each route to be patrolled should be laid out by the responsible manager. The security officer responsible for each route should be given instructions on all details of the route, and what is expected in covering it (Figure 14.7.6). The route should be laid out to prevent shortcuts so that the security officer is required to pass through the entire patrol area. A reasonable rest period between rounds must be provided.

Security officers should make rounds at intervals determined for the particular situation by management. When operations in the property are normally suspended, rounds should be made hourly, unless management is willing to accept rounds at less frequent intervals. When there are special conditions, such as the presence of exceptional hazards or when protection is impaired, management should institute as many additional rounds as necessary to meet the fire safety requirements of such conditions.

The first round of a patrol should begin as soon as possible after the end of activities of the preceding work shift. The officers should be instructed to make a thorough inspection of all buildings or spaces on the route during their first round. Their instructions should cover the following:

- Outside doors and gates should be closed and locked. Windows, skylights, fire doors, and fire shutters should be closed.
- All oily waste, rags, paint residue, rubbish, and similar items should be removed from buildings or placed in approved containers.
- All fire apparatus should be in place and not obstructed.
- Aisles should be clear.
- Motors or machines carelessly left running should be shut off and reported.

(b)

FIGURE 14.7.6 (a) Route Map of Security Officer Path; (b) Route Map Superimposed on a Building (Source: ProxiGuard)

- All offices, conference rooms, and smoking areas should be checked for carelessly discarded smoking materials.
- All gas and electric heaters, coal and oil stoves, and other heating devices on the premises should be checked.
- All hazardous manufacturing processes should be left in a safe condition. The temperature of dryers, annealing furnaces, and similar equipment that continue to operate during the night, holidays, and weekends should be noted on all rounds.
- Hazardous materials, such as gasoline, rubber cement, and other flammable and highly volatile combustibles, should be kept in proper containers or removed from buildings.
- All normally open sprinkler control valves should be open, with gauges indicating proper pressures. Gauges not open should be reported immediately.
- During cold weather, all rooms should be checked to determine if they are heated properly.
- All water faucets and air valves found leaking should be closed. If leaks cannot be stopped, the condition should be reported.
- Particular attention should be given to new construction or alterations that may be in progress.

SECURITY OFFICERS

Selection and Contracts

Management should require individuals considered for security officer service to satisfactorily pass a character investigation. This investigation should attempt to evaluate the individual's reliability, self-control, and potential loyalty to the employer. Applicants for a security officer position should be fingerprinted and particulars of any police records obtained. The local police should be furnished with this information, should corroborate it, and should ask for checks by other police agencies. The fingerprint data should be cleared with state, national, or appropriate international agencies that maintain clearing facilities for police records. All applicants for a position as a fire or security officer or patrol person should be required to state any military service record and to submit evidence of such service that may assist in an evaluation of the individual's suitability for security officer service.

Contracts for security officer service should include a provision that the company furnishing security officer service will replace any employee who, in the judgment of the company purchasing the service, is not qualified.

Qualifications and Examinations

Management should be satisfied that individuals considered for security officer service are mentally alert and have good powers of observation, intelligence, and judgment. Investigation should attempt to evaluate the individual's personality and temperament. Such an evaluation is more realistic than arbitrarily testing education or intelligence or setting an age limit. Very young people may not qualify because they have not acquired a sense of responsibility or judgment. Very old people may have impaired alertness. Individuals should be sought who are known to be "clear-headed" in an emergency.

Officers should be required to pass an annual written examination dealing with information about the property protected and procedures for fire loss prevention with which they are expected to be familiar. Management should also require that individuals considered for security officer service pass an examination to determine whether they are physically able to perform the guard duties to which they will be assigned. Officers should also be required to pass an annual physical examination. The officers do not need to be athletes, but they should not have a heart condition or other physical ailment that might work to their disadvantage in moments of stress.

Training

Management should establish a continuing training program for its officers. Its scope should be established by the manager or by a fire loss prevention and control manager acting for the manager. Courses for security officers and fire fighters, available through training programs of vocational training agencies, schools, universities, and other training and educational agencies, should be considered in any training program for security officer.

Management should require officers to have completed at least elementary courses of instruction in the use of portable fire equipment and emergency first aid. The time spent in such preliminary training should be a minimum of two working days in each subject. During service, security officers should be given not less than the equivalent of two full working days per year of training to increase their knowledge and experience in the use of portable fire extinguishers, first aid, and other useful training. Officers should be required as part of their training to participate in appropriate meetings devoted to prefire planning with operating personnel. Security officers can help accomplish this by working together with the public fire department when it establishes its plan for the premises.

Management should require security officers to know the location of portable fire extinguishers, hand hoses, standpipes and hydrants, valves controlling sprinkler systems, inside riser valves, post-indicator valves, and sectional valves in the property's own water system. They also should know how to start fire pumps. Officers also need to know the location and purpose of valves controlling water for purposes other than fire protection, and valves controlling steam, gas, and other services. Management should require security officers to know the locations of dangerous machinery or materials and inform them of hazardous manufacturing processes, especially those continuing during the night, holidays, or weekends.

EVALUATING FIRE SECURITY SERVICE

There are several items to be considered when evaluating fire security service.

Tour Records

Management's representative should ensure the following:

- All unoccupied areas of the facility are included in each tour.
- All key stations or tour supervisory transmitters in each tour have been recorded clearly in a regular hourly pattern at night and in a bihourly pattern during the day.
- Tours last no longer than 45 minutes, allowing for a rest period of at least 15 minutes each hour.

- Tours begin within one half-hour of the time the area becomes unoccupied and continue to within one half-hour of the resumption of occupancy.
- The "telltale" of a portable or stationary watchclock is recording each time the clock is opened. Look for indications that the clock has been opened more than once a day or at unusual times. This might indicate that unauthorized persons have access to a clock key.

Basic reports on security officer tours can take many forms. Figure 14.7.7 shows a report generated in spreadsheet format.

Inspecting Tour Supervisory System Initiating Devices

Key stations, tour supervisory transmitters, or intermediate stations should be inspected once a month to ensure they are firmly attached and, if required, sealed with a "tamper" seal, and have not been relocated or removed. The key should be checked for damage. If there is evidence of tampering, the key stations, tour supervisory transmitters, or intermediate stations should be checked more often and suitable action taken.

Evaluating Security Officers

Management should expect, and is entitled to receive, security officer service of the highest quality. Officers must be conscientious in the performance of their duties, note and report all infractions of company regulations, and closely follow the orders given to them. When evaluating security officers, management should consider the following:

1. Security officers hold positions of trust, which require individuals who are physically able, mentally alert, and morally responsible. Therefore, their physical and emotional stability should be evaluated by appropriate management personnel.
2. Security officers must be sufficiently intelligent, calm in the face of an emergency, mature with sound judgment, and possess the physical stamina required for the job.
3. A sufficient number of security officers should be provided to maintain proper surveillance in the facility. It is undesirable for officers to be assigned part-time duties unrelated to surveillance. If they are so assigned, however, these duties must not interfere with surveillance responsibilities.
4. Security officers should receive full support of management in the performance of their duties.
5. When the officers are facility employees, management should establish the scope of the service and provide necessary training and supervision for the guards.
6. If a contract security service is used, management should not assume that it will be adequate. Rather, management should prepare detailed specifications and investigate the ability of prospective contractors to meet these specifications. When

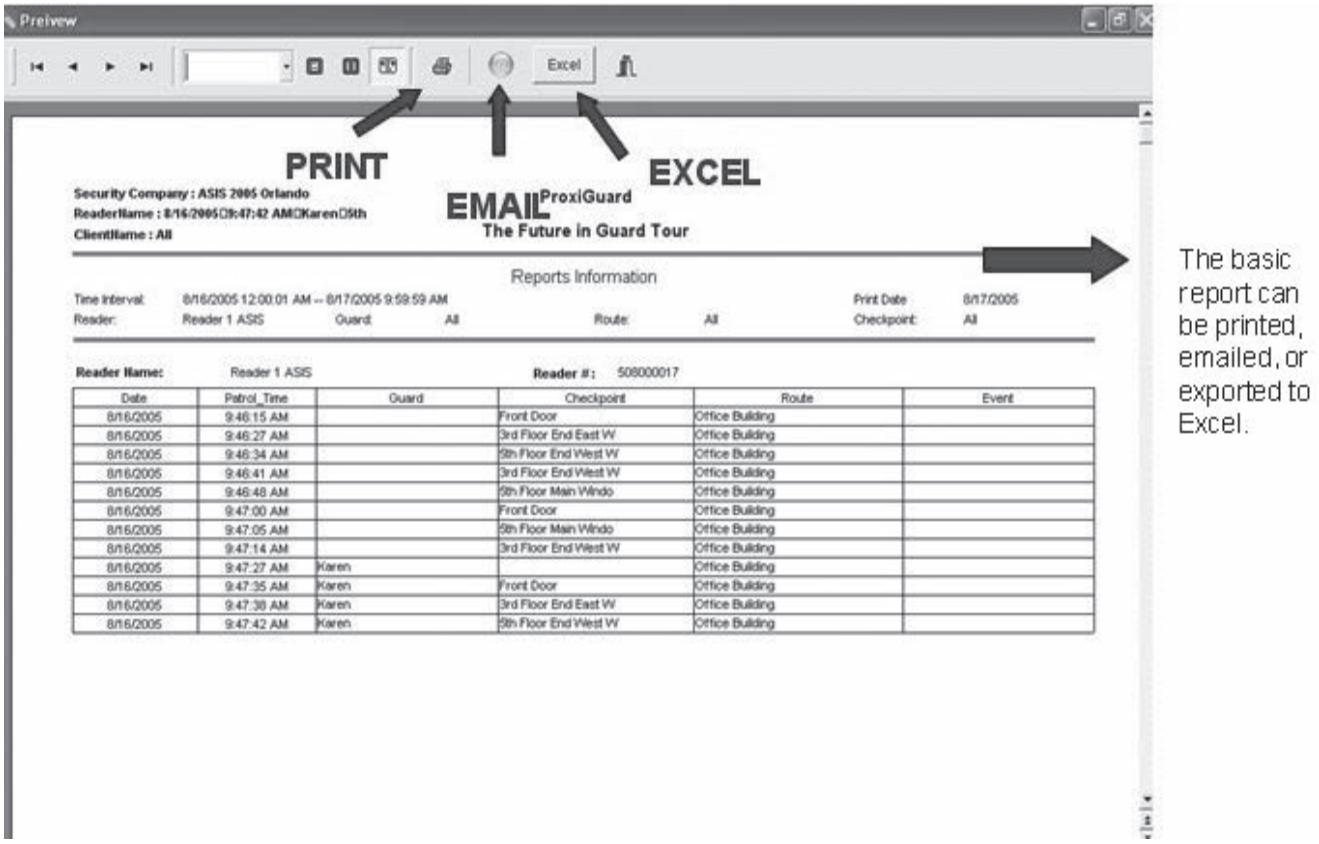

FIGURE 14.7.7 Security Officer Tour Report (Source: ProxiGuard)

the contract has been met, management should make sure that its intent is being carried out.

7. Initial and continued training of officers should be by a formal, comprehensive, written program covering all applicable protection procedures. The following must be met by each guard:
   - Be acquainted with the general nature of the facility's operations and possess specific knowledge of any hazardous operations
   - Be familiar with all of the facility's manual and automatic fire protection equipment. Security officers should be especially aware of the location of all sprinkler valves and know which area each controls. Officers should periodically accompany the person making fire protection equipment inspections, in order to gain a working knowledge of facility protection features and hazards.
   - Be familiar with the location and operation of manual fire alarm boxes and other means of transmitting fire alarms. Such means should be provided throughout the facility so guards can easily report a fire.
   - Be taught to notify the fire department *before* taking any other action
   - Be taught how to admit public fire apparatus to the property and how to direct fire department officers to the location of the fire
   - Be taught to properly notify company officials when an emergency occurs or when potential trouble is observed
   - Be taught to maintain a shift log and to prepare reports to management of observations made and actions taken during tours
8. Security officer service should be integrated into the overall emergency planning program.
9. General and special instructions and other data required by the officers should be written down and kept up-to-date.

Detecting and Reporting Fires

While making regular tours throughout the facility, officers must be alert for all emergencies, paying special attention to known hazardous areas. Security officers are in a position not only to detect and correct unsafe conditions that might develop into or contribute to a serious fire, but also to discover an incipient fire. Therefore, the officers should be familiar with the fundamentals of fire control and with the proper use of all available extinguishing equipment.

The importance of notifying the fire department *before* taking any other action should be stressed in security officer training. Officers should report any situation that may endanger the facility—for example, an exposing fire in adjacent properties. Any unusual condition that the officers cannot correct without assistance must be reported immediately to the proper official so the situation can be remedied without undue delay. Such situations include the interruption of sprinkler service or the failure of heating equipment.

Encountering Natural Hazards

In addition to carefully following written emergency plans, security officers must be resourceful and capable of applying common sense to any unusual conditions, such as "natural" hazard threats, they may encounter. If the facility is being subjected to freezing weather, for example, the guard should be alert to those areas of the facility where fire protection systems or process equipment might be vulnerable to freezing. Such areas should be checked frequently to ensure the heating system is properly maintaining the temperature necessary to avoid damage. If a thermometer is unavailable, a resourceful guard might set out a small container of very cold water to observe whether the area is approaching a dangerously low temperature. See NFPA 601, *Standard for Security Services in Fire Loss Prevention.*

SUMMARY

A fire alarm system in a commercial or industrial facility can monitor a variety of conditions and instruments related to fire protection, including alarm initiating devices, supervisory initiating devices, and environmental conditions such as low temperatures. The fire alarm system can also monitor the patrol tours of the security service. The fire alarm system should be connected to a location that ensures the signals receive immediate attention. The extent of the fire alarm system and security service must be determined by management based on the level of fire protection deemed necessary for the particular facility. The security officers must be supplied with a comprehensive surveillance plan and proper communication equipment in order to perform their duties effectively.

Chapter 8

Gas and Vapor Detection Systems and Monitors

John M. Cholin

Chapter Contents

Terminology
Sensors
Fixed Gas Detection Systems
Portable Gas Monitoring Instruments

Key Terms

carbon monoxide detector, fire alarm system, flammable gas, flammable vapor, gas detection, hazardous (classified) location, resistive-thermal device, sensor

Two concerns drive the use of gas and vapor detection systems and monitors. First, the existence of flammable gases or vapors represents (1) an elevation in the potential for a fire, either in and of itself as the concentration reaches the critical value sufficient to support a flame; or (2) an indication of a leak, implying an immediate potential of loss of containment of a large quantity of fuel. Second, there is a life safety concern whenever breathing air is contaminated with gases or vapors that are not normal constituents of air. Although one could argue the theoretical position that this second concern is not strictly within the purview of the fire protection engineer, in the context of actual applications it is very rare that these two concerns can be rationally separated from each other. Consequently, the fire protection specialist must have a working knowledge of gas and vapor detection systems and monitors both for flammable and toxic materials.

For many years there was no NFPA standard explicitly establishing requirements for the design, installation, and maintenance of gas and vapor detection systems. Currently, one recommended practice, NFPA 720, *Standard for the Installation of Carbon Monoxide (CO) Warning Equipment in Dwelling Units,* has been adopted. Other than this one document, there are no NFPA standards relating to the design of systems to detect combustible or toxic gases or vapors employed in commercial or industrial occupancies, nor is there a standard for gas monitors. Nevertheless, there are a number of NFPA standards that make reference to gas and vapor detection systems in their requirements. For example, NFPA 86, *Standard for Ovens and Furnaces,* governs the fire protective features of drying ovens such as those where painted parts are cured. NFPA 86 allows reduced airflow rates conditioned on a system for monitoring the concentration of combustible vapor in the ventilation air. Since the fire safety of the curing oven is predicated on the vapor monitoring system, that system becomes a critical part of the fire protection for the site. Failure of the flammable vapor detection system to perform its intended function, whether due to flawed system design, installation error, inadequate maintenance, or component failure, could result in a catastrophic fire loss. This dependence on flammable gas and vapor detection systems to maintain the required level of fire safety argues for the application of sound fire protection engineering in the selection, design, installation, and maintenance of gas and vapor detection systems.

This chapter addresses the detection of flammable, combustible, or toxic gases and vapors that represent a hazard to the occupants or the facility. This hazard can be the risk of fire or deflagration due to ignition of an ignitible concentration of the flammable or combustible gases or vapors. It can also be the physiological threat to the health of the occupants resulting from inhalation or exposure to the vapors or gases. This chapter does not address flammable, combustible, or toxic gases that are the *result* of a fire. The term *fire-gas* was used previously in some fire protection standards and references as part of an effort to distinguish the gaseous components of smoke from the particulate components. Subsequent research and standards derived therefrom found that such a distinction was not particularly helpful and the term has fallen into disuse over the past two decades.

For related topics, see Section 6, Chapter 10, "Gases"; Section 6, Chapter 12, "Flammable and Combustible Liquids"; and Section 14, Chapter 4, "Fire Alarm System Interconnections."

John M. Cholin, P.E., FSFPE, is an independent fire protection consultant and engineer with J. M. Cholin Consultants, Inc., Oakland, New Jersey.

TERMINOLOGY

The terminology used in the gas and vapor detection community may not be familiar to many fire protection specialists.

Gas. A gas is matter in which the average thermal kinetic energy of the constituent molecules at standard temperature and pressure (STP) exceeds the cohesive forces between them, and consequently the matter expands to occupy the entire containment volume. STP is 77°F (25°C) and 760 mm(Hg) absolute pressure or 1 atm. It is necessary to stipulate temperature and pressure in this definition, because any normally gaseous compound can be compressed and cooled to the point where it will exist in a liquid state.

The gases that are routinely addressed in the context of gas detection, whether flammable gas or toxic gas, include carbon monoxide, carbon dioxide, sulfur dioxide, hydrogen sulfide, hydrogen, methane, ethane, propane, butane, acetylene, ethylene, propylene, silane, germane, diborane, phosphine, arsine, allane, fluorine, and chlorine.

Vapor. Vapor is matter in the gas phase that normally exists at STP as a liquid. This term is not essential. However, it is used too frequently not to be addressed in the context of this chapter. The term is commonly used because of the inference it provides regarding the source of the gaseous matter. Vapors are the result of the evaporation of a liquid and, consequently, are normally associated with a liquid source. There is an equilibrium state at the interface above a pool of liquid and the gas above it. As liquid molecules attain excess thermal energy, they escape the cohesive forces of adjacent molecules and leave the liquid as a gas. When gas molecules lose thermal energy, they condense back into the liquid phase. When vapors are dispersed in air, they behave as gases until a temperature is reached where they begin to condense. The principal distinction between the compounds normally thought of as gases and those as vapors is the temperature and pressure at which they condense.

Combustible/Flammable Gases and Vapors. Combustible/flammable gases and vapors are those gases and vapors that burn in air when the concentration of the gas or vapor is within the range of concentration where combustion can occur. The distinction between combustible and flammable is established in NFPA 30, *Flammable and Combustible Liquids Code.* This distinction is predicated on the flashpoint of the liquid. The flashpoint is the temperature at which the vapor pressure of the liquid is sufficiently high to produce a concentration of gaseous fuel in the air above the liquid in excess of the lower flammable limit (LFL) and, hence, sufficient to support a flame. This distinction has little relevance in the context of detection of molecular species dispersed in the ambient air, except to imply possible origin. Unfortunately, the community of manufacturers and users of gas detection systems and instruments come from an instrumentation background where the term *combustible* has been adopted. In an effort to provide consistency with the terminology and concepts presented in this handbook, this chapter will use the term *flammable gas* to include all chemical species dispersed in the gas phase in ambient air, regardless of source or chemical composition, that will burn in air.

Concentration of flammable gas is typically measured in percent of the lower flammable limit (percent LFL). If the lower flammable limit of a given gas is 4.0 percent, a measurement of 25 percent LFL means that there is 1 percent of that gas by volume in the measured sample of air.

Lower Flammable Limit (LFL). The lower flammable limit is the lowest concentration of a flammable gas in air that will support a flame. Below the LFL there is insufficient fuel per unit of air volume to sustain a flame through the volume. Therefore, when a source of ignition is introduced, the resulting flame will remain at the source of ignition. Once the concentration exceeds the LFL, a flame front will propagate through the air volume. (Note that the term *lower explosive limit (LEL)* was formerly used for this concentration of flammable gas and is occasionally still encountered in older literature.)

Upper Flammable Limit (UFL). The upper flammable limit is the highest concentration of a flammable gas in air that will sustain a flame. As the concentration of flammable gas increases, the oxygen-containing air is displaced. Eventually, the concentration of flammable gas is so high that there is insufficient oxygen remaining to sustain a flame when an ignition source is introduced. (Note that the term *upper explosive limit (UEL)* was formerly used and is occasionally still encountered.)

Toxic Gases and Vapors. Toxic gases and vapors are molecular species dispersed in air in the gas phase that have an adverse effect on living organisms, as defined by the Occupational Safety and Health Administration (OSHA). The concentration of toxic gas is usually measured and displayed as parts per million (ppm) concentration. To convert from percent to parts per million, multiply by the conversion factor of 10,000 ppm/percent. The commonly monitored toxic gases include carbon monoxide, carbon dioxide, hydrogen sulfide, sulfur dioxide, methane, silane, arsine, phosphine, chlorine, and fluorine. Most flammable gases are also toxic at some concentration, but not all toxic gases are flammable.

Oxygen Concentration. Oxygen concentration is the measure of the portion of the air within a space that is oxygen. This is an important life safety and fire protection parameter. The depletion of the oxygen in a gas volume reduces the ability of life to survive in that volume and also reduces the ability of that gas volume to support combustion. The nominal oxygen concentration of air is 23.2 percent oxygen by weight and 21.0 percent oxygen by volume. The difference in the numerical value of the oxygen concentration by weight versus volume comes from the different densities of the constituent gases in the mixture called "air."

Fixed Gas/Vapor Detection System. A fixed gas/vapor detection system is a permanently installed system usually consisting of at least one sensor, transmitter, and display unit (Figure 14.8.1). The sensor is located in the area where the gas or vapor may occur. It produces a minute current or voltage that is pro-

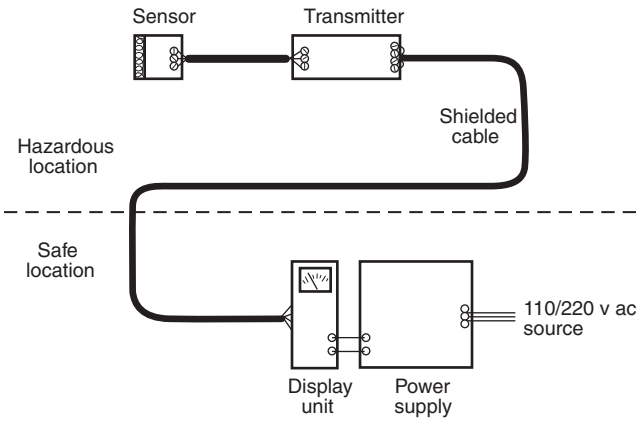

FIGURE 14.8.1 A Fixed Gas Detection System

portional to the concentration of the gas. The sensor is connected via wiring to a transmitter. Generally the distance between the sensor and transmitter is quite limited. The transmitter linearizes the signal from the sensor, corrects it for zero and span (due to variations in sensor output), and converts it into an electrical format that can be transmitted a long distance without interference.

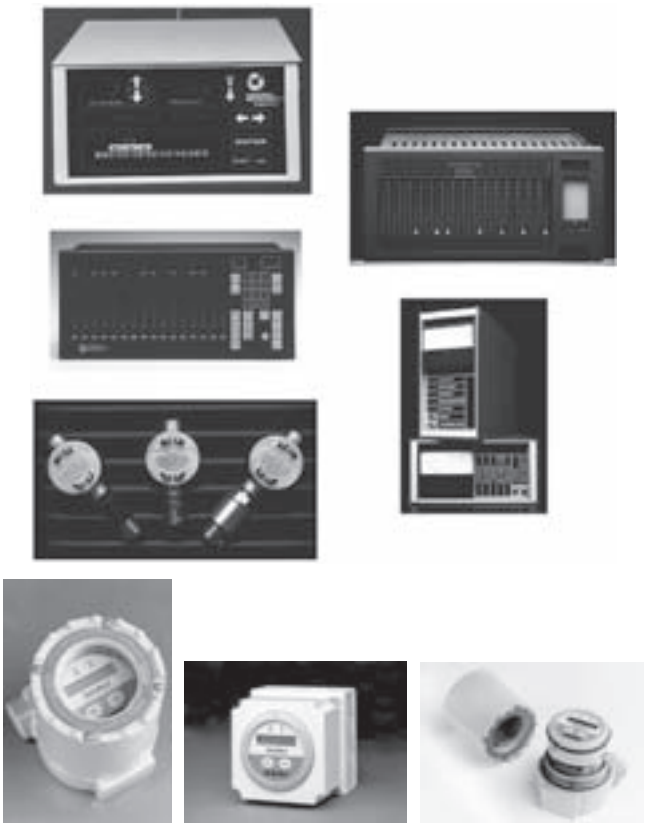

FIGURE 14.8.2 Examples of Modern Fixed Gas Detection Systems and Control Units (Source: Control Instruments® Corp.)

The most popular format is the "4–20 milliampere" format. The transmitter is connected to the display unit via a second set of wires. The maximum wiring distance between the transmitter and the display unit can often be as far as several thousand feet. The display unit expresses the output of the transmitter in a format that is understandable to the operator (Figures 14.8.2 and 14.8.3). Some displays utilize analog meters, whereas others provide bar-graph and numeric displays. Most display units are equipped with output relays that transfer when the measured concentration of gas exceeds pre-established threshold concentrations. This provides for different types of responses as the measured gas concentration increases. For example, a warning response might be activated when the concentration reaches 20 percent LFL, and inerting or shutdown activated when the concentration reaches 50 percent LFL.

Portable Gas/Vapor Monitoring Instrument. Portable gas/vapor monitoring instruments are hand-carried portable instruments, utilizing no external source of power, designed to warn the person carrying it of the presence of dangerous levels of gas or vapor, or dangerously low concentrations of oxygen in the ambient breathing air. Some monitors are simple single gas-warning devices, whereas others are multiple-gas devices. All are designed to measure the gas concentration and warn the user if the concentration begins approaching the threshold limit value (TLV), as established by OSHA, for that particular gas.

FIGURE 14.8.3 Fixed Gas Detection System Using a Sensor and Display Integrated into a Common Unit, Shown Here with the Enclosure Cover Removed (Source: Control Instruments® Corp.)

Hazardous Location. Places where a flammable gas or vapor is able to escape into the surrounding air are considered *hazardous locations.* In the United States hazardous locations are defined in Article 500 of the *NEC* (NFPA 70, *National Electrical Code*®). The *NEC* divides hazardous locations into Class 1, Class 2, and Class 3.

Section 500.5(B) of the *NEC* states that Class 1 hazardous locations are those "in which flammable gases or vapors are or may be present in air in quantities sufficient to produce explosive or ignitible mixtures." Class 2 hazardous locations are those that are hazardous because of the presence of combustible dusts. Class 3 hazardous locations are those that contain ignitible fibers and combustible flyings.

Both flammable gases and vapors and combustible dusts represent an explosion hazard when either is present in the air in sufficient concentration. The NEC further classifies hazardous locations based on the probability that a combustible material will be present at any particular time by assigning a "division" classification to the location. Class 1, Division 1 is assigned to occupancies that (1) contain flammable gases or vapors as part of the normal operating environment, (2) contain flammable gases or vapors frequently due to routine repair, maintenance, or leakage, or (3) contain equipment or processes where breakdown or production upsets could result in both a flammable atmosphere *and* an ignition source.

Class 1, Division 2 is assigned to occupancies where (1) flammable gases or liquids that produce flammable vapors are handled or processed in closed containers or systems and are only subject to release under conditions of equipment malfunction, breakdown, or process upset, (2) the development of a flammable atmosphere is normally prevented by positive mechanical ventilation, the failure of which could lead to a hazardous atmosphere, or (3) areas adjacent to a Class 1, Division 1 location subject to occasional ingress of flammable gas or vapor. Analogous divisions for Class 2 hazardous locations are also established in Article 500 of the NEC for combustible dusts, but these are not relevant to the discussion of gas and vapor detection.

In the European Union a similar hazard classification system has recently been adopted, known as the ATEX Directive. Under the ATEX Directive all process environments that can represent an explosive atmosphere must be so designated by the owner/operator of the facility. Once designated, all equipment used in that environment as well as products and equipment used to manage the hazard must be tested under a set of uniform EU testing standards and found suitable for that environment, as signified by the CE (Communité European) mark on the product labeling. A product that has not been certified by a nationally recognized testing laboratory as being suitable, as evidenced by the CE mark, is prohibited from use within the EU. The hazard classifications under the ATEX Directive are *not* the same as those established by the NEC. Consequently, products must go through two sets of testing if they are to be marketed in both the U.S. and EU markets.

SENSORS

The sensor is the single most critical part of any fixed gas detection system or portable monitoring instrument. The sensor is the portion of either the fixed system or portable instrument that actually does the sensing of the presence of gas in the air. The sensor generates an electrical signal, either current or voltage, proportional to the concentration of gas in the air. The gas detection system can be no better than the sensors used and, consequently, the development of sensors has accounted for much of the research and development effort. As with fire detection, there are a limited number of sensor technologies in common use and then some specialized technologies tailored to the needs of special applications. In general, the design focus has been to develop sensors that are specific to a given gas and that maintain their response characteristics in spite of the presence of other gases.

Most flammable-gas sensors designed to detect the hydrocarbon gases and vapors from hydrocarbon liquids are based on the detection of the heat of combustion of the flammable gas, using resistive-thermal devices (RTDs) and the Wheatstone bridge circuit. An RTD is an electronic component whose resistance varies with temperature. RTDs include metal oxide resistors, resistance wires, and thermistors. These devices can all be wired into a circuit called the Wheatstone bridge, shown in Figure 14.8.4.

The resistors shown as the sample and reference legs of the bridge circuit can be any type of RTD. The sample RTD is coated with a material that acts as a catalyst of the combustion of hydrocarbons. Alloys of both palladium and platinum are often used for this purpose. The reference RTD is enclosed in a manner that prevents contact with the ambient, gas-containing

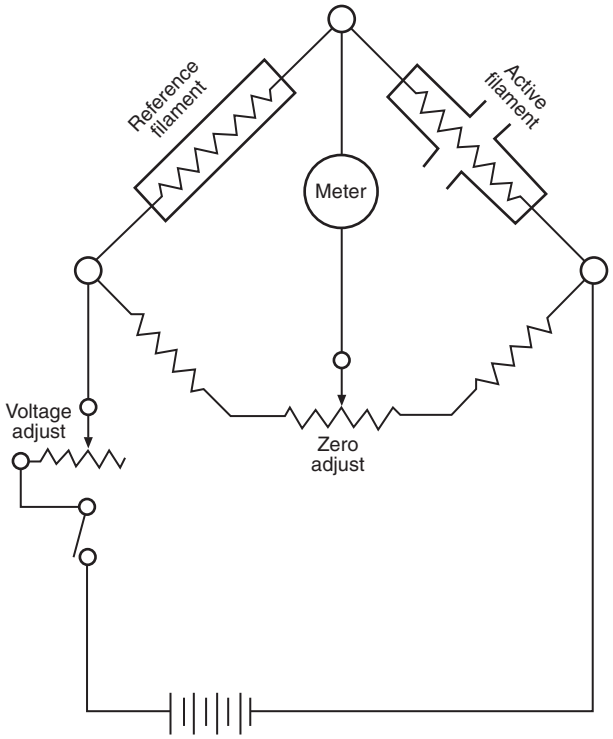

FIGURE 14.8.4 Basic Wheatstone Bridge Circuit as Used in Many Gas Detection Systems

air. Electric current is passed through the bridge circuit, causing all of the legs of the bridge to become warm. When flammable gas impinges upon the sample RTD, the gas oxidizes, releasing heat from the combustion process occurring on the surface of the RTD. This raises the temperature of the sample RTD, and causes the electrical resistance of the sample RTD to change compared to the reference RTD, which remains at normal operating temperature. The change in the sample RTD resistance causes a potential (voltage) difference across the "voltmeter," which is proportional to the concentration of flammable gas.

Theoretically, the heat derived from the combustion of a gas on the surface of a catalyst-coated RTD is dependent on both the concentration and the heat of combustion of the flammable gas. However, the heats of combustion of most chemical compounds encountered in the context of gas detection are very close in value. This allows the heat of combustion term to be considered nominally constant, especially when the gas concentrations are at or below the LFL. This approximation is not perfect. Carbon disulfide vapor yields readings that are lower than the actual concentration under these conditions, while natural gas yields readings that tend to be higher than the actual concentrations. These discrepancies increase as the concentrations increase. However, this is easily addressed with specific calibrations where these gases are present. For most purposes, where the sought-after condition is a hazardous gas–free atmosphere, the differences between various gases disappear as the actual concentration approaches zero.

One of the more popular types of RTD is the catalyst-coated thermistor, called the *catalytic bead.* A *thermistor* is an electrical resistor, fabricated from one of a number of rare-earth ceramics, that exhibits a large change in electrical resistance as a function of temperature, usually referred to as a *temperature coefficient.* Many have a temperature coefficient that is negative, meaning that the electrical resistance goes down as the temperature increases. A *catalyst* is a material, usually a chemical or mixture of chemicals, that facilitates a particular chemical reaction. Certain metals and metal salts catalyze the combustion reaction involving hydrocarbon chemical species. The catalytic effects of such metals and metal salts are often specific for certain hydrocarbon species, meaning that a catalyst that facilitates the combustion of methane would not be particularly effective at facilitating the combustion of butane or gasoline. Coating the thermister of a gas detection sensor with a particular catalyst can make the sensor somewhat selective for particular gases or groups of gases.

Air mixtures containing concentrations of flammable gas much lower than the LFL, approaching zero, will "burn" on the surface of a heated catalytic material, yielding heat in direct proportion to the concentration of the flammable gas. This is called *surface* or *catalytic* combustion. Some RTD designs depend on the flow of electric current through the thermistor bead to generate the requisite operating temperature of the catalyst. Others use a separate resistance heater integrated into the bead. Obviously, the combustion of the flammable gas on the surface of the catalyst could conceivably cause ignition once the concentration exceeded the LFL. Consequently, sensors are contained within a flame arrester of either wire mesh or sintered metal, as shown in Figure 14.8.5, that prevents the propagation of combustion

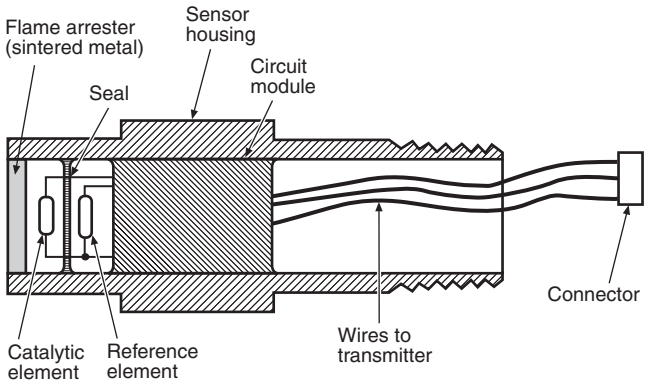

FIGURE 14.8.5 Flammable-Gas Sensor Using Catalytic Bead Technology

outside the sensor. These flame arresters are generally suitable for conventional gas-air mixtures. However, if the atmosphere is oxygen enriched to concentrations greater than 21 percent oxygen by volume, or if the partial pressure of oxygen exceeds 21.27 kPa or 160 mm(Hg), special arresters may be necessary.

Most sensors use a catalyst that is derived from the catalytic properties of platinum, palladium, and nickel. Careful control over the alloying of the catalysts and the operating temperature enables the manufacturer to make sensors that are specific for a particular group of gases. Catalytic beads have a very small mass; therefore, they respond rapidly to the heating produced by the combustion of flammable gas on their surfaces. Response often begins within a few seconds of the introduction of the gas. However, when the influx of flammable gas is large, it may take as long as a minute to attain full-scale response of the sensor. The speed of response of a sensor is an important factor when choosing the best sensor for a given hazard.

Catalytic bead flammable-gas monitoring instruments are designed specifically for measuring combustibles in air. The oxygen in the air is necessary for the combustion of the flammable gas and the generation of heat that the unit senses to infer the presence of flammable gas. These instruments give a reasonably accurate indication of the presence of combustible gas, even when the oxygen concentration has been substantially reduced by oxidation, biological action, or displacement. Generally, one should expect the accuracy of a catalytic-bead sensor to suffer as the ambient oxygen concentration decreases to less than 10 percent. Also note that inerting agents, such as Halon 1301 or the replacement clean agents, interfere with either the combustion reaction on the catalyst surface or increase the heat capacity of air and, hence, reduce the temperature resulting from the combustion of the flammable gas, rendering measurements unreliable when inerting agents are present.

Catalytic bead sensors do suffer from "poisoning" to varying degrees. Poisoning occurs when a noncombustible material impinges upon the bead and only partially burns, leaving a residue on the surface of the bead. The coated surface no longer oxidizes the flammable gas in the air, and the sensor ceases responding to the presence of flammable gas in the air. Although considerable progress has been made in reducing the tendency

for beads to become poisoned, this is a limitation of catalytic sensors that necessitates regular calibration to adjust for the progressive loss of sensing ability over time. Regular field calibration is necessary to adjust the zero and span of the display unit as compensation for drift and aging of the catalytic bead.

Many catalytic bead sensors are supplied with calibration curves showing the response of the particular unit to combustible gases other than that on which the device was calibrated. Calibration curves for one particular model of combustible gas indicator are shown in Figure 14.8.6. Since all manufacturers do not use the same gas for base factory calibrations, the curves for one instrument cannot be used with curves of another type.

Semiconductor (MOS) Devices

Metal oxide semiconductor (MOS) sensors can be used to detect a number of "reducing gases" such as hydrogen, methane, ethane, ammonia, and carbon monoxide. Metal oxide semiconductors can be fabricated with precisely controlled band-gap energies by manipulating the concentrations of the various oxides in the crystal. (This is called "doping.") When a MOS sensor has a voltage across it and a gas with the right chemical structure impinges on it, the current through the sensor changes, indicating the presence of the gas. The semiconductor can be modified to maximize response for a specific gas or group of gases by adjusting the relative concentrations of the constituent oxides (doping) or with the application of specific surface coatings. However, MOS sensors generally cannot be made specific for a single gas and care must be used to ascertain whether an unanticipated gas is causing the response of the sensor. Often, MOS sensors are operated at an elevated temperature to improve the response specificity of the sensor.

Calibration curves for field reference					
Gas or vapor	LEL % by volume	Curve no.	Gas or vapor	LEL % by volume	Curve no.

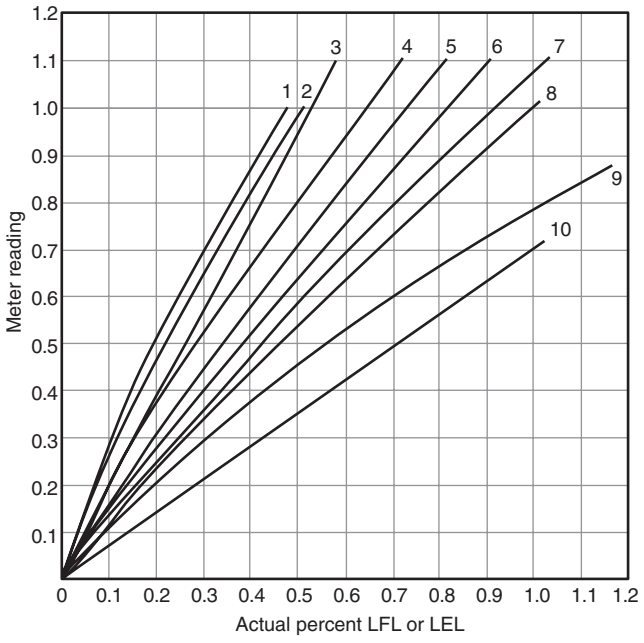

FIGURE 14.8.6 Calibration Curves for a Catalytic Bead Sensor. Note that, despite wide variations at higher concentrations, the error becomes negligible as the zero concentration is approached.

Electrochemical Devices

Electrochemical cells are primarily used for the detection of the toxic gases. The electrochemical cell is designed somewhat like a battery in which air can diffuse into the electrolyte of the cell. If the air contains the toxic gas for which the cell has been designed, an electrochemical reaction takes place, producing a minute voltage within the cell. This voltage causes a current to flow through the sensor electronics. The current is proportional to the concentration of the gas in the air. This enables the concentration to be measured by measuring the current from the cell. The diffusion path and the electrolyte can be varied to limit the response of the sensor to a particular gas.

Electrochemical cells are the predominant method for sensing carbon monoxide, chlorine, nitrogen oxide, sulfur dioxide, and hydrogen sulfide. Electrochemical cells are also used for oxygen-level monitoring by the same means as used for toxic gases. Semiconductor and catalytic bead sensors depend on a level of oxygen in the air in order to provide accurate results, whereas electrochemical cells do not. Furthermore, electrochemical cells usually provide high levels of specificity relative to other technologies.

Flame Cell Devices

When measurement capability for a wide range of hydrocarbon gases and vapors is needed, flame cell technology is often considered. Flame cell sensors are very often employed when LFL monitoring is needed for the atmosphere within an oven where flammable solvent vehicles (vapors) are driven off as part of a curing or finishing operation. This system uses a flame cell that contains a flame fueled by a flammable gas provided by the unit, and ventilated by air sampled from the hazard area. A temperature sensor measures the heat output of the flame. When flammable hydrocarbons are introduced into the hazard area atmosphere, the contaminated air flows from the hazard area to the sensor via sample conveyance tubing to the flame cell. As the hydrocarbon-containing air enters the flame cell, the hydrocarbons burn, adding to the heat available to the temperature sensor. The sensor temperature rises proportional to the concentration of the hydrocarbon gas (vapor) in the air (Figure 14.8.7).

Flame cell sensors are more complex than the other types discussed thus far. However, there are numerous applications where they represent the best cost/benefit solution. They are not affected by poisoning the way catalytic bead sensors are and

(a) (b)

FIGURE 14.8.7 (a) Flame Cell Sensor; (b) Flame Cell Sensor with the Enclosure Open, Showing the Internals (Source: Control Instruments® Corp.)

require far less frequent calibration. However, since sampling tubes convey the sample atmosphere to the detection unit, provisions must be made to ensure that there is no condensation of flammable or combustible vapors on the interior surfaces of the sample conveyance tubing, as this would create serious errors in the flammable gas concentration measurements. The flame cell sensor as a sampling-type device, connected to the hazardous area via a sampling tube, is shown in Figure 14.8.8.

Flame Ionization Devices

In some applications, where a means for detecting very low concentrations of flammable gas is needed, flame ionization detectors are often the sensor of choice. Flame ionization detectors consist of an enclosed flame cell equipped with a high-voltage field. It is fueled from a source of hydrogen, with combustion air coming through the sampling system. When the combustion air includes hydrocarbon molecules, these molecules are pulled apart by the high-voltage electric field, producing ions. These ions flow through the flame to the positive (+) and negative (–) electrodes, creating a current that is directly proportional to the concentration of hydrocarbon gas in the air sample.

Flame ionization sensors, like the flame cell sensors, are more complex than the other spot-type sensors. However, there are numerous applications where they represent the best cost/benefit solution. They are able to measure much smaller concentrations than the other types of gas sensors. They are not affected by poisoning the way catalytic bead sensors are and require far less frequent calibration. Flame ionization sensors (Figure 14.8.9) are installed like the flame cell devices, with a sampling tube that conveys a sample of the hazardous atmosphere to the sensor. Consequently, provisions must be made to ensure that there is no condensation of flammable or combustible vapors on the interior surfaces of the sample conveyance tubing, as this would create serious errors in the flammable gas concentration measurements.

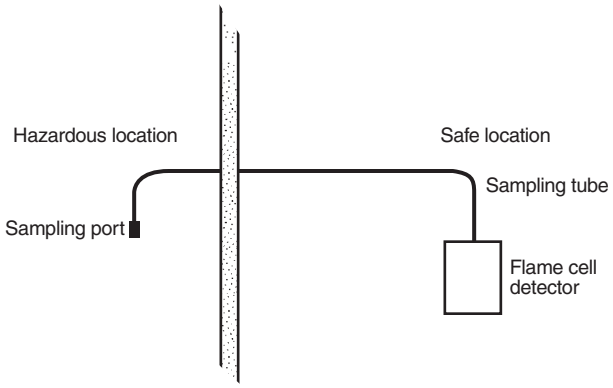

FIGURE 14.8.8 Flame Cell Sensor

Nondispersive Infrared (NDIR) Sensors

Gaseous molecules absorb infrared radiation at specific and characteristic wavelengths. This is analogous to the infrared emission detection that is the basis for many of the advanced technology flame detectors in use today. Infrared gas detectors, using the correlation between specific molecular species and specific wavelengths in the infrared spectrum, have recently been made available. Like smoke detectors, infrared gas detectors are either spot devices or open-path devices analogous to the projected beam smoke detector.

FIGURE 14.8.9 Flame Ionization Sensor (Source: Control Instruments® Corp.)

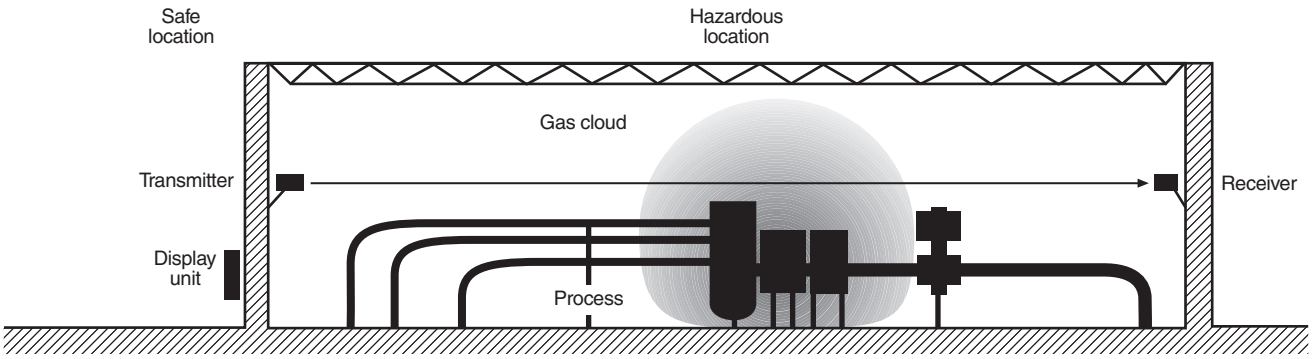

FIGURE 14.8.10 Open-Path Infrared Gas Detector

Open-path gas detectors operate with one or more infrared emitters and one or more receivers. These units compare the optical absorbance of the air in the optical path at two wavelengths, one at which the gas absorbs and a reference wavelength at which the gas does not absorb. The detection system electronics compare the intensities at the two wavelengths. If gas exists along the beam path, it will absorb the sample wavelength while allowing the reference wavelength to pass unattenuated. The difference in received intensities is proportional to the concentration of the gas and the percentage of the path length that contains that concentration. This value is transmitted via the common 4–20 mA analog signal to the display unit. It is displayed as LFL-meters, the product of the percent LFL and the distance. As shown in Figure 14.8.10, the open-path NDIR gas detector covers a large area; however, the reading is the product of the distance and the concentration over that distance.

Spot-type IR gas sensors operate on a similar principle, but the optical path is contained within the detector enclosure. This eliminates the path length as a variable, and they display concentration in simple percent of LFL. The spot-type sensor often contains an integral 4–20 mA transmitter that sends the analog signal to the display unit (Figure 14.8.11).

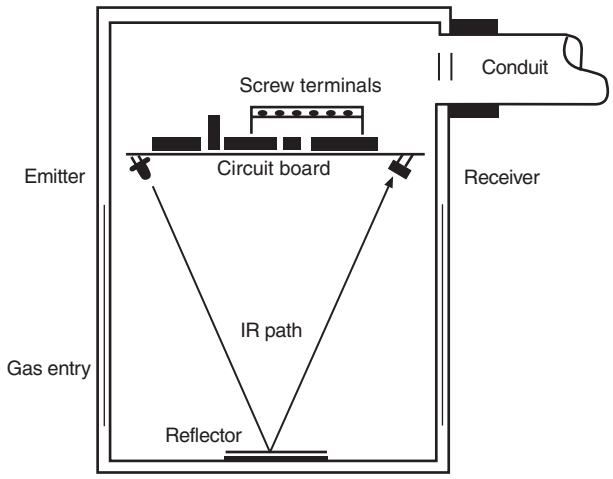

FIGURE 14.8.11 Spot-Type IR Gas Sensor

Infrared gas detectors are reputed to require far less maintenance and calibration than catalytic bead, electrochemical, and semiconductor devices.

FIXED GAS DETECTION SYSTEMS

Throughout modern industry there exist enclosed areas where gaseous contaminants can accumulate. Whether these gases are flammable, toxic, or both flammable and toxic, they represent a serious threat to personnel, the facility, and the operations housed within the facility. Reliable monitoring of known gas hazards is critical if losses are to be prevented.

Where known permanent gas hazards exist, a fixed gas detection system is necessary. These hazards are commonly encountered in public utility electric generating stations; publicly owned water treatment works; petroleum exploration, production, refining, and distribution facilities; pharmaceutical, chemical, and petrochemical production, storage, and distribution facilities; metallurgical facilities; semiconductor fabrication facilities; distilleries; paint and varnish manufacturing facilities; and mines.

Concurrent with the detection of the presence and concentration of both flammable and toxic gases, there is the need to measure the oxygen concentration in the atmosphere in many applications. Measurement of the oxygen concentration is important as a means of evaluating the effectiveness of inerting processes, of protecting personnel from the effects of oxygen deficiency, and of determining that sufficient oxygen is present in the atmosphere to ensure reliable concentration readings from combustible gas detectors.

It is important to note that one cannot use the spacing criteria for smoke detectors in *NFPA 72®*, *National Fire Alarm Code®* as a guide for the location and spacing of gas detectors. The spacing and location criteria in *NFPA 72* for smoke detectors are based on fire plume dynamics in which the heat released by the combustion of the fuel serves as the driving force behind the development of a fire plume and a ceiling jet. No such energy source exists in the context of a gas leak. When a contaminant gas leaks into the surrounding atmosphere, it mixes with the air, changing its density. In a mixture of gases, the density of the mixture is a function of the constituent gases and the portion of the mixture that they represent. Under still air conditions

where there is no ambient air movement, higher concentrations are usually observed at higher locations within the enclosing space when lighter-than-air gases are involved. Conversely, higher concentrations are usually observed at lower locations within the enclosing space when heavier-than-air gases are involved. One can use the specific density of the gas in question to aid in predicting whether the gas in question will tend to rise or sink when a leak occurs (Table 14.8.1).

The data in Table 14.8.1 must be used carefully. It is often necessary to take into account the refrigeration effect that occurs when a gas at high pressure leaks into a region of much lower pressure. The volumetric expansion of the leaking gas causes it to cool the air into which it is flowing. The cooled air is no longer at STP conditions of 77°F (25°C) and 760 mm(Hg) absolute pressure or 1 atm. This cooling causes the air/gas mixture to contract, increasing in density. As the mixture moves from the locus of the leak, it continues to absorb heat from the ambient, and slowly reaches thermal equilibrium with the ambient. These thermodynamics must be observed when using data, such as that in Table 14.8.1, to develop a sensor placement strategy.

Flammable Gas Detection

Most of the fixed gas detection systems in service are designed to measure the concentration of one or more flammable gases.

TABLE 14.8.1 Specific Densities of Commonly Encountered Gases and Vapors*

Standard Conditions of Temperature and Pressure

Gas/Vapor	*Molecular Formula*	*Specific Density, Air = 1.0000*
Air	—	1.0000
Hydrogen	H_2	0.7000
Carbon monoxide	CO	0.9670
Carbon dioxide	CO_2	1.5280
Methane	CH_4	0.5540
Acetylene	C_2H_2	0.9110
Ethane	C_2H_6	1.0490
Hydrogen sulfide	H_2S	0.9109
Phosphine	PH_3	1.1840
Propane	C_3H_8	1.5500
Silane	SiH_4	1.1140
Sulfur dioxide	SO_2	2.2640
Acetone	$(CH_3)_2CO$	2.0
Benzene	C_6H_6	2.8
Carbon disulfide	CS_2	2.6
Cyclohexane	C_6H_{12}	2.9
Ethanol (ethyl alcohol)	CH_3CH_2OH	1.6
Ethyl ether	$CH_3Ch_2OCH_2CH_3$	2.6
Gasoline	mixture	3.4
Mineral spirits	mixture	3.9
Naphtha (VM&P)	mixture	<1.0
Toluene	$C_6H_5CH_3$	3.1

*See NFPA 86, *Standard for Ovens and Furnaces.*

These systems are generally found in petroleum exploration, production, refining, and distribution facilities; power generation plants; water treatment plants; landfills; chemical and pharmaceutical facilities; and numerous industrial processes where flammable solvent (vehicle) vapors are driven off in ovens. Generally, these systems are designed to respond to a broad range of hydrocarbon gases and vapors, such as methane, ethane, propane, butane, ethylene, propylene, acetylene, and similar gases, as well as the vapors from the evaporation of hydrocarbon liquids, such as gasoline, acetone, ethyl ether, methylethyl ketone, methylisobutyl ketone, carbon disulfide, turpentine, and lacquer thinner, to list a few.

The predominant sensor for flammable gas detection in general, normally occupied spaces is the catalytic bead sensor, which is designed to comply with the performance criteria outlined in ANSI/ISA S12.13, *Performance Requirements, Combustible Gas Detectors.*[1] Sensors are situated where there is the probability that gas will accumulate when a leak occurs. When the gas to be detected is methane, natural gas, or other lighter-than-air gases, sensors are generally located above the gas-containing equipment. When propane, butane, and most vapors are involved, the sensors are located low in the air space of the hazard area. Flammable gas sensors must be placed to take advantage of normally occurring air currents and the differences in the density of air and the flammable gas(es) in question. The installation, operation, and maintenance of flammable gas detectors are addressed in ISA RP12.13, Part II-87, *Recommended Practice: Installation, Operation, and Maintenance of Combustible Gas Detection Instruments.*[2]

The gas sensors are connected via multiconductor cable to the appropriate transmitter, which is then connected to the display unit, as shown in Figure 14.8.12. Generally, the distance between the sensor and transmitter is quite limited. The transmitter linearizes the signal from the sensor, corrects it for

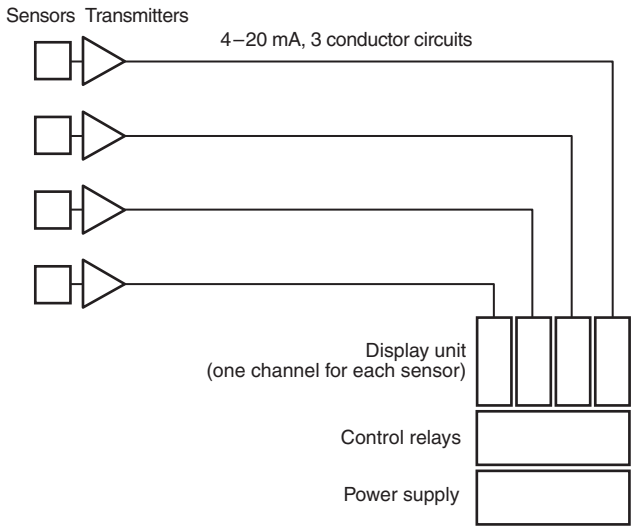

FIGURE 14.8.12 Wiring Architecture for the Traditional and Currently Most Likely Encountered Flammable Gas Detection System

zero and span, and converts it into an electrical format that can be transmitted a long distance without interference. The most popular format is the "4–20 mA" format. A second set of wires connects the transmitter to the display unit. The maximum wiring distance between the transmitter and the display usually can be as far as several thousand feet.

Large numbers of "points" are generally wired to a centrally located display unit where the status of the facility can be monitored by facility staff. The unit displays the output of the transmitter. Some display units utilize analog meters, whereas others provide bar-graph and numeric displays.

Addressable gas detection systems have been introduced that enable the system to be wired in a manner similar to a traditional smoke detector circuit. The transmitter converts the analog data from the sensor into a binary format and transmits it serially along with its identity to the display unit. The display unit presents the analog data in the customary fashion (Figure 14.8.13).

Most display units are equipped with output relays that transfer when the measured concentration of gas exceeds preestablished threshold concentrations. This provides for different types of responses as the measured gas concentration increases. For example, a warning response might be activated when the concentration reaches 20 percent LFL, and inerting or shutdown actuated when the concentration reaches 50 percent LFL.

ANSI/ISA S12.13[1] requires that the flammable (combustible) gas detection system supervise for the following:

1. The failure of the unit power supply
2. The loss of continuity of the sensor element (catalytic bead)
3. The continuity of all conductors to the detector head (the sensor and transmitter)
4. Down-scale reading, below zero, equivalent to a concentration of more than 5 ppm

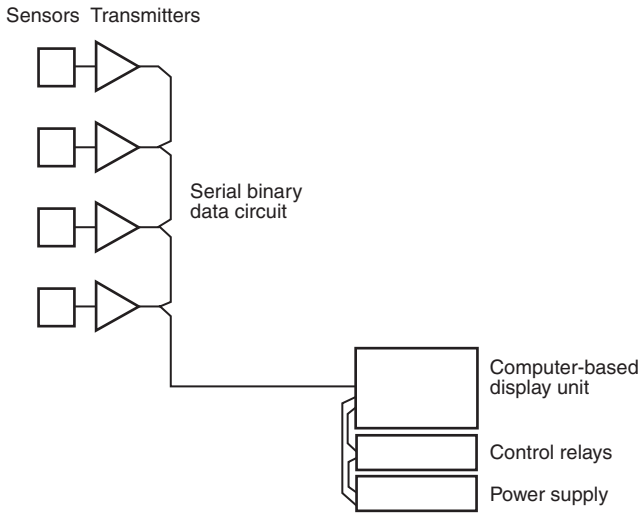

FIGURE 14.8.13 Wiring Architecture of the Addressable Flammable Gas Detection System

This is not entirely consistent with the supervisory requirements of *NFPA 72*. Furthermore, ANSI/ISA RP12.13 does not address supervision of any of the connections that are intended to initiate any type of automatic response to a gas concentration above threshold levels. This inconsistency is one of several system design issues that come into play when integrating or interconnecting flammable gas detection systems with fire protective systems. *NFPA 72* includes specific requirements for the power supplies, electrical supervision, isolation from ground, programming security, and supervision of output circuits that might not have been observed by the manufacturer of the gas detection system. The actuation of inerting, warning, and ventilation systems in response to high-level gas indication are all fire-protective actions that should be achieved with inherently reliable, supervised designs, as described in *NFPA 72*. Some authorities having jurisdiction (AHJ) might apply the requirements of *NFPA 72* to flammable gas detection systems when the flammable gas detection is integrated into the facility fire protection systems.

Toxic Gas Detection

The detection of many toxic gases is necessary in the same environments where flammable gases must be monitored. Most frequently, hydrogen sulfide gas is commonly encountered in petroleum exploration and production involving sour crude and/or sour gas. Consequently, many gas detection systems in place in the petroleum industries include both flammable gas and toxic gas detection for hydrogen sulfide, sulfur dioxide, and fluorine in the same system.

The architecture of most fixed gas detection systems lends itself to this reality. The systems are designed with transmitters and display units that can accommodate a number of interchangeable sensors, specifically designed for a particular gas. Combined flammable and toxic gas detection systems are commonly encountered.

The semiconductor and electrochemical sensors are most commonly used for the detection of toxic gases. The measurements are expressed in ppm and generally the threshold limit value (TLV) established by OSHA for the gas in question is placed in the upper half of the display range.

ANSI/ISA S12.15, PT I-90, *Performance Requirements for Hydrogen Sulfide Detection Instruments (10–100 ppm),*[3] requires that the toxic gas detection system supervise for the following:

1. The continuity of all conductors to the detector head (the sensor and transmitter)
2. The failure of the unit power supply
3. The loss of continuity of a circuit protection device
4. A down-scale reading, below zero, equivalent to a concentration of more than 5 ppm

This is not entirely consistent with the supervisory requirements of *NFPA 72,* which establishes requirements on the equipment design that are not normally assumed to be relevant when a manufacturer outside the fire protection community undertakes the design of a product. This becomes an important issue when integration of gas detection and fire alarm systems is contemplated.

Calibration and Maintenance

Both flammable and toxic gas detection systems require regular calibration and maintenance if reliable measurements are expected.[2,4] Each system has a specific set of calibration and maintenance criteria that is incorporated as part of the listing investigation by the nationally recognized testing laboratory. These procedures must be carefully and meticulously followed. In general, most systems using catalytic bead, semiconductor, and electrochemical sensors require calibration on a monthly schedule. The flame cell and flame ionization detectors usually require less frequent calibration.

The calibration of a gas detector, whether flammable or toxic, involves adjusting the electrical output of the transmitter to accurately reflect the atmosphere at the sensor. The first step is the zero adjustment. While the sensor is under normal ambient conditions with no gas present, the output of the transmitter is adjusted to 4.0 mA output to the display unit. The sensor is exposed to *test gas.* Test gas is a mixture of air and the gas to be detected, stored at elevated pressure in a specially designed cylinder with a sensor test fitting attached. The mixture is certified by the manufacturer as being accurate to within 1.0 percent LFL or 1.0 ppm, whichever is appropriate. Since there is an obvious hazard if the test gas concentration is at 100 percent LFL or 100 percent TLV, the test gas concentration is usually at 50 percent LFL or TLV, again whichever is appropriate. Exposure to the test gas is used to adjust the span output of the transmitter to the appropriate value for the test gas and sensor in question. In this way the electronics of the transmitter are used to correct for any nonlinearities and drift in the sensor. The display unit merely reads the current passing through the 4–20 mA circuit to the transmitter and displays it. Consequently, there is usually no calibration necessary at the display unit.

Eventually, the zero and span adjustments on the transmitter are insufficient to achieve both a zero and a correct span adjustment. This indicates that the sensor has aged to the point where it must be replaced. The rate of aging is very application specific and can occur without any apparent warning. Consequently, regular calibration is the only means to be confident that the gas detection system is operative and displaying an accurate measurement of the actual gas concentrations in the hazard areas.

Integration with Fire Alarm Systems

There are inconsistencies between the *NFPA 72* requirements for fire alarm signaling systems and the ISA standards for gas detection instruments. These inconsistencies become relevant when the conditions in the hazard area demand an integrated approach. Obviously, the presence of a flammable gas in an area sufficiently hazardous to warrant a fire alarm system represents an aspect of that hazard area that warrants immediate remedial action. Whether that remedial action consists of merely the activation of a notification appliance or whether it requires the activation of purge fans, process shutdown, deployment of an inerting agent, or some other response, these actions must be designed into the system in a manner that provides a high degree of intrinsic reliability and supervision if they are to represent a meaningful response. Typically, these responses are executed by a fire alarm system control unit that has been listed for releasing device service, and the flammable gas detection system serves as an initiating device in that system.

Since many gas detection systems use earth-ground as a circuit common, a practice that is forbidden in the context of fire alarm systems, there is often a fundamental power supply incompatibility between the gas detection control unit and the fire alarm system control unit. Consequently, the interface between the gas detection and the fire alarm system is often achieved through dry relay contacts. This is not the ideal means of signal transmission due to the relatively low reliability of dry relay contacts compared to solid-state devices. However, it is often what is found in the field. This circuit is shown in Figure 14.8.14.

It is important to understand that when flammable gas leaks occur it is not unusual for the cause of the leak to also lead to a heat source of ignition, making flammable gas detection an important fire prevention strategy. The commonly encountered flammable gases, such as natural gas, methane, ethane, and propane, are all dielectric materials. Being dielectrics they accumulate static electric charges when the velocity of the flow varies widely across the flow stream. Such velocity differentials regularly exist in the context of a leak of flammable gas from a high-pressure source. Consequently, the flow through the leak may generate large electrostatic potentials that are discharged as the gas escapes, creating electric sparks, which may be of sufficient energy and power to ignite the flammable gas/air mixture. This reality underscores the importance of detecting and expeditiously correcting flammable gas leaks.

PORTABLE GAS MONITORING INSTRUMENTS

Wherever there is the reasonable possibility of an accidental release of either flammable or toxic gas, there is the need to equip personnel with a portable instrument to warn them of such a hazard on entering. Both flammable and toxic gases are encountered in diverse locations throughout industry, for example, as a result of some form of accidental or opportunistic event, such as leakage from piping systems (both above and below ground) into the surrounding soil; from spillage or the decomposition of natural organic material in the soil; or sanitary landfills. Regardless of the source, the possibility and probability that a dangerous concentration of a flammable or toxic gas might exist in an area within a facility establish the need for portable gas monitors (Figure 14.8.15).

There are portable gas monitors designed for a wide range of performance objectives. It is important that the performance objectives for the gas monitoring instrument be fully understood before a unit is selected. Some applications require oxygen monitoring to ensure that there is sufficient oxygen for safe occupation of the space. Many applications require a monitor for only one specific gas, whereas other applications represent a number of concerns justifying the use of a multifunction monitor. Areas that contain concentrations of flammable gas above the LFL will necessitate an explosionproof or intrinsically safe

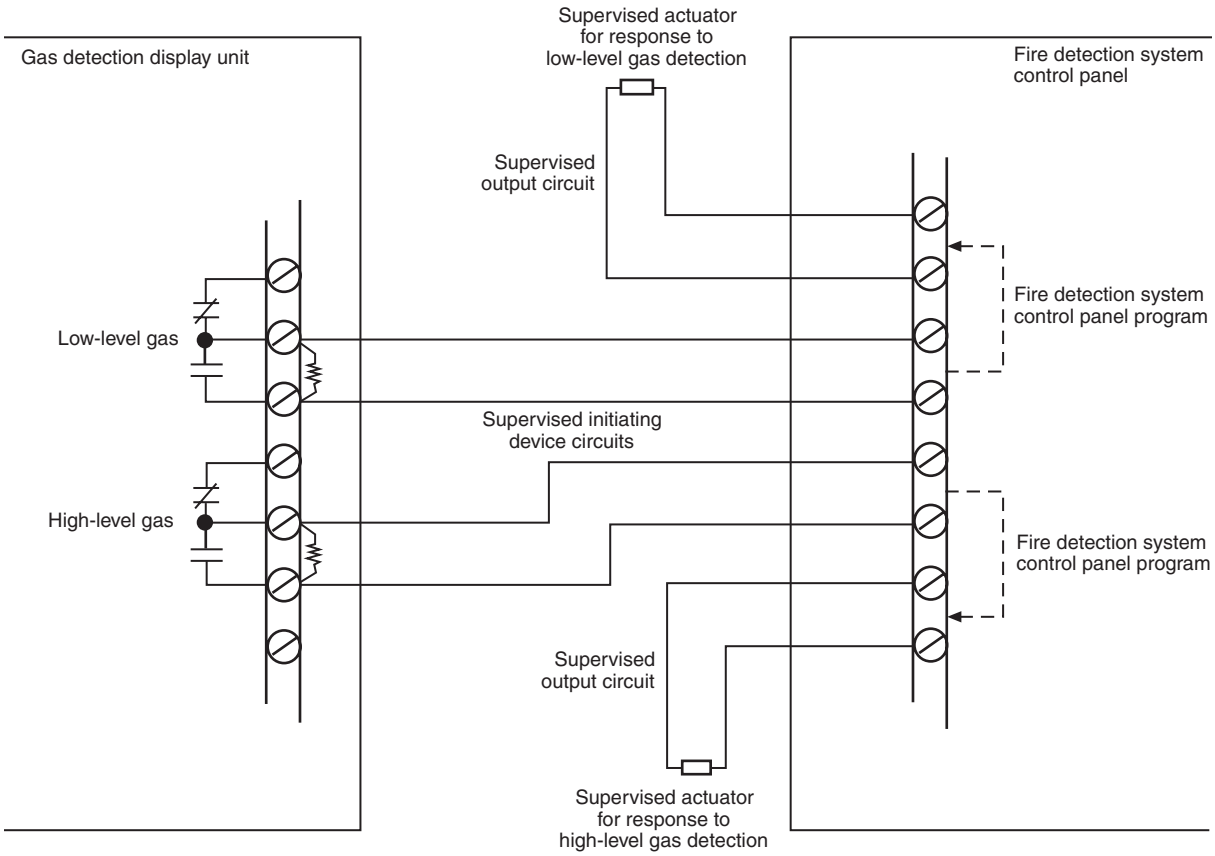

FIGURE 14.8.14 Commonly Encountered Interface Between the Gas Detection and the Fire Alarm System Used to Activate Automatic Responses to the Gas Detection Level Alarms

FIGURE 14.8.15 Portable Gas Monitor

instrument. Finally, some applications require that the unit operate continuously while the user is in the hazardous space, whereas others are intended to be used as a portable survey instrument operated on an intermittent basis. All of these intended use considerations have an important bearing on the selection of an instrument.

Portable gas monitoring instruments are available in a wide variety of forms. Some units depend on the diffusion of the air-gas mixture into the sensor. Others have provisions for a forced sampling means. Samples are drawn through a hose or tube, which is frequently equipped with a rigid extension or probe for ease in reaching inaccessible points. Suction is provided by a hand-operated rubber aspirator bulb or a battery-powered built-in motor-driven pump.

When using portable gas monitoring instruments the operator must keep in mind that all such instruments have a finite range of ambient conditions under which they can operate. Extremes in temperature, humidity, and barometric pressure (altitude) are likely to affect the accuracy and precision of the measurements they provide. Sampling steamy atmospheres is not recommended, since condensation of water within the instrument is likely to cause errors. Sampling from ovens or dryers operating at temperatures much higher than instrument ambient should also be avoided. Unless the solvents in question have flashpoints below instrument ambient temperature, vapors

might condense within the sampling tubing or measuring instrument, again causing errors.

Finally, if the portable gas monitoring instrument is to be used in areas where ignitible concentrations of flammable gas might exist, it should be designed and listed for use in hazardous locations as defined in Article 500 of NFPA 70. The manufacturer's label and instructions indicate the type of approval granted for the particular instrument.

Flammable (Combustible) Gas Monitoring Instruments

Flammable gas monitoring instruments generally use a catalytic bead or semiconductor sensor. The output from the sensor is directly displayed with a number of different techniques, ranging from an analog meter to digital readout. Most also include some form of audible alarm set at a level considered immediately hazardous. As a rule, flammable gas instruments must be set to read "zero" in uncontaminated air each time they are used. Like the fixed systems, the gas concentration is displayed in percent LFL. Generally, flammable gas monitoring instruments respond to all flammable gases or mixtures of flammable gases, irrespective of their chemical composition (Figure 14.8.16). This is usually desirable in a portable monitor, as it is unnecessary to know the exact identity of the flammable gas or gases prior to being able to assess the fire risk of the area being surveyed. Where it is necessary to selectively measure the concentration of some specific flammable gas, especially while in the presence of other combustibles, infrared absorption and gas chromatographic techniques on samples transported to a laboratory must be used.

Toxic Gas Monitoring Instruments

Similar to the flammable gas monitoring instruments, toxic gas monitoring instruments are often necessary in order to ensure personnel safety. Hydrogen sulfide monitors usually employ electrochemical sensors as do the sulfur dioxide, chlorine, and fluorine monitors. Carbon monoxide monitors are available using either the semiconductor sensor or the electrochemical sensor technologies (Figure 14.8.17). Other techniques that involve electrical detection of gas-specific chemical reactions are also employed. These include chemical stain, electro-conductance, and membrane permeability methods. These units generally display the concentration in ppm and include an audible signal when the concentration reaches a threshold value above which the threat to life and health is unacceptable.

Oxygen Concentration Monitoring Instruments

Oxygen concentration monitoring instruments are often critical life safety tools. Generally they utilize an electrochemical sensor. The partial pressure of the oxygen in the atmosphere controls the rate at which it diffuses through a porous membrane and into the electrochemical cell. Once in the cell, the oxygen enters into an electrochemical reaction, generating an electric current that is electronically scaled to display the oxygen concentration. The oxygen concentration is usually displayed as a simple "percent oxygen," usually on a scale graduated from 0 to 25 percent. Portable oxygen monitoring instruments usually include an audible alarm set for a level around 18 percent (Figure 14.8.18).

Except for setting the meter to read 20.8 percent while aspirating fresh air at the elevation (atmospheric pressure) where tests are to be made, no other calibration is necessary

FIGURE 14.8.16 Portable Multiple-Range Gas Monitoring Instrument (Source: Heath Consultants, Inc.)

FIGURE 14.8.17 Electrochemical Carbon Monoxide Monitoring Instrument That Includes an Indicator and Alarm (Source: MSA [Mine Safety Appliances Co.])

FIGURE 14.8.18 Individual Oxygen Indicator for Remote Sampling (Source: MSA [Mine Safety Appliances Co.])

for accurate reading in the range of oxygen concentrations in which it is permissible for people to work. (Current regulations require a minimum of 19.5 percent oxygen; otherwise, air must be supplied or self-contained breathing equipment must be used.) Enclosed spaces should also be tested to ensure sufficient oxygen is present to permit reliable gas measurements. Where readings are intended to be significant in the low range, that is, with inerting systems, the zero setting can be confirmed by sampling an oxygen-free gas, such as propane or nitrogen.

Calibration of Portable Gas Monitoring Instruments

Portable gas monitoring instruments require calibration on a regular basis if their measurements are to be relied on. The procedures for calibration vary from instrument to instrument. However, as with the fixed detection systems, most employ the use of a test gas. The "zero" of the unit is adjusted. Then it is subjected to test gas containing a known, certified concentration of the gas it is designed to measure. The span adjustment is then employed to achieve a measurement reading consistent with the known gas concentration.

The frequency at which units should be calibrated is determined by the authorities responsible for the life safety of the facility staff. Some authorities recommend calibration be verified daily, before use. Such a calibration check is accomplished by passing test gas through the instrument.

SUMMARY

This chapter is by no means a complete, authoritative presentation on gas detection. It is an introduction to this topic. The reader must be cautioned that the gas detection industry has developed over the years as part of the instrumentation industry, serving the needs of the chemical process and petroleum industries. Generally, the language is different from that used in the fire protection industry. Furthermore, the standards that have evolved over the years relating to gas detection do not address the concerns of the fire protection community in the customary manner. For example, consider that the 4–20 mA data transmission circuit is not recognized by *NFPA 72*.

As fire alarm systems become increasingly interactive with the facilities and production processes they protect, conflicts are expected to emerge in the requirements of various standards. These conflicts can only be resolved when fire protection professionals understand the basics of this technology and the objectives the standards were written to ensure. As fire alarm systems are more thoroughly interfaced with process control systems, questions of reliability, operability during impairment, and maintainability must be addressed in a manner that satisfies the needs of both fire protection and rigorous process control.

Although the popularity of carbon monoxide (CO) detectors and requirements for CO detection installation have been growing in recent years, it cannot be assumed that everyone is familiar with the hazards of carbon monoxide, the symptoms of CO poisoning, the requirements for alarms and detectors, or the installation and mounting details for alarms and detectors. The fire service may value further guidance on best ways to respond to CO alarm and detector actuations.

PHYSICAL PROPERTIES AND SOURCES OF CARBON MONOXIDE

Physical Properties

Carbon monoxide is a colorless, odorless gas produced by incomplete combustion. Carbon monoxide is minimally denser than air under ordinary conditions. It burns in air with a characteristic blue flame. As a reducing agent, it removes oxygen from many compounds and is used in the reduction of metals from ores. When air containing carbon monoxide in any amount is inhaled, the oxygen in hemoglobin is replaced by carbon monoxide, resulting in oxygen starvation throughout the body.

Sources

Hazardous concentrations of CO can accumulate in any occupancy, whether a single-family dwelling unit, a hotel guest room, or a nonresidential occupancy. The vast majority of deaths due to CO poisoning, however, occur in one- and two-family dwellings.[1] Generally, the accumulation of CO is the result of improperly operating heating appliances; insufficient make-up air in the space; blocked, poorly designed, or poorly installed chimneys or vents; or a complete absence of needed vents. Other potential sources of CO, however, exist, including idling automobiles in attached garages and portable equipment, such as generators and barbecue grills.

In multiresidential occupancies such as hotels, apartment buildings, or condominium buildings, malfunctioning furnaces, boilers, or swimming pool heaters, or problems with the venting of such appliances, can cause potentially fatal build-ups of CO.

CARBON MONOXIDE HAZARDS

Solid, liquid, or gaseous fuels can produce CO gas in lethal concentrations. According to U.S. death certificate data, 200 to 300 unintentional-injury deaths a year are due to CO. With detection and early warning, the majority of these deaths could be readily prevented. It is also possible that a considerable number of additional CO deaths are not recognized as such, because the symptoms

Art Black is chair of the NFPA Technical Committee on Supervising Stations for Fire Alarm Systems and the past chair of the Technical Committee on Carbon Dioxide Warning Equipment. A 30-year veteran of the fire service, he is the principal of Carmel Fire Protection Associates in Carmel, California, a fire protection consulting company providing fire prevention services to the public sector.

are not sufficiently unique as to prompt a routine postmortem examination. Every year, there are nearly a hundred additional deaths due to gas or vapor—principally CO—for which it is never determined whether the injury was intentional (e.g., suicide) or unintentional.

Exposure

The dangers of CO exposure depend largely on a number of variables, including the subject's health and activity level. Infants, pregnant women, and people with physical conditions that limit their body's ability to use oxygen (including people with emphysema, asthma, and heart disease) can be more severely affected by lower concentrations of CO than healthy adults. The subject's length of exposure and the initial carboxyhemoglobin (COHb) level, which could be elevated by smoking or exposure to operating motor vehicles in a confined space, are additional important variables. A person exposed to CO can be poisoned by a small amount of CO over a longer period of time or by a large amount of CO over a shorter period of time.

Symptoms of Carbon Monoxide Poisoning

The reactions to CO poisoning vary depending on several factors, including the age, general health, fitness, and general activity level of the victim immediately prior to the poisoning. The following equation can be used to determine the estimated percent of carboxyhemoglobin in the blood:[2]

$$\%COHb_t = \%COHb_0[e^{-(t/2398B)}] + 218[1 - e^{-(t/2398B)}] \times [0.0003 + (ppmCO/1316)]$$

where

$\%COHb_t$ = Percentage of COHb at time t

$\%COHb_0$ = Percentage of COHb in the blood at time 0

t = Time (min)

B = 0.0404 (work effort)

The concentration of CO, measured in parts per million (ppm), is a determining factor in the symptoms for an average healthy adult, as shown in Table 14.9.1.

TABLE 14.9.1 Carbon Monoxide Concentrations and Symptoms

Concentration (ppm CO)	*Symptoms*
50	No adverse effects with 8 hours of exposure
200	Mild headache after 2–3 hours of exposure
400	Headache and nausea after 1–2 hours of exposure
800	Headache, nausea, and dizziness after 45 minutes of exposure; collapse and unconsciousness after 2 hours of exposure
1000	Loss of consciousness after 1 hour of exposure
1600	Headache, nausea, and dizziness after 20 minutes of exposure
3200	Headache, nausea, and dizziness after 5–10 minutes of exposure; collapse and unconsciousness after 30 minutes of exposure
6400	Headache and dizziness after 1–2 minutes of exposure; unconsciousness and danger of death after 10–15 minutes of exposure
12,800 (1.28% by volume)	Immediate physiological effects; unconsciousness and danger of death after 1–3 minutes of exposure

CAUTION: The values in Table 14.9.1 are approximate values for healthy adults. Children, the elderly, and persons with pre-existing physical conditions might be more susceptible to the effects of carbon monoxide exposure. Continued exposure after unconsciousness can cause death.

DEVELOPMENT OF CARBON MONOXIDE DETECTION STANDARDS

After several well-publicized incidents in the early 1990s, the U.S. Consumer Product Safety Commission petitioned the National Fire Protection Association to create a standard for CO detection. The NFPA Standards Council acted on this request in 1993 by assigning development of a new document to the Technical Committee on Household Fire Warning Equipment. This committee was chosen because it had the necessary expertise in residential detection principles in its development of *NFPA 72®, National Fire Alarm Code®*.

In 1995 the Technical Committee on Household Fire Warning Equipment presented a "Recommended Practice on the Installation of CO Warning Equipment" to the NFPA membership at the annual meeting, where it was returned to the committee. In early 1996 the Standards Council reassigned the project to a new Technical Committee on CO and Fuel Gas Detection, which was given the task of developing two documents—one on detection of CO and the other on detection of fuel gas vapors.

The first NFPA document on CO detection, NFPA 720, *Recommended Practice for the Installation of Household Carbon Monoxide Warning Equipment,* was approved by the NFPA membership in 1997. NFPA 720 was a recommended practice, not a standard, so the installation details in the document were advisory only. Further, since the scope of the document was for family living units only, the document specifically excluded hotels, motels, and similar occupancies. NFPA 720 made recommendations for the selection, installation, operation, and maintenance of equipment that detects concentrations of CO that could pose a health hazard to occupants of a single-family living unit. Because of the multiple alarm thresholds involved, it was not intended to regulate CO detectors designed to detect hostile fire signatures.

The technical committee attempted a revision of NFPA 720 in 2000, which would have extended the recommendations

to all occupancies; however, that revision was returned to the committee at the NFPA fall meeting. The technical committee made some minor revisions to the 2003 edition of NFPA 720, including revisions pursuant to the changes in NFPA's Manual of Style. With the growing number of jurisdictions adopting requirements for installation of carbon monoxide warning equipment and the difficulty of a jurisdictional authority to reference a recommended practice, the Technical Committee converted the document into a standard in 2005. The Technical Committee is currently working on a modification to NFPA 720 to answer the growing need of jurisdictional authorities who are requiring carbon monoxide detection in other than single-family residences.

INSTALLATION OF CARBON MONOXIDE DETECTION EQUIPMENT

NFPA 720, now titled *Standard for the Installation of Carbon Monoxide (CO) Warning Equipmnt in Dwelling Units,* is the standard that provides guidelines for operation, installation, testing, and maintenance of carbon monoxide detectors in household occupancies (Figure 14.9.1). Currently there are no standards for carbon monoxide detection equipment in commercial occupancies (hotels, congregate residential buildings, and other commercial nonresidential buildings).

Household Dwelling Units

It is important to note that NFPA 720 is an installation standard and does not require the installation of carbon monoxide warning equipment. When required to be installed, or where protection is desired, CO detectors or alarms are to be located in any residential occupancy containing a fuel-burning appliance or fireplace or having an attached garage. A CO detector or alarm needs to be installed outside each separate sleeping area in the immediate vicinity of the bedrooms. Audibility of the warning signal is a determining factor when deciding how many detectors or alarms to install. Where bedrooms are separated and audibility could be impaired, more than one unit may be required.

FIGURE 14.9.1 Typical Household Carbon Monoxide Detector (Source: BRK Brands, Inc.)

CO is minimally denser than air, and concerns have been voiced about "plug-in" detector models that are mounted at the level of convenience receptacles located near the floor. Since the vapor density of CO is very close to that of air, however, it will readily mix with air given any air movement in the room, and detectors can thus be mounted either on the ceiling or on the wall. Underwriters Laboratories Standard 2034, *Standard for Single and Multiple Station CO Alarms,*[3] is the manufacturing standard for CO warning equipment. This standard requires that mounting specifications be part of the documentation required to be included with a CO detector or alarm. These manufacturer's directions need to be followed.

CO detection equipment is recommended in any family living unit containing a fuel-burning appliance or fireplace or any family-living unit having an attached garage. NFPA 720 parallels UL 2034 in the requirements for CO warning equipment as it relates to power supplies, equipment performance, and alarm signals.

NFPA 720 also contains provisions which require carbon monoxide warning equipment be interconnected to a household fire alarm control unit or a household combination fire/burglary alarm unit as a supervisory device. This information is of primary importance to the fire service, because on a fire alarm or combination fire/burglary alarm panel, an alarm signal would mean "fire." It is important to ensure that an incorrect alarm condition is not transmitted to a public fire service communications center.

Hotel and Congregate Residences

Because the scope of NFPA 720 is limited to single-family dwellings, there are no requirements in the document regarding CO detection equipment in hotels and congregate residences. However, where CO detection is required or desired in such occupancies, it is recommended that the CO warning equipment or detectors be installed in close proximity to fuel-burning equipment, such as furnace rooms and pool heater rooms. In addition, these devices should be connected to the premises fire alarm system as supervisory devices. This will allow for the on-site staff to be immediately notified of a CO problem.

Other Commercial Occupancies

As stated above, NFPA 720 applies solely to single-family dwellings. Where carbon monoxide detection is required or desired in commercial occupancies, sound engineering judgment is to be used in determining placement of carbon monoxide detection equipment and the necessary interconnection to building alarm systems.

CARBON MONOXIDE WARNING EQUIPMENT ALERT SIGNALS

The standard signal for a CO alarm is a single-tone "temporal 4" pattern, consisting of four cycles of 100 milliseconds "on"

and 100 milliseconds "off," followed by 5 seconds "off." The signal should continue until the alarm resets or the detector is manually reset. To conserve battery power, an exception allows the manufacturer to extend the 5 seconds "off" period to 60 seconds "off" after the first 4 minutes of alarm. The signal was selected as a unique alternative to existing smoke alarm signals or the temporal 3 pattern required for newer smoke alarms (Figure 14.9.2). Because many CO detectors and alarms resemble smoke detectors and alarms in appearance, developers saw the need to make the audible signal for CO detectors and alarms distinctively different. Another factor in the development of this signal was the need for the CO alarm to have enough power to continue operation for 12 hours, based on the premise that if the CO emissions began after the resident left for the day, the signal would need to last long enough for the resident to hear the signal on his or her return at the end of the day. Some CO detectors have a button to display the highest reading ever taken, so occupants can check for problems even after prolonged absences from the home.

CARBON MONOXIDE DETECTOR TECHNOLOGIES

Most commercially available carbon monoxide alarms use one of three detection technologies: biometric, metal-oxide semiconductor, or electrochemical.

Biometric

Biometric detectors are also called biomimetric, colorimetric, chem-optical technology, or gel-cell detectors. This sensor technology utilizes a material that mimics the response of human hemoglobin to carbon monoxide. In the presence of carbon monoxide, the amount of infrared light that will pass through the sensing material declines. The rate of change of the transmittance is used to calculate CO gas concentrations. Biometric sensors have demonstrated immunity to other gases that may be present and are not prone to false alarms.

Metal-Oxide Semiconductor

These detectors use tin dioxide (SnO_2) as a sensing element. The sensing material is heated by a heating element and CO gas is catalytically broken down at the surface. Electrons are released and reabsorbed by the tin dioxide. Electronics are utilized to measure the sensor resistance and from this to calculate the concentration of CO. These sensors have demonstrated excellent resistance to sensing other gases that may be present.

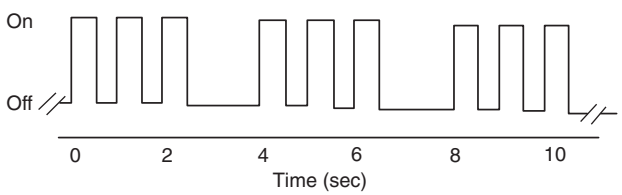

FIGURE 14.9.2 Temporal 3 Pattern Fire Alarm Evacuation Signal

Electrochemical

Electrochemical technology involves an acid electrolyte solution and platinum electrodes. The presence of carbon monoxide causes a chemical reaction that instigates a current flow through the circuit. This technology utilizes external circuitry to monitor the changes in potential and uses this information to calculate the concentration of CO. Electrochemical sensors are mechanically more complex than sensors using other technologies, but can provide much more accurate measurements of CO concentrations. These sensors have demonstrated good immunity to interfering gases.

RESPONSE TO CARBON MONOXIDE ALERTS

Occupant Response

The initial response by the occupant is to take "appropriate action" based on the knowledge that the CO detector has detected CO in the atmosphere. The recommended response includes the following:

- Opening windows to ventilate the area
- Assessing the medical condition of the occupants
- If necessary, calling the public fire service communications center (fire department)

In most cases, because of the low alarm threshold required by UL 2034, there is no need to call the fire department if the residence is immediately ventilated and appropriate service personnel are called to investigate the source of the CO. By the time service personnel (or the fire department responders) arrive, CO may no longer be present because the occupant took appropriate action by opening windows and doors. If any occupants are suffering from symptoms of CO poisoning and require medical attention, the emergency medical services system should be activated.

Emergency Service Response

Emergency response to CO alarms may be provided by first responders, primarily fire department and emergency medical personnel. The purpose of the first responders' action is to protect people, including themselves, from toxic levels of CO. In addition, utility company personnel or other "secondary responders" should respond to a CO alarm. The primary function of secondary responders is to service combustion equipment and appliances that are potential sources of CO.

SUMMARY

Hazardous concentrations of CO, a colorless, odorless gas produced by incomplete combustion, cause several hundred unintentional-injury deaths a year. The majority of these deaths occur in one- and two-family dwellings as the result of improp-

erly operating heating appliances, insufficient make-up air in the space; blocked, poorly designed, or poorly installed chimneys or vents; or a lack of vents. Additional sources of CO include idling vehicles in attached garages and portable equipment such as generators. For protection from toxic levels of CO, CO detection equipment is recommended in any family-living unit containing a fuel-burning appliance or fireplace or having an attached garage.

Chapter 10

Security and Intrusion Detection Systems

Shane M. Clary

Chapter Contents

A Brief History of Security
Security Vulnerability Assessment
Overview of Physical Security
Considerations for a Site Survey
Vaults and Safes
Components and Issues in Electronic Security
Electronic Security and Intrusion Detection Systems
Electronic Security and Access Control
Video Surveillance

Key Terms

central station, electronic premises security system, enhanced call verification, intrusion detection, security, security vulnerability analysis (SVA), site survey

Fire protection and security are interrelated. The installation of an electronic security system within the premises is part of the built environment. How it operates with other systems within the same building is integral to the complete protection platform that may be installed. Such platforms protect occupants, contents, structures, business operations and first responders.

Security has been on the minds of many people since September 11, 2001. Security has many facets, from the protection of our borders, background checks of future employees, physical security, private security force deployment, cybersecurity, electronic security countermeasures, and intrusion detection systems, to name just a few. This chapter will provide a brief overview of premises security systems that are covered by two documents that were approved by the NFPA membership and subsequently by the NFPA Standards Council in 2005:

- NFPA 730, *Guide for Premises Security*
- NFPA 731, *Standard for the Installation of Electronic Premises Security Systems*

This chapter contains very limited text from NFPA 730; the practitioner needs to obtain a copy for a full understanding of the document.

The designer of a premises security system should be familiar with both NFPA 730 and NFPA 731, as well as many other publications available through the literature. Practitioners need to be as familiar with the concepts and principles of security as fire protection engineers are with their skill set. The consequences of a poor design can be just as devastating to the property or building owner, or the victim of a crime that occurs at or within a protected facility, as lack of adequate fire protection.

Also see Section 1, Chapter 6, "Premises Security"; and Section 14, Chapter 7, "Fire Protection Surveillance and Security Services."

A BRIEF HISTORY OF SECURITY

Security in one form or another has been around since at least ancient Egypt, in which the first documented use of locks is recorded.[1] The use of locks is mentioned in both the New and Old Testaments of the Bible.[2,3] One of the first—if not the first—security alarm systems was developed and used by the Romans.[4] Geese were used as both the detector and notification appliance.

Early Technology

Security up to around the 1800s primarily involved the use of private and public security forces. Security was one aspect of their duties; watching for and sounding the alarm for a fire was another. This early linkage of fire and security marked the beginnings of electronic security as we know it today.

Shane M. Clary, Ph.D., is vice-president for codes and standards compliance at Bay Alarm Company in Pacheco, California. He is chair of the Fundamentals of Fire Alarm Systems Technical Committee, is a member of the NFPA Standards Council, serves on several NFPA technical committees, and is the author of the *NFPA Pocket Guide to Electronic Security System Installation*.

The first telegraph was patented in 1837 by Samuel Morse. It occurred to William F. Channing[5] of Boston, Massachusetts, that one should be able to use the technology of the telegraph to transmit the signal of a fire alarm. Up until this time, the transmission of the signal was done manually, generally by ringing bells to alert the fire companies. The use of electricity was new, however, and it was not until 1851 that the first system was approved for installation in Boston. By this time, Channing had teamed up with Moses G. Farmer, an electrical engineer who improved on the original design of the telegraph. This system was the first auxiliary municipal telegraph system, which used a series of 40 signal boxes, consisting of over 40 miles of wire installed throughout Boston and connected to a central station that would receive the signals. The system went operational on April 29, 1852.[6]

As word of this system spread, John N. Gamewell saw the potential of these systems in other cities. By 1859 he has secured most of the U.S. patents for this new technology. Unfortunately, the Civil War got in the way. Gamewell, being a native of South Carolina, was viewed by the United States government as being a supporter of the Confederacy. His patents were seized and sold. Gamewell was not able to return to his concepts and designs until after the end of the war.

While Gamewell continued to expand the fire alarm industry, Edwin Holmes was one of the first to see a need for electric burglar alarm protection. Holmes foresaw an industry that would be resistant to the financial swings of the time. He purchased the patent of Augustus R. Pope, who is thought to have patented the first burglar alarm system. Holmes set up his first shop in Boston, but the level of crime at that time was not sufficient to support an emerging industry. He therefore relocated to New York City. Even in the 1860s, intrusion detection systems were marketed as a deterrent to crime.[7]

The development of fire and burglar alarms continued on a parallel track. One of the most important innovations was the formation of the central station. A key contributor to this new technology was E. A. Calahan, who was also the inventor of the stock market ticker. In 1871, Calahan sold his central station patents to a syndicate of investors in New York City, who formed the American District Telegraph Company. By 1874, they had opened sixteen central stations in the New York City area, twelve being in Manhattan. A number of these central stations shared facilities with Western Union. Over time, American District Telegraph began to offer fire alarm systems in addition to burglar alarm systems. This did not go unnoticed by Gamewell, who in Boston, began to offer security systems.

A key development during this time was the invention of the McCulloh circuit. Up until this time, any break in the circuit would prevent signals from being received until the fault was cleared. Chauncey F. McCulloh designed a circuit that restores or reroutes a circuit around a single fault. This greatly improved the reliability of the signal transmission from the premises to the central station.

As this work was being done, Holmes was developing sensor technology that could be used to automatically detect an intrusion. Systems up until this time were still manual, in that the building occupants had to trip the system to transmit a signal to the central station. This was before the use of telephones and was, at that time, the fastest way to summon assistance. Holmes used a system of protective wiring, metallic foil, and brass contacts. He also developed a use for the galvanometer with directly connected systems so that each premises system could have a unique identifier.

Shift in Technology

Some of the technology that was developed during the 1800s was still in use in the 1990s. Although McCulloh circuits have been replaced, directly connected circuits are still in use. The brass contact has been replaced by the reed contact switch and foil has been replaced by audio discriminators or glass break detectors. Advances in this technology have transitioned from McCulloh and direct connect circuits to digital dialers, long-range radio, and, within the past several years, broadband. Detection technology, as described later in this chapter, has moved from protective wiring, foil, and contacts to space protection, sound and vibration detection, and contacts. The security practitioner needs to know the strengths and weaknesses of both the transmission methods and detection technologies.

SECURITY VULNERABILITY ASSESSMENT

The practitioner must take into consideration the entire property to be protected and the level of the threat against which one is trying to provide protection. Before any design work can be performed, a security vulnerability assessment (SVA) must be performed. According to NFPA 730, an SVA is "a systematic and methodical process for the following: (1) Examining ways an adversary might exploit an organization's security vulnerabilities to produce an undesired outcome [and] (2) developing countermeasures to address adversarial events." NFPA 730 further describes an SVA as "a technique for assessing the current status of an organization's threat exposures, security features and preparedness and can be used in developing and strengthening both security and safety layers of protection."[8]

Steps of an SVA

NFPA 730 outlines seven steps that should be taken as part of the SVA.

Formation of a Team. The team may be made up of both outside experts and key members of the facility to be protected. The goal is to receive as much relevant input as possible to design a system or program that will meet the needs of the end users.

Organization/Facility Characterization. This step involves the identification of assets; physical features and operations; laws, regulations and corporate polices; social and political environment; and internal activities.

Threat Assessment. Threat assessment includes the classification of critical assets, identification of potential targets, consequence analysis, and definition of potential threats.

Threat/Vulnerability Analysis. The threat/vulnerability analysis includes the identification of actual and potential threat scenarios and estimation of a relative security risk level.

Define the Specific Security Countermeasures. All the information obtained in the first four steps are analyzed to develop effective countermeasures to mitigate the defined threats and reduce the security risk.

Assess Risk Reduction. Take into account the countermeasures defined in Step 5 and reassess the relative security risk levels that were developed in Step 4 and consider additional security risk reduction measures that may be appropriate.

Document Findings and Track Implementation. Produce a written document of the findings and recommendations. The report would also track the implementation of the accepted recommendations.

With respect to Step 5 (Define the Specific Security Countermeasures), the practitioner should consider how to increase existing security layers for the premises. There should be a focus on the concentric circles of protection design methodology, as shown in Figure 14.10.1.

Primary Protection Elements

The SVA methodology considers four primary protection elements: deter, detect, delay, and respond.

- *Deter:* discouraging an adversary from attempting an assault by reducing the likelihood of a successful attack
- *Detect:* determining that an undesirable event has occurred or is occurring; includes sensing the event, communicating the alarm to an attended location, and assessing the alarm

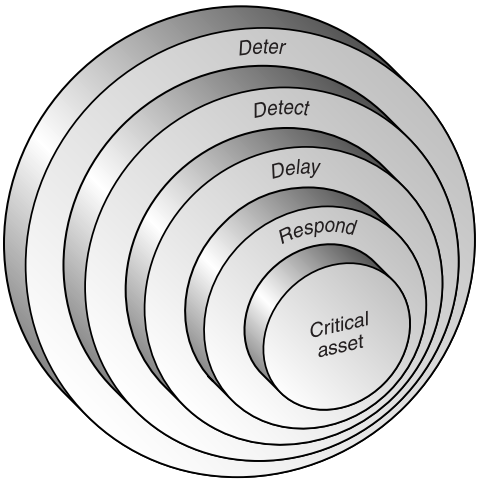

FIGURE 14.10.1 Concentric Circles of Protection (Source: NFPA 730, *Guide for Premises Security,* 2006, Figure A.5.2.5)

- *Delay:* impeding adversary penetration into a protected area
- *Respond:* counteracting adversary activity and interrupting the undesirable event

The threat level may be placed into three categories as shown in Table 14.10.1.

OVERVIEW OF PHYSICAL SECURITY

Security for the protection of a premises can be divided into two broad categories: physical security (environmental design) and electronic security.

TABLE 14.10.1 Threat Analysis Guidelines

Threat Level	*Nature of Threat*	*Required Capabilities*
Low	Stand off surveillance/espionage Minimum/occasional penetration Limited pilferage Minor demonstrations	Denial of surveillance and penetration Detection and deterrence of intruders Selective surveillance of critical areas Apprehension of pilferers
Medium	All of low threat intensified Sabotage Harassment Minor destruction and disablement Dissident demonstrations	Intensify response to low threat Earlier detection Immediate response (small groups) Increased mobility of response forces Identification and location of sabotage Capture of intruders
High	All of medium threat intensified Organized attack/armed conflict Major destruction Combat intelligence	Intensify response to medium threat Complete penetration denial Immediate response (large and small groups) Armed resistance, capture, destroy Sabotage detection and prevention Remote controlled and/or automated response capability Interface with allied forces

Crime Prevention Through Environmental Design (CPTED)

Generally, when one thinks of physical security, an image of fences, gates, and exterior lighting may come to mind. Although these are all forms of physical security, the practitioner must take into consideration the entire site, and if practicable the local environment as well. Crime prevention through environmental design (CPTED) is a holistic approach in which individual citizens and law enforcement come together to apply security concepts to entire neighborhoods or major urban districts, as well as urban subsystems such as a public venue.[9] CPTED is made up of four general principles:

- *Natural surveillance:* provides features that allow for intruders to be readily seen; this would include windows and doors that face streets and well-lit parking lots and sidewalks
- *Territorial reinforcement:* creates a sphere of influence; sets and defines the private property and spaces from public property and spaces
- *Natural access control:* creates a perception of risk; provides gateways that are clearly public and discourages access to private areas
- *Target hardening:* uses window locks, door locks, fencing

Although CPTED should be considered for new large-scale projects or in areas that over time have demonstrated a history of security-related issues, it may not be warranted or possible for a single site.

Role of the Site Survey

Before beginning any security-related project, the practitioner needs to conduct a site survey. Even if the project has yet to be constructed, the designer needs to review the local environment in which the facility will be located. This would include a review of crime statistics for the geographic area. If the facility already exists, the practitioner needs to perform an extensive review of the security features that are in place as well as the general construction of the facility.

CONSIDERATIONS FOR A SITE SURVEY

A site survey deals with the exterior of a premises. Several key components should be taken into consideration when performing an examination or specifying physical security:

- Physical barriers
- Lighting
- Locks
- Glazing
- Passive barriers

Physical Barriers

Physical barriers can be both natural and structural. Natural barriers include mountains, cliffs, canyons, rivers, or other terrain that is difficult to traverse. Structural barriers include fences, walls, bollards, floors, and roofs.

One of the most common types of fence used today is the chain-link. Chain-link fencing can be used almost anywhere there is a need to define the physical boundaries of a facility. To be most effective, a chain-link fence should be designed and installed to a nationally recognized standard. For chain-link fencing this standard is ASTM F567, *Standard Practice for the Installation of Chain-Link Fence*.

When possible, the fence line should be located no closer than 50 ft (15.2 m) to the buildings or outside storage areas, and 20 ft (6.1 m) to other areas. Chain-link fencing comes in a variety of heights; the most common for commercial and industrial use is 8 ft (2.4 m). Depending on the risk to the premises, greater heights can be specified. When an 8 ft (2.4 m) fence is specified, 7 ft (2.1 m) is for the fabric and the top foot is for a top guard. Posts are used to secure the fabric. For a fence with 7 ft (2.1 m) of fabric height, the posts should be set in concrete at a minimum depth of 36 in. (0.9 m). The line posts should be spaced equidistant at intervals not exceeding 10 ft (3 m). End posts, if used, should be set within 2 in. (50 mm) of building walls. A top tension wire should be provided as a support for the fence fabric. A top rail can also be used if appearance is critical but should be avoided as it provides a handhold for one that is attempting to climb over the fence. The fabric of a fence should be steel wire, No. 9 gauge or heavier. The fabric needs to be stretched taught and securely fastened to the posts. The bottom of the fabric should extend to within 2 in. (50 mm) of the hard ground or paving. For soft ground, the fabric should extend below the ground. The top of the fence should be provided with a top guard to deter attempts at climbing the fence. A top guard should be made up of three strands of No. 12 gauge barbed wire, at an angle of approximately 45°. For those facilities that require a higher level of protection, razor ribbon should be considered.

Lighting

The purpose of lighting is to provide and enhance visibility and deter intrusion. The use of protective lighting should be considered both along the fence line and the outside of the premises. Table 14.10.2 provides the recommended minimum illumination levels for fencing. Table 14.10.3 gives recommended minimum intensities for outdoor protective lighting for pedestrian and vehicle use areas among others. The practitioner should also

consult the *Lighting Handbook*, 9th edition, published by the Illuminating Engineering Society of North America (IESNA).

There are a number of light sources that may be considered, based upon the application, including incandescent, fluorescent, and high-intensity discharge (HID). Types of HID lamps include mercury vapor, metal halide, and high-pressure sodium. In addition to the light source, the luminaire must also be considered. The luminaire is a complete lighting unit consisting of a lamp or lamps together with the parts designed to distribute the light, to position and protect the lamps, and to connect the lamps to a power source. The four general types of luminaires used for protective lighting are floodlights, streetlights, Fresnel lens units, and searchlights.

Locks

As mentioned above, locks in one form or another have been around since around 3000 B.C. Table 14.10.4 shows the categories and subcategories of locking systems that are in use today. The practitioner must take into account the level of protection required, the type of door or access portal in which the locking system is to be installed, and the type of key control system that is to be used. If tracking of personnel entering or leaving a secured area is required, the use of an access control system should be considered.

TABLE 14.10.4 Lock Types

Category	*Type*
Mechanical locks	Mortice Rim
Electrical locks	Electric solenoid bolts Electric strikes (fail secure, fail safe) Monitor strikes Motor lock
Electromagnetic locks	Direct hold Shearlock

Source: *NFPA Pocket Guide to Electronic Security System Installation,* 2005, Exhibit IV.33.

Locks are designed to provide various levels of deterrence or delay to entrance. Prior to laying out any locking and access control system, NFPA *101®*, *Life Safety Code®*, *NFPA 5000®*, *Building Construction and Safety Code®*, or the locally adopted building and fire codes should be consulted. It is vital that individuals within a premises are not trapped inside during an emergency event.

Although locking mechanisms that act to prevent access to buildings, floors, or specific rooms are permissible, these locks can in no way impede free egress from the space.

Glazing

Glazing or windows provide a means for natural light from the outside of a premises to be transmitted to the inside. Glazing can also be one of the weakest points of protection for a building. A common method of gaining unauthorized entry into a building is by the method of "smash-and-grab." Glazing can be decorative as well as resistant to attack and bullets. The types of glazing material that can be designed to be burglary-resistant include laminated glass, acrylic, and polycarbonate. When selecting the type of burglary-resistant glazing material to use, the practitioner should use UL 972, *Standard for Burglary Resistant Glazing Material*, 2002, and UL's *Burglary Protection Equipment Directory* as a guide. The directory may also be accessed via the Internet at http://database.ul.com/cgi-bin/XYV/template/LISEXT/1FRAME/index.htm.

In addition to the types of glazing material shown, these materials with the addition of composites may be used for bullet-resisting glazing material. Underwriters Laboratories (UL) has established eight ratings for bullet-resisting glazing material, Levels 1 through 8, based on penetration resistance from medium-, high-, and superpower small arms; high-powered hunting and sporting rifles; submachine guns; assault rifles; and shotguns.

Passive Barriers

Passive barriers, designed to blend into the background of a building or site as a design feature, are in place to deter or delay an attack—not only the smash-and-grab attack but also the crash-and-grab, in which a truck or other vehicle is driven into a building. This method of attack can be used not only for burglary but also by a hostile force attempting to place an explosive device in or near a building. The basic types of passive barriers are concrete planters, bollards, and Jersey barriers. See Figures 14.10.2 through 14.10.4 for examples of each.

VAULTS AND SAFES

Depending on the facility and its use, the practitioner may also have to consider using vaults and safes.

Vaults

The practitioner should be familiar with UL 608, *Burglary Resistant Vault Doors and Modular Panels.* There are four

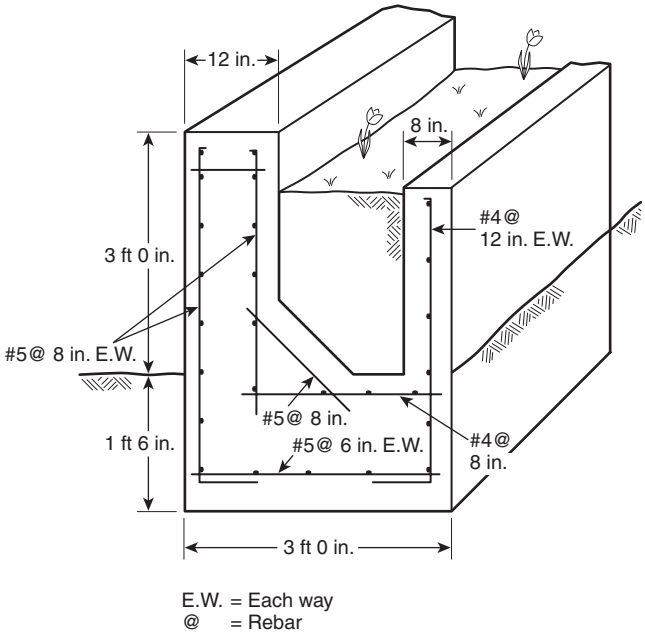

FIGURE 14.10.2 Concrete Planter (Source: NFPA 730, *Guide for Premises Security,* 2006, Figure 6.9.1.1)

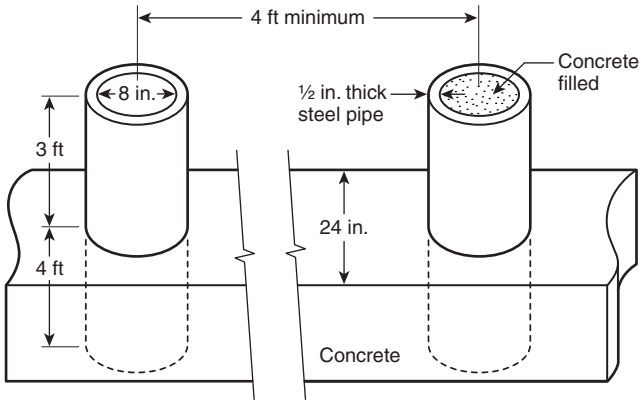

FIGURE 14.10.3 Concrete-Filled Bollard (Source: NFPA 730, *Guide for Premises Security,* 2006, Figure 6.9.2.1)

classifications for vault doors and walls, based on the time that the vault will resist the efforts of an attack:

- Class M ¼ hour
- Class 1 ½ hour
- Class 2 1 hour
- Class 3 2 hours

Alternate means of vault construction allows the use of reinforced concrete, steel lining, reinforced concrete blocks, or a combination of these materials. Table 14.10.5 shows the reinforced concrete equivalencies for the four types of UL-listed vault doors and modular panels.

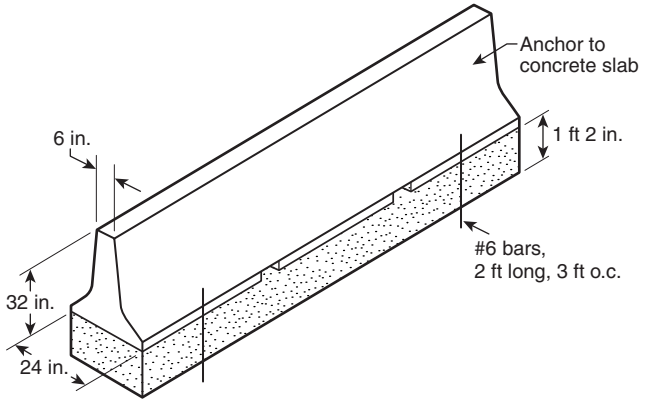

FIGURE 14.10.4 Jersey Barrier (Source: NFPA 730, *Guide for Premises Security,* 2006, Figure 6.9.3)

Safes

If the use of a safe is being considered, the practitioner should refer to UL 687, *Burglary Resistant Safes*. UL rates burglary-resistant safes according to the length of time a safe will resist attack. A UL label affixed to the door of the safe will identify that the safe has been listed by UL. UL-listed safes must also have a combination lock rated as Group 1 or 1R in accordance with UL 768, *Standard for Combination Locks*, and have a relocking device. The group rating signifies the ability of a mechanical lock to withstand expert manipulation. A Group 1 lock must be able to withstand 20 man-hours of expert manipulation. The Group 1R lock has this same specification, as well as being X-ray resistant. The UL-listed safe must also weigh a minimum of 750 lbs (340.2 kg) or be provided with a means of anchoring the safe to the premises. Table 14.10.6 shows UL-listed safe ratings.

COMPONENTS AND ISSUES IN ELECTRONIC SECURITY

Components of electronic security include central station monitoring, exterior and interior intrusion detection systems, access controls, and video surveillance. As mentioned previously, electric and now electronic security protection has been in place since the 1850s. Although the basic principles remain the same, the methods and technology have changed. The first advances from the technology of the 1800s occurred with the development of the ultrasonic detector by Sam Bagno[10] in 1948. This was the first form of volumetric protection using the Doppler effect to trigger the system.

Central Station Monitoring

The second great advance was the use of multiplex and the digital dialer. Prior to this innovation, signals were transmitted to the central station by either the McCulloh circuit or by means of a direct wire connection. These two means of signal transmission limited the distance that the central station could be from the protected premises. Central stations were generally located

TABLE 14.10.5 Reinforced Concrete Equivalencies to UL-Listed Vault Doors and Modular Panels

UL Classification	Thickness of Reinforced Concrete *in.*	*cm*	*Reinforcement Number of Rows of #5 Rebars*	*Reinforcement Number of Grids of Expanded Metal*
Class M	9	22.9	2	2
Class 1	12	30.5	3	2
Class 2	18	45.7	4	3
Class 3	27	68.6	5	4

near a telephone company's central office. During the 1960s the telephone companies began to notify the industry that copper or metallic circuits would in time no longer be available for use. These circuits were classified by the telephone industry as being Series 1000, which only carried direct current. The telephone industry now had Series 3000 circuits, which were of voice grade and carried alternating current. These circuits provided faster transmission rates and more data to be sent and received. Although there were attempts to digitize the McCulloh signal, by 1974 AT&T abandoned its efforts.

By the mid 1970s, a number of firms provided multiplex transmitters and receivers. Despite being more expensive than

TABLE 14.10.6 Safe Ratings

Rating	*Attack Tools*	*Body Construction*	*Area(s) of Attack*	*Entry Requirements*	*Attack Times*
TL-15	Common hand tools, picking tools, mechanical or portable electric tools, grinding points, carbide drills, and pressure applying devices and mechanisms	One-in. (25.4 mm) open hearth steel, or its equivalent, having a tensile strength of 50,000 psi (3,515,347 g/cm^2) or equivalent material	Door and front face	Opening the door or making a 6 in.^{2} (38.71 cm^2) opening	15 minutes
Record Safe	Same as TL-15 and including fishing and trapping devices and mechanisms			Same as TL-15 and including fishing and trapping	
TL-30	Same as TL-15 and including abrasive cutting wheels and power saws			Same as TL-15	30 minutes
TRTL-30	Same as TL-30 and including the oxyacetylene torch	Same as TL-15, with body encased in 3 in. (36.2 mm) of reinforced concrete or constructed of equivalent material	Door and front face	Opening the door or making a 2 in.^{2} (12.9 cm^2) opening	30 minutes
TL-15×6	Same as TL-30	Composite materials	Door and body	Same as TL-15	15 minutes
TL-30×6					30 minutes
TRTL-15×6	Same as TL-30 plus impact tools	Composite materials	Door and body	Same as TRTL-30	15 minutes
TRTL-30×6					30 minutes
TRTL-60×6					60 minutes
TXTL-60×6	Same as TRTL-15×6 plus explosives				

Notes: TL = Tool resistant.
TRTL = Torch and tool resistant.

Source: *NFPA Pocket Guide to Electronic Security System Installation,* 2005. Originally in UL 687, *Standard for Burglary Resistant Safes,* Underwriters Laboratories, Northbrook, IL, 2000.

McCulloh and direct wire, they did provide more information from the protected premises than the former technologies. The central station could now begin to receive zone annunciation from a single transmitter, allowing the central station to have a clearer picture of where the signal was coming from within the protected facility. As the multiplex system was constantly poling between the receiver and the transmitters, the central station could always be aware of the status of the phone line and the transmitter. With further advances in cryptographic transmission methods, multiplex transmissions are still used today for high-security assets.

But multiplex did not solve the larger problem of freeing the central station industry from its dependence on the Bell Operating Companies. Developed during the late 1970s and early 1980s, the digital dialer allowed the transmission of signals via Plain Old Telephone Service (POTS) lines. With the release and use of this technology, the central station was no longer required to be near the central office. A new industry of third-party central stations came into being, and the local alarm company no longer had to maintain their own central station. Today, although there are a number of firms that operate their own central stations, the majority of firms use a third-party central station. Although either type of firm can provide a high level of service, the practitioner should inquire into the location of the central station and whether it is operated by the security provider. In some cases, the central station may be located thousands of miles from the protected premises. The practitioner should always review the signal handling protocols of the central station and be aware of any restrictions that the local law enforcement provider might have placed on the response to alarms.

Issues in Electronic Security

Enhanced Call Verification. At the present time, a number of law enforcement agencies are requiring the use of Enhanced Call Verification, in which the protected premise and then a subscriber are contacted prior to making a service call. Although this has been successful in reducing the number of false alarms, it does insert a delay in the actual response. A number of agencies have promulgated ordinances that there is to be no response until the alarm is physically verified to ensure that an intrusion has occurred. This is a new concept. In bygone days, the police would respond prior to a third party verifying that an actual break-in had occurred.

Line Security. Digital dialers or communicators have one weakness that other transmission methods do not have, which is line security. When the phone line is cut from a premises that has a digital dialer, the central station will not be made aware of the loss. Other forms of signal transmission, including McCulloh, direct wire, multiplex, derived channel and long-range radio, provide the central station with an indication that a break has occurred. The practitioner needs to determine during the risk assessment phase if a backup communications path is required. The most common methods today are via cellular phone transmission or long-range radio. These methods may also be used as the primary path. If POTS is to serve as the primary means, the phone line should be supervised, either locally or by a second path. The supervision detects the voltage on the phone line. When the voltage is decreased or cannot be detected, the alarm control unit at the premises will activate a local trouble alarm or will transmit a supervisory signal over the second path to the central station. The practitioner should either review or specify the procedure that will be followed by the central station and the responsible party of the premises in the event of a lost phone line.

Broadband Communications. At the time that this chapter was written, broadband communications or the Internet was starting to be used for signal transmission. As with any new technology, there may be bends in the road before the final results are known. The practitioner should verify the operation of this method of signal transport if it is to be considered.

ELECTRONIC SECURITY AND INTRUSION DETECTION SYSTEMS

Intrusion detection systems can protect both the exterior and interior of a premises. The security practitioner should be familiar with NFPA 731, *Standard for the Installation of Electronic Premises Security Systems*, when laying out an intrusion detection system, closed-circuit television (CCTV) system, or access control system. One of the objectives of the risk assessment and site survey is to determine the level of protection to be provided. In addition to physical security as discussed previously, various forms of electronic security may also be seen as being appropriate.

UL Certification

Depending on the value of the property being protected, the practitioner may specify that the installed intrusion detection system be certificated by Underwriters Laboratories Inc. UL provides third party oversight and review of security systems that are installed in accordance with UL 681, *Standard for Installation and Classification of Burglar and Holdup Alarm Systems*. UL 681 provides a number of levels of protection or extents that the designer can specify. As the extent of protection increases, the level of detection within the premises increases. Table 14.10.7 provides an overview of the UL protection extents.

Exterior Detection

Exterior sensors must have a high probability of detection for all types of intrusions and a low unwanted-alarm rate for all expected environmental and site conditions.

The designer, in addition to the threat and risk assessment, needs to take into consideration the cost of the protection, both the equipment and its installation, as well as the cost of maintaining the equipment after the installation. For example, methods and equipment used for a power plant may not be required for a lumber storage yard.

Exterior devices include the following, several of which will be discussed in more detail:

- Audio
- Contacts
- Motion detection

TABLE 14.10.7 Extents of Intrusion Detection Protection for Premises and Stockrooms

Extent of Protection		External Openings				External Surfaces	
		Accessible	*Inaccessible*	*Movable Accessible*	*Movable Inaccessible*	*Walls, Floors, and Ceilings*	*Special Considerations*
4		Partial (2)					Contacts on at least two interior doors; or motion or sound detection on one or more selected areas; or one or more channels of radiation to limit movement within the premises.
3	Perimeter	Complete					
	Motion (4)			Partial (2,5)			Four-step (6) movement in each enclosed area with external openings.
	Sound			Partial (5)			Sound detectors in each enclosed area with external openings. Limited to buildings with good acoustical qualities.
	Channels			Partial (5)			Minimum length of beams equal to longest dimension of each enclosed area with external openings. Motion detectors can be used for channel protection.
2	Perimeter	Complete (3)			Partial (5)	Complete (7)	Exterior surfaces of monolithic concrete do not require protection.
	Motion			Partial (5)			Four-step (6) movement in each enclosed area with external openings.
	Sound			Partial (5)			Sound detectors in each enclosed area with external openings. Limited to buildings with good acoustical qualities.
	Channels	Complete (3)					Beams arranged to divide each enclosed area with external surfaces into at least three subdivisions. Maximum 1000 ft^2 for each subdivision.
1	Perimeter	Complete (3)	Complete (3)			Complete (7)	Protective wiring installed on all external surfaces.
	Sound or Vibration			Partial (5)	Partial (5)		Detectors adjusted to initiate an alarm if a manhole size opening is created in an opening, ceiling, floor, or wall.

Notes

1. Accessible means less than 18 ft (5.5 m) for grade or adjacent roofs; less than 14 ft (4.3 m) from horizontal openings; or less than 3 ft (0.91 m) from openings on same wall.
2. Doors only.
3. Complete protection of an opening means wiring or other recognized means applied to protect the opening (fixed or movable) plus contacts on movable openings.
4. Motion detection is provided by equipment such as ultrasonic, microwave, and passive infrared motion detectors. It is installed throughout each area.
5. Partial protection means a contact installed on a movable opening.
6. Four-step movement is a means of confirming volumetric radiation coverage by performing a series of walk tests through the enclosed area.
7. Complete protection of a surface means wiring or other recognized means to protect a wall, floor, or ceiling.

- Fence strain system
- Protective cabling
- Electric-field system
- Proximity
- Shock sensors
- Stress sensors
- Photo-electric cell
- Leaky coaxial

Motion Detection. The principal type of motion detection used for exterior protection is the microwave. Microwave detection sensors are categorized as bistatic or monostatic. Bistatic sensors use transmitting and receiving antennas located at opposite ends of the microwave link. Monostatic use the same antenna. Care should be taken when selecting a microwave detection system so that the field of detection does not extend beyond the area to be protected. Microwave energy can extend beyond the intended target area and cause false alarms from movement outside of the protected field.

When it has been determined that a fence is to be protected by a detection system, a paramount consideration in selecting the detection system is that the false or unwanted alarm rate is low. The fence itself must be in good condition and meet the minimum requirements of the detector's manufacture.

Fence-Strain System. The fence-strain system uses cables as transducers that are uniformly sensitive along their entire length. They generate an analog voltage when subject to mechanical distortions or stress resulting from fence motion.

Electric-Field System. An electric-field system consists of an alternating-current field generator, one or more field wires and one or more sensing wires, and a signal processor. The generator excites the field wires around which an electrostatic field pattern is created. The electrostatic field induces electrical signals in the sense wires, which are monitored by the signal processor.

Capacitance-Sensor System. A capacitance-sensor or proximity sensor measures the electrical capacitance between the ground and an array of sense wires. Any change in capacitance caused by an intruder approaching or touching one or more of the sense wires initiates an alarm.

Leaky Coaxial Cable System. Leaky coaxial cable (LCX) has been used for a number of years for perimeter protection. This method is also referred to as a ported cable system. The system involves lining the perimeter with two parallel LCX cables buried just below the surface of the ground. The depth is determined by the manufacture and coverage the designer wishes to obtain. These cables are generally buried in soil, but they can also be placed underneath asphalt and concrete. The LCX cable is slotted or ported so as to allow RF energy to be released. Two LCX cables are run parallel, one for transmission and the second for receiving. This generates a constant volume of EM field above the ground. Movement of objects with high capacitive properties above the cables will disturb the field, leading to detection when the coupled signal deviates from the stable reference signal.[11]

Interior Detection

Interior detection includes both perimeter and space detection. Perimeter protection is installed along the perimeter of the premises—doors, windows, walls, and roofs. Space protection provides detection within the interior of the premises.

Interior devices include the following, several of which are discussed further:

- Protective wiring
- Foil
- Traps
- Shock sensors
- Glass break sensors
- Sound detectors
- Motion detectors

Protective Wiring. Protective wiring is primarily found in older systems. The designer may find these methods useful for the protection of vents, skylights, and high windows. Protective wiring within mesh screens are still in common use for residential applications.

Shock Sensors. Shock sensors detect any vibration caused by attempted forced entry. The practitioner should take care in their application and avoid locations subject to high vibrations.

Glass Break Sensors. Glass break sensors are both audio (sound discriminators) and shock. They are activated by the frequency of breaking glass, or a combination of the frequency of breaking glass and the shock or vibration to the structure of the glass being broken. The use of glass break detectors has replaced the used of foil as the principal method of protecting glass. The practitioner should be aware that the placement of various films on the glazing material may dampen the effectiveness of the detector.

Sound Detectors. Sound or audio detectors can be used effectively to protect enclosed areas, vaults, warehouses, and similar enclosures. Microphone speaker sensors are installed on walls and ceilings of the protected area. The sensitivity of the system can be adjusted.

Motion Detectors. Motion detectors include microwave, passive infrared (PIR), two or more technologies (hybrid), and video motion. As discussed previously, the first form of motion detection was ultrasonic. Due to a high probability of false alarms, this method of space detection is rarely used today. The designer must use care in selecting and placing these detectors. Improper placement of these otherwise effective devices causes false and unwanted alarms.

Microwave. Microwave detectors used for interior detection are typically monostatic. The shape of the transmitted beam is a function of the antenna configuration. A variety of detection

patterns can be generated. Movement in the area will produce a Doppler frequency shift in the reflected signal and will produce an alarm if the signal satisfies the sensor's alarm criteria. Microwave detectors are best at detecting movement toward and away from the source. The practitioner should use care in selecting and placing this detection technology. Microwave energy can pass through glass doors and windows as well as lightweight walls or partitions constructed of plywood, plastic, or fiberboard. Microwave motion detectors are also susceptible to fluorescent lighting.

Passive Infrared. Passive infrared motion sensors detect a change in the thermal energy pattern caused by a moving intruder and initiate an alarm when the change in energy satisfies the detector's alarm criteria. The sensor's detection pattern is determined by the arrangement of lenses or reflectors. The pattern is not continuous but consists of a number of fingers, one for each mirror or lens segment. Numerous detection patterns are available, and the designer should select the one which meets the requirements of the protected space. PIR motion sensors are best at detecting movement across the field of view. PIR detectors should not be pointed toward a heat source or outside window that may catch the lights of traffic during the evening hours. Under no circumstances is a PIR motion detector that is listed for security to be used as part of an automatic fire detection system.

Video Motion. Video motion detection (VMD) combines space protection and closed-circuit TV (CCTV). A camera is mounted to cover the field of view. The active component for the VMD is not within the camera, but is a part of the processing equipment that is located at the receiving and viewing end of the system. During the programming of the system, active cells are selected within the field of view that is displayed by a camera to the monitor. When an object passes through an active field, the VMD will detect the movement and trigger an alarm. Detection is caused by the stable static view being disturbed by the motion through the active cells within the field of view.

ELECTRONIC SECURITY AND ACCESS CONTROL

Another form of electronic security is the access control system. Access control systems can control, restrict, and track the flow of personnel and visitors through a protected premises. The components of an access control system are controllers, readers, and tokens and credentials.

Controller

The controller is the front end of most access control systems. The controller may be a stand-alone unit or integrated with a computer. The controller contains information related to time schedules, access groups, and enrolled personnel. Before laying out any access control system, the practitioner should be familiar with the operating protocols of the premises. For larger systems the use of groups and access areas may come into play.

Readers and Credentials

Readers and credentials are closely related. The type of reader selected will dictate the type of credential to be used, and vice versa. Card readers may be of the following types:

- Hollerith
- Magnetic stripe
- Barium ferrite (BaFe)
- Radio frequency identification (RFID) (Proximity)
- Bar code
- Wiegand

Table 14.10.8 compares these systems according to various factors.

For enhanced security the practitioner may use biometric readers, which require a unique data set from the holder of a credential. Biometric credentials may be one of the following:

- Hand/finger geometry

TABLE 14.10.8 Comparison of Reader/Card Technologies

Card Type	*Technology*	*Durability*	*Resistance to Compromise*	*Reprogramming*	*Cost*
Magnetic Stripe	Magnetic media stripe	M	M	Y	L
BaFe	Magnetic pattern	H	M	Y	L
Wiegand	Magnetic pattern	H	H	N	M
Bar Code	Light/dark patterns	L	L	N	L
Hollerith	Hole patterns	L	L	N	L
Proximity	Electromagnetic	H	H	N	M

Notes:
L = Low
M = Medium
H = High
Y = Yes
N = No

- Fingerprints
- Handwriting
- Eye scan
- Voice recognition
- Face recognition

VIDEO SURVEILLANCE

Video surveillance systems, or CCTV, allow one to view and capture images from a protected location. The basic CCTV system is made up of a camera and monitor. If the image is to be captured for future viewing, then a recording device is required. CCTV systems can vary from a single camera with no recording device, perhaps located in a small mercantile shop for the manager to view the sales floor from the office, to systems that have over 1000 cameras with multiple monitors and recording devices, such as in a gaming establishment. Systems can monitor conditions both inside and outside the building.

The most important question that the practitioner must consider is "What is to be viewed?" Is the target to be the transactions that occur at a point-of-sale or activity along an exterior fence line? Does the system need to make out a car's license plate number or just the type of vehicle? The entire image recorded is the *field of view*; the focus of attention, such as a license plate, is the *critical viewing area.* For cameras placed to record images at a point of customer transactions, such as a teller window, the critical viewing area (face) should cover 15 percent of the camera's field of view under normal resolution. Action within the scene should cover at least 20 percent or more of the overall width of the field of view. The designer should always consider the appearance of the final image when making camera and lens selections.

CCTV cameras that are produced today for the majority of systems are charge-coupled device (CCD) units. Table 14.10.9 provides an overview of the various types of CCD cameras that are available at the time this chapter was written.

CCD cameras come in a variety of imager formats, the most common being the following:

- ¼ in.
- ⅓ in.
- ½ in.
- ⅔ in.
- 1 in.

The imager format is the usable part of the imager that is to be used. It is measured diagonally across the chip. The format of the camera will affect the view provided by the lens selected. The practitioner must look at both the camera format and the lens in order to make certain that the view selected is the view achieved.

Field of View

One can calculate the field of view by scene width as shown in Equation 1 or by scene height as shown in Equation 2.

TABLE 14.10.9 CCD (Charge-Coupled Device Cameras)

Camera Type	*Light Type*	*IR Sensitivity*	*Resolution*	*Lag Time*	*Retain Image*	*Auto-Iris Lens*	*Expected Life*
C-MOS/CCD	Full/fairly consistent 20–50 lx	Extreme high 1050–1300 nm average	Good/fair—Inside Fair/poor—Outside 300–400 TVL	None	None	Dependent on application	3–5 years dependent on conditions
Interline Transfer CCD	Low/full variable 3–5 lx	Extreme high 1050–1300 nm average	Very good to good 350 TVL & up average	None	None	Dependent on application	3–5 years dependent on conditions
Frame Transfer CCD	Low/full variable 0.1–5 lx	Excellent 800–850 nm	Excellent to very good 400 TVL & up	None	None	Dependent on application	3–5 years dependent on conditions
Hyper HAD CCD	Note 1 1–50 lx	None	Very good to good 375 TVL & up	None	None	Dependent on application	3–5 years dependent on conditions
Intensified CCD	Low/full variable .003 lx	None Visible light only	Good to fair 275 to 400 TVL	Note 2	Chip-None Note 3	Always	1–2 years dependent on conditions

Editor's Note: The CCD camera is the most popular CCTV camera in use at this time. They are entirely solid state.
Notes:
1. Due to design of chip, telephoto lenses will produce a sharper image.
2. The method of light amplification that is used will determine the amount of lag time in lower light conditions.
3. It is possible to burn an image into the 2nd generation intensifier that may be used in these cameras.

nm = nanometers
TVL = TV lines

Source: Exhibit V.9, *NFPA Pocket Guide to Electronic Security System Installation,* 2005. Originally in Charlie Pierce, *Application & Design of CCTV,* LeapFrog Training & Consulting, Davenport, IA, 2002, p. 28.

$$f = c\left(\frac{d}{w}\right) \quad (1)$$

where

c = Width of the charge-coupled device (CCD) chip

d = Distance from camera

w = Width of field of view

f = Focal length of camera lens

$$f = v\left(\frac{d}{h}\right) \quad (2)$$

where

v = Height of CCD chip

d = Distance from camera

h = Height of field of view

f = Focal length of camer lens

Another method takes into account the total critical viewing area as a percentage of the monitor. If the critical object takes up only a quarter of the total field of view within the monitor, then it would be 25 percent of the view. If the critical object took a third of the total field of view it would be 33.3 percent of the view and so forth (Table 14.10.10). Calculate the viewing area of the scene and also of the critical viewing area by multiplying the horizontal and vertical dimensions. Divide the critical viewing area by the total viewing area to obtain the critical viewing area in the monitor.

If the proportion of the critical viewing area is as expected, use the calculated focal length. If not, then change the focal length until the correct proportion is found, or change the distance of the camera until the correct proportion is found. In some cases, the solution will be in a new lens being selected.

Lenses

Lenses come in a number of formats. Table 14.10.11 lists common lens formats used with CCD cameras. The designer should use a field of view calculator to make the final determination. These calculators are available from most lens manufacturers. To select the proper lens for the format of the camera and the field of view, the designer should make an object distance calculation (Figure 14.10.5). When calculating the target view of the camera, the object distance must be considered. In addition to the actual distance of the camera from the target, the height of the camera must also be taken into consideration. The Pythagorean theorem is used in part to calculate the actual view distance. The square root of the number calculated is the object distance. Once the actual object distance is known, the designer can calculate the target size for a given, as seen in Table 14.10.12. CCTV cameras use a 4:3 aspect ratio. As such, the vertical view will always be 75 percent of the size of the horizontal view.

TABLE 14.10.10 Viewing Area as a Percentage of the Monitor

Camera Formats (in.)	*Horizontal (mm)*	*Vertical (mm)*
1/4	3.2	2.4
1/3	4.4	3.3
1/2	6.4	4.8
2/3	8.8	6.6

Source: NFPA 731, *Standard for the Installation of Electronic Premises Security Systems,* 2005, Table B.1(c).

TABLE 14.10.11 Lens Formats

Focal Length	*Lens*	*Range*
4 mm	Very wide angle	4–6 ft (1.2–1.8 m)
8 mm	Wide angle	12 ft (3.6 m)
16 mm	Standard	25 ft (7.6 m)

Depth of Field

Finally, when setting up an image to be viewed, lighting and depth of field must be considered. Depth of field is the region within the picture that will appear sharp in focus (Table 14.10.13). The format of the lens will affect the depth of field. The amount of available light will also affect the depth of field for a camera. In order to calculate the depth of field for an object that is not close to the camera, Equation 3 should be used.

Far Focus Limit

$$FF = (H \times D)/[H - (D - L)] \quad (3)$$

where

FF = Far focus limit (in mm)

H = Hyperfocal distance (in mm)

D = Lens focus distance (in mm)

L = Lens focal length

Example: 16 mm focal length, f-8 f-stop, ⅓ in. format, 150 ft focus distance (45.72 mm or 45,720 mm)

FF = (246,153 mm × 45,720 mm)/[246,153 mm – (45,720 mm – 16 mm)]

FF = 11,254,115,160 mm/246,153 mm – 45,704 mm

FF = 11,254,115,160 mm/200,449 mm

FF = 56,144 mm (56.144 m or 184 ft)

Editor's Note: In the example given, the object or target would be in focus. The hyperfocal distance is the plane on which everything within the view is at optimal focus.

To calculate the depth of field for an object that is close to the camera, Equation 4 should be used.

Near Focus Limit

$$NF = (H \times D)/[H + (D - L)] \quad (4)$$

where

NF = Near focus limit (in mm)

H = Hyperfocal distance (in mm)

D = Lens focus distance (in mm)

L = Lens focal length

Example: 16 mm focal length, f-8 f-stop, ⅓ in. format, 150 ft focus distance (45.72 mm or 45,720 mm)

NF = (246,153 mm × 45,720 mm)/[246,153 mm + (45,720 mm – 16 mm)]

NF = 11,254,115,160 mm/246,153 mm + 45,704 mm

NF = 11,254,115,160 mm/291,857 mm

NF = 38,560 mm (38.56 m or 126.5 ft)

To obtain the optimal image, in which the entire view would be in focus, Equation 5 would be used.

Hyperfocal Distance

$$H = (L \times L)/(f \times d) \quad (5)$$

where

H = Hyperfocal distance (in mm)

L = Lens focal length

f = Lens aperture f-stop

d = Diameter of circle of least confusion (in mm)

Example: 16 mm focal length, f-8 f-stop, ⅓ in. format

H = (16 mm × 16 mm)/(8 × 0.00013)

H = 256/0.00104

H = 246,153 mm

The circle of least confusion is the area that is out of focus before and after the hyperfocal distance. The circle is the area of greatest light concentration behind the lens but in front of the imager of the camera. See Table 14.10.14.

Recording

At the time that this chapter was written, the primary method of image storage was the digital video recorder (DVR). The number of images that can be stored on a single DVR is dependent on the size of the storage disk within the DVR, the image size, number of images per second, and quality.

SUMMARY

This chapter is only a snapshot of the knowledge base that the practitioner should understand prior to designing and specifying the security for a premises. The practitioner should also consult a number of the text references that are listed in the Bibliography.

This chapter did not cover such topics as private security, data and information services security, pre-employment background checks, and a host of other subjects. Security can be both for the exterior and interior of the site. A site survey is an important step to be taken prior to any design or installation work being performed. A risk and vulnerability assessment should also be conducted. Present technology provides a vast variety of options that may be used in providing effective layers of protection and detection at a site. The objective of any security program is to deter, delay, detect and respond.

15.2 Water Supply Requirements for Public Supply Systems
15.3 Hydraulics for Fire Protection
15.4 Water Supplies for Sprinkler Systems
15.5 Microbiologically Influenced Corrosion in Fire Sprinkler Systems
15.6 Water Distribution
15.7 Fire Pump Controllers and Power Supply Arrangements for Motor-Driven Fire Pumps

Section 15 of the *Fire Protection Handbook*® is the first of three sections concentrating on the myriad forms of fire suppression. Because water is the most prevalent fire suppression agent and water supply can determine the success or failure of fire suppression efforts, it is appropriate that the first of this handbook's suppression sections addresses water supplies for fixed fire suppression.

Chapter 1, "Fixed Water Storage Supplies for Fire Protection," contains information on the design, installation, and maintenance of constructed water storage supplies and the ways in which naturally occurring surface and groundwater supplies can be used for fire protection. Of particular interest are the provisions described for preventing water stored for fire protection supplies from freezing during cold weather and maintaining stability and functionality following a seismic event.

Chapter 2, "Water Supply Requirements for Public Supply Systems," gives information on planning for public water supply systems and outlines the methods used to evaluate public supplies for their adequacy and reliability. Hydraulic calculations and the Insurance Services Office (ISO) grading schedule are introduced.

Chapter 3, "Hydraulics for Fire Protection," provides a more in-depth review of material introduced in Chapter 2. Topics covered include relevant formulae, coefficient of flow, flow measurement, elastic wave theory, friction loss, K-factor, and use of a Moody diagram.

The next two chapters explore water and automatic sprinkler systems. Chapter 4, "Water Supplies for Sprinkler Systems," identifies the types of water supplies that are acceptable for fire sprinkler systems and the variables that must be considered in the system design. Chapter 5, "Microbiologically Influenced Corrosion in Fire Sprinkler Systems," addresses MIC and biological growth control, which have been extensively researched in allied engineering fields, but whose treatment in fire sprinkler systems is relatively new.

Chapters 6 and 7 turn to the important topic of fire pumps used in fixed fire protection. Chapter 6, "Water Distribution," covers types of pumps, their principles of operation, curves, head, horsepower, drives, and tests. Chapter 7, "Fire Pump Controllers and Power Supply Arrangements for Motor-Driven Fire Pumps," focuses on the electrical and control aspects of electric motor-driven fire pump installations and is specific to fire pump controllers, motors, and electrical power supply arrangements. Chapter 7 was expanded for this edition of the handbook to introduce variable speed motor-driven fire pumps, their applications, and field experience.

David R. Hague, P.E., is principal fire protection engineer in NFPA's Systems and Applications Engineering Division.

Chapter 1

Fixed Water Storage Supplies for Fire Protection

Bruce A. Edwards

Chapter Contents

Storage Tanks (Gravity and Suction)
Tank and Tower Foundations
Tank Towers
Tank Heating Equipment
Tank Equipment and Accessories
Embankment-Supported Coated Fabric Suction Tanks
Pressure Tanks
Natural and Constructed Suction Facilities

Key Terms

air lock, alternative water supply, fire pump, freezing prevention, static water supply, storage tank (elevated), storage tank (embankment-supported), storage tank (gravity), storage tank (ground-level), storage tank (suction), water supply

In a broad sense, fire protection water storage supplies include all bodies of water available as sources of supply, whether they are contained by constructed or natural barriers. Elevated, ground-level, or underground storage tanks of metal, wood, plastic, or rubberized fabric are examples of constructed storage facilities; rivers, ponds, and lakes, or other surface water sources are examples of natural storage facilities.

Open bodies of water, such as human-made reservoirs and freshwater pools created by the damming of streams, are sometimes used in private fire protection to supplement public water supplies or furnish the primary source of water for fire protection if public supplies are unavailable, insufficient in volume or pressure, or both or if they lack dependability. A common method of providing a fire protection water supply is to use elevated gravity tanks or ground-level suction tanks with fire pumps. Pressure tanks, with their limited capacity, may be used where storage requirements are relatively small or other means of storing water for fire protection are impractical.

This chapter contains information on the design, installation, and maintenance of constructed water storage supplies and the ways in which naturally occurring surface and groundwater supplies can be used for fire protection. Of particular interest are the provisions described for preventing water stored for fire protection supplies from freezing during cold weather and in seismic areas maintaining stability and functionality following a seismic event.

For related topics, see Section 13, Chapter 4, "Alternate Water Supplies"; Section 15, Chapter 4, "Water Supplies for Sprinkler Systems"; Section 15, Chapter 6, "Water Distribution"; and chapters in Section 16, "Water-Based Fire Suppression Equipment."

STORAGE TANKS (GRAVITY AND SUCTION)

The prevalence of the installation of hydraulically designed automatic fire sprinkler systems in new construction and renovations has reduced the reliance and use of elevated tanks for fire protection water supplies. The use of ground-level suction tanks, combined with fire pumps, has increased (Figure 15.1.1). Nevertheless, there are many elevated gravity tanks still in service used solely for fire protection water supplies, and they require high standards of maintenance to continue their reliability and functionality as sources for systems.

Tanks used for fire protection water supplies should not be used for any other purpose. In addition to negatively affecting the quantity of water and duration of flow available, tanks used for other purposes must usually be refilled frequently, and they become settling basins that collect large accumulations of sediment. When water is drawn from the tank, the sediment also is drawn into the yard or extinguishing system and may block the system.

If the tank is wood and is refilled frequently, the alternate drying and wetting of the lumber may appreciably shorten the life of the tank; with a steel tank, more frequent painting may be

FIGURE 15.1.1 Suction Tank with Attached Pump House (Source: Columbian TecTank)

necessary, which means not only greater expense but also more time out of service.

Dual-purpose tanks will seldom be full, because domestic and industrial consumption constantly draws them down. In addition, the normal water level may continue to drop if the industry grows. If a fire occurs several years after the tank is installed, sufficient water at sufficient pressure might not be available. Should a dual-purpose tank be necessary, the outlet for the domestic and industrial supply should be set at a water level above the water dedicated for fire protection service.

Location

A gravity tank supported on an independent steel tower with foundations placed in the ground rather than on a building is the best arrangement. The tank should be built so that it will not be exposed to fire or physical damage. If lack of yard room makes this impossible, the exposed steelwork should be suitably protected by fire-resistant construction or coverings. The steel protection, when necessary, should include steelwork within 20 ft (6 m) of combustible buildings or openings from which fire might issue.

If the tank and supporting trestle are to be placed on the rooftop of a building, the building must be designed and constructed to carry the maximum load.

Suction tanks should be located so as to minimize yard piping. The pump house is generally placed close to the tanks to minimize suction piping. The tanks should not be located where they will be exposed to physical damage or fires from adjacent combustible construction or yard storage (Figure 15.1.2).

Design for Earthquake Resistance

Fire protection water storage tanks need to be designed to resist earth movement including earthquakes. In an earthquake, ground shaking sets up a rocking action and sloshing of water in the tank. These forces may produce stresses beyond those provided for in a design that allows only for ordinary dead, live, and wind loads. In areas where earthquakes are likely or possible, or where earthquake protection is required by local codes or authorities, fire protection water storage tanks should be designed to resist earthquakes. The primary goals are first to improve the reliability and likelihood that the fire protection system will remain in service after an earthquake and then to minimize potential water damage from a fire protection system

leakage, with an understanding of the unpredictable nature of the size and severity of seismic events.

Water tanks and reservoirs fall into three categories—ground-level tanks, elevated tanks, and embankment-supported tanks.

Ground-Level Tanks. Ground-level tanks that either provide a suction supply for an adjacent fire pump or act as gravity tanks to provide sufficient water pressure for the fire protection system are the most common type in areas where seismic protection is required. For ground-level tanks, the four main seismic considerations are as follows:

1. Flexibility of pipe connections to tank. When the tank discharge pipe runs horizontally to a pump, two flexible couplings on the pipe should be provided between the tank and the pump. One should be as close to the tank wall as possible and the other within 24 in. (0.6 m) of the pump. When the tank discharge pipe feeds into an underground main, two flexible couplings must be provided between the tank and the ground entrance. One should be as close to the tank wall as possible; the other should be within 24 in. (0.6 m) of the ground entrance.
2. Anchorage of the tank and foundation to prevent horizontal and vertical displacement. Ground-level tanks should be anchored for seismic protection for the appropriate seismic ground motion. Additionally, the foundation design, which is often done separately from the tank design, should be coordinated with the tank design to ensure that the foundation is of sufficient size and mass to prevent rocking of the tank. Anchorage and foundation design details are best provided and/or reviewed by a qualified structural engineer. American Water Works Association standards D100, *Welded Steel Tanks for Water Storage,* and D103, *Factory-Coated Bolted Steel Tanks for Water Storage,* provide seismic design criteria for anchorage of tanks.
3. Clearance around pipe penetrations through pump house or other structural walls. At least 2 in. (50 mm) clearance should be provided on all sides of piping that passes through structural walls or other fixed structures.
4. Proper steel thickness near base of tank to avoid elephant footing. In areas with a high probability of strong ground motion, unanchored tanks may have significant vertical and horizontal displacements. Depending on the diameter of the tank and the height-to-diameter ratio, these expected displacements may vary. However, the main point is that unanchored tanks may create displacements that may not only damage the tank but also rupture the attached piping.

Elevated Tanks. Elevated tanks, where the tank body is mounted on legs or a pedestal, are less common in areas where seismic protection is required. Because of the complexity of any seismic analysis for this type of tank, a qualified structural engineer can best handle seismic analysis and design.

Embankment-Supported Tanks. Embankment-supported fabric tanks have an earthen embankment that supports a lined reservoir. Because of the complexity of any seismic analysis for this type of tank, seismic analysis and design are best handled by a qualified structural engineer.

Tank Capacities

Today it is usually uneconomical to install a gravity tank big enough and tall enough to be connected directly into the fire protection system and furnish an adequate supply for both hose streams from hydrants and water-based fire protection systems.

Years ago, because of limited capacity and pressure requirements, a gravity tank holding at least 30,000 gal (114 m^3) with its bottom at least 75 ft (22.9 m) above the ground could adequately supply both hose lines from hydrants and the extinguishing systems. Storage tank selection is still determined by the capacity and pressure required for both hose streams and areas' fire sprinklers for the possible duration of a fire; but because of the increased design density requirements of today, the suction tank and pump are often more economical than a gravity tank or gravity tank and booster pump.

Gravity and suction tanks are generally erected in standard sizes (Tables 15.1.1 and 15.1.2). The capacity required is determined by the intended use of the tank and is specified in the number of gallons (cubic meters) available from the tank (1 gal = 0.00379 m^3).

Steel gravity tanks are constructed on single pedestals or with suspended bottoms erected on towers with four columns for capacities from 50,000 to 200,000 gal (190 to 750 m^3) inclusive, six columns for capacities from 200,000 to 300,000 gal (750 to 1100 m^3) inclusive, and eight columns for tanks over 300,000 gal (over 1100 m^3).

Construction of Tanks

Existing gravity tanks are built of wood or steel and are supported by steel towers. Most new gravity tanks are built of steel

TABLE 15.1.1 Standard Sizes of Gravity Tanks

Steel Tanks		Wood Tanks		Standard Height	
gal	*m^3**	*gal*	*m^3**	*ft*	*m**
30,000	115	30,000	114	75	22.9
40,000	150	40,000	150	100	30.5
50,000	190	50,000	190	125	38.1
60,000	230	60,000	230	150	45.7
75,000	290	75,000	290	—	—
100,000	380	100,000	380	—	—
150,000	570	—	—	—	—
200,000	760	—	—	—	—
300,000	1100	—	—	—	—
400,000	1480	—	—	—	—
500,000	2000	—	—	—	—

75,000	290	300,000	1100
100,000	380	400,000	1500
125,000	475	500,000	2000
150,000	575	750,000	3000
200,000	750	1,000,000	4000

*Figures rounded off as approximations from nominal customary American tank sizes.

with some wood on pedestals. Reinforced concrete towers are sometimes used, and tanks can also be placed directly on top of the structures they supply. In a few cases, concrete has also been used for the tank shells themselves. Typical gravity tanks are shown in Figures 15.1.3 and 15.1.4. In Figure 15.1.4, note that the higher the tank, the greater the water pressure at the base of the tank.

Tanks should be designed and installed according to NFPA 22, *Standard for Water Tanks for Private Fire Protection,* which gives full requirements for construction materials, loads, unit stresses, details of design, foundations, accessories, and workmanship. Welding of towers should conform to code requirements for welding in building construction.[1]

Steel for tanks and towers should conform to the specifications in NFPA 22. Chief among these specifications are the American Water Works Association standards for steel tanks,[2,3] which give the thickness of steel plates and the welding and bolting practices that should be followed. Other standards referenced in NFPA 22 cover steel shapes, plate materials, bolts, anchor bolts and rods, forgings, castings, reinforcing steel, and filler material for welding.

Steel tanks and towers should be riveted, welded, or bolted (if factory coated). Unfinished bolts and nuts should be used only where not exposed to weather, water, or corrosive environments and in (1) field connections of nonadjustable tension

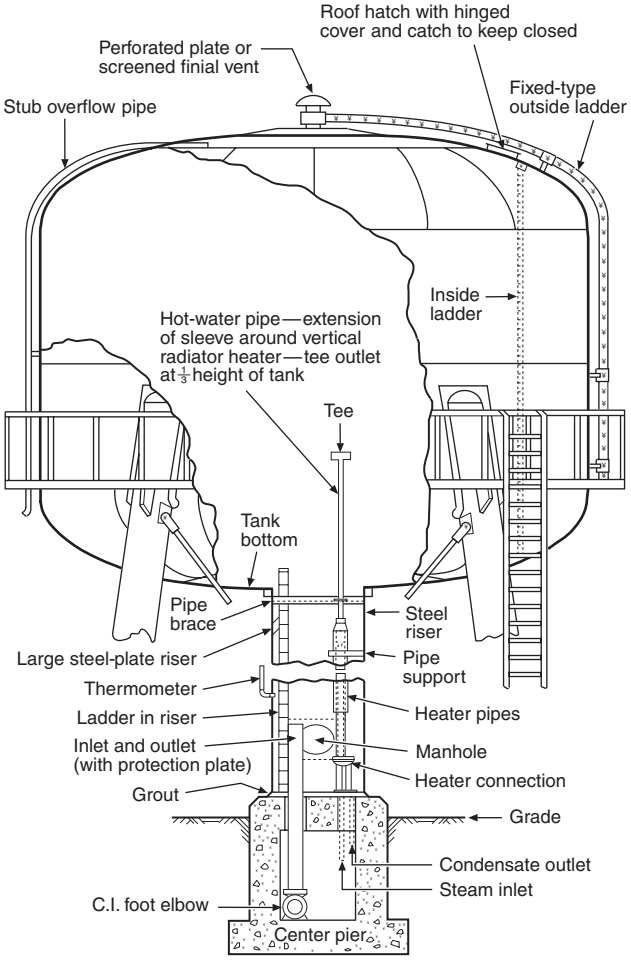

FIGURE 15.1.3 Typical Tower-Supported Double Ellipsoidal Tank

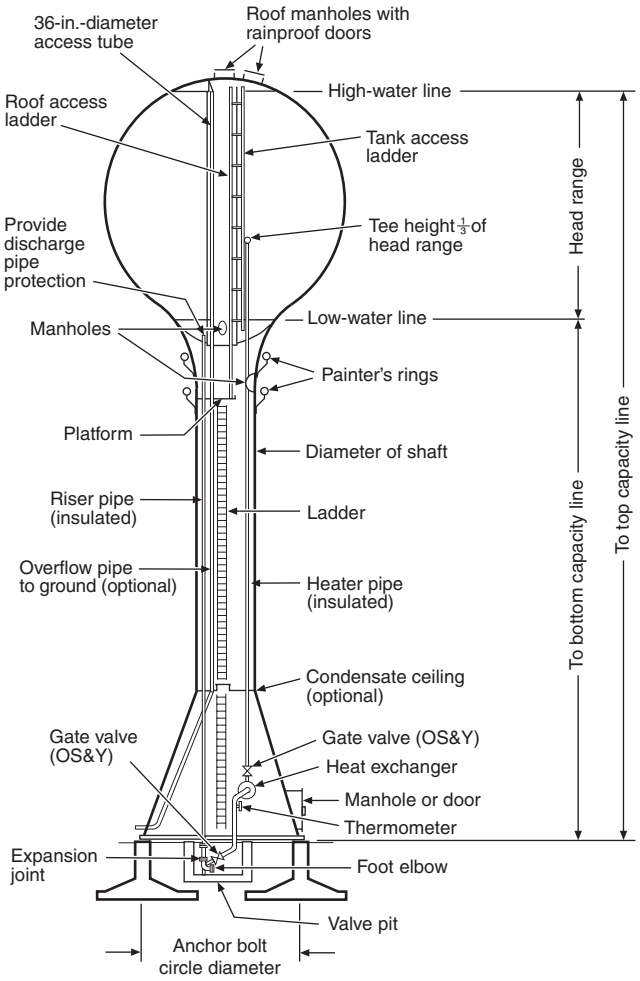

FIGURE 15.1.4 Typical Pedestal Tank

members carrying wind stress and (2) field connections of compression members and grillages in towers supporting tanks of 30,000 gal (114 m^3) or less capacity. Wood tanks and towers should conform to the specifications in NFPA 22, including types and dimensions of wood suitable for use, processes that should be used, and proper hoop materials and design, as well as unit loads and unit stresses for steel tanks and towers, and working stresses for timber for wood tanks.

During assembly and erection, plates should be bolted firmly together before riveting. Drift pins should not be used to bring parts together or to enlarge unfair holes.

No waste material, such as boards, roofing, paint cans, and so on, should be left in the tank or in the space at the top of the tank after its completion, because it may obstruct the piping.

Tanks should be put in service promptly after completion. Wood tanks may be damaged by shrinkage if left empty.

TANK AND TOWER FOUNDATIONS

The following are principles of good foundations for suction tanks and gravity tank towers.

Foundations in the Ground

Foundations should be designed to carry the maximum loads without excessive settlement. If wood piles are used above permanent low-groundwater level, they should be protected as specified by the American Wood Preservers Association.[4] Foundations should not be constructed over buried pipes or immediately adjacent to existing or former deep excavations unless the foundation bases go below the excavation.

Material. Foundations and footings should be built of concrete with a specified compressive strength not less than 3000 psi (20.69 MPa). The cement and aggregates, and the mixing and placing of the concrete, should conform to American Concrete Institute requirements for reinforced concrete.[5] Concrete work should conform to all requirements of ACI 301.[6]

Steel or wood pump suction tanks should be set on compacted crushed stone or granular base, or on concrete foundations. At least 3 in. (76.2 mm) of clean, dry sand, laid on compacted grade should be provided at the finished tank grade and should slope up toward the center of the tank at the rate of 1 in. in 10 ft (25.4 mm in 3 m). If the soil is good, at least 4 in. (100 mm) of crushed stone or sand is suggested. The material should then be laid on moistened and compacted gravel after removing unsuitable soil. Special consideration (outlined later) must be given if soil is poor.

A reinforced concrete ring wall at least 2½ ft (760 mm) deep below finished grade and 10 in. (250 mm) thick should surround the tank foundation. This ring normally projects 6 in. (152 mm) above the surrounding grade and should be reinforced against temperature and shrinkage and reinforced to resist the lateral pressure of the confined fill with its surcharge. If the ring wall is outside of the tank shell, asphalt flashing should be installed between the tank and the ring wall at ground level.

Where the soil does not provide direct support for the tank without excessive settlement, shallow foundation construction is not adequate, and a proper foundation needs to be designed by a structural engineer.

Form. The tops of foundations should be level and at least 6 in. (150 mm) above ground. The bottoms of foundation piers for towers should be located at a level that is below the frost line and, in the case of piers, at least 4 ft (1.2 m) below grade, resting on thoroughly tamped soil or rock.

Grouting and Flashing. Bearing or base plates should have complete bearing on the foundation or be laid on minimum 1 in. (25.4 mm) thickness cement grout to secure a complete bearing. The stressed portion of anchor bolts should not be exposed. If the stressed portions of anchor bolts must be exposed, they should be encased in cement mortar to protect against corrosion unless they are accessible for complete cleaning and painting. If structural shapes, plates, and bolts enter or are supported by masonry or concrete, the joint between the metal and masonry or concrete should be flashed with asphalt. (This does not refer to base plates under columns.)

Soil-Bearing Pressure. In order to find the proper depth of the foundation, the soil-bearing pressure must be determined by analyzing the subsurface and checking the foundations of other structures in the area. Test borings should be made by or under the supervision of an experienced soils engineer or soils testing laboratory. The borings should be made deep enough to determine the adequacy of the support (usually a minimum of 20 to 30 ft [6 to 9 m]). Evaluate the potential for subsidence, collapse, soil liquefaction, and settlement where the presence of limestone or other soluble rock types are present or suspected and include cavity investigation and competency of bedrock with the subsurface investigation.

Avoid constructing foundations over buried pipes or adjacent to existing or former deep excavations.

Piers

Pier foundations may be of any suitable shape and may be either plain or reinforced concrete. If they support a tower, their center of gravity should lie in the continued center of the gravity line of the tower column or else be designed for eccentricity. The height of piers should not be less than the mean width. The top surface should extend at least 3 in. (756 mm) beyond the bearing plates on all sides and be generally chamfered at the edges.

The tops of foundation piers should be level and at least 6 in. (152 mm) above grade, located at the correct elevations. The bottom of foundations should be located at a level that is the greater of either below the frost line or at least 4 ft (1.2 m) below grade.

Anchorage. The weight of piers should be sufficient to resist the maximum net uplift that occurs when the wind blows from any direction on the empty tank. The weight of dirt directly above the base of the pier may be included in the calculations.

Anchor bolts should be arranged to engage a weight at least equal to the net uplift with the tank empty and the wind blowing from any direction. Their lower ends should be hooked or fitted with anchor plates.

Anchor bolts should be accurately located with sufficient free length of thread to fully engage their nuts. Expansion bolts are not acceptable. The minimum size of anchor bolts should be 1½ in. (38 mm).

Center Pier. In addition to the weight of the water in a large plate riser, the weight of the column of water directly above the riser in the tank, and the weight of the steel plate, the center pier should be considered as supporting a hollow cylinder of water in the tank. If the hemispherical or ellipsoidal bottom is rigidly attached to the top of the large riser by a flat horizontal diaphragm plate, the radius of the hollow cylinder of water should be determined as specified under large risers discussed later in this chapter.

TANK TOWERS

Steel is generally used for the construction of tank towers (Figure 15.1.5). Details on the specific types of steel used in tanks can be found in NFPA 22.

Both dead loads and live loads should be considered when designing towers. The dead load is an estimate of the weight of all permanent construction and fittings. The live load is considered as the weight of the water when it overflows the top of the tank. Consideration should also be given to temporary loading, such as ice and snow.

The weight of the water located directly above any riser need not be considered when figuring loads unless the riser is suspended from the tank bottom. If the riser is used to support the tank bottom, the entire weight supported by the riser should be considered, including the weight of the water.

Additional factors to consider are wind, balcony, and earthquake loads. Wind loads are based on 30 lb/ft^2 (147 kg/m^3) for vertical plain surfaces and 18 lb/ft^2 (88 kg/m^3) over the total area of the vertical projection on cylindrical surfaces. These loads are applied to the center of gravity of the projected areas. A vertical load of 1000 lb (454 kg) should be applied to any 10 ft^2 (0.93 m^2) of area on a balcony floor and on each platform; 500 lb (227 kg) applied to any 10 ft^2 (0.93 m^2) of area on the tank roof; and 350 lb (159 kg) applied to each vertical section of the ladder. Snow loading is additional and considered in these loadings. Earthquake loading must be designed specifically for local conditions.

Ladders and Balconies

All tanks should have ladders on both the outside and inside, with convenient passage from one ladder to the other and through the roof hatch, arranged not to interfere with the opening of the hatch cover. Ladders are for inspection and maintenance of the tank's interior and exterior surfaces; they should be constructed of materials compatible to those of the tank and tower, and they should be easily accessible. Equipment exceeding 20 ft (6.1 m) should be equipped with a cage, a rigid notched rail, or another listed ladder safety device.

FIGURE 15.1.5 Elevated Wood Gravity Tank on Steel Tower (Source: Isseks Brothers)

Balconies and walkways constructed of wood or steel are recommended for towers over 25 ft (7.6 m) high. Balconies on tanks having a diameter in excess of 15.5 ft (4.7 m) should have a minimum width of 24 in. (607 mm) and, for smaller diameter tanks, a width of not less than 18 in. (457 mm). Railings should be at least 42 in. (1067 mm) high. Balconies and walkways should also be made of materials compatible with the tank and tower materials.

Tower Construction

During field erection, the columns of towers should be built on thin metal wedges driven to equal resistance so that all columns will be loaded equally after the structure is completed. The

spaces beneath the base plates and the anchor holes should be completely filled with cement mortar.

Sections of structural members for towers should be symmetrical and built of standard structural shapes or tubular sections. Structural shapes should be designed with open sections so that all surfaces exposed to air or moisture and subject to corrosion can be painted. Tubular sections of columns and struts should be airtight.

TANK HEATING EQUIPMENT

Fire protection water supplies in tanks subject to freezing must be heated. An ice plug in a riser pipe may make the tank water unavailable in case of fire and may break the pipe. Ice in or on tank structures has been the direct cause of collapse in several cases. The heating system must, therefore, be reliable and allow convenient and economical operation to 50°F (10°C). However, overheating can seriously damage wood tanks and the paint on steel tanks and, thus, it should be avoided.

Determination of Heater Capacity

To prevent freezing in any part of a tank during the coldest weather, the heating system must be of such capacity that the temperature of the coldest water in the tank or riser, or both, will be maintained at or above 42°F (5.6°C). The coldest weather temperature used to determine the need of heating should be based on the lowest mean temperature for one day, as shown on the isothermal map (Figure 15.1.6).

Tables 15.1.3 and 15.1.4 show the heat losses from tanks of common sizes exposed to various atmospheric temperatures. To determine, for example, what heater capacity would be needed for a 75,000 gal (284 m^3) steel tank in Duluth, Minnesota, one could interpolate from Figure 15.1.6 that the lowest mean temperature for one day in Duluth is –28°F (–33°C). According

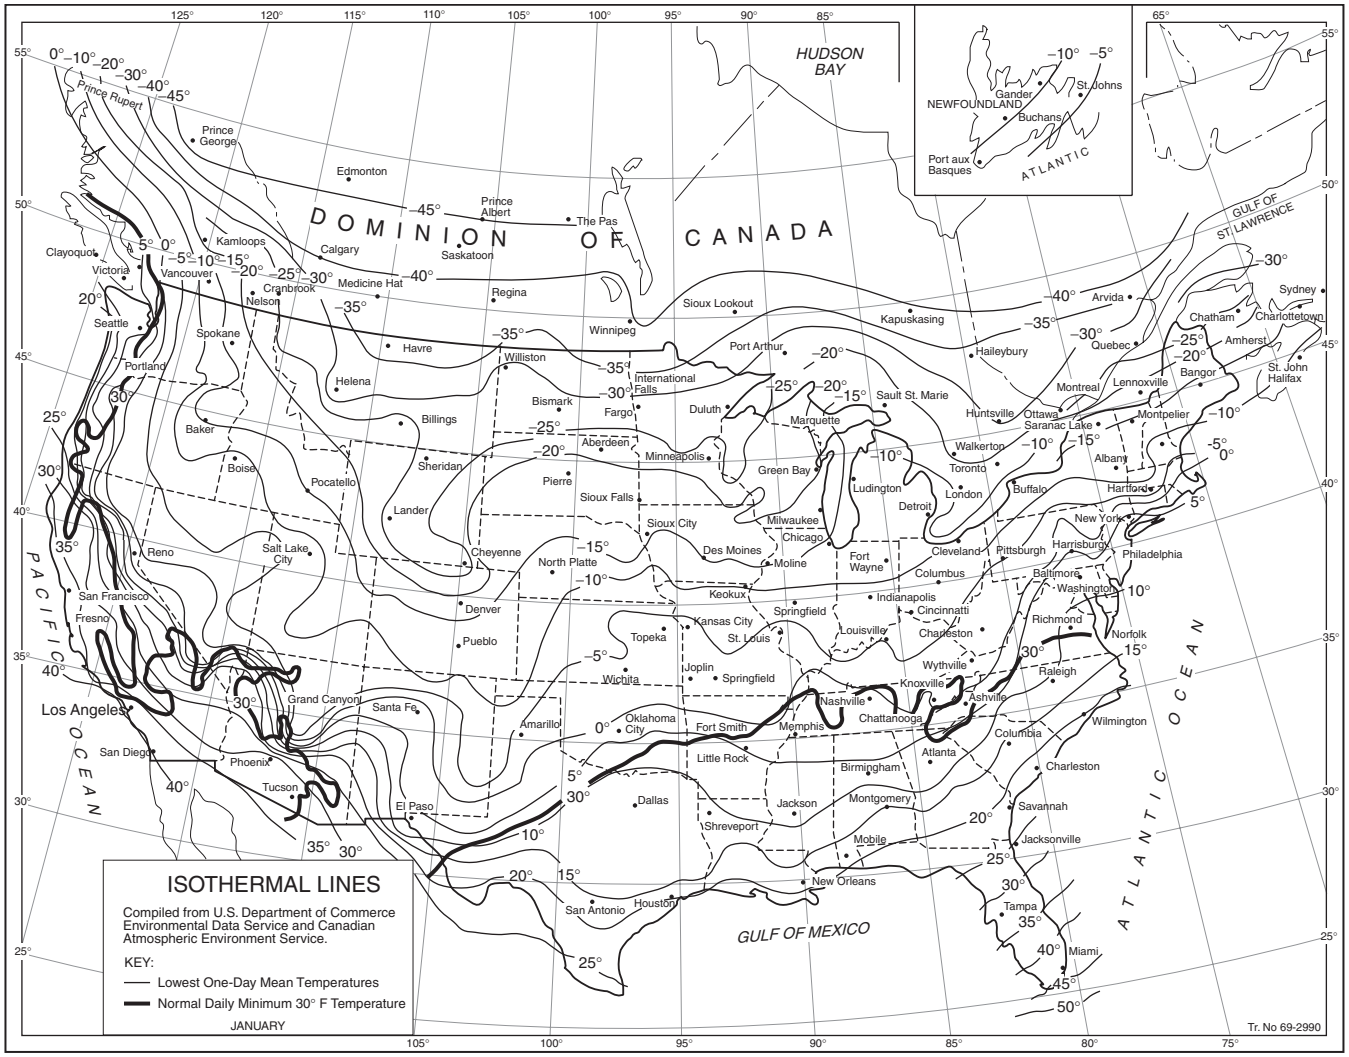

FIGURE 15.1.6 Isothermal Lines—Lowest One-Day Mean Temperature (for SI units, °C = (°F – 32) × 5/9)

TABLE 15.1.3 Heat Loss from Standpipes and Steel Suction Tanks

Thousands of British thermal units lost per hour when the temperature of the coldest water is 42°F (5.6°C). To determine capacity of heater needed, find the minimum mean atmospheric temperature for one day from the isothermal map, Figure 15.1.6, and note the following corresponding heat loss.

Temperature		Tank Capacities (thousands of gallons)															
		100,000 gal (378 m^3)		150,000 gal (567 m^3)		200,000 gal (757 m^3)		300,000 gal (1135 m^3)		400,000 gal (1514 m^3)		500,000 gal (1892 m^3)		750,000 gal (2838 m^3)		1,000,000 gal (3785 m^3)

to Table 15.1.4, the heat loss at –28°F (–33°C) for a 75,000 gal (284 m^3) steel tank is approximately 659,000 Btu per hour (19,300 W). For a wood tank with these same specifications, Table 15.1.4 indicates a maximum heat loss of approximately 254,000 Btu per hour (74.4 kW).

Selection of Heating Method

The selection of a heating method depends primarily on the type of tank (height, construction, material, size, and shape) and its geographical location. The recommended methods of heating are covered in detail in NFPA 22.

There are three basic methods of heating tank water: (1) gravity circulation of hot water, (2) steam coils inside tanks, and (3) direct discharge of steam.

Gravity Circulation of Hot Water

Heating by gravity circulation is dependable and economical if correctly planned. Cold water received through a connection from the discharge pipe or from near the bottom of a suction tank or standpipe is heated and rises through a separate hot water pipe into the tank. Steam, coal burning, or oil heaters are ordinarily used; gas heaters or electric heaters are also satisfactory.

A steam heater ordinarily consists of a cast-iron or steel shell through which water circulates by gravity around steam tubes or coils of brass or copper. It should be located in a valve pit, in a heater house, or in a nearby building at or near the base of the tank. When the tank is over a building, the steam heater should be located in the top story.

Heater Thermometer. The convenience of a gravity system is that it permits discovery of the temperature of the coldest water in the system. A recording thermometer should be placed in the cold-water return pipe near the heater; it should be checked frequently to make sure that the temperature does not fall below 42°F (5.6°C). The temperature reading should be observed daily during subfreezing temperature conditions. (Water has its maximum density at 39.2°F [4°C]. When the temperature of the water falls below 39.2°F [4°C], there is an inversion, and the warmer water settles to the bottom of the tank while the colder water rises. Therefore, if the circulation heater is to be effective, sufficient heat must be provided so that the temperature of the coldest water will be above 42°F [5.6°C].)

Water Circulating Pipes. The size of pipe used for the circulation of heating water is given in Table 15.1.5. Pipe should be either copper water tubing or brass (85 percent copper) throughout. The hot water discharges into the tank through a tee fitting at the end of the hot-water pipe at a height about one-third up from the bottom of the tank. The return pipe connects into the discharge pipe at a point that guarantees circulation throughout

TABLE 15.1.4 Heat Loss from Elevated Tanks

Thousands of British thermal units lost per hour when the temperature of the coldest water is 42°F (5.6°C). To determine capacity of heater needed, find the minimum mean atmospheric temperature for one day from the isothermal map, Figure 15.1.6, and note the following corresponding heat loss.

the portion of the discharge pipe subject to freezing. A typical arrangement of a circulating heater and piping in a valve pit is shown in Figure 15.1.7.

Steam Coils Inside Tanks

Steam coils inside the tank do not permit convenient observation of water temperatures and have other faults that make them unsuited for heating elevated tanks except in areas of the South where only intermittent heating is necessary. This method may, however, be used for heating suction tanks and standpipes with flat bottoms supported near the ground level if coils are submerged continuously. The coil consists of at least 1¼ in. (32 mm) brass or copper pipe or 2 in. (50 mm) steel pipe, pitched to drain, supplied with steam at not less than 10 psi (0.7 bar) pressure through a pipe of sufficient size to furnish the needed quantity of steam from a reliable source. The coil should contain an area of heating surface to maintain the temperature of the coldest water at not less than 42°F (5.6°C). The surface water temperatures for elevated tanks, standpipes, and suction tanks should be determined by means of a listed temperature-detecting device.

Direct Discharge of Steam

Steam from a reliable supply is blown directly into the tank water through a pipe not less than 1 in. (25 mm) in diameter extending inside the frost-proof casing and through the bottom to a point above the maximum water level, then extending horizontally for a short distance and then downward to a point 3 or 4 ft (0.9 or 1.2 m) below the normal fire service water level. An air vent and check valve in the pipe above the surface of the water keeps the water from siphoning back down the steam line. This method is employed where the lowest mean temperature for one day is 5°F (–15°C) or above.

Solar Heating of Elevated Steel Tanks

With the increase in fossil fuel prices, work was done in Canada on the feasibility of solar heating of elevated steel tanks.[7] The basic technique is to insulate the entire tank, leaving a window on the south side through the insulation. The tank shell in the

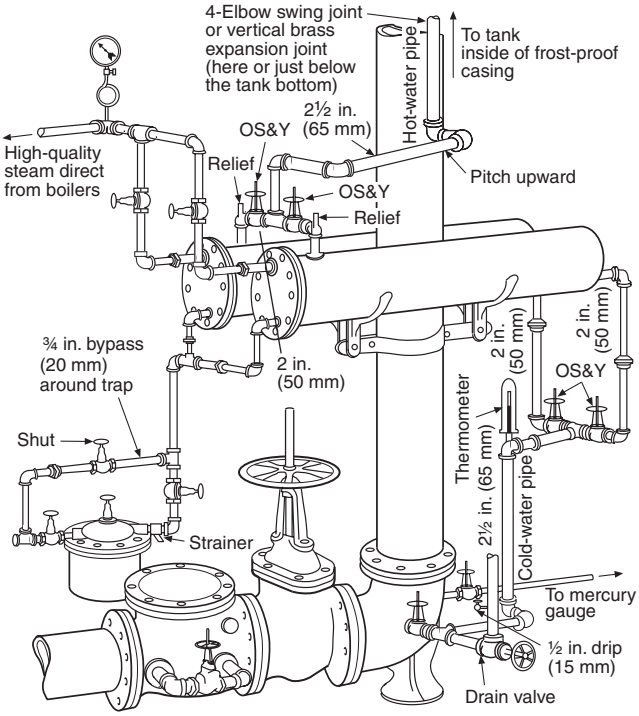

FIGURE 15.1.7 Piping Arrangement for a Multi-Unit, Steam-Heated Water Heater for a Gravity Circulation System

opening is painted flat black to absorb heat from the sun and the opening is double glazed.

Retrofit installations of solar heating systems on existing tanks involve special precautions in the attachment of components to the tank, such as the use of adhesives. The costs would be relatively high and the payback period long.

For new tanks, low-cost welding techniques can be used for attachment of collector components to the tank. With substantially all energy being supplied by the sun, a backup heating system can be a low-cost electrical system. Compared to a conventional tank with a fossil fuel–fired boiler heating system, a solar-heated tank with an electrical backup heating system is likely to have a lower capital cost. A solar-heated tank should have a backup heating system.

TANK EQUIPMENT AND ACCESSORIES

A complete installation of a gravity or suction tank includes the necessary pipe connections, valve enclosures, and, where appropriate for the particular tank, such features as a frost-proof casing for the riser.

Valve Pits

A valve pit should be of sufficient size to provide at least 12 in. (305 mm) to 18 in. (457 mm) around all necessary and contained equipment. Details of the construction of the pit and its arrangement, including clearance around equipment, waterproofing, manhole and ladder, and drainage, should conform to the recommendations given for valve pits (Figure 15.1.8).

Valve Enclosures

The tank heater and other fittings are sometimes installed in an enclosure above grade. In such a case, the indicating valve and the check valve are generally placed in the horizontal pipe below the frost line in a small pit heated sufficiently to maintain a temperature of at least 40°F (4.4°C) during the most severe weather. Ground fault interruption should be provided on all electrical circuits.

The enclosure may be of concrete, brick, cement plaster on metal lath, or any other noncombustible material with suitable heat-insulating properties. The roof should be strong enough to support the frost-proof casing and other loads without excessive deflection.

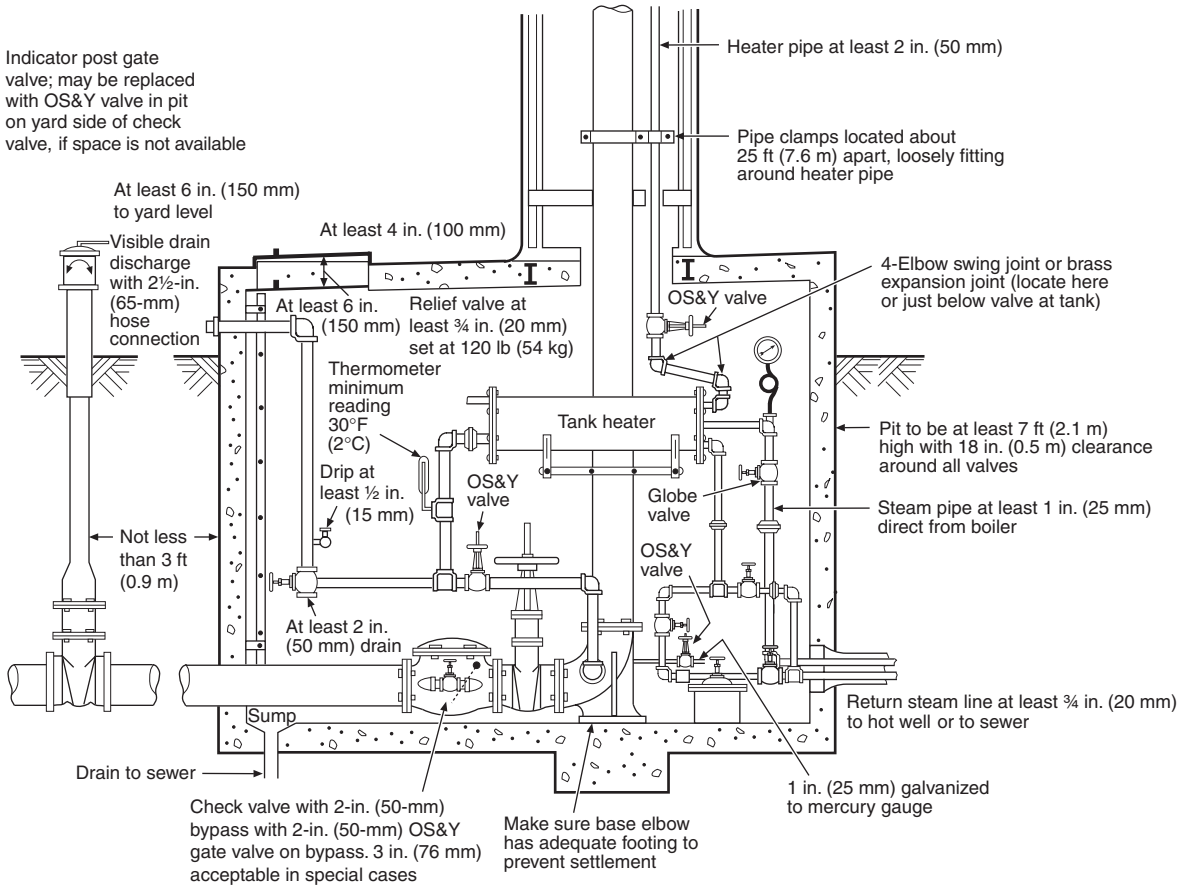

FIGURE 15.1.8 Valve Pit and Tank Connections at Base of Riser

Frost-Proof Casings

Except in the case of a large steel riser, a frost-proof casing around all exposed tank piping is necessary in localities where the lowest mean atmospheric temperature for one day as shown by the isothermal map (see Figure 15.1.6) is 20°F (–6.7°C) or lower. Tank piping subjected to temperatures below freezing within unheated buildings or dry risers of elevated tanks must also be adequately protected. Noncombustible frost-proof casings should be used where there is danger of serious fire exposure.

Large Risers

Large steel-plate riser pipes 3 ft (0.9 m) or more in diameter, without frost-proof casings, are often desirable and acceptable where properly heated. The fire hazard and upkeep of the frost casing are thereby avoided, the expansion joint in the discharge pipe is eliminated, and it is not necessary to have a walkway to reach the valves. When the tank is on an independent tower, a concrete valve pit at the base of the discharge pipe and the pier are usually built as a single unit to support the riser (see Figure 15.1.3). On the other hand, the larger valve pit at the base of the riser makes the initial cost higher than it is for equipment with small risers.

Water-Level Indicators

A water-level gauge of suitable design must be provided and located to prevent it from freezing. Careful installation, adjustment, and proper maintenance of the gauge are necessary. Where an altitude gauge is used, it should be a minimum 6 in. (152 mm) in diameter and of noncorrosive construction.

Mercury gauges are no longer permitted for new installations. Where existing mercury gauges are used/installed, they should be maintained in accordance with NFPA 22.

Overflow Pipes

The inlet of the overflow pipe should be located at the top capacity or high-water line of the tank. The pipe below the roof support structure and below any unwelded seams should be of adequate capacity for the operating conditions, but should not be less than 3 in. (80 mm) in diameter. Overflow pipes should be brought to grade. However, if dripping water or a small accumulation of ice is not objectionable, the overflow may pass through the side of the tank near the top and extend not more than 4 ft (1.2 m), with a slight downward pitch to discharge beyond the balcony and away from the ladders.

When a stub pipe is undesirable, the overflow pipe can be extended down through the tank bottom and inside the frost-proof casing or steel-plate riser, discharging through the casing near the ground or roof level. The section of the pipe inside the tank should be brass, flanged cast iron, or steel.

Painting Tanks, Seams, and Margins

All interior surfaces of steel tanks exposed to water immersion of the vapor phase zone above the high water level, inside dry surfaces, and exterior surfaces shall be cleaned, primed, and painted. After construction, all weld seams, unprimed margins, and any areas where the primer has been damaged shall be cleaned, primed, and painted. Only lead-free paints and primers should be used. Wax coating systems are no longer permitted.

EMBANKMENT-SUPPORTED COATED FABRIC SUCTION TANKS

Embankment-supported coated fabric (ESCF) tanks can be used as suction tanks for fire protection. NFPA 22 contains details on construction, installation, and maintenance of ESCF tanks.

The tank is usually composed of a reservoir liner with an integral flexible roof and is designed to be supported by earth underneath and on all four sides. The material of some ESCF tanks is a nylon fabric coated with an elastomer compounded to provide resistance to abrasion and weather. Support is provided by a specifically prepared excavation and earthen berm.

Preparation of the installation site is critical to the reliability of an ESCF tank. The embankment should be designed for stability and drainage. Usually, a shallow excavation the size of the bottom of the tank is made where local soil and groundwater conditions permit. The excavated earth is then graded to form a stable embankment for the upper sides of the tank. The exterior of the berm should be graded to allow for rain and snow drainage and pipe connections, and the interior graded to match the contour of the tank, including rounded corners. ESCF tanks may be placed underground with the top of the tank at grade level, or they may be placed above ground where the earthen berm provides the entire support.

When the excavation meets the shape requirements of the tank and all sharp rocks and debris have been carefully removed from the floor of the tank excavation, a 6 in. (150 mm) layer of fine sand or clean soil is spread over a 3 in. (75 mm) underlayment of selected pea gravel, which provides a firm smooth bed with good drainage. The tank is then placed in the foundation, and all connections are made. Installation of the tank in the prepared embankment shall be accomplished with the assistance of the tank manufacturer's field technician. The tank should be shipped to the site packaged in a material that is designed for ease of handling by a crane and winch and that facilitates efficient placement in the enclosure. The fittings shall be installed on site. At the time of installation, the tank should be filled and final adjustments on the tank made to ensure that it rests uniformly against the embankment on all four sides. The tank must be tested for leakage after installation. After the tank is filled, a coating is applied to the exposed surface to protect it from the atmosphere. See Figure 15.1.9 for a typical ESCF installation.

As with other types of storage tanks, water temperature in ESCF tanks should be maintained at not less than 42°F (5.6°C). An acceptable method of providing heat is a water recirculation system with a heat exchanger (Figure 15.1.10). When the ambient water temperature drops below 42°F (5.6°C), a thermostat activates a pump that draws water from the tank through an inlet-outlet fitting and pumps the heated water back into the tank through a recirculation fitting located in the bottom of the tank diagonally opposite the inlet-outlet fitting. Heat losses in ESCF tanks are given in Table 15.1.6.

PRESSURE TANKS

Pressure tanks are used for limited private fire protection services, such as sprinkler systems, standpipe and hose systems, and water spray fixed systems. A typical pressure tank installation is shown in Figure 15.1.11.

Tank capacity should be approved by the authority having jurisdiction (AHJ) and is considered to be the total contents, both air and water in the cylinder. Pressure tanks are sized by the supply of water needed to meet the demand of the fire protection system as calculated in Chapter 14 of NFPA 13, *Standard for the Installation of Sprinkler Systems*. The pressure shall be sufficient to push all of the water out of the tank while maintaining the necessary residual pressure required by NFPA 13 at the top of the sprinkler system.

Most pressure tanks are located above the top level of the sprinklers. Tanks exposed to combustible contents within the room or enclosure, or within rooms or enclosures of combustible construction, should be protected by automatic sprinklers.

Subject to the approval of the AHJ, tanks may be located in the basement or elsewhere. When the AHJ permits the tank to be buried, the requirements of NFPA 22 must be followed. Tanks for this service generally are not over 15,000 gal (34 m^3)

TABLE 15.1.6 Heat Loss from Embankment-Supported, Rubberized Fabric Suction Tanks

Thousands of British thermal units lost per hour when the temperature of the coldest water is 42°F (5.6°C). To determine capacity of heater needed, find the minimum mean atmospheric temperature for one day from the isothermal map, Figure 15.1.6, and note the following corresponding heat loss.

Exposed Tank Surface				Tank Capacities													
Atmospheric Temperature		Heat Loss Tank Radiating Surface		100,000 gal (378 m^3) 2,746 ft^2 (255 m^2)		200,000 gal (757 m^3) 4,409 ft^2 (410 m^2)		300,000 gal (1,136 m^3) 6,037 ft^2 (561 m^2)		400,000 gal (1,514 m^3) 7,604 ft^2 (706 m^2)		500,000 gal (1,893 m^3) 9,139 ft^2 (849 m^2)		600,000 gal (2,274 m^3) 10,630 ft^2 (988 m^2)		800,000 gal (3,407 m^3) 13,572 ft^2 (1,261 m^2)		1,000,000 gal (3,785 m^3) 16,435 ft^2 (1,527 m^2)

Note: Heat loss for a given capacity with a different radiating surface than shown above is obtained by multiplying the radiating surface by the tabulated heat loss per ft^2 (m^2) for the atmospheric temperature involved. The minimum radiation surface area is the wetted surface exposed to atmosphere. No heat loss is figured for tank bottoms resting on grade.

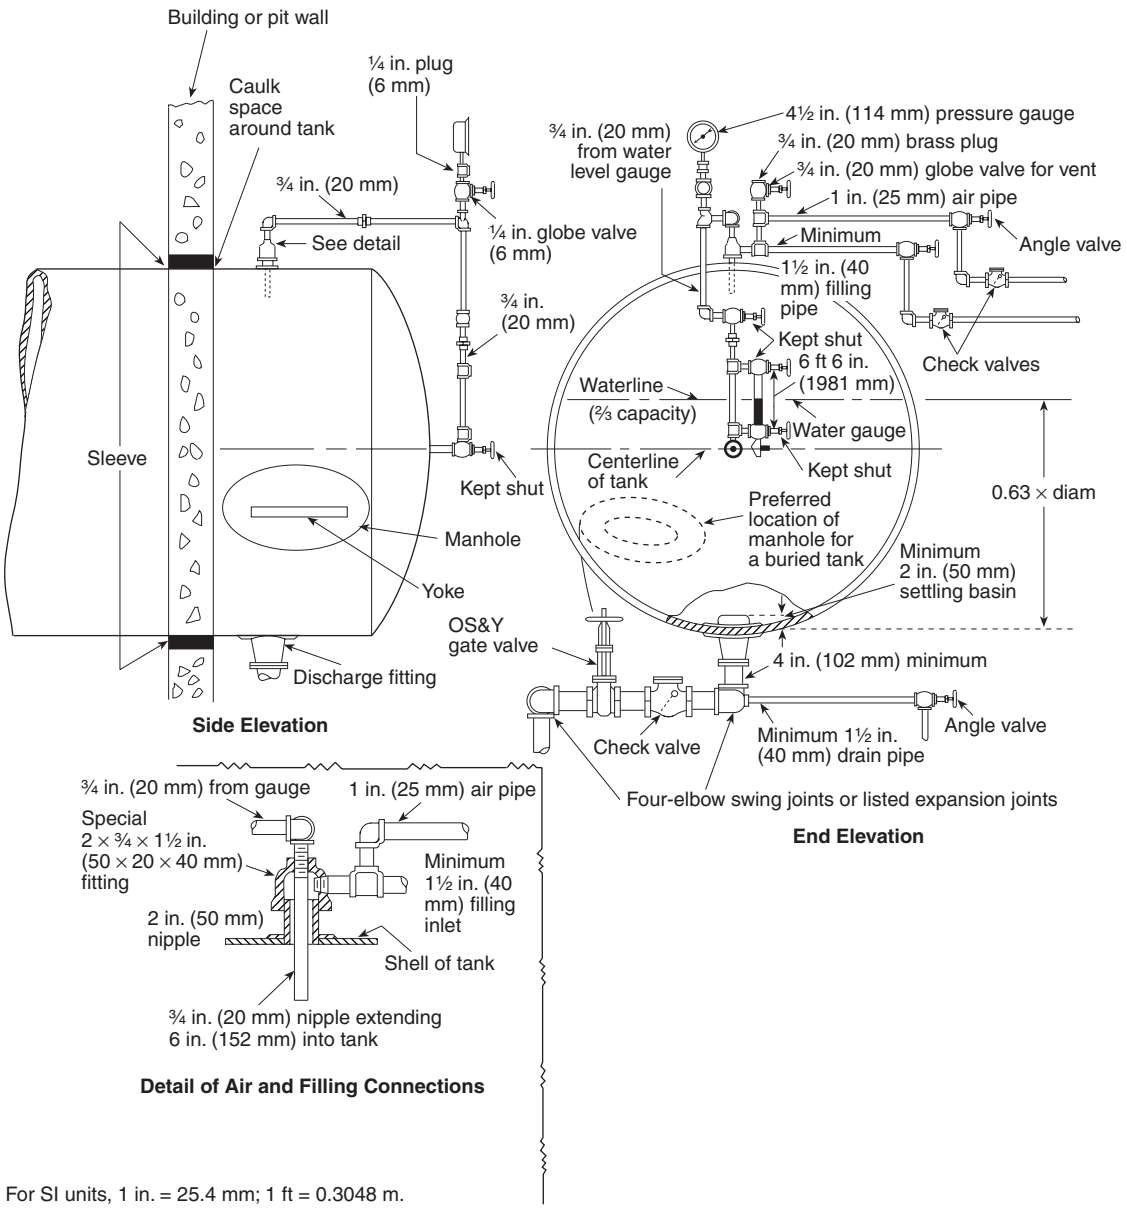

FIGURE 15.1.11 Typical Pressure Tank Installation (Source: Adapted from NFPA 22, *Standard for Water Tanks for Private Fire Protection*, Figure B.1(a), 2003, pp. 22–65)

capacity. For larger supplies, more than one tank would be employed (Table 15.1.7).

The tank is normally kept two-thirds full of water (a water-level gauge provided and the tank plate marked "2/3 capacity line") and a gauge pressure of at least 75 psig (517 kPa) is maintained. A listed air pressure gauge with a maximum range equivalent to twice the normal working pressure should be installed. As the last of the water leaves the pressure tank, the residual pressure shown on the gauge should not be less than zero and should give at least 15 psi (103 kPa) pressure at the highest automatic discharge device under the main roof of the building.

Air for pressure tanks should be supplied by compressors capable of delivering not less than 16 ft^3/min (0.045 m^3/min) of free air for tanks of 7500 gal (28.4 m^3) total capacity and not less than 20 ft^3/min (0.057 m^3/min) for larger sizes.

Relationship of Air Pressure and Volume in Tanks

The volume of air in the tank at any time varies inversely with the pressure:

$$\frac{P_1}{P_2} = \frac{V_2}{V_1}$$

Pressures are absolute pressures, not gauge pressures, as used in the preceding general formula. Let us apply this

TABLE 15.1.7 Typical Dimensions of Horizontal Pressure Tanks of Standard Sizes

Note: 4500 gal (17 m^3) gross capacity is the minimum ordinarily accepted for pressure tanks for automatic sprinkler systems.

formula to the special condition that exists in a tank used to supply water for sprinklers. Except where there is danger of air lock, it is desirable to have a gauge pressure of 15 psi (103 kPa) remaining in the tank when the last water leaves. Thus,

P_2 = Residual pressure required + atmospheric pressure

= 15 psi + 15 psi

= 30 psi

Since at this condition the tank is full of air,

$$V_2 = 1$$

If the tank is at or above the top line of sprinklers, the tank will be normally kept two-thirds full of water, so,

$$V_1 = \frac{1}{3}$$

Therefore,

$$P_1 = P_2 \times \frac{V_2}{V_1} = 30 \times \frac{1}{1/3} = 30 \times 3 = 90 \text{ psi}$$

The corresponding gauge pressure would be 90 psi (710 kPa), minus the atmospheric pressure, 15 psi (103 kPa), or 75 psi (517 kPa).

If the tank is below the top line of sprinklers, the required residual pressure would be increased 0.434 psi for every foot (0.912 kPa/m) of elevation represented in the distance between the base of the tank and the highest sprinkler. If we call this value *H,* we have

$$P_1 = P_2 \times \frac{V_2}{V_1} = (30 + 0.434H)\frac{V_2}{V_1}$$

Gauge pressure to be carried in the tank would be $P_1 - 15$, or

$$(30 + 0.434H)\frac{V_2}{V_1} - 15$$

For a tank ⅓ full of air $\frac{V_2}{V_1} = 3$, and gauge pressure would be

$$3(30 + 0.434H) - 15 = 75 + 1.30H$$

For a tank ½ full of air $\frac{V_2}{V_1} = 2$, and gauge pressure would be

$$2(30 + 0.434H) - 15 = 45 + 0.87H$$

Air Lock

A condition known as air lock can occur when a pressure tank and a gravity tank are connected into the sprinkler system through a common riser. Air lock occurs when the gravity water pressure at the gravity tank check valve is less than the air pressure trapped in the pressure tank and the common riser by a column of water in the sprinkler system, after water has been drained from the pressure tank. For example, if the pressure tank is kept two-thirds full of water with an air pressure of 75 psi (5.2 bar), and a sprinkler opens 35 ft (10.7 m) or more above the point the common tank riser connects to the sprinkler system, the pressure tank drains, leaving an air pressure of 15 psi (1.0 bar) balanced by a column of water of equal pressure (35 ft [10.7 m] of head) in the sprinkler system. The gravity tank check valve is held closed unless the water pressure from the gravity tank is more than 15 psi (1 bar) (35 ft [10.5 m] head).

Air lock can be prevented by increasing the volume of water and decreasing the air pressure in the pressure tank so that little or no air pressure remains after water has been exhausted. For example, if the pressure tank is kept four-fifths full of water, with an air pressure of 60 psi (4.1 bar), the air pressure remaining in the tank after water has been drained is zero, and the gravity tank check valve opens as soon as the pressure at that point from the pressure tank drops below the static head from the gravity tank.

Under normal conditions, air lock can be conveniently avoided in new equipment by connecting the gravity tank and pressure tank discharge pipes together 45 ft (13.7 m) or more below the bottom of the gravity tank (Figure 15.1.12) and by placing the gravity tank check valve at the level of the connection.

Construction of Pressure Tanks

Pressure tanks are constructed in accordance with *ASME Boiler and Pressure Vessel Code,*[8] with modifications given in NFPA 22. Important modifications are a minimum hydrostatic test at 150 psi (10 bar) and a test for tightness.

Where subject to freezing, tanks should be located in substantial noncombustible housings. Tank rooms should be large enough to provide free access to all connections, fittings, and manholes, at least 18 in. (457 mm) around the rest of the tank. The distance between the floor and any part of a tank should be at least 3 ft (0.9 m).

The interiors of pressure tanks are inspected at three-year intervals to determine whether corrosion is taking place and whether repainting or repairing is needed. When necessary, tanks should be scraped, wire brushed, and repainted with an approved metal-protective paint. Relief valves should be tested at least once each month.

Provisions should be made to drain each tank independently of all other tanks and the sprinkler system by means of a pipe not less than 1½ in. (40 mm) in diameter.

The filling supply or pump should be reliable and capable of replenishing the water to be maintained in the tank against the normal tank pressure in not more than 4 hours.

Plastic Tanks

Plastic tanks are increasingly being used for fire protection water supplies, however, not without limitations mainly related to capacity. Polyethylene tanks used in aboveground applications as gravity tanks have maximum capacities of 12,000 to 15,000 gallons. Fiber reinforced plastic (FRP) tanks used in underground applications as suction tanks have a maximum capacity of 50,000 gallons. Advantages of plastic tanks are that they do not rust or corrode, are lighter in weight, and do not require assembly. Disadvantages of plastic tanks include their limited capacity and combustibility (requiring sprinkler protection where installed in buildings).

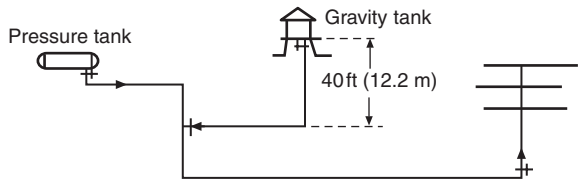

FIGURE 15.1.12 Gravity Tank and Pressure Tank Showing How Risers Are Connected to Avoid Air Lock

NATURAL AND CONSTRUCTED SUCTION FACILITIES

The advantages of piped systems make them the first choice for a water supply for fire protection, but sometimes other water may be more convenient or less expensive. Examples are rural areas and resorts without a piped water system for fire protection. In many of these, however, water is available for fire protection in the ocean, lakes, ponds, rivers, and streams. Cisterns or tanks can be used at locations distant from natural water sources. Small ponds in parks and swimming pools are not particularly good sources of emergency water because this competes with their regular purposes.

For water sources such as those mentioned, the general term *suction supplies* is used to distinguish these supplies from the conventional public water systems for fire protection. Static suction supplies must, in general, be used where they are found and require drafting to lift the water and pumping to move the water to the point of use by fire protection systems. Although there have been instances where water in suburbs, farms, and forests was used to provide effective fire streams at very long distances, laying hose lines more than 750 to 1000 ft (225 to 300 m) seldom makes it possible to provide good protection because of the time required to lay the long lines and the greater difficulty in operating them. Before using naturally occurring water supply sources such as rivers, streams, ponds, lakes, and wells, their reliability, accessibility, and ability to meet required fire protection system demands must be verified. Seasonal fluctuations due to other usage, drought, and freezing must be considered and evaluated. Water supplies from rivers, streams, ponds, lakes, and wells need to be managed to avoid the introduction of mud, sediment, and vegetation. In addition, these water supplies should pass through removable screens and strainers that are installed and maintained to ensure an unobstructed water supply.

Ground Tanks and Cisterns

If no hydrant on a water system is available, one way to ensure the amount of water required for fire fighting is to store it in underground tanks or cisterns at locations where hydrants would normally be installed. The fire department pumper can then get water from a connection on the tank or by dropping a suction hose into the tank. Such tanks and cisterns are filled from domestic water sources too small for fire fighting. The water does not have to be changed so frequently that it presents difficulties.

Static water supplies are of obvious value in rural, farm, and remote areas, but they are equally important for emergency conditions in more urban areas. Before the present

public water systems were developed, some cities provided underground reservoirs or cisterns for fire protection. When water was needed for fire fighting, a pumper suction hose was simply dropped through a manhole. Some of these cisterns are still used in San Francisco and Chicago. Even though San Francisco has a regular water system and a separate system of high-pressure mains, it has been considered prudent, because of the threat of earthquake, to keep over 100 cisterns in service, most of which hold 75,000 gal (284 m^3). Some of the oldest cisterns have brick walls. Newer ones are reinforced concrete.

Rivers and Ponds

Rivers and ponds are important auxiliary water sources, but merely because the water can be seen does not mean that it can be used for fire fighting. These sources of water must have suitable approaches so that fire apparatus can get near the water without becoming mired. A cleared space and some fill in many cases will provide access. These sources must be studied to determine that the water is available all year round and to select the best possible approach. They should also be recorded and mapped and given periodic attention in much the same manner that hydrants are maintained.

At such locations, it is usually necessary to provide a wet pit, basin, or cistern into which water can flow and the pumper suction strainer can be placed. There should be a screen or weir so that large objects will not interfere with the suction strainer. In some places, a permanent suction pipe and strainer can be installed. The details of such an arrangement are the same as those for a fire pump operating under a lift. NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection,* contains guidelines for proper arrangement of wet pits for supplying vertical shaft fire pumps taking suction under a lift. The suction pipe should be laid with enough cover so that it will not freeze. It can be connected at the top to a hydrant with one or more pumper suction connections.

Small Streams and Brooks

Where water supply comes from a brook or stream, it is usually best to drain the water into a sump rather than attempt to use it straight from the flowing stream. If there is a marshy bank or shore, it may be best to go out into the pond or stream to a point where water can be collected in a sump. From the sump in the pond or stream, a pipe should be laid for draining to another sump, the latter located near where the fire apparatus will stand.

In some sumps, and particularly in open water that freezes over in winter, covers may not be feasible at the point where the sump is provided for pumper suction. At such locations, an anchored plug of wood can be floated where the pumper suction should be taken. Such a plug should have a minimum diameter larger than the pumper suction hose and be tapered so that, when frozen in ice, it can be driven down and out of position with a sledgehammer.

In some parts of the country, streams do not flow continuously. A covered cistern of generous capacity may be filled when water flows. Thus, the water may be stored for a longer period than it would keep in an open reservoir.

Water from streams and ponds is more important in areas without public water systems. There are areas where even a brook, if dammed and with a proper pumper approach and a suction basin, can provide good protection at little cost.

For projects in which a stream will be dammed to form static water, experienced civil engineers should be consulted. Details of the dam construction and decisions about the amount of water to be impounded depend on many factors and may require a comprehensive engineering survey. The dam's effect on users of the stream and flood conditions also has to be considered.

Harbors and Rivers

The principal problem with using harbors and rivers as suction supplies is that their water levels change. In harbors, ocean tide levels vary continuously throughout any given 24 hour period. River water levels are seasonal, but the problem is generally the same.

Where there is little fluctuation in the level of a natural water source, a simple pier or platform may be all that is needed to make the water available. If a pumper can be driven onto a sturdy pier, it can go to work when its suction line is dropped over the side. But where the water level varies, special arrangements are needed. If the water is always deep enough for drafting, a hinged ramp leading down to a large float is feasible. But more common is a sloping beach down which the water recedes too far to be accessible at all times. Reservoirs that can be filled at high tide are one solution to this problem.

Where a bridge passes over tidewater, water can be obtained by permanently installing a deep-well pump with a discharge pipe to a point convenient for fire department pumper use. The most practical way to use tidewater supplies is to provide pumps on boats, supplementary to any fireboats in service. Relatively large quantities of water for fire fighting can be obtained from river and harbor sources because large-capacity pumps are normally provided on fireboats, and where there are no fireboats, large pumps can be installed on a boat or barge and pressed into use to supply water for fire protection. To use the water on land, it is necessary to provide a place at which a fireboat or a barge with pumps can tie up and discharge into tanks or a special pipe system with hydrants from which land-based pumping equipment can take the water.

Wells

Wells have become increasingly popular for both domestic use and fire supply for industrial sites, and in more rural areas, located beyond the reach of a piped water supply. Before a well is constructed, a thorough examination of the groundwater must be made. This examination generally includes an aquifer performance analysis and a review of the history of nearby wells. The water in the ground must be of sufficient capacity and dependability and of reasonably good quality. A vertical-shaft turbine pump is used to draw the water from wells into the fire system or into a storage tank.

SUMMARY

Water storage facilities and pump suction supplies are a crucial element for fire protection systems. To ensure an adequate and usable water supply for fire protection, it is necessary to properly design and engineer these supplies to (1) ensure an adequate capacity and duration for the fire protection system being supplied; (2) make sure that the structural design includes all necessary features for resistance to earthquakes and other external exposures (including fire); and (3) ensure that an adequate heating system is provided to prevent freezing of the stored water supply. The discussion within this chapter is intended to make that process easier. For best results, it would be prudent to employ the services of experienced designers and suppliers to meet those goals.

The amount of water needed and the economics of supplying it are basic questions underlying the planning of water supply systems for fire suppression.

This chapter gives information on planning for public water supply systems and outlines the methods used to evaluate public supplies for their adequacy and reliability. The chapter does not cover the specifics of water supply requirements for automatic suppression systems within individual properties.

Specifics are covered in the following chapters of Section 16: Chapter 3, "Automatic Sprinkler Systems"; Chapter 6, "Residential Sprinkler Systems"; Chapter 8, "Water Mist Fire Suppression Systems"; Chapter 9, "Water Spray Protection"; and Chapter 10, "Standpipe and Hose Systems."

FACTORS AFFECTING PUBLIC WATER SUPPLY DESIGN

Most public water supply systems serving a substantial number of customers are, and should be, designed for a dual purpose: (1) to supply water for normal domestic demands, such as drinking and sanitary purposes, as well as for processing and industrial uses, and (2) to provide water for emergency purposes. The latter purpose would include the supply for fire department use, such as through hydrants, and for fixed automatic suppression systems, such as automatic sprinklers and standpipe systems.

The variety of hazards encountered in most communities and the need to plan for future growth must be considered when evaluating these objectives. In some cities, there may be a heavy industrial demand. At the same time, demands for industrial use and lawn sprinkling may affect the required capacity of the system. The adequacy of a public water system for fire protection cannot be taken for granted, and the other demands must be determined to estimate their effects on the capacity of the system.

Public water systems must also be reliable. Because the occurrence of a fire should not affect domestic demands, the water system must be designed to meet the simultaneous demand rates for both purposes. In addition, portions of the pumping or distribution system may be out of service due to breakdown or scheduled maintenance, so the consequences of these interruptions must be examined for acceptability when evaluating system reliability.

When assessing reliability, another factor to take into account is the system's ability to supply increased amounts of water in peak periods that may last only a relatively short time. For example, oceanfront communities in northern climates, such as areas on Cape Cod, Massachusetts, will have a much higher seasonal demand that will begin Memorial Day and end around Labor Day each year. The increase in demand due to the influx of people has a definite effect on the system's ability to supply water at the time of an emergency. The system's ability to provide fire flow during peak usage seasons must be considered in any evaluation. Thus, testing to evaluate a system's reliability must consider the time that the system will be subjected to its highest flows.

Lawrence J. Wenzel, P.E., is a senior engineer with Hughes Associates, Inc., in Baltimore, Maryland.

WATER REQUIREMENTS

Demands for Domestic Purposes

To determine the domestic demands on a public water supply, it is necessary to focus on variations in water consumption with respect to the time of year, the day of the week, and even the hour of the day. Obviously, as more water is used in a given system for normal consumption, less remains for fire protection. Normal consumption demands are usually expressed in the following terms:

- Average daily demand, or the average of the total amount of water used each day during a 1 year period.
- Maximum daily demand, or the maximum total amount of water used during any 24 hour period in a 3 year period. Unusual situations that might have caused an excessive use of water, such as refilling a reservoir after cleaning, should not be considered when determining this figure.
- Peak hourly demand, or the maximum amount of water used in any given hour of a day.

A joint report of committees from the American Society of Civil Engineers, the American Water Works Association (AWWA), and others suggested that the maximum general service demand on a waterworks system be taken as the peak hourly demand during a test year.[1] The report noted that this figure was the only figure that could be fairly compared with the maximum fire flow requirement.

The maximum daily demand can be estimated as 1.5 times the average daily consumption if the actual maximum is not known. The peak hourly rate usually varies from two to four times the normal hourly rate. The effect these varying consumption rates have on the ability of the system to deliver required fire flows varies with the system design. Both maximum daily consumption and peak hourly consumption should be considered to ensure that water supplies and pressures do not reach dangerously low levels during these periods and that adequate water will be available if there is a fire. But keep in mind that these are only estimates and there may be other issues to consider. For example, a water supply for an area that has a high concentration of carpet or textile mills as its primary industrial base may have periods that can severely skew these estimates. If all of the carpet mills open their "dye beks" at the same time on a given day, and conduct a heavy amount of dyeing operations for an extended period of time, there can be a severe spike in the daily consumption. For the period that their operations are being conducted, the water supply in the area may be dangerously low. These types of industrial periods must be considered.

Water Requirements for Fire Fighting

The water requirements for fire fighting include the rate of flow, the residual pressure required at that flow, and the total quantity required. The American Water Works Association defines the required fire flow as "the rate of water flow, at a residual pressure of 20 psi and for a specified duration that is necessary to control a major fire in a specific structure."[2] The fire protection community has informally adopted the figure of 20 psi as the lowest pressure to which fire protection systems will be designed. These include sprinkler systems and fire pumps using the municipal supply as a suction or supply source.

CALCULATING FIRE FLOW RATES

The required flow rate for properties protected by automatic sprinklers is based either on the sprinkler system design as required by NFPA 13, *Standard for the Installation of Sprinkler Systems* (hereinafter referred to as NFPA 13), or on the exact details of the hydraulic sprinkler system design for the systems installed in the structure. (Also see NFPA 13R, *Standard for the Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height,* and NFPA 13D, *Standard for the Installation of Sprinkler Systems in One- and Two-Family Dwellings and Manufactured Homes.*) The flow required is that of the sprinkler system plus the anticipated hose stream or manual fire-fighting requirements. It also may be necessary to consider additional water supply needs for buildings with neighboring structures that present an exposure to the structure being considered.

Several methods are currently used to calculate required waterflow rates for *nonsprinklered* properties. These include the following:

- The Insurance Services Office (ISO) method
- The Iowa State University (ISU) method
- The Illinois Institute of Technology Research Institute method

Insurance Services Office (ISO) Method

Probably the most comprehensive and widely recommended methods for estimating fire flow requirements are found in the Insurance Services Office's *Fire Suppression Rating Schedule.*[3] It provides guidance for estimating fire flow requirements for specific structures and was designed for insurance rating purposes. The flows determined by this method are generally considered a good estimate, and, as a result, the ISO method has received widespread use. The ISO method considers building construction, occupancy, adjacent exposed buildings, and fire communication paths between buildings.

The basic formula in the schedule is

$$NFF_i = (C_i)(O_i)(X + P)_i$$

where

NFF_i = Needed fire flow (*NFF*) in gal per min (L/min)

C_i = A construction factor that depends on the construction of the structure under consideration

O_i = An occupancy factor that depends on the combustibility of the occupancy

$(X + P)_i$ = An exposure factor that depends on the extent of exposure from and to adjacent structures

The subscripts in the formula indicate that, where portions of a building have differing characteristics, a factor can be calculated for each section and multiplied by the percentage it represents of the effective area to obtain a weighted factor. The

weighted C_i factor should not be less than the individual factor required for any individual section.

Construction Factor. The construction factor, C_i, is calculated from the following formula:

$$C_i = 18f\sqrt{A_i}$$

where

F = Coefficient related to the class of construction
= 1.5 for construction class 1 (frame)
= 1.0 for construction class 2 (joisted masonry)
= 0.8 for construction class 3 (noncombustible) or construction class 4 (masonry, noncombustible)
= 0.6 for construction class 5 (modified fire resistant) or construction class 6 (fire resistive)

A_i = Effective building area

The effective building area is the total square foot (m^2) area of the largest floor plus one of the following:

- For construction classes 1 through 4, 50 percent of all other floors
- For construction classes 5 and 6, 25 percent of the area not exceeding the two other largest floors when all of the vertical openings have at least 1½-hour-rated protection, or 50 percent of the area not exceeding eight other floors when vertical openings are unprotected or have less than 1½ hour protection

The value of C_i should never be less than 500 gpm (1893 L/min) for any construction class, nor greater than 8000 gpm (30,280 L/min) for construction classes 1 and 2, and 6000 gpm (22,710 L/min) for construction classes 3, 4, 5, and 6, or any single, one-story building, regardless of construction.

Occupancy Factor. The occupancy factor, O_i, reflects the combustibility of the occupancy on the needed fire flow and is determined from the occupancy combustibility class. Occupancy factors can be found in Table 15.2.1. Typical occupancies and their classification can be found in Table 15.2.2. For more detailed occupancy classification information, see NFPA *101*®, *Life Safety Code*®.

Exposure and Communication [$(X = P)_i$] Factors. The exposure and communication factors are determined as

$$(X + P)_i = 1 + \sum_{i=g}^{n} X_i + P_i$$

where

n = Number of sides of subject building
$(X + P)_i$ = A maximum value of 1.75

The exposure factor, X_i, reflects the need for additional water to reduce the exposure to adjacent buildings. It depends on the separation distance, the construction of the exposed building wall, and a length-height value—that is, the length of the exposed wall in feet (m) multiplied by the height in stories. Values can be obtained from Table 15.2.3.

TABLE 15.2.1 Occupancy Factors

Occupancy Combustibility Class	*Occupancy Factor (O_i)*
C-1 (Noncombustible)	0.75
C-2 (Limited combustible)	0.85
C-3 (Combustible)	1.00
C-4 (Free burning)	1.15
C-5 (Rapid burning)	1.25

The fire communication factor, P_i, reflects the potential fire spread through open or enclosed communicating passageways between buildings and is taken from Table 15.2.4. Where there is more than one connection, only the one with the largest factor is used. Where there are no openings, $P_i = 0$.

Needed Fire Flow. The needed fire flow (*NFF*) is calculated from the formula given previously and from the foregoing factors. The *NFF* calculated from the formula should be rounded to the nearest 250 gpm (946 L/min) for flows under 2500 gpm (9463 L/min) and to the nearest 500 gpm (1893 L/min) for larger flows and then adjusted by the following:

- For buildings with a wood roof, add 500 gpm (1893 L/min).
- The needed flow should not exceed 12,000 gpm (45,420 L/min) nor be less than 500 gpm (1893 L/min). The practical reason for these figures is that manual fire-fighting methods using hose streams and heavy stream appliances are not likely to need a larger supply, considering the general arrangement of buildings and the availability of hydrants.
- For habitational buildings, use the calculated *NFF* up to 3500 gpm (13,248 L/min) maximum.
- For groupings of one-family and small two-family dwellings not more than two stories high, the required fire flow given in Table 15.2.5 may be used.

Iowa State University (ISU) Method

The Iowa State University method[4] is another common method used to determine waterflow rates for fire fighting. It uses a more theoretical approach and is based on the amount of water needed to deplete the oxygen in a confined area when the water is vaporized into steam by the heat of the fire. Tests conducted by the university indicate that a fire is best controlled if the amount of water necessary to deplete the oxygen is applied within 30 seconds.

The required flow in gpm is given as

$$\text{Required flow} = \frac{V}{100}$$

where V is the enclosed volume (length of the structure multiplied by its width and height) in cubic feet. (For SI units: 1 gpm = 3.785 L/min; 1 ft^3 = 0.0283 m^3.)

This method is unique in that it does not consider the occupancy hazard, only the volume of the building to be filled with steam. It is essentially a formula that is used in determining the

TABLE 15.2.2 Occupancy Classification

C-1 (Noncombustible)	C-4 (Fire burning)
Steel or concrete products storage, unpackaged	Aircraft hangers, with or without servicing/repair
	Apparel manufacturing
C-2 (Limited combustible)	Auditoriums
Apartments	Breweries
Ceramics manufacturing	Building material sales and storage
Churches	Cotton gins
Concrete products manufacturing	Food processing
Courthouses	Freight depots, terminals
Dormitories	Furniture—new or secondhand
Hospitals	Metal coating or finishing
Hotels	Paper and paper product sales and storage
Metal products fabrication	Paper products manufacturing
Metals industries (primary)	Printing shops and allied industries
Motels	Rubber products manufacturing
Offices	Theaters, other than motion picture
Parking garages	Warehouses
Schools	Wood product sales and storage
	Woodworking industries
C-3 (Combustible)	
Amusement park buildings, including arcades and game rooms	C-5 (Rapid burning)
Automobile sales and services	Cereal or flour mills
Baking and confectionery	Chemical manufacturing
Dairy processing	Chemical sales and storage
Department stores	Cleaning and dyeing material sales and storage
Discount stores	Distilleries
Food and beverage—sales, service, or storage	Meat or poultry processing
General merchandise—sales or storage	Paint sales and storage
Hardware, including electrical fixtures and supplies	Plastic or plastic product sales and storage
Leather processing	Plastic products manufacturing
Motion picture theaters	Rag sales and storage
Pharmaceutical retail sales and storage	Textile manufacturing
Repair or service shops	Textile products fabrication, except clothes
Soft drink bottling	Upholstering shops
Supermarkets	Waste and reclaimed materials sales and storage
Tobacco processing	
Vacant buildings	

amount of water required to begin to reduce the size of a compartment fire.

Due to inefficiencies in applying water, some experts feel that the rate should be 2 to 4 gal per 100 ft^3 (7.6 to 15.0 L/2.8 m^3) of building volume rather than the 1 gal per 100 ft^3 (3.785 L/2.8 m^3) in the formula. Other variations include changing the value in the denominator based on the occupancy hazard. Obviously, high-hazard occupancies require more water to absorb the heat release of the burning occupancy.

This formula has been used for approximately 50 years and is extremely simple to apply. For most buildings, the entire volume of the structure should be used, including the volume of basements, attics, crawl spaces, and other concealed spaces. For groups of buildings, the largest calculated flow rate should be used.

Illinois Institute of Technology Research Institute Method

The Illinois Institute of Technology method was based on a survey of 134 fires in the Chicago area. The results of the survey were used with regression analysis to develop fire flow formulas based on building area. The fire flow rate is based on one of the following formulas:

$$\text{Flow for residential occupancies} = 9 \times 10^{-2}A^2 + 50 \times 10^{-2}A$$

$$\text{Flow for other occupancies} = -1.3 \times 10^{-5}A^2 + 42 \times 10^{-2}A$$

where A is the area of the fire in square feet. (For SI units: 1 ft^2 = 0.0929 m^2.)

OTHER FLOW CONSIDERATIONS

Regardless of the method used to determine the flow rate, the required fire flow should be available simultaneously with consumption at the maximum daily rate.

When evaluating the flow required for general public protection, both the AWWA and the ISO suggest that 3500 gpm (13,248 L/min) is the upper limit to be provided and that large facilities or those with severe hazards that need flow rates up to 12,000 gpm (45,420 L/min) be individually analyzed to determine the required flow rate.

There are fires in which quantities of water in excess of the required fire flow are used. Water supplies of 50,000 gpm (189,250 L/min) or greater have been used in fire suppression, but designing systems capable of delivering flows of that magnitude is not cost-effective nor practical. Expecting the municipal system to deliver these large flow rates is not reasonable; thus, private supplies are often developed to become the primary supply for large-flow industrial sites, or to augment the municipal supply. This development is a site-by-site determination, based on the available municipal flow rates and supplies.

Fire Flow Duration

The number of hours during which the required fire flow should be available varies from 2 to 10 hours, as indicated in Table 15.2.6. It should be noted that many water authorities place an upper limit of 2 to 4 hours on fire water supply duration due to economics.

Evaluating System Capacity

The capacity of a water system is determined by the total amount of water it must furnish. This amount is the sum of water required for domestic or industrial uses and water required for the fire service. In small towns the requirements for fire protection almost always exceed other requirements.

The AWWA recommends that the rate used be either the peak hourly rate or the maximum daily rate plus fire flow,

TABLE 15.2.4 Factors for Communications, P_i

For SI units: 1 ft = 0.305 m.
Note: When a party wall has communicating openings protected by a single automatic or self-closing Class B fire door, it qualifies as a division wall (defined in greater detail in the ISO *Commercial Fire Rating Schedule*) for reduction of area.
Note: Where communications are protected by a recognized water curtain, the value of P_i is 0.
[a]For over 50 ft, $P_i = 0$.
[b]For unprotected passageways of this length, consider the two buildings as a single fire division.

TABLE 15.2.5 Fire Flows for Groups of Dwellings

Exposure Distances		Suggested Required Fire Flow	
ft	*m*	*gpm*	*L/min*
Over 100	30.5	500	1893
31–100	9.5–30.5	750–1000	2839–3785
11–30	3.4–9.2	1000	3785
10 or less	3.1 or less	1500	5678

whichever is larger. In most large cities, the peak hourly rate exceeds the maximum daily consumption rate plus fire flow and is, therefore, the controlling factor in the supply system design. In smaller communities, however, the reverse is true and the maximum daily consumption rate plus fire flow is the controlling factor. For many years, water consumption has been increasing in most municipalities, resulting in increased peak hourly rates. Consequently, there has been an increase in the number of municipalities in which the peak hourly rate controls designs of the supply system. However, there is no guarantee that a fire will not occur at the peak hour, and some recommend that the capacity of the system be sufficient to meet the peak hourly rate plus the fire flow rate.

Fire flows are a very important consideration in all areas served by the distribution system and, in many instances, they govern the size of pipe used in these locations. In all systems, the supply should be sufficient to provide for automatic sprinklers and other automatic water-based fire suppression systems, in addition to the other demand rates imposed on the system. For example, many smaller cities and large towns restrict lawn watering in summer months to specified periods, depending on local conditions. The demand rates imposed by lawn watering are excessive in many water supply systems, possibly depleting storage facilities and reducing pressure throughout the system for many hours. In such situations, there would be little or no water available for fire suppression systems, particularly at higher elevations.

PRESSURE CHARACTERISTICS OF SYSTEMS

The pressures for which systems are normally designed are the result of practical attempts to provide adequate pressures both for domestic consumption and for fire protection. If either demands special ranges of pressure, materials and design methods are available that will allow almost any desired range.

For example, San Francisco has a separate system, designated the "high-pressure system," that is under the control of the fire department. All system pipe is heavy cast iron, tar coated, and lined, and it is tested on installation and repair to 450 psi (3103 kPa). Two steam-operated pump stations can pump water from San Francisco Bay into the system, and 20,000 gpm (75,700 L/min) at 250 psi (1724 kPa) can be delivered to most of the principal mercantile district. San Francisco provided this

system primarily because an earthquake might put the regular public water system out of service. A few other cities have similar high-pressure systems.

Modern fire department pumpers make heavy streams and high pressures available from ordinary water systems where adequate volume is provided. Cities that formerly had separate fire main systems operating at so-called high pressures now generally keep them at normal public water pressures. The second system still provides an advantage, though, even if it is not at high pressure, because it is still available and becomes a valuable source of "volume."

Public water systems reflect a compromise on the question of pressures. Pressures in the range of 65 to 80 psi (448 to 552 kPa) are common. This range, which is adequate for ordinary consumption in buildings up to about 10 stories, will provide a good supply of water for automatic sprinkler systems in buildings of about four stories, in which occupancies are classified as "ordinary" or "light." Where pressures of this order are provided, it is reasonably easy to compensate for local fluctuations.

Because of the increased cost of energy, closer scrutiny is being given to the water pressure that systems should provide. A reduction in water pressure will substantially reduce pumping costs. Before a general reduction is made, however, a study should be conducted as to the effects it could have on sprinklers and other fixed fire suppression systems. If a reduction in pressure is planned, it is imperative that the system remain capable of meeting anticipated demand rates, or steps must be taken to lower the demand rates to a point where they will be within the capability of the system. In many cases, the reduction of pressure will have an adverse effect on private industrial and commercial-building fire protection systems using pumps, as the municipal supply is the suction source for many private systems.

A minimum residual pressure of at least 20 psi (138 kPa) should be maintained at hydrants delivering the required fire flow. Pumpers will operate where hydrant pressures are less. Where hydrants are well distributed and of the proper size and type so that friction losses in the municipal system will not be excessive, it may be possible to set 10 psi (69 kPa) as the minimum operating pressure. Sufficient hydrant pressure should be maintained to prevent a negative pressure from developing in the street mains, which might cause damage to the municipal system. In some older systems, back siphonage of polluted water from some interconnected source may still be a problem. But, in most areas and municipal systems, better backflow prevention has eliminated this problem. Many state health departments prohibit the use of residential pressures of less than 20 psi (138 kPa). However, in a severe fire situation in many locations, a pressure lower than 20 psi (138 kPa) may have to be used to develop necessary fire flows and the movement of water volume from one area to another. Proper emergency planning on the part of the public fire officials can generally eliminate this situation.

Pressures in a public water system may be considered excessive as they approach 150 psi (1034 kPa). As pressures increase, they tend to cause leaks in domestic plumbing, and special attention is required to restrain pipelines in the ground. Pipe and fittings used in ordinary public water systems are designed for maximum working pressures of 150 psi (1034 kPa), but it is not good practice to operate with pressures that high. Pressure-reducing valves can be used in sections of a system where variations in topography result in excessive pressures. Individual water services to buildings may require pressure-reducing valves to keep the pressure on domestic piping at safe levels.

SYSTEMS FOR HIGHER ELEVATIONS

When water must be supplied to high elevations, a separate water distribution system is usually provided for the elevated section so that reasonable pressures are maintained. In such cases, the elevated area should be provided with its own water storage facility, and pumps may be provided to boost the water from other parts of the system.

Likewise, the upper stories of a high-rise building are sometimes provided with dedicated risers (express risers) to deliver water to these upper floors. High-rise structures are normally divided into a number of pressure zones, and zones of more

than 12 stories can be outside the normal pressure ranges. In any case, each pressure zone must be provided with water in the amounts needed for sprinkler system and hose stream use, and each system is usually supplied by a series of pumps and, sometimes, tanks arranged so that each zone is fed from the zone below. Care should be taken to ensure that pumps would be able to operate even during power failures.

For information and guidance concerning water supplies for high-rise structures, see NFPA 13; NFPA 14, *Standard for the Installation of Standpipe and Hose Systems;* and NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection.*

ADEQUACY AND RELIABILITY OF SUPPLY

The adequacy of any given water supply system can be determined by engineering estimates. The source (e.g., storage facilities and distribution system) must be sufficient to furnish all the water that combined fire and domestic needs may call for at any one time. The arrangement of the supply and pumping facilities may render the supply inadequate or affect its reliability.

Pumping systems commonly are arranged so that one set of pumps takes suction from wells or from a river, lake, or other body of water. If the water does not have to be filtered, the pumps may discharge directly into the distribution system. Where filtration or other treatment is necessary, pumps take suction from the primary or raw water source and discharge to sedimentation basins or other facilities and then to filter beds. After the water is processed, it flows to clear-water reservoirs from which a second set of pumps takes suction and discharges the water directly into the supply system. Unfortunately, failure of any part of the equipment may affect the entire system.

There are still communities that use direct-pumping methods and have no stored water capacity. These types of systems rely on pumps operating in stages, based on the demand. These "pump-only" systems require constant attention to the mechanics of the equipment, as each piece of pumping equipment is that much more important. Without storage capacity, which can buy maintenance time for repairs and parts replacement, additional thought has to be put into keeping critical equipment maintained and backed up.

When assessing the reliability of the supply works, one should evaluate the following:

- Minimum yield
- Frequency and duration of droughts
- Condition of intakes
- Possibility of earthquakes, floods, and forest fires
- Ice formations
- Silting up or shifting of river channels
- Security of installations to prevent physical damage
- Availability of replacement equipment and parts
- Ability to divert flow within the system to avoid local outages and reduced pressure

Reservoirs out of service for cleaning and the interdependence of parts of waterworks also affect reliability. The condition, arrangement, and dependability of individual units of plant equipment, such as pumps, engines, generators, electric motors, fuel supply, electric transmission facilities, and similar items, are also factors. Pumping stations of combustible construction may be destroyed by fire unless they are protected by automatic sprinkler systems.

Duplication of pumping units and storage facilities, and arrangement of mains and other distribution piping so that water may be supplied to any area from more than one direction, are measures that can ensure continuous operation. The importance of duplicate facilities is shown by the frequency of their use. Many utilities design their systems so that the peak hourly rate and required fire flow rate can be supplied when any pump or section of the distribution system is out of service.

The amount of water needed to control and extinguish a fire in a given property currently cannot be established in precise terms. Better fire experience databases should make it possible to tailor fire flows more specifically to conditions that might be expected at the time of a fire. Better analysis may indicate a need to increase fire flow beyond what is presently required, or it may result in a water system design based on a balance between the risk involved and the economics of maintaining the water system.

A detailed discussion of all the factors to be considered in designing a water supply system is beyond the scope of this handbook. An overview of the subject can be found in AWWA M24, *Dual Water Systems,* and AWWA M31, *Distribution System Requirements for Fire Protection.*

FACTORS AFFECTING WATER REQUIREMENTS

Codes and Ordinances

Fire prevention codes can effectively limit hazards and ignition sources within buildings, which, in turn, may limit the number and size of fires by controlling combustibles in a fire area. A good building code further reduces the chance for a serious fire by requiring construction materials and building assemblies that will contain a developing fire to a given area. Codes alone can reduce considerably the amount of water needed for fire fighting. Zoning ordinances that establish distances between properties can be effective in controlling exposure situations.

Fire Detection and Extinguishing Systems

The increased use of automatic suppression systems, whether they use water or some other agent, will affect the quantities of water required. As more widespread use is made of early warning systems and automatic suppression systems, it will be possible to equate the effect of these systems with required fire flow, and there may well be a reduction to the amount of water needed to suppress a fire. Water supply requirements are just one factor in a system that determines what the potential for a fire is, how extensive that fire will be, and what measures will be needed to suppress it. Research continues to measure all these factors, and experience adds valuable information, allowing the establishment of fire flows on the basis of thoroughly researched and documented principles.

HISTORY OF WATER SUPPLY SYSTEMS

Historically, water supply systems for cities and towns were developed primarily to provide drinking water and water for sanitary purposes rather than for fire protection. However, it was found that large cities that required substantial amounts of water for domestic purposes usually had enough water to provide a useful supply for fire-fighting purposes.

This supply issue led to inquiries in the late nineteenth century into the additional cost of waterworks that could provide water for fire fighting, as well as other uses. A number of distinguished engineers associated with individual waterworks examined the problem and presented their findings in technical papers at engineering society meetings. Papers by J. Herbert Shedd,[5] J. T. Fanning,[6] and Emil Kuichling[7] give the details of discussions in which standards for American and Canadian waterworks were first developed (Table 15.2.7). Keep in mind that at the turn of the century, when these engineers practiced, the advent of automatic sprinkler protection was just arriving. Thus, most of their research and findings dealt with the effectiveness of hose streams. It continues to be a cornerstone in determining the validity of hose stream use by today's fire service, in a very general nature.

NUMBER OF HOSE STREAMS

In these discussions, the starting point for computing the cost of water for fire protection was to estimate the number of hose streams that a fire department might need for fire fighting. This was usually estimated using as a basis the central portion of a city where the largest buildings were located and where there was the greatest building congestion. The number of streams was found to be related, in a very rough way, to the population. Shedd's proposal,[5] which was the first, used hose streams discharging 200 gpm (757 L/min). He suggested that a community of 5000 would need about 5 such streams and that the needs of other cities could be graduated up to 30 streams in a city of 180,000. Fanning[6] proposed streams requiring about 54 psi (372 kPa) pressure. His figures were similar to Shedd's,[5] beginning at 7 streams for a community of 4000 and going up to 25 streams for a city of 150,000.

Kuichling[7] suggested a formula in which the number of streams required would be the square root of the population in thousands multiplied by 2.8. There were arithmetical differences as to how these estimates worked out for individual cities, but they were all of the same general order (see Table 15.2.7). Most important, they provided a basis from which waterworks designers could estimate costs.

The most important paper produced during this time was John R. Freeman's "The Arrangement of Hydrants and Water Pipes for the Protection of a City Against Fire," published in 1892.[8] Freeman had done the fundamental work on waterflow through hose and nozzles, so he was able to pin down the definition of a standard fire stream to one with a discharge of 250 gpm (946 L/min) at 40 to 50 psi (276 to 345 kPa) pressure. He said that the relationships suggested by Shedd[5] and Fanning[6] between population and the number of streams required were of the right order, but he did not think the needs of individual cities could be quite so definitely ascertained. He suggested two to three streams as a minimum for a population of 1000, graduated up to 30 to 50 streams at 200,000 (see Table 15.2.7). Most significantly, he warned, "Ten streams, or as large a proportion thereof as the financial consideration will permit, may be recommended for a compact group of large, valuable buildings, irrespective of a small population."[8]

ENGINEERING: DISTRIBUTION NETWORK, HYDRANT SPACING, STORAGE

Freeman[8] noted a fundamental difference between systems designed to supply ordinary water needs and those for fire

TABLE 15.2.7 Estimates of Fire Flow

Sources: Shedd,[5] Fanning,[6] Kuichling,[7] Freeman,[8] and Metcalf, Kuichling, and Hawley.[9]

protection: fire draft required concentration of the water, whereas domestic draft was a matter of distribution.

Freeman[8] asserted that, if a water system were to supply fire protection needs, the distribution system should be designed to concentrate the needed amounts of water. Small pipes were sufficient for distribution, but larger ones were needed to concentrate supply to fire streams. He suggested 6-in. (152-mm) diameter pipe as the minimum for residential districts and noted that 8 in. (203 mm) pipe was adequate only if it formed part of a network of distribution pipes whose intersections were not far apart.

Another important point Freeman[8] made was that hydrants should be placed where they could concentrate streams at specific blocks or groups of buildings rather than be placed arbitrarily a certain number of feet (m) apart on the street mains. His work on hose streams showed how long hose lines reduced the water that can be delivered promptly to a fire. Therefore, he suggested a working rule for hydrant spacing of 250 ft (76 m) between hydrants in compact mercantile and manufacturing districts and 400 ft (122 m) to 500 ft (153 m) in residential districts. These working rules are still used as guides for good design.

Freeman[8] further insisted that fire supply should be in addition to maximum domestic consumption, and he laid the foundation for the eventual recognition of this principle. He also calculated how much water should be stored in standpipes, elevated tanks, or elevated reservoirs. He figured that flow for all of the hose streams required should be supplied from a reliable source, such as an elevated storage reservoir, for at least 6 hours when the system was also furnishing maximum demands for domestic and other uses. He also calculated that to supply the combined fire and domestic needs in a system provided with reliable pump capacity a 1 hour supply in a standpipe, elevated tank, or elevated reservoir would be acceptable.

THE INSURANCE GRADING SCHEDULE

As early as 1889, the National Board of Fire Underwriters (NBFU) began to make fire protection surveys of municipalities. This work was intensified in 1904 after a conflagration in Baltimore, Maryland. Today the ISO surveys communities in all but a few states. The ISO survey, called the *Fire Suppression Rating Schedule,*[3] was discussed in detail earlier in this chapter.

The current ISO procedure for establishing fire flows is different from the original NBFU formula, which was commonly used for many years as a guide to determine the fire flow required in downtown business districts of municipalities (see Table 15.2.7). The formula gave the fire flow, G, in gpm as a function of the population, P, in thousands. (For SI units: 1 gpm = 3.785 L/min.)

$$G = 1020\sqrt{P}\,(1 - 0.01\sqrt{P})$$

In making fire protection surveys, engineers from NBFU and insurance bureaus estimated the fire flow requirements in sections of municipalities outside the downtown business district. As cities became more decentralized, the formula based on population became less reliable as a guide for the fire flow needed downtown. In addition, it became apparent that a guide to engineering judgment was needed for the other sections of the cities. In 1948, a paper by A. C. Hutson,[10] assistant chief engineer at NBFU, provided some specific suggestions for estimating fire flow requirements in these sections, based on the type of construction and the area of a building. This eventually led to the current ISO rating system.

SUMMARY

The time to worry about the requirements of a fire protection water supply is not when the fire has broken out but rather long before the incident occurs. Fire protection water is almost always a shared entity with the domestic users, and fire protection supplies are needed only when there is an emergency. However, the total supply available to an area has to consider both normal and emergency uses.

The fire service has a number of methods available to help determine the adequacy and reliability of the water supply in the event of a fire. The amount of water needed will always be a function of the occupancy and the construction of the building in question, and in many cases, the outside exposures to the structure. There are quick ways to develop fire flow needs that encompass all of these parameters, and the fire service uses these routinely.

Adequacy and reliability of the water supply system when needed are not to be taken for granted. Careful planning as to what is needed and then careful analysis of availability are key to planning before an incident occurs.

Chapter 3

Hydraulics for Fire Protection

Kenneth W. Linder

Chapter Contents

Hydraulic Properties of Water
Bernoulli's Theorem
Flow of Water Through Orifices
Coefficients of Flow
Flow Measurement
Flow of Water in Pipes
Water Hammer
Elastic Wave Theory

Key Terms

Chezy formula, coefficient of flow, Darcy-Weisbach formula, elastic wave theory, friction loss, Hazen-Williams formula, hydraulic calculations, hydraulically designed system, K-factor, Moody diagram, velocity head, velocity pressure, water hammer

Hydraulics is a subset of fluid mechanics that deals with the flow of water. As applied to fire protection, it involves the flow of water through pipes, valves, fittings, and orifices such as hydrant outlets, nozzles, and sprinklers. This chapter describes the physical properties of water that are pertinent to hydraulic calculations and the basic formulas used to calculate flow and pressure loss in fire protection systems. It does not include details on the specific rules required to design hydraulically calculated sprinkler systems in accordance with NFPA 13, *Standard for the Installation of Sprinkler Systems,* or the algorithms used to determine how the flow splits in looped systems or more complex gridded piping systems.

For related topics see Section 17, Chapter 3, "Characteristics and Hazards of Water and Water Additives for Fire Suppression."

HYDRAULIC PROPERTIES OF WATER

As used in this handbook, water refers to fresh water unless otherwise specified. All calculations are made in U.S. gallons (gal), unless otherwise indicated. One U.S. gal equals 3.78 L. An Imperial gal equals 1.20 U.S. gal (4.54 L).

Material Properties

Density. Density, ρ, is defined as mass per unit volume:

$$\rho = \left(\frac{\text{mass}}{\text{volume}}\right)$$

The density of water, as with many other liquids, varies with temperature. The maximum density of water occurs at 39.2°F (4.0°C) and is 62.43 lbm (pound mass) per ft^3 (1000 kg/m^3 [kilograms per m^3]) in vacuum or 62.35 lbm per ft^3 (998.7 kg/m^3) in air. For most hydraulic calculations, an approximate value of 62.4 lbm per ft^3 (1000 kg/m^3) is usually used. Average seawater has a density of 64.1 lbm per ft^3 (1030 kg/m^3) at 39.2°F (4.0°C).

Specific Weight. The specific weight of a material, *w,* is defined as $w = \rho g$ where g is the acceleration due to gravity. The specific weight is usually measured in lbf (pound force) per ft^3 in U.S. customary units and kgf (kilogram force)/m^3 in SI units and is

$$w = \rho g = 62.4 \frac{\text{lbm}}{\text{ft}^3} \times 32.2 \frac{\text{ft}}{\text{sec}^2} \times 1 \frac{\text{lbf} \cdot \text{sec}^2}{32.2\ \text{lbm} \cdot \text{ft}} = 62.4 \frac{\text{lbf}}{\text{ft}^3} = 1000\ \text{kgf per m}^3$$

A common, though incorrect, practice is to use the terms *pound mass* (lbm) and *pound force* (lbf) interchangeably, since one lbm has a weight of one lbf under standard gravity. (A similar situation exists in SI units with kg (kilogram) and kgf [kilogram force].) In this chapter, pound (lb)

Kenneth W. Linder is NAT CAT manager for Swiss Re, Industrial Risk Insurers, and also serves as a senior research consultant to Global Asset Protection Services.

means pound force (lbf) and kilogram (kg) means kilogram force (kgf), as is common in engineering practice.

One ft^3 (0.028 m^3) equals 7.48 U.S. gal. Assuming the specific weight of water is 62.4 lb per ft^3 (1000 kg/m^3), 1 gal of water, therefore, weighs 62.4 lb per ft^3 ÷ 7.48 gal per ft^3, or 8.34 lb (3.78 kg).

Viscosity. Viscosity is a measurement of a fluid's resistance to flow and is usually measured in pound sec per $foot^2$ ($lb\ sec/ft^2$) in U.S. customary units or newton sec per $meter^2$ ($N{\cdot}sec/m^2$) in SI units. Viscosity, like density, varies with temperature. At 32°F (0.0°C), water has an absolute viscosity, μ of 3.746×10^{-5} lb sec/ft^2 (1.793×10^{-5} $N{\cdot}sec/m^2$). In hydraulic problems, viscosity is often divided by density. This relative viscosity, called kinematic viscosity, υ, is defined as

$$\upsilon = \frac{\mu}{\rho}$$

Although viscosity is an important factor in fluid flows, most fire protection hydraulics applications assume water at ambient conditions, and the empirical formulas normally used to calculate losses do not take into account changes in viscosity.

An exception are hydraulic calculations involving foam concentrate solutions in foam-water sprinkler systems or large antifreeze solutions in blast freezers or other very cold areas where the solution is significantly more viscous than water at ambient conditions.

Pressure

Pressure, *p,* is the unit that measures the force, caused by compression, per unit area in a fluid. In fire protection hydraulics, pressure is normally measured in pounds per square inch (psi) or in kilopascals (kPa), as indicated by a pressure gauge, or as head, *h,* in feet (ft) or meters (m) of water. Pressure is also commonly measured as a head of mercury, atmosphere, bar, or newtons per square meter (N/m^2).

For waterflow in pipes, the total pressure, p_t, is the sum of normal pressure, p_n and velocity pressure, p_υ:

$$p_t = p_n + p_\upsilon$$

Normal Pressure. Net or normal pressure is the pressure exerted against the side of a pipe or container by the liquid in the pipe or container with or without flow. Without flow, this pressure is called "static pressure" or "static head." With flow, this pressure is called "residual" pressure.

The pressure exerted by a column of water is related to its specific weight. Expressed slightly differently, the specific weight is

$$\frac{62.4\ \text{lb}}{\text{ft}^3} = \frac{62.4\ \text{lb}}{\text{ft}^2\ \text{ft}} \times \frac{1\ \text{ft}^2}{144\ \text{in}^2} = 0.433\ \text{psi per ft}$$

It follows that pressure and static head are related by the following formulas:

$$p = wh = 0.433h$$

$$h = \frac{p}{w} = \frac{p}{0.433} = 2.31p$$

For SI units, the weight of a 1 m column of water equals a force of 9.81 kPa or

$$p = 9.81h$$

$$h = \frac{p}{9.81} = 0.102p$$

A 1 in. (25.4 mm) head of mercury generates a pressure of 0.491 psi (3.39 kPa) and is equivalent to a 1.135 ft (0.3456 m) head of water.

Normal atmospheric pressure is taken as 14.7 psi (101.4 kPa), equivalent to a head of water of 33.95 ft (10.35 m) and a head of mercury of 29.9 in. (760 mm).

Velocity Head or Velocity Pressure. The velocity, υ, produced in a mass of water by pressure acting upon it is the same as if the mass were to fall freely, starting from rest, through a distance equivalent to the pressure head in feet. This relationship is represented by Torricelli's equation:

$$\upsilon = 2\sqrt{gh}$$

where υ = the velocity produced in ft/sec (m/sec), g = the acceleration due to gravity or 32.2 ft/sec^2 (9.81 m/sec^2), and h = the head in ft (m) producing the velocity.

Just as a static head can be converted into a velocity head, velocity head can be converted to an equivalent static pressure head. This relation is

$$h_\upsilon\ (\text{velocity head}) = \frac{\upsilon^2}{2g}\ (\text{ft})$$

Because

$$p_\upsilon = 0.433h_\upsilon$$

the velocity pressure can be expressed as

$$p_\upsilon = 0.433\ \frac{\upsilon^2}{2g}\ (\text{psi})$$

In SI units

$$p_{\upsilon m}\ (\text{kPa}) = 9.81\ \frac{\upsilon^2}{2g}$$

for υ in m/s.

Values of velocity pressure for different rates of flow in various pipe sizes are shown in Figure 15.3.1. (For SI units see Figure 15.3.2.) Velocity head or velocity pressure may be calculated by formulas involving velocity and pipe diameter:

$$h_\upsilon = \frac{\upsilon^2}{64.4}\ \text{ or }\ p_\upsilon = \frac{0.433\upsilon^2}{64.4} = \frac{\upsilon^2}{149}$$

In SI units

$$h_{\upsilon m} = 0.0151\upsilon^2\ \text{ and }\ p_{\upsilon m} = 0.5\upsilon^2$$

A convenient equation for calculating velocity in feet per second (fps) from the rate of flow can be developed from the principle of conservation of mass. For a steady-state one-dimensional flow with average velocity υ, this principle can be stated as

$$Q = a\upsilon$$

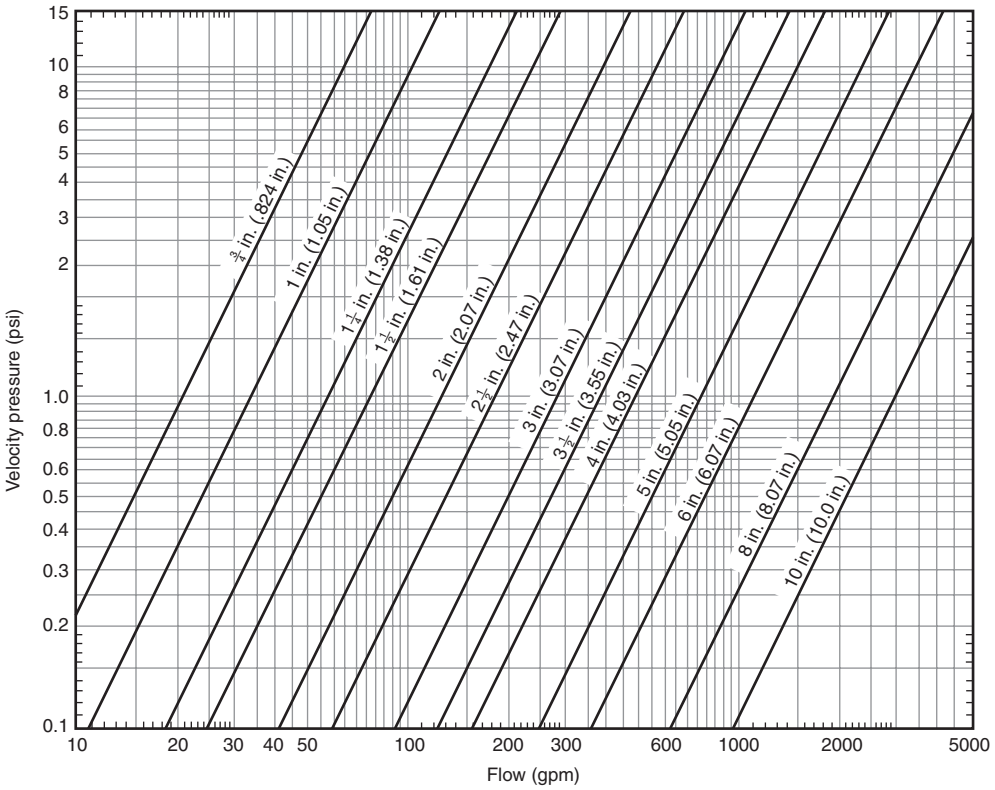

FIGURE 15.3.1 Graph for the Determination of Velocity Pressure (English Units)

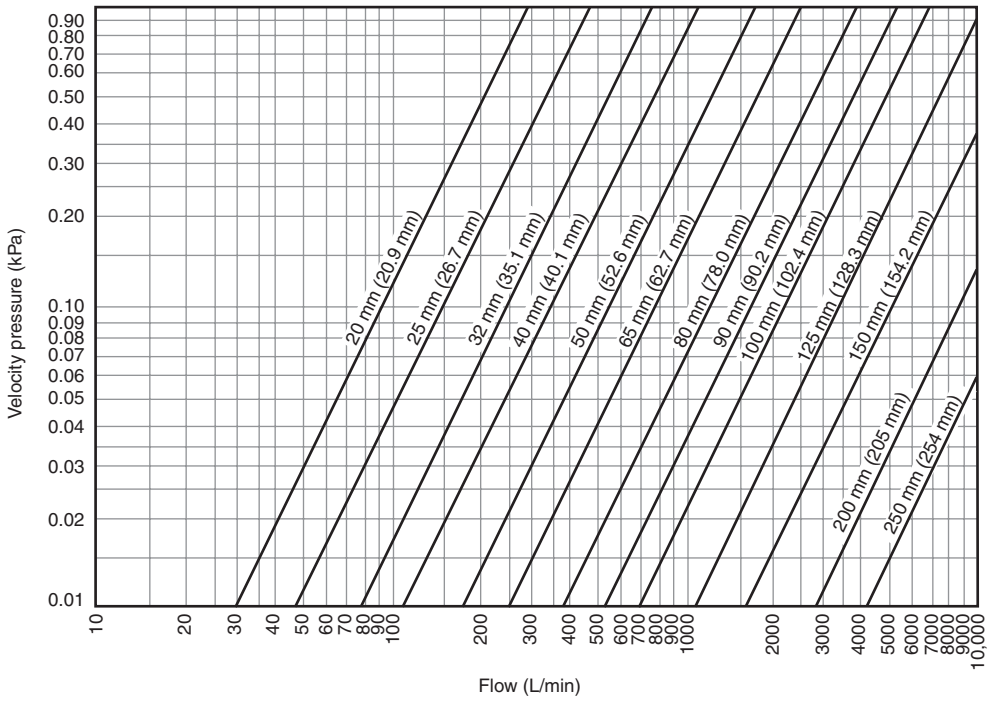

FIGURE 15.3.2 Graph for the Determination of Velocity Pressure (SI Units)

It follows that

$$\upsilon = \frac{Q}{a}$$

where υ = the average velocity in ft/sec, Q = the flow in ft^3/sec, and a = the cross-sectional area of the pipe in ft^2.

For a pipe with flow in gpm and diameter in in., the velocity is

$$\upsilon(\text{fps}) = \frac{Q(\text{gal/min})}{60 \text{ sec/min} \times 7.48 \text{ gal/ft}^3} + \frac{\pi d^2 \text{ (in.)}^2}{4 \times 144 \text{ in.}^2/\text{ft}^2}$$

$$= \frac{Q \times 4 \times 144}{60 \times 7.48 \times \pi d^2} = \frac{0.4085 \times Q}{d^2}$$

It follows that h_υ and p_υ are

$$h_\upsilon = \frac{\upsilon^2}{2g} = \frac{(0.4085Q)^2}{(d^2)^2} \div 64.4 = \frac{Q^2}{d^4}\frac{(0.4085)^2}{64.4} = \frac{Q^2}{386d^4}$$

$$p_\upsilon = \frac{Q^2}{d^4} \times \frac{0.433}{386} = \frac{Q^2}{891(d)^4}$$

In SI units, the formula for velocity pressure is expressed as

$$p_{\upsilon m} = 225\frac{Q_m^2}{d_m^4}$$

where

$p_{\upsilon m}$ = Velocity pressure (kPa)
Q_m = Flow (L/min)
d_m = Inside diameter (mm)

EXAMPLE 1: Find the velocity pressure in 1-in. Schedule 40 pipe with 36 gpm flowing. The actual diameter of the pipe is 1.049 in.

SOLUTION: $p_\upsilon = \frac{Q^2}{891(d)^4} = \frac{36^2}{891(1.049)^4} = 1.20$ psi

EXAMPLE 2: Find the velocity pressure in a 25-mm (actual diameter) pipe with 100 L/m flowing.

SOLUTION: $P_{\upsilon m} = 225\frac{Q_m^2}{(d_m)^4} = \frac{225 \times (100)^2}{(25)^4} = 5.8$ kPa

Total Head. At any point within a piping system that contains water in motion, there is a pressure head, h_p (normal pressure head), acting perpendicular to the pipe wall independent of velocity, and a velocity head, h_υ acting parallel to the wall but exerting no pressure against the wall. Therefore, the total head, $H = h_p + h_\upsilon$, expressed as pressure (psi) instead of feet is

$$p_t = 0.433h_p + 0.433\frac{\upsilon^2}{2g}$$

In SI units, total head expressed in kPa is

$$p_{tm} = 9.81h_{pm} + 9.81\frac{\upsilon_m^2}{2g}$$

where

p_{tm} = Total pressure (kPa)
h_{pm} = Head (m)
υ_M = Velocity (m/sec)

Pressure Sources

The sources of pressure head commonly found in fire protection hydraulic systems include the following.

Gravity (Elevated Tanks, Reservoirs, Standpipes). Head is the elevation of the water supply surface above the point under consideration, measured directly in ft (m) or converted from a pressure gauge reading.

Pumping. Head is the combination of pump discharge pressure and any difference in elevation between the pump discharge gauge and the point under consideration.

Pneumatic (Pressure Tanks). Head is the tank air pressure combined with any difference in elevation in tank water surface and the point under consideration.

Combination. Any combination of the above pressure sources.

BERNOULLI'S THEOREM

Bernoulli's theorem expresses the physical law of conservation of energy applied to problems of incompressible fluid flow. The theorem can be defined as follows: "In steady flow without friction, the sum of the velocity head, pressure head, and elevation head is constant for any incompressible fluid particle throughout its course." In other words, the total pressure (head) is the same at all locations within the system.

(Note that, in Bernoulli's theorem, all of the individual head terms, i.e., velocity head, pressure head, and elevation head are expressed in ft [m]. When using velocities in fps [m/sec] and gauge pressure in psi [kPa], they must be converted to ft [m], or all of the terms expressed as pressures.)

Bernoulli's Theorem Expressed Mathematically

Real systems are not frictionless, however, and in practice, losses due to pipe friction and other factors are accounted for. Expressed mathematically, Bernoulli's theorem, when applied to locations A and B, is

$$\frac{\upsilon_A^2}{2g} + \frac{p_A}{w} + z_A = \frac{\upsilon_B^2}{2g} + \frac{p_B}{w} + z_B + h_{AB}$$

where

υ (υ_m) = Velocity in fps (m/sec)
g (g_m) = Acceleration of gravity (32.2 fps [9.81 m/sec^2])
p (p_m) = Pressure (lb/ft^2 [kPa])
z (z_m) = Elevation head (distance above assumed datum, in ft [m])
w (w_m) = Specific weight of the fluid in lb/ft^3 (64.4 pcf or 9.81 kN/m^3 for water)

$\frac{\upsilon^2}{2g}\left(\frac{\upsilon_m^2}{2g}\right)$ = Velocity head in ft (m)

$\frac{p}{\omega}\left(\frac{p_m}{\omega_m}\right)$ = Pressure head in ft (m)

$h_{ab}(h_{abm})$ = Lost head between location A and location B in ft (m)

Application of Bernoulli's Theorem

Consider a reservoir and a pipeline discharging water to atmosphere at *B* (Figure 15.3.3). Assuming datum through B, Bernoulli's theorem applied from the water surface at A to the outlet at B is

$$\frac{v_A^2}{2g} + \frac{p_A}{w} + z_A = \frac{v_B^2}{2g} + \frac{p_B}{w} + z_B + h_{AB}$$

The velocity at A is practically zero because the tank is very large, and the gauge pressure is zero because only atmospheric pressure works on the water surface. At A, the elevation is z_A measured in ft (m) above the datum.

At B, the elevation above the datum is zero; the gauge pressure is zero, since the water is discharging to atmosphere; and only velocity pressure is available as the water leaves the outlet. (A gauge at a right angle to the emerging stream would register zero pressure.)

Therefore,

$$0 + 0 + z_A = \frac{v_B^2}{2g} + 0 + 0 + h_{AB}$$

or

$$\frac{v_B^2}{2g} = z_A - h_{AB}$$

Lost head, h_{AB}, is the sum of (1) hydraulic losses at the reservoir where water enters the pipeline, at the valve, and at the discharge outlet, plus (2) the friction loss in the pipeline. The values of the components producing lost head can be estimated, as discussed later in the chapter.

As another example, calculate the head loss across 1000 ft of 8 in. pipe with 750 gpm flowing from a 2½ in. hydrant outlet at B and a residual pressure at hydrant A of 40 psi. With no flow, hydrant A has a 60 psi static pressure, and hydrant B has an 80 psi static pressure. Assume a datum through hydrant B. Again, Bernoulli's theorem applied from point A to point B applies:

$$\frac{v_A^2}{2g} + \frac{p_A}{w} + z_A = \frac{v_B^2}{2g} + \frac{p_B}{w} + z_B + h_{AB}$$

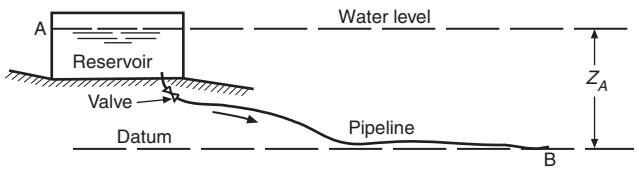

FIGURE 15.3.3 Graphic Representation of the Application of Bernoulli's Theorem to a Reservoir and Pipelines

Because we are interested in finding the head loss from A to B (h_{AB}), we rearrange Bernoulli's equation to solve for this term:

$$h_{AB} = \frac{v_A^2}{2g} + \frac{p_A}{w} + z_A - \frac{v_B^2}{2g} - \frac{p_B}{w} - z_B$$

The next step is to use the information provided to calculate each of the terms on the right side of the equation, starting with the velocity head at A:

$$v_A = \frac{Q}{a} = \frac{Q}{\frac{\pi d^2}{4 \times 144}}$$

$$= \frac{750 \text{ gpm}}{\frac{7.48 \text{ gal/ft}^3 \times 60 \text{ sec/min}}{\frac{3.1416 \times (8 \text{ in.})^2}{4 \times 144 \text{ in.}^2/\text{ft}^2}}} = 4.79 \text{ fps}$$

$$\frac{v_A^2}{2g} = \frac{(4.79 \text{ fps})^2}{64.4 \text{ fps/sec}} = 0.36 \text{ ft} \approx 0.4 \text{ ft}$$

Next we calculate the pressure head at A:

$$\frac{p_A}{w} = \frac{40 \text{ psi} \times \frac{144 \text{ in.}^2}{\text{ft}^2}}{62.4 \text{ pcf}} = 93.2 \text{ ft}$$

$$z_A = (80 \text{ psi} - 60 \text{ psi}) \times 2.31 \text{ ft/psi} = 46.2 \text{ ft}$$

Because we are using point B as our datum or zero-elevation reference, z_A is the elevation difference between points A and B. We can use Bernoulli's equation with no flow to determine this difference. Because there is no flow, the velocity head terms are zero. Also, because there is no flow, there is no friction or head loss. We know that because the static pressure at B is greater than the static pressure at A, the elevation of A is positive. Solving for the elevation difference we get

$$z_A - z_B = \frac{p_B}{w} - \frac{p_A}{w}$$

We know the pressure head at B is 80 psi and that head at A is 60 psi. Because the elevation at B is zero, substituting and converting the units we get

$$z_A = (80 \text{ psi} - 60 \text{ psi}) \times 2.31 \text{ ft/psi} = 46.2 \text{ ft}$$

The velocity at B is calculated in the same manner as at A:

$$v_B = \frac{Q}{a} = \frac{750 \text{ gpm}}{\frac{7.48 \text{ gal/ft}^3 \times 60 \text{ sec/min}}{\frac{3.1416 \times (2.5 \text{ in.})^2}{4 \times 144 \text{ in.}^2/\text{ft}^2}}} = 49.02 \text{ fps}$$

$$\frac{v_B^2}{2g} = \frac{(49.02 \text{ fps})^2}{64.4 \text{ fps}} = 37.3 \text{ ft}$$

There is no normal pressure, as the flow discharges to atmosphere.

$$\frac{p_B}{w} = 0$$

$z_B = 0$ since the datum goes through hydrant B. Thus

$$h_{AB} = 0.4 + 92.3 + 46.2 - 37.3 - 0 - 0 = 101.6 \text{ ft}$$

One further problem is expressed in SI units. Water is pumped via a pipeline, up a 5.0 m incline from A to B. The pipeline at A has an inside diameter of 80 mm and a static pressure of 300 kPa. If the pipeline has changed in diameter to 70 mm at B and there is frictional head loss over the length of the pipe (h_{AB}) of 12 m, determine the residual pressure at B for a flow rate of 4200 L/min.

The solution is expressed as

$$\frac{\upsilon_A^2}{2g} + \frac{p_A}{w} + z_A = \frac{\upsilon_B^2}{2g} + \frac{p_B}{w} + z_B + h_{AB}$$

Rearranging for the pressure head at B,

$$\frac{p_B}{w} = \frac{\upsilon_A^2}{2g} + \frac{p_A}{w} + z_A - \frac{\upsilon_B^2}{2g} - z_B - h_{AB}$$

Substituting,

$$\upsilon_a = \frac{Q}{a_a} = \frac{4200 \text{ L/min}}{\dfrac{60 \text{ sec/min} \times 1000 \text{ L/m}^3}{\pi (80 \text{ mm})^2 / 4 \times 10^6 \text{ mm}^2/\text{m}^2}}$$

$$\frac{\upsilon_A^2}{2g} = \frac{(13.9 \text{ m/sec})^2}{2 \times 9.81 \text{ m/sec}^2} = 9.8 \text{ m}$$

$$\frac{p_A}{w} = \frac{300 \text{ kPa}}{9.81 \text{ kPa/m}} = 30.6 \text{ m}$$

$$z_A = 0 \text{ (datum through A)}$$

$$\upsilon_B = \frac{Q}{a_B} = \frac{4200 \text{ L/min}}{\dfrac{60 \text{ sec/min} \times 1000 \text{ L/m}^3}{\pi (70 \text{ mm})^2 / 4 \times 10^6 \text{ mm}^2/\text{m}^2}} = 18.2 \text{ m/sec}$$

$$\frac{\upsilon_B^2}{2g} = \frac{(18.2 \text{ m/sec})^2}{2 \times 9.81 \text{ m/sec}^2} = 16.9 \text{ m}$$

$$z_B = 5.0 \text{ m}$$

$$h_{AB} = 12 \text{ m (friction loss)}$$

Then

$$\frac{p_B}{w} = 9.81 + 30.6 + 0 - 16.9 - 5 - 12 = 6.5 \text{ m}$$

In pressure terms

$$6.5 \text{ m} \times 9.81 \frac{\text{kPa}}{\text{m}} = 64 \text{ kPa}$$

that is, the residual pressure at B is 64 kPa.

FLOW OF WATER THROUGH ORIFICES

As a liquid leaves a pipe, conduit, or container through an orifice and discharges to atmosphere, the normal pressure is converted to velocity pressure. The rate of flow though an orifice can be expressed in terms of velocity and cross-sectional area of the stream, the basic relations being $Q = a\upsilon$, where Q = rate of flow in ft^3/sec (m^3/sec); a = area of cross section in ft^2 (m^2); and υ = velocity at the cross section in ft/sec (m/sec) (Table 15.3.1). From the previous discussion in this chapter on velocity head, it is known that

$$Q = a\sqrt{2gh}$$

and h (ft) = 2.307p (psi). It follows that, with the orifice diameter in inches, Q in gal/min, and h in psi,

$$Q = 60 \times 7.4805 \times \frac{\pi d^2}{4 \times 144} \times \sqrt{64.4 \times 2.3077 p_\upsilon}$$

$$Q = 29.84 d^2 \sqrt{p_\upsilon}$$

In SI units, the flow formula is expressed as

$$Q_m = 0.0666 d_m^2 \sqrt{p_{\upsilon m}}$$

where

Q_m = Flow rate (L/m)

d_m = Inside diameter (mm)

$p_{\upsilon m}$ = Velocity pressure (kPa)

The above equations (and tables derived therefrom) assume that (1) the jet is a solid stream the full size of the discharge orifice, and (2) 100 percent of the available total head is converted to velocity head, which is uniform over the cross section. This is a theoretical situation only, however, as these two conditions are not totally attainable, as the following discussion will show.

COEFFICIENTS OF FLOW

In actual flow from nozzles or orifices, the velocity, considered to be average velocity across the entire cross section of the stream, is somewhat less than the velocity calculated from the head. The reduction is due to friction of the water against the nozzle or orifice and turbulence within the nozzle and is accounted for by a coefficient of velocity, designated c_υ. Values of c_υ are determined by laboratory tests. With well-designed nozzles, the coefficient of velocity is nearly constant and is approximately equal to 0.98.

Some nozzles are designed so that the actual cross-sectional area of the stream is somewhat less than the cross-sectional area of the orifice. This difference is accounted for by the coefficient of contraction, designated c_c. Coefficients of contraction vary greatly with the design and quality of the orifice or nozzle. For a sharp-edged orifice, the value of c_c is about 0.62.

The coefficients of velocity and contraction are usually combined as a single coefficient of discharge, designated c_d:

$$c_d = c_\upsilon \times c_c$$

The basic flow equation can now be written as

$$Q = 29.84 c_d^4 d^2 \sqrt{p_\upsilon}$$

In SI units the formula is

$$Q = 0.0666 c_d d_m^2 \sqrt{p_{\upsilon m}}$$

TABLE 15.3.1 Theoretical Flow Through Circular Orifices—gpm (L/min)

This table may be computed from the formula $Q = 29.84cd^2\sqrt{p}$ ($Q = 0.0666cd_m^2\sqrt{p_m}$) with $c = 1.00$. The theoretical discharge from seawater, as from fireboat nozzles, may be found by subtracting 1 percent from the figures in the following table or from the value computed using the formulas.

When pressures are read with a Pitot gage at a nozzle, the nozzle discharge in most cases will correspond to the values in the table within a range of 1 to 3 percent for nozzles up to 1⅜ in. (35 mm) in diameter. For larger diameter nozzles, the principles discussed in "Nozzle Method of Measuring Flow" in this chapter of the handbook apply. Appropriate coefficients should be applied where it is read from a hydrant outlet. Where more accurate results are required, a coefficient appropriate to the particular nozzle must be selected and applied to the figures of the table.

The discharge from circular openings of sizes other than those in the table may readily be computed by applying the principles that quantity discharged under a given head varies as the square of the diameter of the opening.

The coefficient of discharge, c_d, is defined as the ratio of the actual discharge to the theoretical discharge. For any specific orifice or nozzle, values of c_d are determined by standard test procedures using this definition. The actual rate of flow is measured by calibrated meters, or "weigh tanks." The theoretical flow is calculated using $c_d = 1.0$, the carefully measured orifice or nozzle diameter, and the measured velocity pressure in the flow equation.

Standard Orifice

An orifice with a sharp entrance edge, shown as form (1) in Figure 15.3.4, is known as a standard orifice and is commonly used to measure waterflow. If the shape of the orifice is changed so as to decrease the contraction, its capacity will be increased. Form 1 in the illustration is a standard orifice having a sharp edge on the approach side. Form 2, when in a thin plate, gives the same stream characteristics as Form 1. Form 3 is the reverse of 1. In Form 4, the edge is rounded to conform to the shape of the stream. The coefficients of discharge of 3 and 4 are greater than those of the standard orifices, approaching a value of 1.0 in the case of 4. As water leaves the orifice, it contracts to form a jet whose cross-sectional area is less than that of the orifice. The contraction is complete at the plane a', which is located a distance from the plane of the orifice equal to approximately half the diameter of the jet (Figure 15.3.5).

The quantity flowing is obviously the same at the orifice a as at the contracted section a', so the quantity flowing could be obtained by measuring the velocity and area at either of these planes. Expressed in a formula, where Q is ft^3/sec (m^3/sec), υ is velocity in ft/sec (m/sec), and a is the area in ft^2 (m^2),

$$Q = \upsilon a = \upsilon' a'$$

The coefficient of discharge for a standard orifice is the product of the coefficient of velocity and the coefficient of contraction, or $c = 0.98 \times 0.62 = 0.61$.

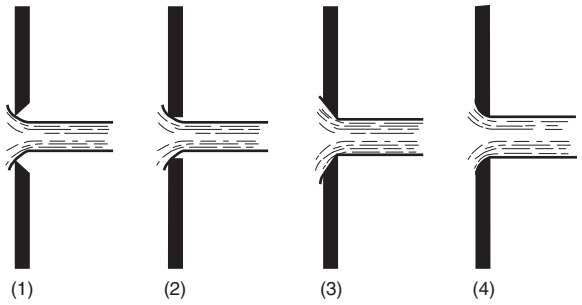

FIGURE 15.3.4 Orifices of Various Shapes

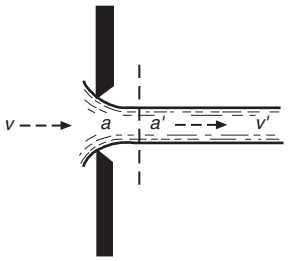

FIGURE 15.3.5 Flow Through a Standard Orifice

Other Orifices

The hydraulic characteristics of good solid-stream nozzles are consistent within a wide range of flow conditions. The velocity at the surface of the stream of most such nozzles is reduced slightly by friction against the orifice or nozzle. A coefficient of velocity of 0.97 is usually applied to nozzles of fire stream sizes to account for this friction.

Coefficients of discharge are available for the flow through hydrants, hose nozzles, automatic sprinklers, and other common fire protection discharge outlets. Representative values for the coefficients of discharge are given in Table 15.3.2. Again, these coefficients only apply when there is flow through the full orifice or nozzle opening with a reasonably uniform velocity profile. Three general types of hydrant outlets and their coefficients of discharge are shown in Figure 15.3.6.

TABLE 15.3.2 Typical Discharge Coefficients of Solid-Stream Nozzle

Spray sprinkler, average (nominal ½-in. dia.)	0.75
Spray sprinkler, average (nominal 17/32-in. dia.)	0.95
Large-drop sprinkler (0.64 in. dia.)	0.90
Standard orifice (sharp edge)	0.62
Smooth-bore nozzles, general	0.96–0.98
Underwriter playpipes or equal	0.97
Deluge or monitor nozzles	0.997
Open pipe, burred opening	0.80
Open pipe, smooth, well rounded	0.90
Hydrant butt, smooth and well-rounded outlet, flowing full*	0.90
Hydrant butt, square and sharp at hydrant barrel*	0.82
Hydrant butt, outlet square, projecting into barrel*	0.70

*See Figure 15.3.6.

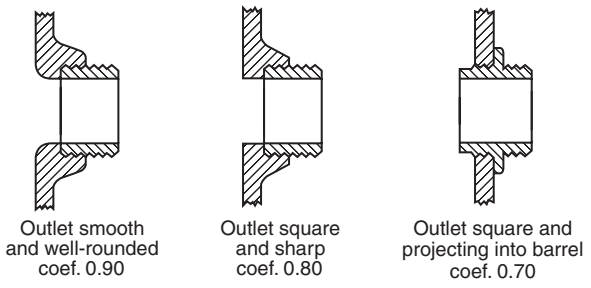

FIGURE 15.3.6 Three Types of Hydrant Outlets and Coefficients of Discharge

Flow in Short Tubes

A tube attached to an orifice is known as a standard short tube if it is 2½ to 3 times longer than the diameter of the orifice, and its diameter is the same as the orifice. A shorter tube will not flow full, and friction losses in a longer tube will affect results when used as a measuring device, hence the specified length limit.

The characteristics of a standard short tube and a short conical converging tube are shown in Figures 15.3.7 and 15.3.8, respectively. The principles of flow in orifices apply, but with different coefficients. With the conical tube, the coefficients c_v and c_c vary with the angle β. When β is 0 degrees, the converging tube becomes a cylindrical tube, with $c_c = 1$ and $c_v = 0.82$; c_d is then 0.82. As the angle β increases, the coefficient of contraction (c_c), develops, and the coefficient of velocity (c_v) increases, approaching the 0.98 value for a sharp-edge orifice. Relations are such that the coefficient of discharge attains a maximum value of 0.94, with a β angle of about 13 degrees.

FLOW MEASUREMENT

Pitot Tube Method of Measuring Flow

The most commonly used method of measuring flow in an open stream discharging from an orifice, nozzle, or open pipe is by direct measurement of the velocity head that produces the flow. This measurement process makes use of the well-known Pitot tube and pressure gauge combination.

When the small opening (usually not over 1/16 in. [1.6 mm] in diameter) is inserted into the center of a stream at the point of maximum contraction, with the opening directly in the line of flow, the gauge will indicate the total head at that location. With the stream open to the atmosphere, there will be no pressure head, so the indicated reading will be velocity head alone, and thus the velocity of the stream can be calculated directly. As a result, velocity pressure is sometimes referred to as Pitot pressure.

If the area of the cross section of the stream at the location of the velocity measurement location is known, the quantity flowing can be determined from the relation, $Q = av = 29.84 c_d d^2 \sqrt{p}$ or in SI units, $Q_m = 0.0666 c_d d_m^2 \sqrt{p_{vm}}$, previously derived. In practice, discharge tables are usually used to determine the flow from hydrants and nozzles (see Table 15.3.1).

A typical Pitot tube as used in the measuring of the flow from a fire stream nozzle is shown in Figure 15.3.9. For the usual forms of orifices and nozzles, the coefficient of discharge (c_d) is accurately known, so that $a = c_d \times$ actual discharge opening. For example, with a sharp-edge orifice the area of the stream may be determined from the actual diameter of the orifice opening and the use of the 0.62 coefficient of discharge, as outlined in the previous section on flow-through orifices.

When measuring flow from a straight-stream fire nozzle, the use of the Pitot tube method only holds with reasonable accuracy for tip sizes up to 1⅜ in. (35 mm) supplied from 2½-in. (64-mm) hose. Above that, the error rate increases beyond acceptable limits, as the assumptions of uniform velocity and full flow become less valid. An exception is the Underwriters playpipe that maintains a uniform coefficient over a wide range of flows and pressures for tip sizes of 1⅛ or 1¾ in. (29 or 45 mm).

The Pitot tube method is also commonly used to measure the flow discharging from the outlets of fire hydrants to determine the water supply available for fire protection. Unlike the flow entering a nozzle on the end of a pipe or hose line, the flow through large hydrant outlets, or through smaller hydrant outlets at high velocities, has neither a uniform velocity profile nor full flow, since the additional turbulence generated by the flow passing through the hydrant has not dissipated.

In cases such as these, the flow conditions must be changed so that the assumptions needed for the Pitot tube method are valid, or an alternative method, such as the one described next under "Nozzle Method of Measuring Flow," should be used. If

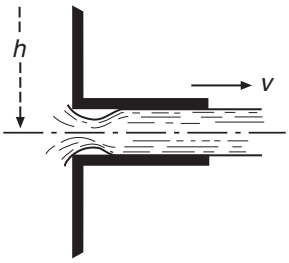

FIGURE 15.3.7 Flow in Cylindrical Short Tube

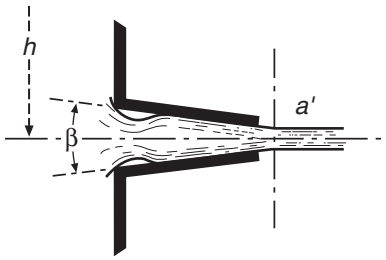

FIGURE 15.3.8 Flow in Short Conical Converging Tube

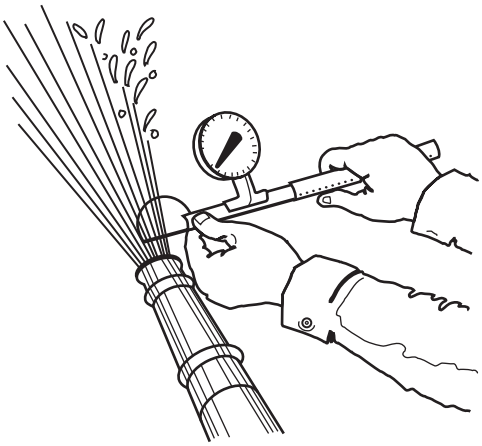

FIGURE 15.3.9 Taking Nozzle Pressure with a Pitot Tube

flow is from an open hydrant outlet, hoses and nozzles, a reducer, or a short tube can often be connected to the outlet to improve the flow characteristics.

Nozzle Method of Measuring Flow

The rate of discharge can also be calculated from the gauge pressure at the base of the nozzle. The flow formula for using base pressure is

$$Q = \frac{29.84cd^2\sqrt{p_1}}{\sqrt{1 - c^2\left(\frac{d}{D}\right)^4}}$$

where

Q = Flow in gallons per minute

c = Coefficient of discharge

d = Diameter of outlet (in.)

p_1 = Gauge pressure at base of nozzle (psi)

D = Inside diameter of fitting to which gauge is attached (in.)

For SI units, the formula is expressed as

$$Q = \frac{0.0666cd_m^2\sqrt{p_{1m}}}{\sqrt{1 - c^2\left(\frac{d_m}{D_m}\right)^4}}$$

where

Q_m = Flow (L/min)

c = Coefficient of discharge

d_m = Diameter of outlet (mm)

p_{1_m} = Gauge pressure at base of nozzle (kPa)

D_m = Inside diameter of fitting to which gauge is attached (mm)

This is the same formula that is used for discharge from an orifice, except that (1) gauge pressure at the base of the nozzle is substituted for Pitot pressure, and (2) a factor is added that represents the ratio between gauge pressure (normal) and total pressure at the nozzle base. (Total pressure is gauge plus velocity pressure.)

When base pressure is to be used, the gauge is attached to a fitting close to the nozzle with a straight piece of approach pipe or hose to eliminate turbulence or unstable flow conditions. To obtain greater accuracy than provided by a simple fitting, a piezometer fitting may be used. With this device, the gauge is connected to an annular tube or channel having a number of small holes drilled into the waterway around the circumference. The mean or resultant static pressure indicated by the gauge is p_1 in the formula above.

Although accurate and convenient for fixed test arrangements, the measurement of pressure at the base of a nozzle is not practical for usual hose stream operations. However, because a Pitot gauge is useless with spray-type nozzles, or other devices producing special types of discharge, the base pressure method is necessary.

Discharge Calculations

The most common method of estimating nozzle or orifice discharge is to use Table 15.3.1. The flow from the table, corresponding to the measured Pitot pressure and orifice diameter, is multiplied by the discharge coefficient (see Table 15.3.2).

EXAMPLE 1: A Pitot reading of 20 psi was measured on an open 2½-in. smooth and well-rounded hydrant butt. From Table 15.3.2, the discharge coefficient is 0.90. From Table 15.3.1, theoretical flow for a 20-psi velocity head is 834 gpm. The discharge is $Q = 834 \times 0.90 = 751$ gpm. (Or subtract 10 percent from 834 and get 751 gpm.)

EXAMPLE 2: A Pitot reading was 200 kPa at a 38.1-mm pipe with a square sharp opening (discharge coefficient = 0.80). From Table 15.3.1, 200 kPa gives a theoretical flow of 1370 L/min. The actual flow would be $0.8 \times 1370 = 1100$ L/min

Discharge curves, such as those shown in Figure 15.3.10, are available for many nozzles and are sufficiently accurate for most fire flow calculations. These usually incorporate the specific discharge coefficients for the nozzle involved, but occasionally plot theoretical flow. Nozzle discharge can also be determined by the standard formulas previously discussed. (See "Flow of Water Through Orifices" and "Nozzle Method of Measuring Flow" in this chapter).

EXAMPLE 3: Calculate the rate of discharge from a 2 in. (51 mm) nozzle with a pressure measured by a 2½ in. (64 mm)

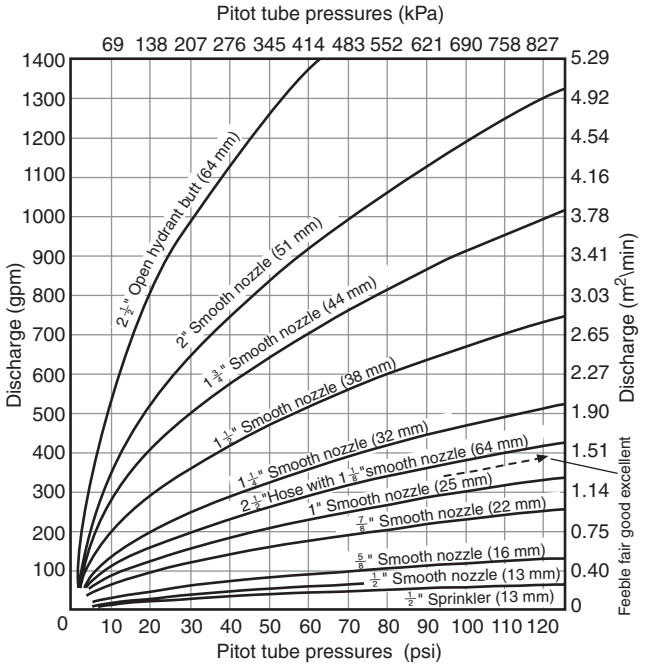

FIGURE 15.3.10 Relative Discharge Curves

piezometer ring and gauge of 80 psi (552 kPa) at the base of the nozzle. The nozzle has a coefficient of discharge of 0.99.

Using the formula for the nozzle method of measuring flow,

$$Q = \frac{29.84cd^2\sqrt{p_1}}{\sqrt{1 - c^2\left(\frac{d}{D}\right)^4}}$$

$$Q = \frac{29.84 \times 0.99 \times (2)^2\sqrt{80}}{\sqrt{1 - (0.99)^2\left(\frac{2}{2.5}\right)^4}}$$

$$Q = 1366 \text{ gpm } (5171 \text{ L/min})$$

To simplify calculations for a specific orifice or nozzle, the constants in the flow formula can be combined, reducing the formula to

$$Q = K\sqrt{p}$$

where K combines the constants 29.84 (0.0666 in SI units), c_d, and d^2. Table 15.3.3 lists K-factors of some common discharge orifices used for fire protection. For SI units, use the K_m values.

Because

$$K = \frac{Q}{\sqrt{p}}$$

the K values of spray nozzles can be calculated from data in testing laboratory listings of nozzles. For some nozzles, the flow rate at 25 and 125 psi (170 and 162 kPa) pressure is given, from which the K-factor can be calculated.

EXAMPLE 4: A certain fire service spray nozzle is rated for 83 gpm at 50 psi. What is the discharge at a pressure of 25 psi? Since we know the flow at a known pressure, we can calculate the K-factor. The K-factor is

$$K = \frac{83}{\sqrt{50}} = \frac{83}{7.07} = 11.7$$

At 25 psi pressure, the discharge would be

$$11.7\sqrt{25} = 11.7 \times 5 = 58.5 \text{ gpm}$$

Because the K-factor is constant, we can also calculate the new flow directly. Since $Q = K\sqrt{p}$, it follows that $K = \frac{Q}{\sqrt{p}}$ and that $\frac{Q_1}{\sqrt{p_1}} = \frac{Q_2}{\sqrt{p_2}}$.

Therefore, $\frac{83}{\sqrt{50}} = \frac{Q_2}{\sqrt{25}}$ and $Q_2 = \frac{83 \times \sqrt{25}}{\sqrt{50}} = 58.5$.

EXAMPLE 5: Determine the discharge from a 51 mm hydrant butt ($c_d = 90$) at a pressure of 350 kPa.

$$K_m = 0.0666cd_m^2 = 0.0666 \times 0.90 \times 51^2 = 156$$

Thus,

$$Q_m = K_m\sqrt{p_m} = 156\sqrt{350} = 2918 \text{ L/min}$$

Alternatively, from Table 15.3.3, $K_m = 154.7$. Thus,

$$Q_m = K_m\sqrt{p_m} = 154.7\sqrt{350} = 2894 \text{ L/min}$$

TABLE 15.3.3 Values of K for Various Discharge Orifices

Type of Orifice	Nominal Diameter *(in.)*	Nominal Diameter *(mm)*	K-Factor *gpm/p$^{1/2}$*	K-Factor *lpm and P$_m^2$*
Sprinkler	1/4	7	1.3–1.5	1.9–2.2

Sprinkler	5/8	16	11.0–11.5	15.9–16.6
Sprinkler	3/4	19	13.5–14.5	19.5–20.1
Sprinkler	25/32	19.8	16.0–17.6	23.1–25.4
Sprinkler	15/16	23.6	23.9–26.5	38.9–43.0
Nozzle	1/2	13	7.2	10.3
Nozzle	7/8	22	22.2	32.0
Nozzle	1	25	29.1	41.9
Nozzle	1 1/16	27	32.8	47.2
Nozzle	1 1/8	29	36.8	53.0
Nozzle	1 3/16	30	41.0	59.0
Nozzle	1 1/4	32	45.4	65.4
Nozzle	1 5/16	33	50.1	72.1
Nozzle	1 3/8	35	54.9	79.1
Nozzle (c = 0.97 for all nozzles)	1 7/16	37	60.0	86.4
Nozzle	1 1/2	38	65.4	94.2
Nozzle	1 9/16	40	70.9	102.0
Nozzle	1 5/8	41	76.8	110.6
Nozzle	1 11/16	43	82.8	119.2
Nozzle	1 3/4	44	89.0	128.2
Nozzle	1 13/16	46	95.5	137.5
Nozzle	1 7/8	48	102.0	146.9
Nozzle	1 15/16	49	109.0	157.0
Nozzle	2	51	116.0	167.0
Hydrant butt (c = 0.90)	2	51	107.4	154.7
Hydrant butt (c = 0.90)	2 1/4	57	135.9	195.7
Hydrant butt (c = 0.90)	2 1/2	64	167.8	241.6

Note that in this example the answers from the two methods are close but do not exactly match. Care needs to be taken that the results do not imply a higher degree of accuracy than actually exists. Given the nature of the flow from a hydrant butt, assuming a flow of about 2900 L/min would be appropriate in this case.

Flow Meters

When it is not convenient to discharge water to the atmosphere, meters are used to determine flow.

Venturi Tube. The Venturi principle has a number of applications in fire protection. The Venturi tube is essentially a tapered

constriction in a pipe. In the constricted part, the velocity must be greater than in the straight tube, and the pressure is correspondingly less, in accordance with Bernoulli's theorem. If the increase in velocity through the restricted portion is sufficient, the pressure at that point will be less than atmospheric, and a suction will be created at any opening into the side of the tube. The Venturi tube is illustrated in Figure 15.3.11. The diverging portion of a Venturi tube serves only to restore the system pressure with a minimum of friction loss.

Venturi Meter. The Venturi principle as applied in the Venturi meter for the measurement of flow in closed pipelines under pressure is as follows.

With no elevation difference along the line of flow, Bernoulli's theorem becomes

$$\frac{\upsilon_1^2}{2g} + \frac{p_1}{w} + 0 = \frac{\upsilon_2^2}{2g} + \frac{p_2}{w} + 0$$

In Figure 15.3.11,

$$\frac{p_1}{w}$$

is represented by h_1, and

$$\frac{p_2}{w}$$

by h_2, which are used in the following equations.

The quantity of liquid passing through all portions of the Venturi meter must be the same. Therefore,

$$Q = a_1\upsilon_1 = a_2\upsilon_2 \text{ or } \upsilon_1 = \frac{Q}{a_1} \text{ or } \upsilon_2 = \frac{Q}{a_2}$$

Substituting in Bernoulli's theorem,

$$\frac{\left(\frac{Q}{a_1}\right)^2}{2g} + h_1 = \frac{\left(\frac{Q}{a_2}\right)^2}{2g} + h_2$$

$$\frac{\left(\frac{Q}{a_2}\right)^2}{2g} - \frac{\left(\frac{Q}{a_1}\right)^2}{2g} = h_1 - h_2$$

$$Q^2\left(\frac{1}{a_2^2} - \frac{1}{a_1^2}\right) = 2g(h_1 - h_2)$$

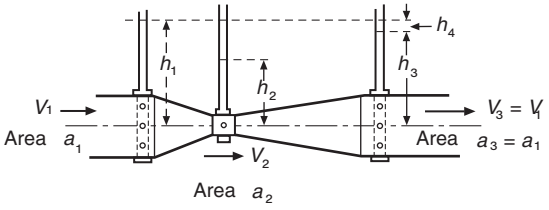

FIGURE 15.3.11 The Venturi Tube

$$Q^2\left(\frac{a_1^2 - a_2^2}{a_1^2 a_2^2}\right) = 2g(h_1 - h_2)$$

$$Q = \frac{a_1 a_2}{\sqrt{a_1^2 - a_2^2}}\sqrt{2g(h_1 - h_2)}$$

For any specific Venturi meter, a_1 and a_2 are known constant values. There is also a friction loss coefficient, which is usually determined by test and which does not remain constant with very low velocities. Combining the known constant values, the Venturi meter formula is generally expressed as

$$Q = \mathrm{K}\sqrt{(h_1 - h_2)}, \text{ or } Q = \mathrm{K}\sqrt{\frac{p_1}{w} - \frac{p_2}{w}}$$

By test, a value of k for any specific meter can be established with reasonable accuracy, thus allowing the measurement of flow to be calculated from the pressure differential across the meter.

When used as a device for inducing gas or liquid into the stream, as is made possible by the reduced pressure, in the throat section, the hydraulic performance will not be in strict accordance with the above theoretical calculations because energy is expended on the induced substance.

Orifice Meters. When water flows through a thin sharp-edged orifice (such as the standard orifice discussed earlier) within a pipe, the flow diameter contracts the same way it does when the flow discharges to atmosphere and then increases back to the full pipeline diameter. The pressure at the pipe wall is reduced due to this change in flow and is related to the flow rate (Figure 15.3.12).

Bernoulli's equation can be applied to an orifice meter in the same way as it is applied to the Venturi meter. The resultant K-factor or discharge coefficient depends on several factors, including the ratio of orifice/pipe diameter and the location of the pressure taps upstream and downstream of the orifice.

ASME Flow Nozzle. Flow can also be measured by an ASME flow nozzle, as shown in Figure 15.3.13. The pressure taps for this device are normally one pipe diameter upstream of the nozzle and one-half pipe diameter downstream from the nozzle inlet. Combining known constant values, the Venturi meter formula is generally expressed as

$$Q = \mathrm{K}\sqrt{(h_1 - h_2)}, \text{ or } Q = \mathrm{K}\sqrt{\frac{p_1}{w} - \frac{p_2}{w}}$$

FLOW OF WATER IN PIPES

The theory of liquid flow in pipes involves the same continuity principles used in the previous discussions. These include continuity of energy (Bernoulli's theorem with friction) and continuity of flow.

When water flows through a pipe, there is always a drop in pressure. Theoretically, the lost head between two points is caused by (1) friction between the moving water and the pipe wall and (2) friction between water particles, including that produced by turbulence when flow changes direction or when

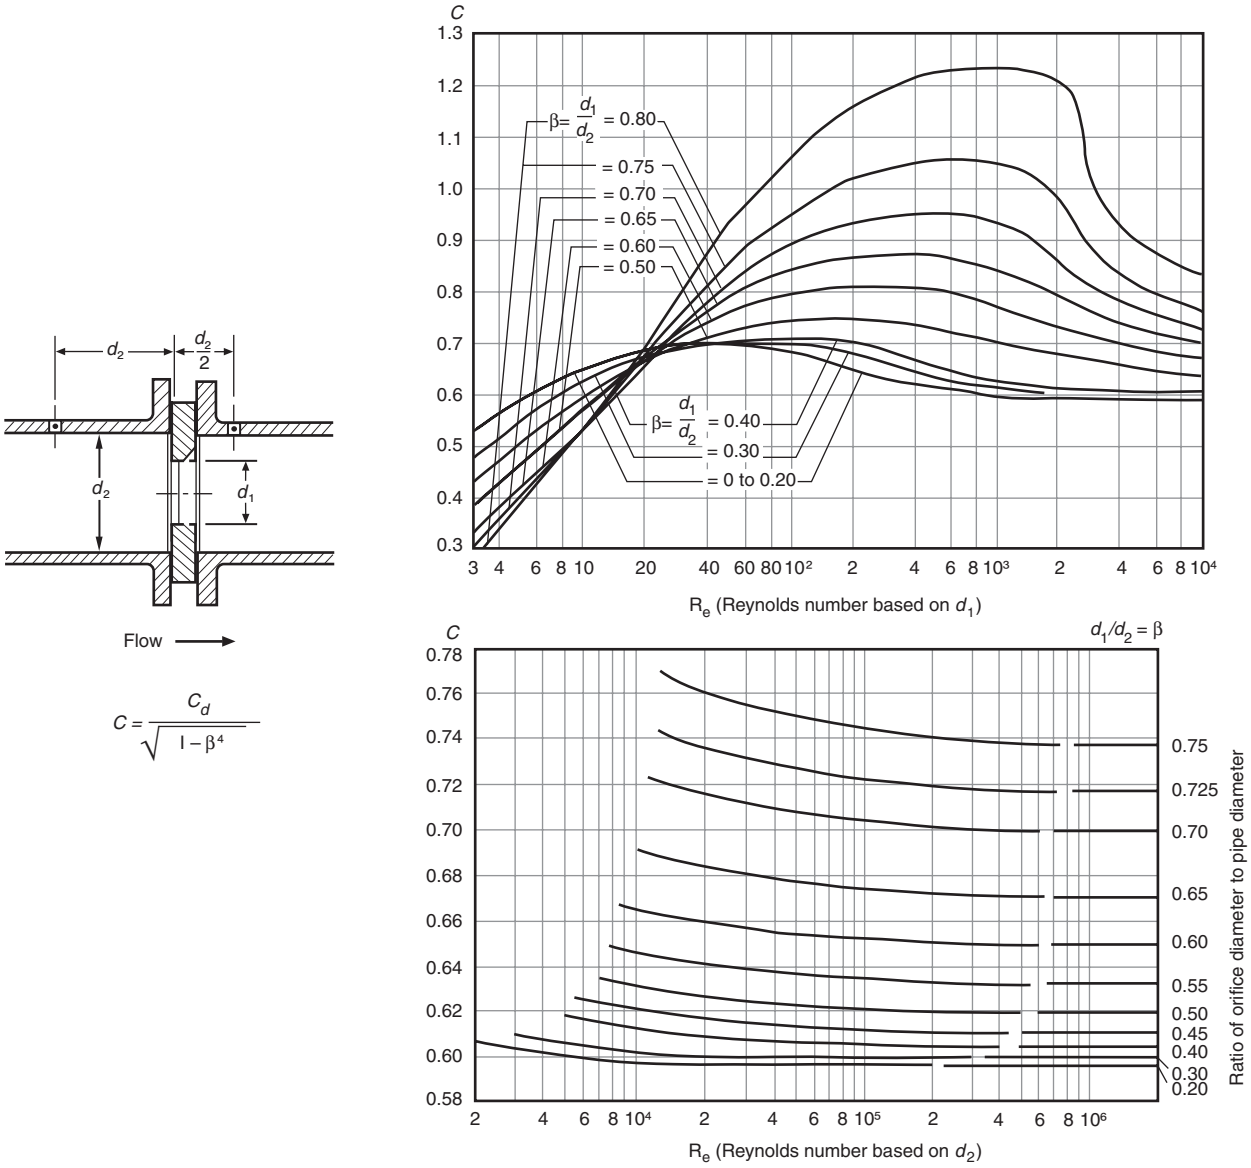

FIGURE 15.3.12 Flow Coefficient *C* for Square-Edged Orifice Meters

a rapid increase or decrease in velocity takes place, such as at abrupt changes in pipe diameter. A change in velocity results in some conversion of velocity head to pressure head, or vice versa.

At low velocity in a smooth pipe, very little turbulence is produced, and the flow is called "laminar" or "streamline" flow. With this condition, all particles of water move along the pipe in definite paths, which are essentially straight lines in concentric layers. Friction loss occurs due to shear stress, mainly in a thin boundary layer at the pipe wall, and also between adjacent stream layers. The friction loss is small compared to that of turbulent flow.

The flow within either a smooth or a rough pipe remains laminar until the velocity reaches what is called critical velocity. At this point, there is a range of unstable flow that is neither laminar nor completely turbulent, which is called the transition zone.

As the flow continues to increase, it becomes turbulent. In turbulent flow the fluid moves in an eddying mass, and, at any point, the individual water particles move rapidly in a random manner rather than in a straight line.

Reynolds demonstrated that for any fluid the critical point at which the flow changes from laminar to turbulent could be predicted. In circular pipes, the critical point occurs when the dimensionless parameter $d\nu\rho/\mu$ (called the Reynolds number) is approximately 2000. The transition to complete turbulence is complete for Reynolds numbers exceeding 4000.

Most fire protection systems and water distribution mains function under turbulent flow conditions, and friction losses within the pipe itself account for most of the lost head. Other

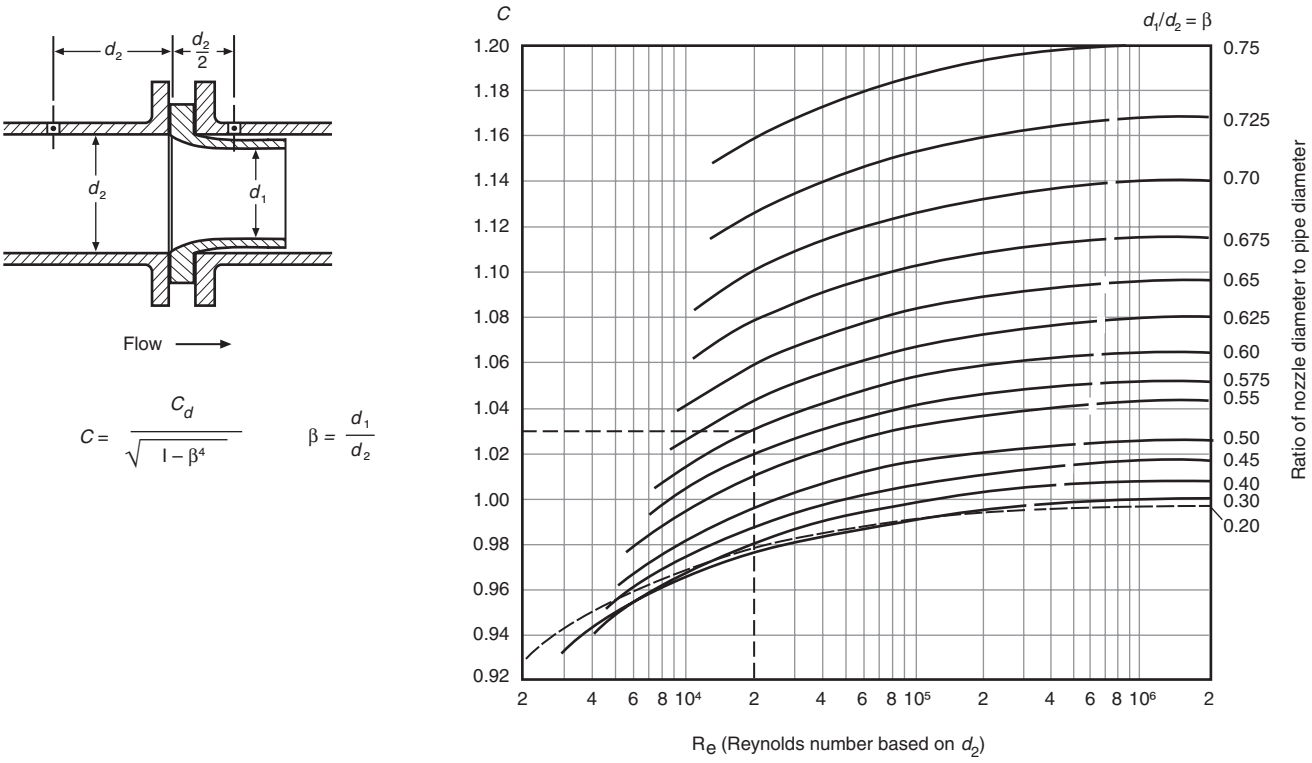

FIGURE 15.3.13 Flow Coefficient *C* for ASME Flow Nozzles

losses are usually considered together and are called "minor losses" or "losses in fittings."

Friction (Head) Loss Flow Formulas

Experimental data have established that frictional resistance in a pipe shall be as follows:

1. Independent of pressure in the pipe
2. Proportional to the amount and character of the flow
3. Variable with the velocity of the flow (nearly proportional to the second power of the velocity for velocities above the critical; if velocity is below critical, resistance varies with the first power)

The Chezy Formula. One of the best-known and oldest expressions relating velocity to friction loss in piping is known as the Chezy formula:

$$v = c\sqrt{rs}$$

where

c = A factor that is dependent on the kind and roughness of the pipe

r (the hydraulic radius) = Area/circumference = $d/4$ where d = diameter of the pipe in ft (m)

s = The hydraulic slope = h/l = slope of hydraulic gradient in which h is the head loss in length of pipe l in ft (m). (See Section 15, Chapter 1, "Fixed Water Storage Supplies for Fire Protection," for a discussion of hydraulic gradients.)

Therefore,

$$v = c\sqrt{d/4 \times h/l} \text{ or } h = \frac{4lv^2}{c^2 d}$$

The Darcy-Weisbach Formula. Another classic formula for friction loss, applicable to long, straight pipes of uniform diameter and roughness, is ascribed to Darcy, Manning, Fanning, and others. In modern textbooks, the formula is derived by analysis of forces acting on a flowing particle of water in a pipe. Often called the Darcy-Weisbach formula, it is a variation of Chezy's formula, with a friction factor f replacing c, and expressed as follows:

$$h = f\frac{l}{d}\frac{v^2}{2g}$$

where

h = Friction head

f = Friction factor

l = Length of pipe

d = Diameter of pipe

v = Velocity

g = Acceleration of gravity

The Darcy-Weisbach formula is suitable for all Newtonian fluids. (A Newtonian fluid is one where the viscosity is constant at a specific temperature, regardless of pressure and the rate of

shear.) The friction factor f is dimensionless and variable and depends on the pipe roughness and the Reynolds number.

The value of f can be computed by the Colebrook-White equation, which is neither a completely empirical nor rigidly theoretical formula. This equation is usually written as

$$\frac{1}{\sqrt{f}} = -2 \log_{10}\left[\frac{\varepsilon}{3.7D} + \frac{2.51}{R\sqrt{f}}\right]$$

where

ε = Linear measure of roughness

f = Darcy-Weisbach friction factor

D = Pipe diameter (ft)

R = Reynolds number

(For SI units: 1 ft = 0.305 m.)

Computing f by the formula can be avoided by using tables and charts known as "Moody" diagrams.

Figure 15.3.14 is a Moody diagram (© Hydraulic Institute, 1954) from which f can be read directly off the chart. Values for friction factor are on the vertical scale, at left. The dimensionless parameter, ε/D is sometimes difficult to obtain, and it may be necessary to assume a value for ε/D based on experience and judgment. The roughness factor of new pipe usually can be provided by the manufacturer.

The Hazen-Williams Formula. The friction-flow formulas commonly used in fire protection hydraulics have been developed by experiment and experience. These formulas (which are variations of the Chezy formula) are usually exponential in the form $v = Cr^x s^y$, where v is velocity, c the coefficient of friction, r the hydraulic radius (area divided by circumference), and s the hydraulic slope (loss of head divided by length). The most popular exponential formula is the Hazen-Williams, its basic form being $v = 1.31Cr^{0.63}s^{0.54}$. The friction coefficients in formulas of this type are constant for a specific roughness of pipe and are independent of velocity, and thus the accuracy of these formulas is variable. However, the fixed values generally assumed for viscosity and density are considered adequate for most fire protection hydraulic work.

The basic form of the Hazen-Williams formula ($v = 1.31cr^{0.63}s^{0.54}$ is not practical for ordinary fire protection flow calculations. The form normally used is expressed in terms of pressure loss in psi rather than velocity, in terms of actual diameter rather than the hydraulic radius, and in terms of flow in gpm.

Because the hydraulic radius is the area divided by the circumference, it can be expressed as

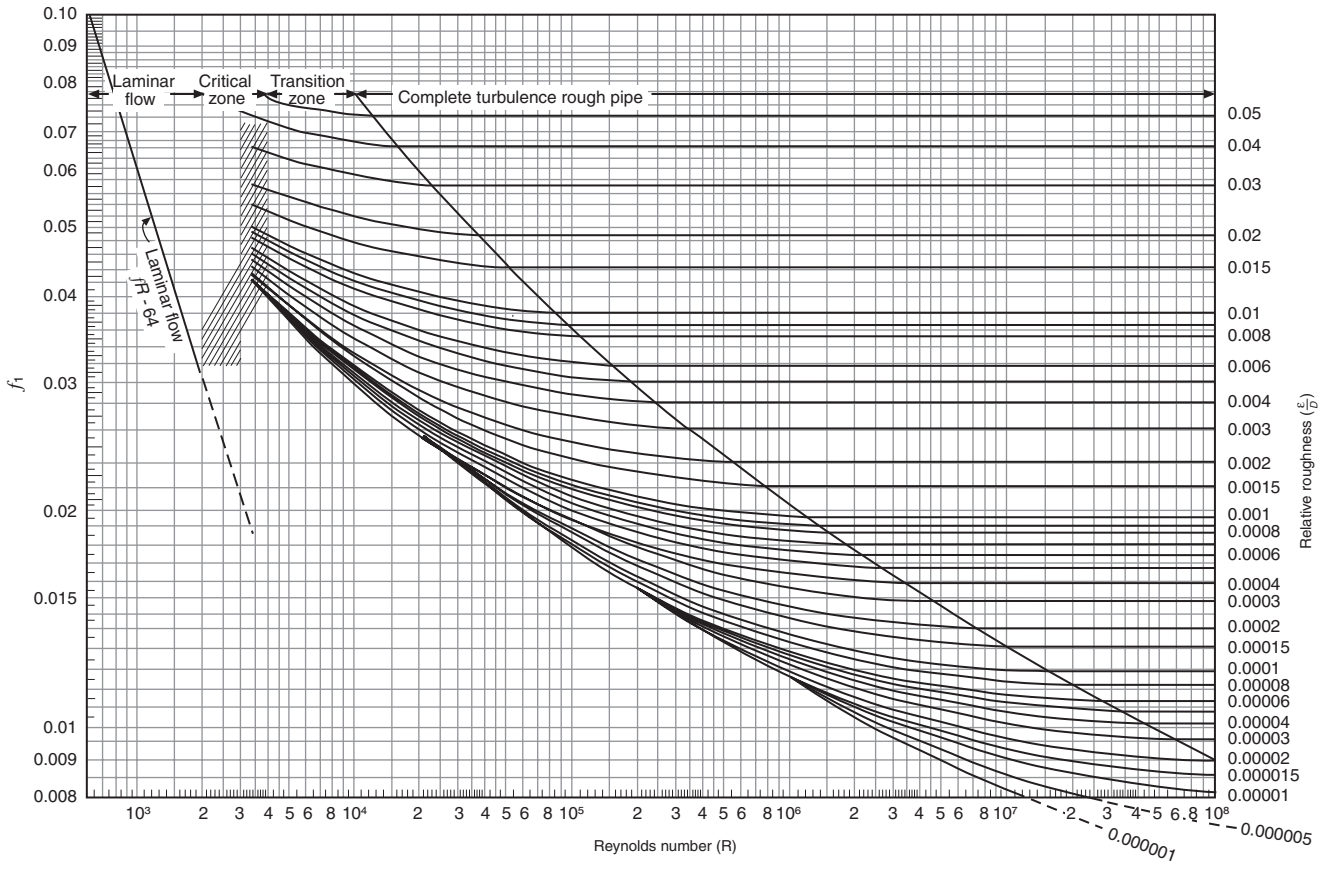

FIGURE 15.3.14 Moody Diagram for Friction in Pipe

$$r = \frac{\text{Area}}{\text{Circumference}} = \frac{\pi d^2/4}{\pi d} = \frac{d}{4}$$

where the diameter is in terms of feet or

$$r = \frac{d}{4} \times \frac{1 \text{ ft}}{12 \text{ in.}} = \frac{d}{48}$$

where the diameter is expressed in inches.

The hydraulic slope (s) is simply the pressure loss divided by the length. The Hazen-Williams formula is usually used to determine the pressure loss per ft of pipe, so the length is 1 and can be replaced by the pressure loss (p), again in ft.

Because we want to use flow rather than velocity, we know from the discussion on velocity pressure that

$$v = \frac{Q}{a} = \frac{0.4085Q}{d^2}$$

where Q is expressed in gallons per minute and d is expressed in inches. Substituting,

$$\frac{0.4085Q}{d^2} = 1.31C\left(\frac{d}{48}\right)^{0.63}(2.31p)^{.54}$$

Solving for p we get

$$(2.31p)^{.54} = \frac{0.4085Q/d^2}{1.31C(d/48)^{0.63}} = \frac{0.3118Q}{Cd^2(d/48)^{0.63}}$$

$$2.31p = \frac{0.3118^{1/0.54}Q^{1/0.54}}{C^{1/0.54}d^{2/0.54}(d/48)^{0.63/0.54}}$$

$$= \frac{0.3118^{1.85}Q^{1.85}}{C^{1.85}d^{3.7}(d/48)^{1.17}} = \frac{0.11579Q^{1.85}}{C^{1.85}d^{4.87}48)^{1.17}}$$

$$p = \frac{4.64Q^{1.85}}{C^{1.85}d^{4.87}} \cong \frac{4.52Q^{1.85}}{C^{1.85}d^{4.87}}$$

which is the formula normally used for fire protection purposes. The derived constant 4.64 is slightly different than the normally accepted constant of 4.52 due to rounding errors in the derivation and the constants in the original formula. The remainder of this discussion will use the generally accepted formula with a constant of 4.52.

In SI units the formula is

$$p_m = 6.06 \times \frac{Q_m^{1.85}}{C^{1.85}d_m^{4.87}} \times 10^2$$

where

p_m = Pressure loss (kPa) per m of pipe

Q_m = Rate of flow (L/min)

d_m = Inside diameter (mm)

Friction Loss Calculations. The solutions of many fire protection problems involving pipe flow and friction do not require direct calculation using formulas, since tables and charts are readily available. However, in using the simplifying charts and tables, great care must be taken to identify the C value (coefficient of friction) on which the chart or table is based. Where the type or condition of a pipe necessitates the use of a different C value, the friction loss from the table must be multiplied by a conversion factor to obtain the correct results for the desired C value.

By way of illustration, Table 15.3.4 gives values of p when C = 100 for standard pipe sizes from ½ in. to 30 in. in diameter. For values of C other than 100, the tabular value losses are multiplied by the corresponding factor in Table 15.3.5. Where a different type of pipe is used, the friction loss from the table can be corrected using the formula

$$\Delta p_a = \Delta p_{40}\left(\frac{d_{40}}{d_a}\right)^{4.87}$$

where

Δp_a = Actual friction loss

Δp_{40} = Friction loss in Schedule 40 pipe

d_{40} = Internal diameter of Schedule 40 pipe

d_a = Internal diameter of actual pipe

EXAMPLE: Determine the friction loss with 700 gpm, flowing in 700 ft of 8-in. cast-iron pipe having a C value of 80.

SOLUTION: From Table 15.3.4, the loss for 700 gpm per 100 ft of 8 in. pipe with C = 100 is 0.662 psi. From Table 15.3.5, the conversion factor for C = 80 is 1.51. Because friction loss is directly proportional to the length of pipe, multiply 0.662 × 7 × 1.51 = 6.95 psi (answer). Since other than Schedule 40 steel pipe is used, this value must be adjusted using the previously discussed formula:

$$\Delta p_a = \Delta p_{40}\left(\frac{d_{40}}{d_a}\right)^{4.87}$$

$$= 6.95\left(\frac{8.071}{8.23}\right)^{4.87}$$

$$= 6.32 \text{ psi}$$

The Hazen-Williams Diagram. Figure 15.3.15 is a graphical representation of Table 15.3.4, except that it is based on a Hazen-Williams coefficient of C = 120 rather than C = 100, as used in the table. For other C values use: Value of C: 80 100 120 130 140 150; multiplying factor: 2.12 1.40 1.00 0.86 0.75 0.66. It is limited in scope to pipes not over 10 in. in diameter, and due to the reduced scale is less accurate than the table.

Figure 15.3.16 gives data in SI units for pipes up to 10 in. (254 mm) in diameter, again based on C = 120. For other C values use: Value of C: 80 100 120 130 140 150; multiplying factor: 2.12 1.40 1.00 0.86 0.75 0.66.

EXAMPLE 1: What is the friction loss in 300 ft (90 m) of 8-in. cement-lined cast-iron pipe, flowing 1500 gpm (5678 L/min)?

SOLUTION: From the intersection of the 1500 gpm vertical line with the sloping 8 in. pipe diameter line in Figure 15.3.15, read

TABLE 15.3.4 Friction Loss[a] in Pipe

For SI units: 1 psi = 6.895 kPa; 1 gpm = 0.378 L/min; 1 in. = 25.4 mm.

Note: Actual inside diameter for sizes ½ in. through 3½ in. is given for greater accuracy as these sizes include sprinkler branch lines and the smaller sizes of cross mains. For sizes 4 in. and greater, the nominal diameters were used as a fairly safe average for the diameters of various types of underground pipes as follows: cast-iron unlined and Enameline, greater than nominal; cast iron cement lines and Class 200 asbestos cement, less than nominal; Class 150 asbestos-cement sizes 6 and 8 in. less than nominal, and other sizes even nominal. (A 0.10 variation is true for Class 150 cement lined only—see ASHD FT-9 through 45 for actual IDs.)

This table will be useful in approximating friction loss in flow through existing underground piping where the type, inside diameter, and condition are frequently unknown. However, in such cases, a flow test is recommended.

When the type, inside diameter, and condition are known, and in designing new systems for all sizes and types of pipes, the friction loss tables should be used. Friction tables based on Hazen-Williams formula are published in *Automatic Sprinkler Hydraulic Data* by "Automatic" Sprinkler Corporation of America, and tables based on the Darcy-Weisbach formula are published in *Standards of the Hydraulic Institute.*

[a]Friction loss in lb/in.^{2} per 100 ft of pipe and are based on a Hazen-Williams *C* of 100. To convert friction loss to other values of *C,* see Table 15.3.5.

[b]Calculations are based on the internal pipe diameter of Schedule 40 steel pipe for pipe sizes ½ to 3½ in. and the nominal pipe diameter for pipe sizes 4 to 30 in.

TABLE 15.3.5 Conversion Factors for Friction Loss in Pipe for Values of Coefficient Other Than 100

C	*Factor*	*C*	*Factor*	*C*	*Factor*
150	0.472	110	0.838	70	1.93
145	0.503	105	0.914	65	2.22
140	0.537	100	1.00	60	2.57
135	0.574	95	1.10	55	3.02
130	0.615	90	1.22	50	3.61
125	0.662	85	1.35	45	4.38
120	0.714	80	1.51	40	5.48
115	0.772	75	1.70	35	6.97

left horizontally for a loss of head value, which is found to be 0.019 psi per foot. For 300 ft, the loss would be 300 × 0.019 psi or 5.7 psi. The probable *C* value of cement-lined pipe is 140 (Table 15.3.6), and the conversion factor is 0.75 (Figure 15.3.15). Therefore, the friction loss is 5.7 × 0.75 = 4.3 psi. Since other than Schedule 40 steel pipe is used, this value must be adjusted using the previously discussed formula.

$$\Delta p_a = \Delta p_{40}\left(\frac{d_{40}}{d_a}\right)^{4.87}$$

$$= 4.3\left(\frac{8.071}{7.98}\right)^{4.87}$$

$$= 4.54 \text{ psi}$$

EXAMPLE 2: What is the friction loss in 400 m of 150 mm 30-year-old unlined cast-iron pipe (*C* = 80) for a flow of 10,000 L/min?

SOLUTION: From the intersection of the 10,000 L/min vertical line with the sloping 150 mm pipe diameter line in Figure 15.3.16, read left horizontally for a loss of head value, which is 480 kPa per 100 m. For 400 m, the loss would be 4 × 480 kPa or 1920 kPa, based on *C* = 120. For cast-iron pipe, *C* = 80 and the conversion factor is 2.12 (see Figure 15.3.16). Therefore, the friction loss is 1920 × 2.12 = 4070 kPa.

Equivalent Pipes. Problems involving piped water supplies and fire protection systems occasionally require substitution of one pipe for another. The term "equivalent pipe" usually means a pipe having the same friction loss as the pipe for which it is

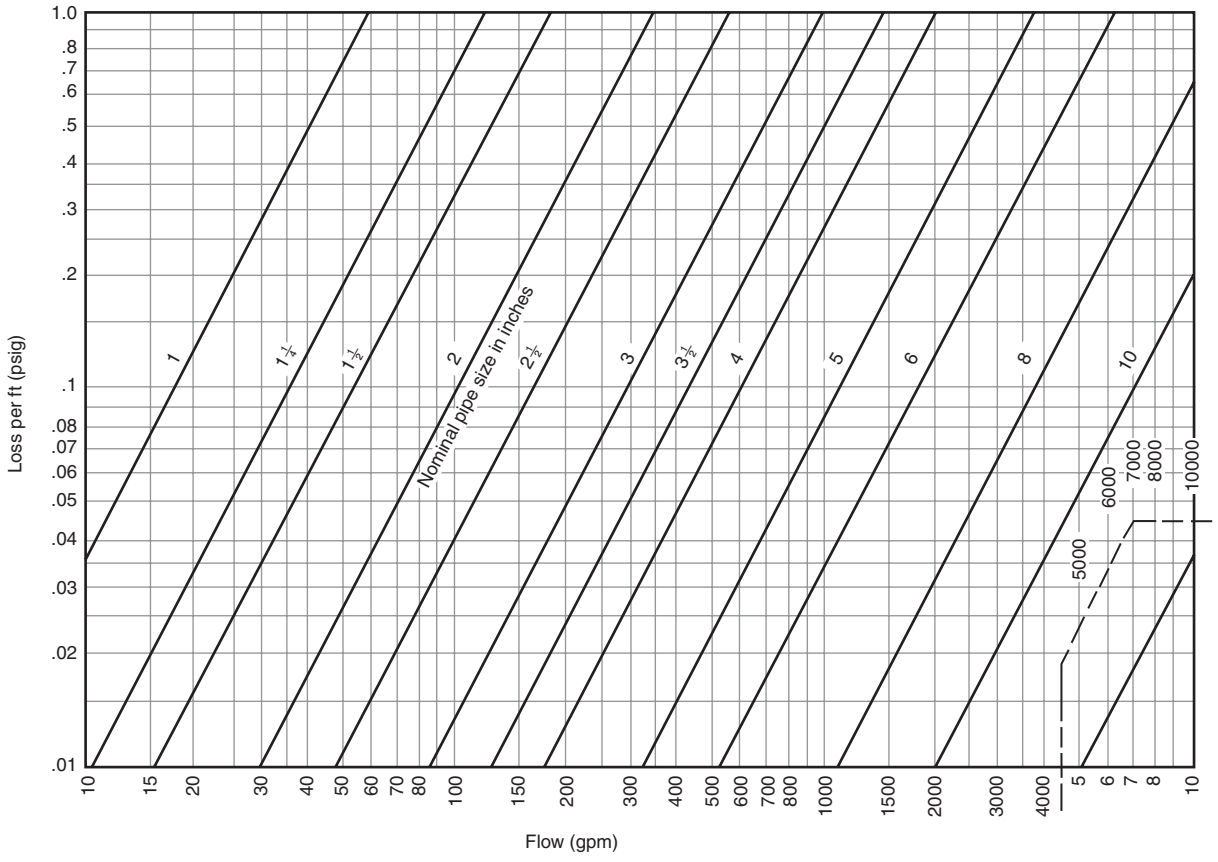

FIGURE 15.3.15 Friction Loss in Schedule 40 Steel Pipe, Hazen-Williams *C* = 120

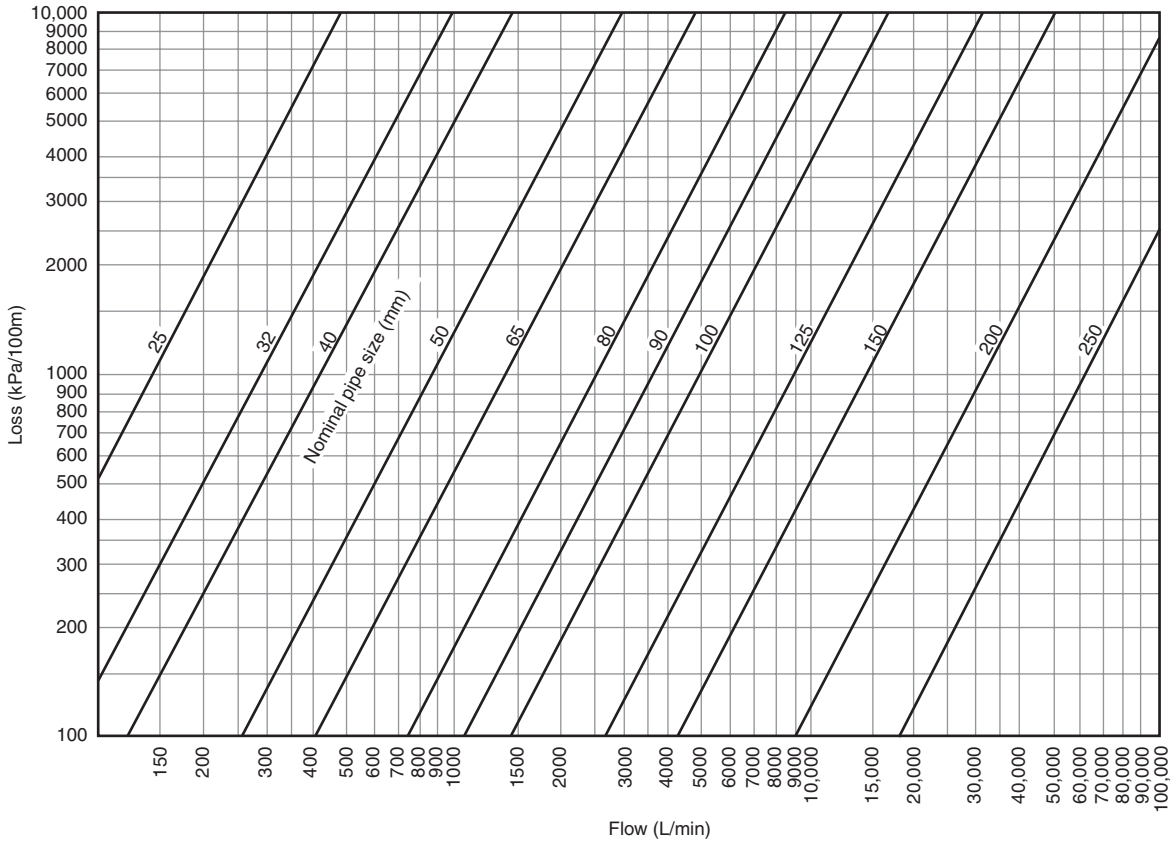

FIGURE 15.3.16 Friction Loss (SI units) in Schedule 40 Steel Pipe, Hazen-Williams $C = 120$

TABLE 15.3.6 Guide for Estimating Hazen-Williams *C*

Kind of Pipe	Value of *C* 1[a]	2[b]	3[c]
Cast iron, unlined			
10 years old	110	90	75
15 years old	100	75	65
20 years old	90	65	55
30 years old	80	55	45
50 years old	70	50	40
Cast iron, unlined, new		120	
Cast iron, cement-lined		140	
Cast iron, bitumastic enamel-lined		140	
Average steel, new		140	
Riveted steel, new		110	
Asbestos-cement		140	
Reinforced concrete		140	
Plastic		150	

Note: *C* values chosen for design of piping systems should be based on applicable NFPA standard or the authority having jurisdiction.
[a]Water mildly corrosive. Use same values for fire-protection mains having no mill-use or domestic draft.
[b]Water moderately corrosive.
[c]Water severly corrosive.

being substituted. The formula for using the friction loss table is applicable here.

EXAMPLE: What length of 8 in. pipe ($C = 110$) is equivalent to 700 ft of 6 in. pipe ($C = 85$)?

SOLUTION: $N_1 \times \frac{L_1}{100} \times T_1 = N_2 \times \frac{L_2}{100} \times T_2$

where

$N = C$ factor conversion for each pipe

$L =$ Length of each pipe

$T =$ Friction loss from Table 15.3.4

Assume a rate of flow (say, 1000 gpm) and substitute known values:

$$1.35 \times \frac{700}{100} \times 5.20 = 0.838 \times \frac{L_2}{100} \times 1.28$$

Solving for L_2,

$$\frac{1.35 \times 700 \times 5.20}{0.838 \times 1.28} = 4581 \text{ ft}$$

which can be rounded off to 4600 ft.

Minor Losses

Although the friction loss within the pipe normally accounts for most of the lost head, head losses also occur when the flow in a pipe changes direction, the pipe size changes, or a valve or other fitting is encountered. These losses are typically referred to as minor losses even though they can be significant for some fittings, such as swing check valves or backflow preventers, that are commonly found in fire protection systems.

The amount of minor losses from fittings can be found in many references and is often expressed in various forms. The most common are as an equivalent length (l/d), a resistance coefficient (k), or a flow coefficient (C_v).

Equivalent Length. For most fire protection calculations, friction loss is obtained by using the equivalent length method from a table such as Table 15.3.7, which expresses the friction loss of the fitting as an "equivalent pipe length" having the same friction loss as the fitting. This length is then added to the length of the pipe to which the fittings are connected to obtain the total friction loss of pipe and fittings.

EXAMPLE: Calculate total friction loss for 600 L/min flow through 200 m of nominal 2 in. (50 mm) pipe ($C = 120$) that incorporates three 90 degree elbows, one tee junction (90-degree turn), and two butterfly valves.

SOLUTION: Using Table 15.3.7 for equivalent lengths of fittings ($C = 120$),

Fittings or Pipe	*Number*	*Equivalent Length per Fittings (m)*	*Total Equivalent Length (m)*
Std. elbow	3	1.5	4.5
T-junction	1	3.1	3.1
Butterfly	2	1.8	3.6
Pipe	1	200.0	200.0
		Total equivalent pipe length =	211.2

From Figure 15.3.15, the total friction loss of 600 L/min flow in 50 mm (2 in. nominal) pipe is 500 kPa per 100 m of

TABLE 15.3.7 Equivalent Pipe Length Chart

	Fittings and Valves Expressed in Equivalent ft (m) of Pipe						
	¾ in. (20 mm)	*1 in. (25 mm)*	*1¼ in. (32 mm)*	*1½ in. (40 mm)*	*2 in. (50 mm)*	*2½ in. (50 mm)*	*3 in. (80 mm)*

Swing check*	19 (5.8)	22 (6.7)	27 (8.2)	32 (9.8)	45 (13.7)	55 (16.8)	65 (19.8)

Use with Hazen-Williams $C = 120$ only. For other values of C, the figures in this table should be multiplied by the factors below.

Value of C	80	100	120	130	140	150
Multiplying factor	0.472	0.713	1.00	1.16	1.32	1.51

(This is based on the friction loss through the fitting being independent of the C factor applicable to the piping.)
Specific friction loss values or equivalent pipe lengths for alarm valves, dry pipe valves, deluge valves, strainers, and other devices or fittings should be made available to the authority having jurisdiction.
Note: Use the equivalent ft (m) value for the "standard elbow" on any abrupt 90 degree turn, such as the screw-type pattern. Use the equivalent ft (m) value for the "long-turn elbow" on any sweeping 90 degree turn, such as a flanged, welded, or mechanical joint elbow type.
*Due to the variations in design of swing check valves, the pipe equivalents shown in this table should be considered average.

pipe. Because friction loss is directly proportional to length of pipe, total loss is given by

$$\frac{211.2}{100} \times 500 = 1056 \text{ kPa}$$

The loss due to fittings is given by

$$\frac{11.2}{100} \times 500 = 56 \text{ kPa}$$

or 5.3 percent of the total friction loss.

Resistance Coefficients. Resistance coefficients are sometimes used to express the head loss in a fitting as a function of velocity according to the relationship:

$$h_f = k\frac{v^2}{2g}$$

The equivalent length and the resistance coefficient methods are related. Using the basic Darcy-Weisbach formula,

$$h = f\frac{l}{d}\frac{v^2}{2g} = k\frac{v^2}{2g}$$

or

$$k = f\frac{l}{d}$$

Most entrance losses are calculated using resistance coefficients. Figure 15.3.17 provides resistance coefficients for some common entrance conditions and fittings.

Flow Coefficients. Where the loss in a fitting is defined by a flow coefficient C_v, the coefficient is defined as the flow of water that will produce a known friction loss (usually 1 psi) through the fitting. The relationship is usually shown as

$$Q = C_v\sqrt{h}$$

We know from our discussion on pressure that pressure (expressed in terms of psi) and head (expressed in terms of ft) are related by the formula

$$h = \frac{p}{w} = \frac{p}{.433}$$

Substituting, we get

$$Q = C_v\sqrt{\frac{p}{4.33}} \quad \text{or} \quad \sqrt{\frac{p}{4.33}} = \frac{Q}{C_v}$$

Squaring both sides and solving for p we get

$$p = 0.433\frac{Q^2}{C_v^2}$$

The flow coefficient can be shown to be related to the resistance coefficient. Because

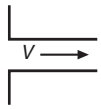
$$h = k\frac{v^2}{2g} \quad \text{and} \quad h = \frac{Q^2}{C_v^2} \quad \text{then} \quad k\frac{v^2}{2g} = \frac{Q^2}{C_v^2}$$

Rearranging we get

$$C_v^2 = \frac{2gQ^2}{kv^2}$$

FRICTION LOSS COEFFICIENTS

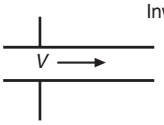
Head loss = $h = k\frac{v^2}{2g}$



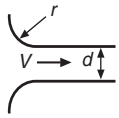
Sharp-edged inlet

$k = 0.5$

Inward projecting pipe



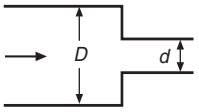
$k = 0.8 - 1.0$



Rounded inlet

r/d	0.05	0.1	0.2	0.3	0.4
k	0.20–0.25	0.09–0.17	0.08	0.05	0.04

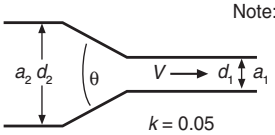
SUDDEN CONTRACTION



D/d	1.1	1.5	2.0	3.0	10
k	.15	0.28–0.30	0.36–0.40	0.42–0.50	0.50

GRADUAL CONTRACTION

Note: Use k with V of small pipe section



NOTE: Use k with V from large pipe

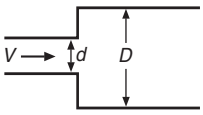
$k = 0.05$

2 $\beta = \frac{d_1}{d_2}$

IF $\theta \le 45$ degrees $k = \frac{0.8 \sin\frac{\theta}{2}(1-\beta^2)}{\beta^4}$

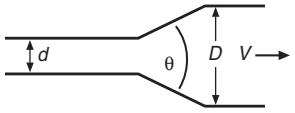
$\theta > 45$ degrees $k = \frac{0.5(1-\beta^2)\sqrt{\sin\frac{\theta}{2}}}{\beta^4}$

SUDDEN ENLARGEMENT



d/D	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9
k	0.98	0.92	0.83	0.71	0.56	0.41	0.28	0.13	0.04

GRADUAL ENLARGEMENT



NOTE: Use k with V in large pipe

$\beta = d/D$

If $\theta \le 45$ degrees $k = \frac{2.6 \sin\frac{\theta}{2}(1-\beta^2)}{\beta^4}$

If $\theta > 45$ degrees $k = \frac{(1-\beta^2)^2}{\beta^4}$

FIGURE 15.3.17 Friction Loss Coefficients

Because $Q = av$ and $a = \pi d^2/4$ we get

$$C_v^2 = \frac{2g(\pi d^2 v/4)^2}{kv} = \frac{2gd^4\pi^2 v^2}{16kv^2} = \frac{gd^4\pi^2}{8k}$$

Solving for C_v we get

$$C_v = \frac{\sqrt{g}d^2\pi}{\sqrt{8k}} = \pi d^2\sqrt{\frac{g}{8k}}$$

For d in inches, and C_v in gpm/$\sqrt{\text{psi}}$, the formula is normally expressed as

$$C_v = \frac{29.9d^2}{\sqrt{k}}$$

EXAMPLE 1: Water at a flow rate of 1500 gpm is flowing into an 8 in. pipe with a sharp entrance where it attaches to the side of a tank. What is the friction loss in psi due to the losses caused by the sharp entrance?

SOLUTION: From Figure 15.3.17, a sharp entrance has a resistance coefficient (k) of 0.5. We know that $h = k\frac{v^2}{2g}$, and from the earlier discussion on velocity that $v = \frac{0.4085 \times Q}{d^2} = \frac{0.4085 \times 1500}{8^2} = 9.37$ ft/sec. We want the pressure loss in terms of psi, and not feet, so

$$p = 0.433h = 0.433 \times 0.5 \times \frac{9.37^2}{2g} = 0.30 \text{ psi}$$

EXAMPLE 2: Given the same tank and pipe, what flow would result in an entrance loss of 1 psi?

SOLUTION: We could use the same equations as in the first example and solve for the velocity that creates a loss of 1 psi. An alternative solution is to calculate the flow coefficient, which is defined as the flow that generates a 1 psi loss. We know that for d in inches and C_v in gpm/$\sqrt{\text{psi}}$ that

$$C_v = \frac{29.9d^2}{\sqrt{k}}$$

In this case $d = 8$ and the resistance coefficient k is 0.5, so

$$C_v = \frac{29.9 \times 8^2}{\sqrt{0.5}} = 2706 \text{ gpm}$$

WATER HAMMER

Water hammer is an effect of the pressure rise (surge) that accompanies a sudden change in the velocity of water flowing in a pipe. When deceleration of velocity is rapid or completely stopped, the kinetic energy of the moving water column is absorbed temporarily by elastic deformation of the pipe and by the compressibility of water. A pressure wave is then formed that is reflected back and forth within the pipe.

Pressure surges may be initiated by the closing of a valve, stopping of a pump, or by the sudden development of abnormal water demand when a water main breaks. Occasionally, the operation of automatic control valves in sprinkler systems may result in the reversal of flow and a buildup of high pressure in the fire protection system.

Consideration of water hammer and transient pressure surges is traditionally based on the elastic wave theories of Joukowski and Allievi. Chapter 4-2 of the *SFPE Handbook of Fire Protection Engineering* provides an alternative discussion based on the elastic wave theories of Zhukovsky.

The force of water hammer is sometimes sufficient to rupture pipes, fittings, or hose lines. Theoretically, the resultant forces could be infinite if the system were totally inelastic.

The elasticity of hose tends to reduce the danger from water hammer, but the sudden closing of shutoff nozzles on long hose lines may cause a pressure rise sufficient to rupture the hose. Tests on water hammer were conducted by Robert Fitzgerald of the New York City Fire Department and published in that department's *WNYF Magazine* in July 1949. Tests with low-pressure hydrants indicated that pressure surges from the closing of nozzles became acute in long hose lines and that shock waves developed that traveled from the nozzle to the hydrant and back toward the nozzle, developing pressure surges approximately twice the hydrant pressure. These tests point to the advantage of operating nozzle valves slowly.

Discharge lines from pumps are subject to water hammer caused by water column separation. This may occur when a pump suddenly stops (due to power failure, manual shutdown, etc.) or if the discharge valve is closed too quickly with the pump operating. Separation takes place somewhere downstream, especially at a summit, or where the downward slope of the pipe increases sharply. When forward movement becomes exhausted, the flow reverses direction and closes the gap.

When a pump is located at an elevation above the system outlet, a vacuum breaker in the line may provide effective control. When there is static head on a pump at discharge, it is practically impossible to completely eliminate a water column reversal. Surge suppressors or special-type vacuum breakers designed to bypass a portion of the reverse flow water column around the check valve or control valve may be effective.

The restarting of a fire pump too quickly after a tripout may cause excessive surging, and installations subject to intermittent operation should be protected by time-delay relays. Simple relief valves are considered useless, because their operation is too slow to counteract the speed of the pressure rise. In fire protection systems, a jockey pump is used to maintain a high pressure on the system and reduce the water hammer causing surge when the fire pump starts. If the jockey pump pressures are set too low, the starting of a fire pump can cause a significant surge of water into the fire protection system and result in water hammer. To avoid this surge the jockey pump should be set to maintain a pressure just above the churn pressure of the pump, so that when the pump starts, there is minimal waterflow and pressure increase on the piping system.

The principal factors contributing to water column separation are (1) rate of flow stoppage, either by rapid closing of a valve, or the fast deceleration of a pump; (2) length of pipe system (this factor determines the time that pressure continues to fall before positive-pressure waves returning from the far end of the line counteract the initial pressure drop); (3) the normal operating pressure at critical points, such as the crests of hills;

and (4) the velocity of the water just before pump stoppage or valve closure occurs; the greater the velocity, the larger the size of the void, reverse flow velocity, and the final pressure rise.

ELASTIC WAVE THEORY

The basic concepts of elastic wave theory (EWT) are as follows:

1. The magnitude of the pressure rise is proportional to the fluid velocity destroyed and to the velocity of the pressure wave.
2. The pressure rise is independent of the length and profile of the pipe.
3. The velocity of the pressure wave is the same as the velocity of sound through water.

The theoretical pressure rise when flow is stopped instantly may be calculated by the formula

$$\Delta p = \frac{0.433av}{g}$$

where

Δ_p = Pressure rise (psi)

a = Velocity of the pressure wave (ft/sec)

v = Waterflow velocity (fps)

g = Acceleration of gravity (ft/sec^2)

In SI units, the formula is

$$\Delta p_m = \frac{9.81a_m v_m}{g_m}$$

where

Δp_m = Pressure rise (kPa)

a_m = Velocity of the pressure wave (m/sec)

v_m = Waterflow velocity (m/sec)

g_m = Acceleration of gravity (m/sec^2)

In practice, the calculated Δp may be reduced, allowing for valve closure characteristics and friction loss in the pipe. Usually, this is a matter of judgment and experience. For the pipe sizes used in fire protection systems, an allowance of 100 to 125 psi (690 to 860 kPa) is suggested.

The pressure rise, Δp, is at maximum when the flow is stopped in a time equal to or less than the critical time of the pipe, which is the time required for the pressure wave to travel from the point of closure to the end of the pipe and return. The formula for critical time is

$$T = \frac{2L}{a}$$

where L = length of pipe.

The wave velocity, a, is

$$a = \frac{12}{\sqrt{\frac{w}{g} \times \left(\frac{1}{k} + \frac{d}{E \times e}\right)}}$$

where

w = Weight of water (lb/ft^3)

g = Acceleration of (ft/sec^2)

k = Bulk modulus of compressibility of water (psi)

E = Young's modulus of elasticity of pipe wall material (psi)

e = Thickness of the pipe wall (in.)

d = Inside diameter of the pipe (in.)

To avoid calculating a, use the chart in Figure 15.3.18. The figures on the curves represent values of E in millions of pounds per inch^2 (bulk modulus of elasticity).

The calculated pressure rise in a 6-in. cast-iron pipe is about 60 psi per foot (1357 kPa/m) of arrested velocity.

The water hammer potential of distribution systems, especially those with automatic pumps, should be examined and practical steps taken to reduce the probability of destructive pressure surges. It should be noted, however, that because of the conditions under which dedicated fire protection distribution systems are designed (automatic operation of pumps with check valves in their discharge lines), the potential for water hammer cannot be completely eliminated.

To prevent water hammer, valves and hydrants should be maintained in good condition and operated carefully to prevent an abrupt reduction in flow; remote-controlled power-operated valves should be carefully timed to prevent them from closing too fast (never less than 5 sec).

SUMMARY

Water is the most universally used agent for fire protection. It can be applied manually using hydrants, standpipes, and hose lines or automatically via sprinkler, water spray, or other water-based

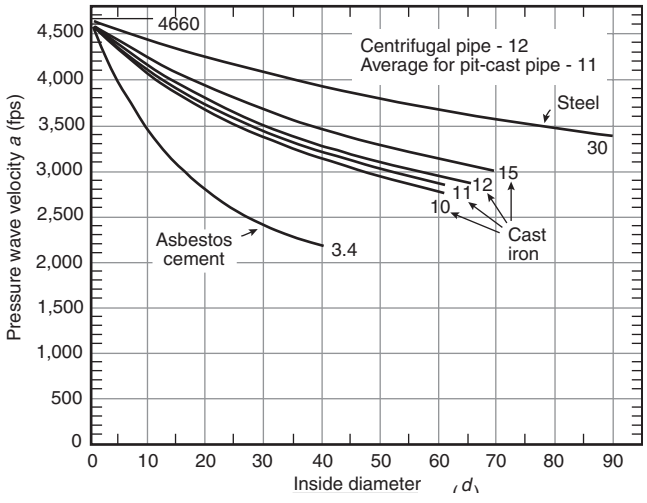


FIGURE 15.3.18 Surge Wave Velocity Chart for Water

systems. It is commonly available through public or private piping systems and storage tanks on the protected property.

The fundamentals of hydraulics presented in this chapter are applied in the design of these systems. The chapter covered the basic properties of water; the concepts of pressure, velocity, and velocity head were combined with Bernoulli's theorem on the conservation of energy for noncompressible fluids to derive the basic equations for the flow of water through orifices and ways to measure that flow. Energy losses occur in real systems, and several methods can be used to calculate those losses. The empirical relationship developed by Hazen and Williams is the most widely used and accepted of these methods to determine the friction loss of water in pipes of fire protection systems. Finally, methods were provided to deal with losses to fittings that are found in piping systems and a glimpse into the problem of water hammer in closed piping systems. The methods provided can be used to make most of the common fire protection water calculations and are the basis for calculating more complex piping arrangements, including those involving looped or gridded piping systems and those with multiple sources of water supply.

Types of Supplies
Influence of Various Factors on Water Supply Need
Water Supply Requirements for Sprinkler Systems
Occupancy Classifications
Water Supply Requirements for Hose Stream Protection
Hydraulically Designed Sprinkler Systems

Key Terms

automatic sprinkler system, fire department connection, fire pump, hydraulically designed system, hydraulic calculations, K-factor, microbiologically influenced corrosion (MIC), pipe schedule method, private water supply, public water supply, reduced pressure zone, velocity pressure

Every automatic sprinkler system must have at least one automatic water supply of adequate pressure, capacity, and reliability. An "automatic" supply is one that is not dependent on any human intervention to manually operate valves, start pumps, or make connections to supply water at the time of a fire. Both the rate of flow and the duration of that flow must be considered.

This chapter identifies the types of water supplies that are acceptable for fire sprinkler systems and the variables that must be considered in the system design. The following factors are to be considered: occupancy hazard classification, supplementary hose stream demand, adequate pressure demands, the fundamentals of a hydraulically designed sprinkler system, and sprinkler system piping sizes matched with the available water supply.

Chapters in Section 15 of this handbook covering water supplies for fixed fire suppression focus on understanding the complexities of providing adequate water supplies for sprinkler systems. Of particular interest are the following chapters in Section 15: Chapter 1, "Fixed Water Storage Supplies for Fire Protection"; Chapter 2, "Water Supply Requirements for Public Supply Systems"; Chapter 6, "Water Distribution"; and Chapter 3, "Hydraulics for Fire Protection," which discusses the fundamentals of waterflow through pipes and orifices. Also relevant is Section 16, Chapter 9, "Water Spray Protection," which is of value because there is no definitive line between sprinkler systems and water spray systems, and many of the water supply requirements that pertain to sprinkler systems apply equally to water spray systems.

TYPES OF SUPPLIES

Automatic fire sprinkler systems can be supplied from a single source or a combination of sources such as a municipal water supply, elevated gravity tanks, at-grade tanks or reservoirs, pressure tanks, rivers, lakes, and ground well water.

In theory, a single water supply would seem to be all that is necessary for satisfactory protection. However, a single supply may be temporarily out of service, it may be disabled at the time of a fire or before a fire is completely extinguished, or its pressure or capacity may be below normal during an emergency. Therefore, a secondary supply is recommended depending on the strength and reliability of the primary supply; the value and importance of the property; the area, height, and construction of the building; the use or occupancy; and the outside exposures.

Connections to Public Waterworks Systems

A connection from a reliable public waterworks system of adequate capacity and pressure is the preferred single or primary supply for automatic sprinkler systems. In determining its adequacy, one must consider not only the normal capacity and pressure of the system but also the minimum

Wayne M. Martin, P.E., is retired from the Los Angeles City Fire Department. He is a licensed civil engineer and fire protection engineer, and is principal of Wayne Martin & Associates, Inc., a fire protection and code consulting firm. He is a member of the NFPA 13 Technical Committee on the Installation of Sprinkler Systems.

pressures and flows available at unfavorable times, such as the summer months; periods of heavy demand on the system, such as those created by large industrial areas; or periods of impairment caused by flood or by ice conditions in winter. These conditions are typically referred to as seasonal lows.

Daily demands will fluctuate as well. Consider the early morning hours when the population is preparing for work or school. Demands created by domestic plumbing system use will be greater than at other times of the day.

The size and arrangement of street mains and feeders from public water supplies are also important. Connections from large mains fed two ways or from two mains on a grid system may provide an excellent supply. Street mains less than 6 in. (152 mm) in diameter are usually considered inadequate and unreliable. Feeds from dead-end mains are also undesirable. Water meters, if required, should be of types listed for the fire service. Flow and pressure tests under varying conditions of demand are generally necessary to determine the amount of public water available for fire protection.

Cross Connections Between Public and Private Supplies

Where a secondary supply is needed to supplement the public water supply, public and private fire service mains can be connected to feed into a single fire protection system. When the private fire service main is from a nonpotable source and it is connected to the public main, the systems are said to be cross connected. In some localities, cross connections may be prohibited or closely regulated by health authorities.

Federal regulations approved in 1986 require states to provide quality water when it is intended for public consumption. States and municipal governments have taken various steps beyond the federal mandate to protect the potable water supply. Double check valves and reduced pressure zone (RPZ) backflow prevention devices may be required when the sprinkler system will be supplied by a potable water source.

These devices, which are intended to protect the public water supply from potential contamination, are oftentimes costly and have a negative impact on the available water supply and pressures to the sprinkler system. Although no documentation exists of any actual problems with respect to sprinkler systems and potable water, many state health and environmental agencies have been successful in mandating such devices to protect the public from some perceived or potential threat.

Gravity Tanks

Gravity tanks of adequate capacity and elevation make a good primary supply and may be acceptable as a single supply. Details of the construction, heating, and maintenance of gravity tanks are given in NFPA 22, *Standard for Water Tanks for Private Fire Protection.* In determining tank size and elevation, the following information should be considered: sprinkler system design area; density or rate of water application; duration of operation; water allowances for inside hose, outside hydrants, water curtain, and exposure sprinklers; and arrangement of the underground supply piping and fire department connections.

Suction Tanks

With the advent of hydraulically designed sprinkler systems, suction tanks have become an acceptable means of design. Suction tanks are typically constructed of steel, concrete, or embankment-supported coated fabric. NFPA 22 should be consulted for details.

Fire Pumps

A fire pump with a reliable source of power and a reliable suction water supply is a desirable piece of equipment. Fire pumps are used to a great extent because of the hydraulic advantages of having a water supply available at high pressure. With ample water, a fire pump can maintain a high pressure over a long period of time and may be a necessary part of some installations requiring greater water pressure than would be available otherwise. For details of power sources, pump construction, installation, and methods of control and operation, consult NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection*.

Most fire pumps today are started automatically. Automatic control of fire pumps is needed where an immediate water demand is necessary, as with a sprinkler or standpipe system. Automatic fire pumps must have their suction under a positive pressure to avoid the delays and uncertainties of priming.

Most fire pumps are powered by electric motors or diesel engines. Where a reliable source of power is available at all times, an electrically driven installation may be the most desirable. Where the power supply is questionable, a diesel-driven fire pump would be preferred. In some critical installations, such as hospitals and high-rise buildings, a diesel-driven emergency power generator may be used to supply secondary power to the electric motor. The use of a diesel-driven fire pump in a critical installation would eliminate the need for much of the capacity of the emergency generator.

The automatic control of electrically driven centrifugal pumps must be arranged to prevent frequent, repeated starting of the motor, either by initiating continuous running until stopped manually or by using a timing device that stops the motor automatically only after a predetermined period of operation. The frequent repeated starting and stopping of a fire pump can be alleviated by the installation of a pressure maintenance pump or jockey pump.

Pressure Tanks

Pressure tanks have several possible uses in automatic sprinkler protection. An important limitation is the small volume of water that can be stored in such tanks.

In situations where an adequate volume of water can be supplied by a public or private source but where the pressure is not sufficient to serve a sprinkler system directly, the pressure tank gives a good starting pressure for the first sprinklers that operate. In tall buildings where the public water pressure is too low for effective water distribution to the highest sprinklers, pressure tanks may be used to supply such sprinklers during the time required for an automatically operated fire pump to begin supplying water.

Each proposed use of pressure tanks calls for special consideration and analysis of water capacity, location, and arrangement of the connection to the sprinkler system. Each installation must usually have specific approval. Details on the construction and installation of pressure tanks are given in NFPA 22.

Fire Department Connections

Under fire conditions that cause a considerable number of sprinklers to operate, public water or tank supplies may not provide water at sufficient pressure for effective sprinkler discharge and distribution. In addition, the pressure in many public water supplies to sprinkler systems may be reduced materially by hose streams from hydrants. In such cases, a connection through which the fire department can pump water into the sprinkler system provides an important secondary supply. A fire department connection is a standard part of a fire sprinkler system installation and would be omitted only if the building were inaccessible to the fire department or the sprinkler system exceeded the pumping capacity of the fire department, such as a deluge system. A fire department connection may also be omitted from a single-story building that does not exceed 2000 ft^2 (186 m^2) in size.

Fire department connections must be located and arranged so that hose lines can be readily and conveniently attached without interference from nearby objects. Each fire department connection must be properly identified with a sign, for example, autosprinkler or standpipe. Each connection must be fitted with a check valve, but not with a gate valve, so that the connection will not be shut off inadvertently. There should be a proper drain, as well as a drip device between the check valve and the outside hose coupling. Figures 15.4.1 and 15.4.2 show the main features of a fire department connection. In Figure 15.4.1, a check valve allows the use of a single hose line. Other details of installation and pipe size are given in NFPA 13, *Standard for the Installation of Sprinkler Systems.*

Where a wet pipe sprinkler system has a single riser, the fire department connection should be attached to the system side of the controlling valve, as shown in Figure 15.4.3. For a dry pipe system, the fire department connection should be between the

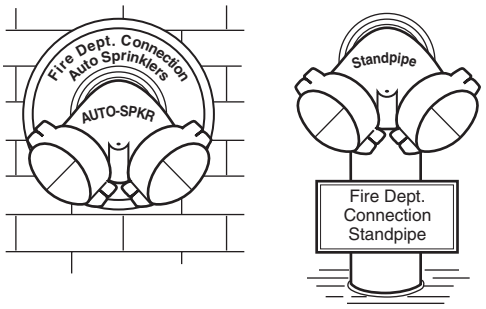

FIGURE 15.4.1 Typical Siamese Connections for Sprinkler Systems and Standpipes

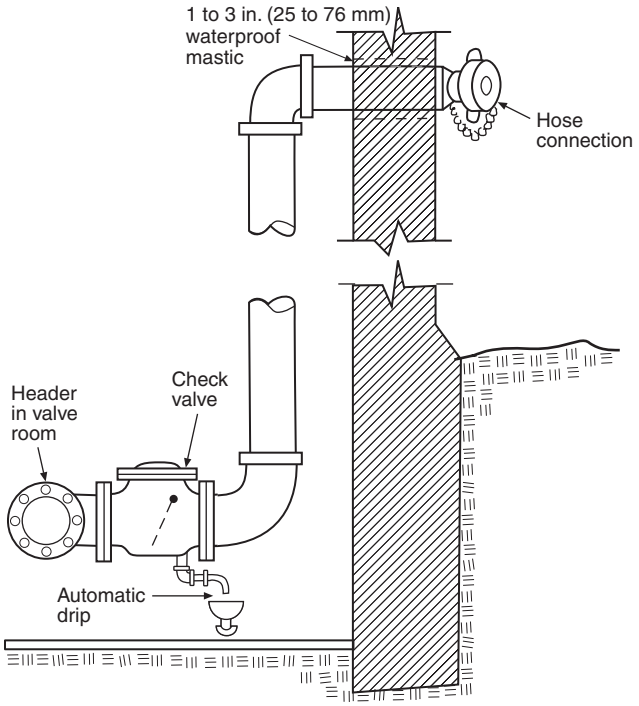

FIGURE 15.4.2 Typical Fire Department Connection

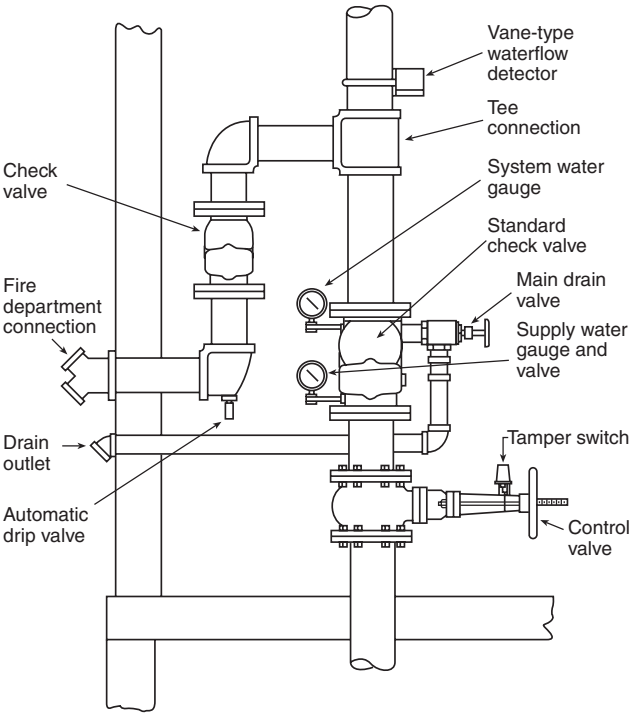

FIGURE 15.4.3 Straight Pipe Riser (Source: *Automatic Sprinkler Systems Handbook,* 1999, Exhibit 5.26)

system control valve and the dry pipe valve. This makes it possible to pump water into the system even if the valve is closed. If there are two or more sprinkler system risers, each with its own separate connection to a public main, each system must have its own fire department connection. If more than one riser is connected to a yard system, the fire department connection should feed into the yard system on the supply side of all riser shutoff valves, and there must be a check valve in all other water supply connections into the yard system to prevent backflow and loss of water supplied through the fire department connection. If one riser is shut off, the fire department connection can still supply all other risers. If two or more sprinkler system risers are fed by one sprinkler connection, one fire department connection can supply both risers.

In an emergency, a fire department can pump water from public hydrants or other sources of water into a sprinkler system through hose connected to a yard hydrant or other hose connection using a double female hose coupling, if other supply connections have a check valve or a gate valve that can be closed.

INFLUENCE OF VARIOUS FACTORS ON WATER SUPPLY NEED

Determining the water supply requirement for most sprinkler systems is not always easy because of the many variables involved. If a water source that can supply all the sprinklers is available, there is no problem, but such a water supply is seldom practical except in the case of small systems. The water supply requirement for any sprinkler system is directly related to the number of sprinklers expected to operate, which is determined by the hazard classification and the anticipated use of outside and inside hose stream demands.

Records kept by NFPA before 1970 show that 20 or fewer sprinklers opened in 93 percent of all anecdotally reported fires in sprinklered buildings. Older data are almost certainly skewed to bigger fires and more severe outcomes. Given this history, it is not surprising that water supply adequacy is not usually difficult to assure and inadequacy is rarely the cited reason for unsatisfactory sprinkler performance. Thus, water supply is a significant concern, particularly with large sprinkler systems and with systems protecting greater-than-ordinary hazards.

Establishing the water supply requirement for a sprinkler system requires the system designer to consider factors relating to sprinkler control and sprinkler system extinguishment. Where the cooling effect from the water discharged by sprinklers is greater than the heat liberated by the fire, the sprinklers can gain control. When the reverse occurs, as when a water supply is overtaxed or system design is inadequate, the sprinklers cannot control the fire and the sprinkler system may ultimately fail. Where all conditions are favorable, the fire should be controlled by the operation of only a small number of sprinklers. Because conditions vary with different classes of occupancy, areas, and types of buildings, the number of sprinklers expected to operate to control a fire may range up to the total number in the design area, and the water supply should be provided accordingly.

The following factors affect the number of sprinklers that might open in a fire and must therefore be considered in determining the water supply requirement.

Hazard of Occupancy (Including Flash Fire Hazard and Potential Rate of Heat Release)

This is the most important factor and one requiring experienced judgment to evaluate. Where a flash fire hazard is present, it is usually necessary to provide enough water to operate all of the sprinklers in any individual fire area.

Initial Water Pressure

When fire sprinklers are submitted to testing laboratories for listing, they are subjected to water distribution and fire tests. These tests are conducted at a minimum flow of 15 gpm (57 L/min) per sprinkler. The pressure required to produce this flow through a standard ½ in. orifice (12.7 mm) sprinkler with a nominal K-factor of 5.6 is approximately 7 psi (0.5 bar). The minimum operating pressure of any sprinkler is 7 psi (0.5 bar) according to NFPA 13. The designer must verify the listing for a specific sprinkler. The listing may require minimum operating pressure greater than 7 psi (0.5 bar).

At higher initial water pressures, the discharge is correspondingly greater. For example, at a pressure of 15 psi (1.03 bar), a sprinkler (K = 5.6) will discharge 22 gpm (83 L/min) or an average of approximately 0.17 gal/ft^2/min (6.8 L/min/m^2) for one sprinkler with an area of coverage of 130 ft^2 (12 m^2). At 30 psi (2.07 bar), the discharge is 31 gpm (117 L/min), and at 50 psi (3.45 bar), it is 40 gpm (151 L/min). With a greater discharge, there is a better chance of fire control from a small number of sprinklers and less need for large volumes of water to supply a large number of sprinklers.

Obstructions to Distribution of Water from Sprinklers

Nonstructural building elements such as high piled stocks, pallets, racks, and shelving must be considered, especially in extra hazard and various types of storage occupancies. Obstructions create a greater chance that a larger number of sprinklers needing larger water supplies will open and a lesser likelihood that the fire will be controlled in its initial stages.

High Ceilings and Air Current Conditions

With ceilings of unusual height, there is a greater chance that natural air movement will carry heat away from the sprinklers immediately over a fire, resulting not only in a delay in the application of water, but also resulting in the opening of sprinklers remote from the area of fire origin. More water or a larger sprinkler density is usually needed under such conditions. The same situation exists wherever there are drafts, such as in areas open on the sides to the outside where winds can divert heat from sprinklers over the fire.

Unprotected Vertical Openings

Sprinkler systems in multistory buildings are usually designed on the assumption that fire will be controlled on the floor of origin. Where there are unprotected openings up through which heat and fire may spread, it may be expected that more sprinklers will

open, particularly in the case of a fire originating near the vertical opening. In the case of high combustibility, the interconnected floors may need to be considered as one fire area. This means more water and larger pipe sizes in risers and supply lines.

Wet Pipe versus Dry Pipe Systems

Because of the delay due to exhausting air from dry pipe systems, more sprinklers are expected to open on dry pipe systems than on wet pipe systems. This may call for greater water supplies. Design areas are increased by 30 percent to account for this delay.

Obstructions to Sprinkler Discharge

Sprinkler discharge patterns may be significantly affected by an obstruction. Historically building structural members and other building elements such as ducts were considered. Recently other types of smaller building elements such as piping and light fixtures were considered as obstructions to water distribution. Columns, beams, girders, bar joists, light fixtures, soffits, and HVAC ductwork can obstruct water distribution to the point where additional sprinklers may be necessary to account for the obstruction, the result being more sprinklers in the design area. Floor-mounted obstructions, such as privacy curtains, freestanding interior partitions, and room dividers, require similar special treatment. NFPA 13 addresses the areas of concern with regard to obstructions. Each type of sprinkler—that is, standard spray, sidewall, large drop, extended coverage, and early suppression fast response (ESFR)—is treated separately with its own obstruction requirements.

Extent of Coverage and Exposures

Any fire in an unsprinklered space extending to an area with automatic sprinklers places an abnormal demand on the sprinkler system and requires increased water supplies so that the system may function effectively.

Regardless of the size of the building, NFPA 13 requires a specific design area that relates to the occupancy fire hazard rather than the size of the building. The idea behind this concept is to provide a water supply that is adequate to cover this design area for a given period. The sprinklers in the most remote portion (hydraulically remote areas) of this area are used as the basis of design. The capability of supplying sprinklers in this area automatically means that sprinklers that are physically closer to the water supply source can be supplied as well.

WATER SUPPLY REQUIREMENTS FOR SPRINKLER SYSTEMS

Notwithstanding the general problems involved in arriving at water supply requirements, the fire hazard represented by different building occupancies has made it possible to establish requirements for water supplies for sprinkler systems. The occupancy classification is the primary consideration, with latitude allowed for other contributing factors.

Selection of the appropriate water supply guide table in NFPA 13 is based on the design approach for sprinkler piping. The pipe schedule approach is the oldest version and first appeared in the standard in 1896. The concept of hydraulically designed systems was advanced in 1969 and is the predominate design approach method used today. Minimum water supply requirements for the pipe schedule design method, as shown in Table 15.4.1, are based on occupancy classification (light or ordinary hazard).

The total water supply required is determined from Table 15.4.1, and the water for hose streams is included. If stored water is used, the total waterflow required would have to be multiplied by the duration of flow to determine whether the capacity of the stored supply is adequate, a factor that would not be pertinent for a reliable municipal water source.

The pipe schedule method that is the basis of Table 15.4.1 has certain limitations and should be used only with experienced judgment. The pipe schedule method is permitted only for new installations of 5000 ft^2 (465 m^2) or less at a minimum residual of 15 psi (1.03 bar) at the base of the riser, or if the area exceeds 5000 ft^2 (465 m^2) the minimum residual must be 50 psi (3.4 bar) at the elevation of the sprinkler. The pipe schedule design method is also permitted for modifications to existing pipe schedule systems. The effectiveness of a pipe schedule system is limited to the use of ½ in (12.7 mm) orifice sprinklers. Extra hazard occupancies and storage occupancies involve complex factors requiring special consideration and the use of the hydraulic calculation design method.

Where fire pumps contribute to the sprinkler system water supply, pumps of standard size used with adequate rates of discharge are required. The water supply for a pump must be adequate and reliable to provide for continuous pump operation.

Where pressure tanks furnish the water supply, the tank installation should comply with the appropriate provisions of NFPA 22. Where a combination of different water supplies is provided in the interest of reliability, it is good practice to have the rate of supply from each source at least equal to the minimum requirement for the system.

OCCUPANCY CLASSIFICATIONS

Light-Hazard Occupancies

The quantity or combustibility of contents is low and fires with relatively low rates of heat release are expected. Examples of

TABLE 15.4.1 Water Supply Requirements for Pipe Schedule Sprinkler Systems

Occupancy Classification	*Minimum Residual Pressure Required (psi)*	*Acceptable Flow at Base of Riser (Including Hose Stream Allowance) (gpm)*	*Duration (min)*
Light hazard	15	500–750	30–60
Ordinary hazard	20	850–1500	60–90

For SI units: 1 gpm = 3.785 L/min; 1 psi = 0.0689 bar.

light-hazard occupancies are residential buildings, dormitories, office buildings, the seating areas of restaurants, and hospitals. In these occupancies, the potential rate of heat release is low, areas are usually subdivided, and a small number of sprinklers normally should control any fire. For hydraulically designed systems, 150 gpm (568 L/min) for sprinkler operation and an additional 100 gpm (378 L/min) for hose stream demand (Table 15.4.2) will generally make a good starting point for system demand. A total of 500 to 750 gpm (1893 to 2839 L/min) for pipe schedule systems may be necessary for the same hazard, thereby making this a less desirable design approach.

Ordinary-Hazard Occupancies

Ordinary-hazard occupancies are divided into two groups: Group 1 and Group 2.

Group 1. This ordinary-hazard classification includes occupancies, such as parking garages, bakeries, laundries, and canneries, in which the combustibility of contents is moderate, stockpiles of combustibles do not exceed 8 ft (2.4 m), and the rate of heat release for a fire is greater than that for the light-hazard classification. Ordinary-hazard Group 1 occupancies will require a minimum of 225 gpm (851 L/min) for sprinkler operation and an additional 250 gpm (946 L/min) to support inside and outside hose streams. If a pipe schedule approach is selected, a minimum flow of 850 gpm (3217 L/min) is necessary.

Group 2. This ordinary-hazard classification includes occupancies such as clothing factories, mercantile, pharmaceutical manufacturing, certain woodworking occupancies, and repair garages. With this group, the combustibility of contents, storage heights, and obstruction features are moderate to high, stockpiles do not exceed 12 ft (3.7 m), and the rate of heat release is greater than Group 1. Ordinary-hazard Group 2 occupancies will require a minimum flow of 300 gpm (1125 L/min) for sprinkler operation, plus an additional 250 gpm (946 L/min) to operate the inside and outside hose streams. If design is based on the pipe schedule method, a minimum total flow of 850 gpm (3217 L/min) is necessary.

Extra Hazard Occupancies

Extra hazard occupancies consist of properties where quantity and combustibility of contents is very high. Flammable and combustible liquids, dust, lint, or other materials may be present, introducing the probability of rapidly developing fires with high rates of heat release. Closely spaced sprinklers and larger pipe sizes are expected. Extra hazard occupancies are divided into two groups: Group 1 and Group 2.

Group 1. Extra hazard occupancies (Group 1) include those that may produce severe fires where little or no flammable or combustible liquids are present. These include such occupancies as die casting, plywood and particleboard manufacturing, printing (using inks with below 100°F [37.8°C] flashpoints), rubber manufacturing operations, sawmills, textile operations, and upholstering with plastic foam operations.

Group 2. Extra hazard occupancies (Group 2) include those that may produce severe fires where moderate to substantial amounts of flammable or combustible liquids are present, or where shielding of combustibles is extensive. These include such occupancy hazards as asphalt saturating, flammable liquids spraying, flow coating, open oil quenching, solvent cleaning, and varnish and paint dipping.

In any treatment of hazards by general groups of occupancy, it must be noted that individual properties differ markedly and that buildings of the same nominal occupancy classification may show widely different individual hazards that should be considered in any determination of water supply.

WATER SUPPLY REQUIREMENTS FOR HOSE STREAM PROTECTION

The values given in Table 15.4.1 include hose stream requirements. In considering water requirements for hose streams, one should realize that if sprinklers perform effectively, little hose stream assistance is required. Although this is generally the case, a realistic view must be taken of possible contingencies and of the amount of water that might be needed for hose stream protection under adverse conditions. Hose streams may also be necessary to accomplish final extinguishment of the fire. However, it should be noted that current sprinkler system technology is intended to control a fire, not necessarily to extinguish it.

In evaluating hose stream requirements, one should consider several possibilities, such as the amount of water necessary for final extinguishment and cleanup operations, or the steps that may have to be taken in the event that sprinklers are retarding fire spread but are not fully effective in gaining control of the fire and extinguishing it.

HYDRAULICALLY DESIGNED SPRINKLER SYSTEMS

Planning new water supplies or evaluating existing supplies for sprinkler systems requires information about the hydraulic behavior of sprinkler piping systems.

A hydraulically designed sprinkler system is one in which pipe sizes are selected on a pressure loss basis to provide a prescribed density in gallons per minute per square foot ([L/min]/m^2), or a prescribed minimum discharge pressure or flow per sprinkler, distributed with a reasonable degree of uniformity over a specified area. This system permits the selection of pipe sizes in accordance with the characteristics of the water supply available. The stipulated design density and area of application will vary with occupancy hazard. This language is the verbatim definition of a hydraulically designed system, taken from NFPA 13. This definition sets the basic premise for the preferred method of sprinkler system design.

Table 15.4.2 and Figure 15.4.4 are used to determine density, area of sprinkler operation, and water supply requirements for hydraulically designed sprinkler systems. Systems must be calculated to satisfy a single point on the appropriate design curve, and interior piping must be based on this design point. It

TABLE 15.4.2 Hose Stream Demand and Water Supply Duration Requirements for Hydraulically Calculated Systems

Hazard Classification	*Inside Hose (gpm)*	*Total Combined Inside and Outside Hose (gpm)*	*Duration (min)*
Light	0, 50, or 100	100	30
Ordinary	0, 50, or 100	250	60–90
Extra hazard	0, 50, or 100	500	90–120

For SI units: 1 gpm = 3.785 L/min.

is not necessary to meet all points on the selected curve. In some cases where a large water supply is available, it might be advantageous, because of the elimination of a fire pump, to design the system using the top portion of the curve. In other cases, it might be better to design with smaller areas of application and higher densities, because these tend to limit fire size, even though a fire pump is required.

When selecting a point on the curve in Figure 15.4.4, it should be noted that more total water is necessary in terms of flow and capacity as one moves up the curve. As an example, for a light-hazard system, a 1500-ft^2 (139-m^2) area requires a density of 0.10 gpm/ft^2 (4.1 [L/min]/m^2), or a flow of 150 gpm (568 L/min). If a 2500-ft^2 (232-m^2) area is selected, the density is only 0.08 gpm/ft^2 (3.2 [L/min]/m^2), but the total flow is increased to 200 gpm (757 L/min).

The same hazard occupancy classifications that apply to pipe schedule sprinkler systems apply to hydraulically designed sprinkler systems. However, the recommended water supply figures are somewhat lower due to the greater efficiency of a calculated system.

The water allowances for inside and outside hose streams may be combined and added to the system requirement at the system connection to the underground main. The total water requirement must be calculated through the underground main to the point of supply.

For deluge and water spray systems with open orifices, calculations are essential. Automatic sprinkler systems protecting high-piled storage require a specific water density for fire control. Because the hydraulic design approach results in superior design, it always should be selected as the preferred method.

Hydraulic Calculation Programs

Since NFPA 13 first permitted the use of hydraulic calculations, several computer programs have been developed that can assist the designer with this particular task. These programs are not required to be listed nor are they governed by NFPA 13. They must, as a minimum, be capable of providing the information required for any hydraulic calculation procedure. This information includes, but is not limited to, the hydraulic reference points, the flow and pressure at specific points, the pipe diameter, and, for a grid system, a printout showing the flow direction and quantities.

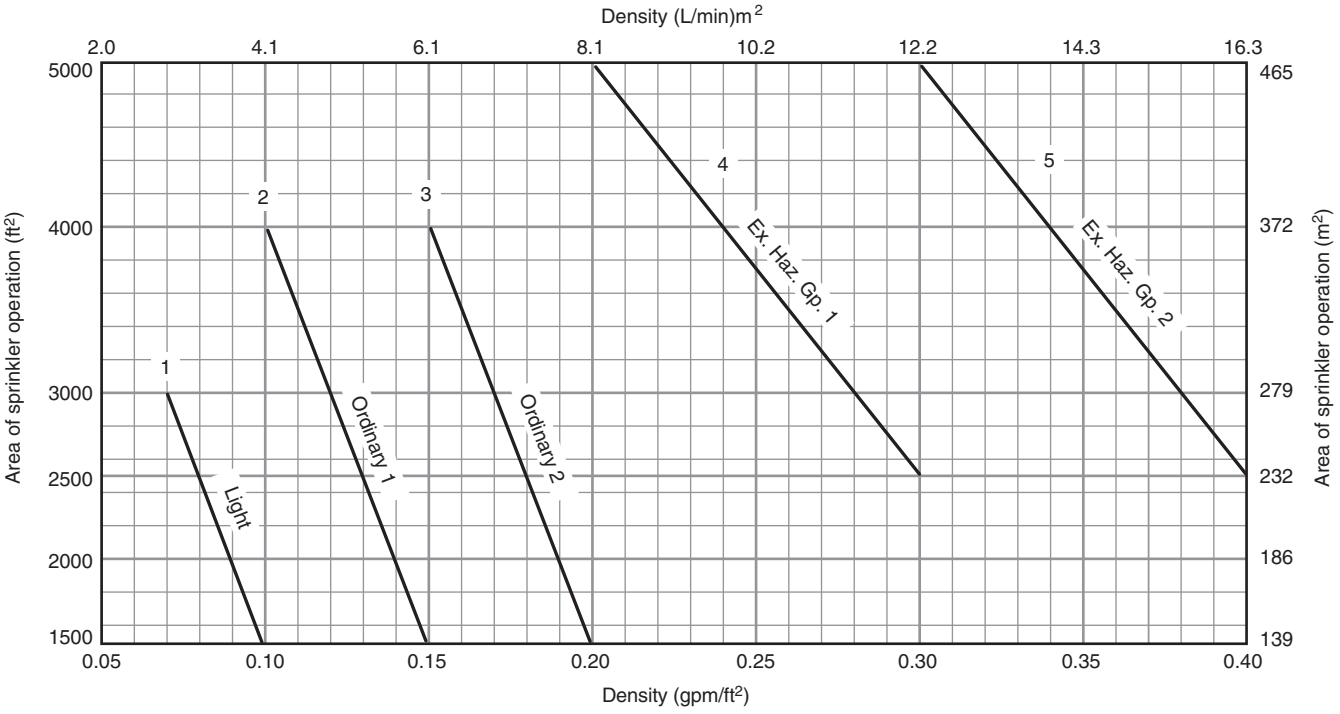

FIGURE 15.4.4 Design Curves for Hydraulically Calculated Sprinkler System

The capabilities and limitations of computer programs are as wide ranging as the cost differences among them. Before buying one of these programs, the user should investigate and compare the various hydraulic software programs, including the support the programs offer.

Flow Calculation Method

A method of making flow calculations for sprinkler systems is given in NFPA 13.

The design area for flow calculations should be chosen as the most hydraulically demanding area for the sprinkler system. The area should have a dimension parallel to the branch line of 1.2 times the square root of the area of anticipated sprinkler operation. The 1.2 times the square root of the area is added to ensure that the long side of the rectangle is along the branch line. In grid systems, the hydraulically most demanding area must be verified using at least two additional sets of calculations. This technique is referred to as "peaking," and it is merely a check to prove that the most demanding area has been calculated.

Each sprinkler in the design area must discharge at a flow rate at least equal to the stipulated minimum water application rate or density. Begin calculations at the sprinkler hydraulically farthest from the supply connection. In common system configurations, this will be the end sprinkler on the end branch line. The minimum operating pressure for any sprinkler must not be less than 7 psi (48 kPa) or the pressure necessary to deliver the design density at the hydraulically most remote sprinkler or a higher minimum pressure as specified in the laboratory listing. Special sprinklers, such as extended-coverage, ESFR, in-rack, and large drop, will require operating pressures well in excess of this 7 psi (48 kPa) minimum.

Most Remote Sprinkler

Assuming a minimum pressure of 10 psi (69 kPa) at the most remote sprinkler and a discharge coefficient of 0.75 for a standard ½ in. (12.7 mm) orifice sprinkler, there is a discharge of 17.7 gpm (67 L/min) calculated from the formula

$$Q = 29.83cd^2\sqrt{p}$$

used in calculating flows through orifices and short tubes. For a given sprinkler, the product of these numbers in the equation—$29.83cd^2$—becomes a constant and is denoted as the sprinkler K-factor. In the case of a ½ in. (12.7 mm) orifice sprinkler, the constant is 5.6 and is derived by multiplying the following numbers: $29.83 \times 0.75 \times (½)^2 = 5.6$. A simplified equation may now be used to describe flow through the sprinkler orifice. The new equation is

$$Q = K\sqrt{p}$$

Velocity pressure is not a factor at the most remote sprinkler, but it may be considered at all the other sprinklers in the example that follows. Some organizations ignore velocity pressure in their calculations. The omission of velocity pressure is conservative and on the safe side.

Example for Second Sprinkler from the End

The following example considers the effects of velocity pressure. Some computer programs consider velocity pressure and others do not. The hydraulic calculation example presented in the Annex of NFPA 13, Figure A.14.3.2(a) through Figure A.14.3.2(d), does not consider velocity pressure and is an example of hydraulic calculations by the old-fashioned method, by hand, not computer generated.

Assuming sprinklers 10 ft (3.05 m) apart on branch lines, with the end section of pipe 1 in. (25.4 mm) nominal diameter, the friction loss at 17.7 gpm (67 L/min) flow with a Hazen-Williams formula coefficient of 120 (value for black steel pipe) will be 1.0 psi (7 kPa).

The total pressure at the second sprinkler will be 10.0 + 1.0 psi (69 +7 kPa) = 11.0 psi (76 kPa). Velocity pressure, if used in the procedure, is calculated from the formula

$$P_v = 0.001123\frac{Q^2}{D^2}$$

where

P_v = Velocity pressure (psi)

Q = Flow (gpm)

D = Inside pipe diameter (in.)

The velocity pressure relates to the system design by

$$P_n = P_t - P_v$$

where

P_n = Normal pressure

P_t = Total pressure

P_v = Velocity pressure

Of this, velocity pressure based on a flow of 17.7 gpm (67 L/min) will be 0.3 psi (2 kPa). The normal pressure (pressure acting perpendicular to the pipe wall) acting on the second sprinkler is the total pressure of 11.0 psi (76 kPa), less the velocity pressure of 0.3 psi (2 kPa), which equals 10.7 psi (74 kPa). On all sprinklers except the end sprinkler, only normal pressure is considered as acting on the sprinklers. The discharge from the second sprinkler, at a pressure of 10.7 psi (74 kPa), will be 18.3 gpm (69 L/min).

The pipe between the second and third sprinkler, also 1 in. (25.4 mm) in diameter, 10 ft (3.05 m) long, and with a flow of 17.7 gpm (67 L/min) + 18.3 gpm (69 L/min) = 36.0 gpm (136 L/min), will have a friction loss of 3.8 psi (26 kPa) and a velocity pressure of 1.2 psi (8 kPa). Normal pressure at the third sprinkler is 10.7 psi (74 kPa) + 3.8 psi (26 kPa) – 1.2 psi (8 kPa), or 13.3 psi (92 kPa).

Other Sprinklers on a Branch Line

Figure 15.4.5 can be used to establish the velocity pressure correction needed for various pipe sizes and flows. This figure may be used for any pipe type, but it is based on the use of Schedule

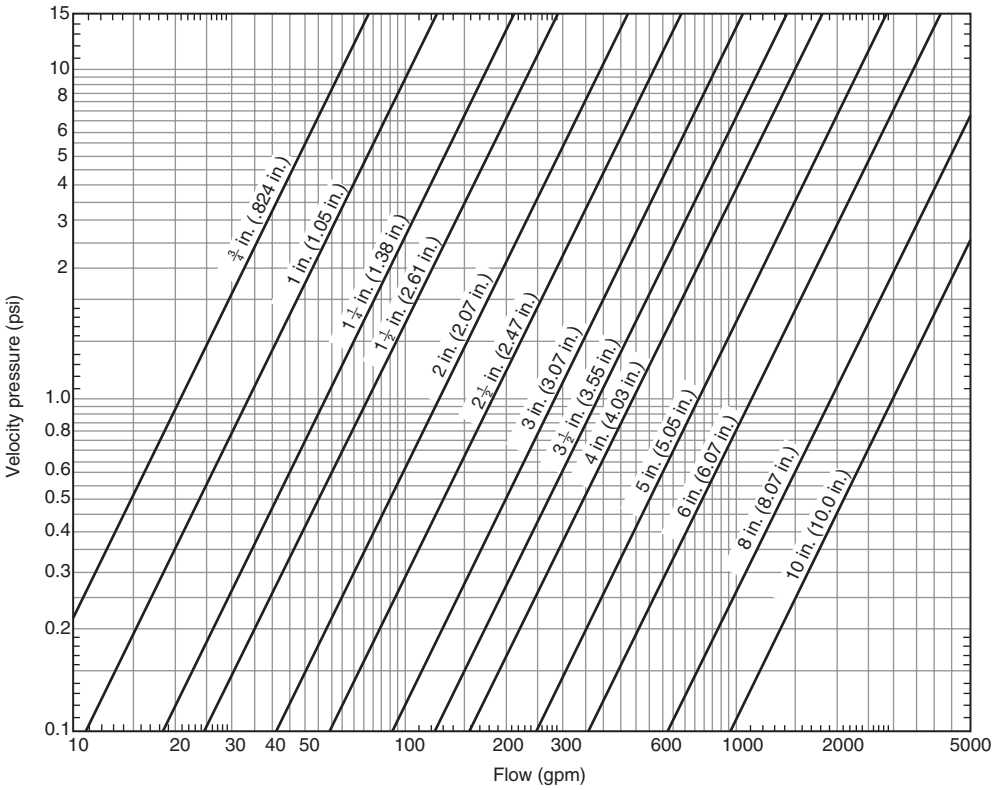

FIGURE 15.4.5 Graph for the Determination of Velocity Pressure

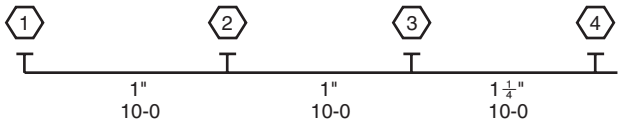
40 pipe. The difference in velocity pressure is minuscule as it relates to schedule of pipe.

Figure 15.4.6 is an example of the velocity pressure component, determined as follows: The flow between the last sprinkler and the next to last sprinkler on the branch line was determined to be 17.7 gpm (67 L/min) and the pipe size is 1 in. (25.4 mm). The graph in Figure 15.4.5 is now used to locate a flow of 17.7 gpm (67 L/min) on the *x*-axis, going vertically from this point until the 1 in. (25.4 mm) line is intercepted. The corresponding pressure is taken from the *y*-axis and is determined to be 0.3 psi (2.1 kPa). This procedure can now be repeated for each combination of pipe sizes and flows.



Summary

	Flow (gpm)	Friction loss (psi)	Velocity pressure (psi)	Normal pressure (psi)
1 2	17.7	1	0.3	11
2 3	36	3.8	1.2	13.3
3 4	57.5	3.9	1.0	15.0

FIGURE 15.4.6 Example of Velocity Pressure

Up to this point, velocity pressure has been based on flow downstream from the sprinkler being considered; this has been confirmed by tests. It has also been shown by those tests that beyond the second sprinkler, velocity pressure should be figured from the flow on the upstream side of the sprinkler being considered. This figuring is done by trial and error, assuming a flow from the sprinkler, calculating the velocity pressure from the total flow, determining a normal pressure, and calculating a flow from the normal pressure. If the calculated flow is not reasonably close to the assumed flow, assume a different flow and repeat the procedure until the two are close.

For example, assume a flow from the third sprinkler of 19.0 gpm (72 L/min) and assume that the pipe between the third and fourth sprinkler is 1¼ in. (32 mm). Total flow is 36.0 gpm (136 L/min) + 19.0 gpm (72 L/min) = 55.0 gpm (208 L/min). Velocity pressure is 0.9 psi (6 kPa), and normal pressure at the third sprinkler is therefore 15.7 psi (108 kPa) – 0.9 psi (6 kPa), or 14.8 psi (102 kPa). Corrected flow then becomes 21.6 gpm (82 L/min), which is not close enough to the 19.0 gpm (72 L/min) assumed. Try an assumed flow of 21.4 gpm (81 L/min). Velocity pressure at 57.4 gpm (217 L/min) is 1.0 psi (7 kPa); normal pressure is 14.7 psi (101 kPa), and the new corrected flow is 21.5 gpm (81 L/min). Total flow at the third sprinkler then becomes 36.0 gpm (136 L/min) + 21.5 gpm (81.4 L/min) = 7.5 gpm (217.6 L/min). The calculating procedure for the other

sprinklers on the branch line is the same as it is for the third sprinkler. If this set of conditions is compared to pipe schedule design, it will be seen that the 15 psi (103 kPa) minimum riser pressure has been exceeded, unless, as is quite probable, the pressure with 57.5 gpm (217.6 L/min) flow is substantially higher than that with a 500 gpm (1893 L/min) flow. Whether the pressure with 57.5 gpm (217.6 L/min) flow is higher than 15 psi (103 kPa) depends on the characteristics of the water supply. In any case, it appears that with not many more sprinklers open, the pressure at the most remote sprinkler will be less than the 10 psi (69 kPa) selected in this example.

Branch Lines, Cross Mains, Risers, and Fittings

Cross-Main Pressure at the Branch Line Connection. This pressure is the normal pressure at the nearest open sprinkler increased by the friction loss and the velocity pressure in the intervening pipe. If the branch line is fed through a tee and nipple, additional friction loss allowances must be made, although the friction loss in nipples less than 6 in. (152 mm) long is customarily neglected.

Two Branches in One Line of Sprinklers. These may have the same or different numbers of sprinklers. The pressure at the entrance to the two branches will always be the same. The computations starting at the end sprinklers will be duplicated for the number of open sprinklers. After the discharge from any number of sprinklers on a branch line has been computed and the pressure needed to produce the flow has been determined, the entire branch line can be considered to have the discharge characteristics of a single orifice, and the discharge constant K in the formula $Q = K\sqrt{p}$ can be determined, P being the net pressure where flows are taken from tees in the cross main.

Branches on Opposite Sides of a Cross Main. These branches may have different numbers of sprinklers open, in which case the cross-main pressure must be the higher of the two computed values. This situation increases the discharge from the branch giving the lower computed pressure, and the actual discharge must be calculated for the higher pressure using the equation

$$\frac{Q_1}{Q_2} = \sqrt{\frac{P_1}{P_2}}$$

where P_2 is taken as the higher pressure, Q_2 the corresponding increased discharge to be determined, and P_1 and Q_1 the pressure and corresponding discharge from the branch requiring only the lower pressure. This proportion and its associated concept is important in that only one pressure can be present at a particular junction point.

After the appropriate increased discharge has been determined, the two rates of flow can be combined and K calculated for the combined branches.

When sprinklers on the second branch line are assumed to have opened, starting at the cross-main sprinkler, the opened sprinkler most remote from the cross main is considered as the end sprinkler in the branch line computation, the next opened is the second, and so on, regardless of nonoperating sprinklers on the outer end of the branch.

Cross-Main Pressures. Cross-main pressures are calculated with the same procedure used for sprinklers on a single branch line, except that it is not necessary to use the trial-and-error procedure for the third and additional branch lines because the effect of change in velocity pressure with flows passing through tees in the cross main is usually negligible. The net pressure producing the flow in successive branch lines is taken as the normal pressure at the end branch line, increased by the friction loss in the pipe between the branches.

Riser Pressure. Riser pressure is taken as the normal pressure at the nearest flowing branch, increased by the total friction loss between this branch and the riser and by the velocity pressure in the cross main at the riser connection.

Friction Loss in Fittings. This friction loss is generally included in calculations only when the fitting involves a change in the direction of flow. An exception to this is the fitting immediately preceding the sprinkler. Friction loss in control, gate, and check valves and in strainers, meters, backflow devices, and similar devices is always included. The friction loss in piping between the source of supply and the opened sprinklers obviously must be included in all calculations.

Differences in elevation must be allowed for on the basis that each foot (meter) of height represents 0.433 psi (9.82 kPa/m). In multistory buildings, this may be a substantial factor. Feed mains, cross mains, and branch lines within the same system may be looped or gridded to divide the total water flowing to the design area.

Grid Systems. Many grid systems are currently being installed. The use of grid systems means that every sprinkler is fed from several directions, with a resulting reduction in pipe sizing. The hydraulic calculations required for a grid system are complex and almost impossible without the use of computers.

Water Supply Treatment

Microbiologically influenced corrosion (MIC) is now addressed in NFPA 13. In areas with water supplies known to have contributed to MIC, water supplies shall be tested and appropriately treated prior to filling or testing the metallic piping systems.

MIC is corrosion occurring on the interior of copper tubing and all types of steel piping that is accelerated by microorganisms. The overall effect is the formation of deposits or colonies and the pitting of metallic system piping in relatively short periods of time. Aside from the pinhole leaks that MIC creates, obstructions caused by tubercles can change the friction factor and the cross sectional area of the pipe.

Corrosion experts have known about MIC for decades, but the presence of MIC in fire protection systems is a relatively new phenomenon.

SUMMARY

Perhaps the most important item of an automatic fire sprinkler system is the water supply. The sprinkler system discharge criteria must be satisfied by the water supply in terms of adequacy and reliability. Adequacy refers to the pressure, rate of flow, du-

ration, and in general the amount of water present. Reliability is more subjective and dependent on the availability of the water from the source or combination of sources.

Many variables are involved in determining the water supply requirements for most sprinkler systems. System design, occupancy classifications, obstructions to discharge, and hose stream allowances are a few of the variables to be considered.

An adequate water supply is the crucial factor when a fire occurs in a fire sprinkler protected property. Sufficient water must be available to control or suppress the fire when sprinklers actuate.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on water supplies for sprinkler systems discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 1, *Uniform Fire Code*™
NFPA 13, *Standard for the Installation of Sprinkler Systems*
NFPA 13D, *Standard for the Installation of Sprinkler Systems in One- and Two-Family Dwellings and Manufactured Homes*
NFPA 13R, *Standard for the Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height*
NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection*
NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection*
NFPA 22, *Standard for Water Tanks for Private Fire Protection*
NFPA 291, *Recommended Practice for Fire Flow Testing and Marking of Hydrants*

Defining Corrosion
The Corrosion Problem
Defining MIC
Sources of MIC Infection
MIC Corrosion Process
Prevention and Treatment

Key Terms

automatic sprinkler system, corrosion (general), C-factor, Hazen-Williams formula, microbiologically influenced corrosion (MIC)

Beginning in the early 1990s, concerns began to increase about microbiologically influenced corrosion (MIC) affecting fire sprinkler systems due to multiple cases involving the abnormally rapid development of pinhole-sized leaks and highly obstructive interior biological pipe growths. Most of these occurred in systems well before the end of the system's life expectancy, after 5 to 20 years of service. However, some systems began to show signs of critical obstruction and began developing leaks in less than one year. Research into the cause of these leaks, which have greatly increased in the last two decades, has led to a growing awareness of the problem. In the past 20 years MIC has grown from a relatively unknown topic of regional discussions to one now generating widespread concern throughout several countries. MIC in fire protection systems also has become the subject of a wide array of speculation, debate, and, in some cases, gross inaccuracies.

At the time this chapter is being written, there are still few well documented time-proven solutions that are also universally accepted "best practices" throughout the fire protection industry. Although MIC and biological growth control have been extensively researched in many allied engineering fields for decades, treatment in fire sprinkler systems is relatively new. And although there are several detection and treatment systems that appear to be effective, long-term data to support overall effectiveness claims are still limited. This chapter will provide an overview of the issues related to microbiologically influenced corrosion in the fire protection industry.

For related topics, see the following chapters in Section 16: Chapter 1, "Principles of Automatic Sprinkler System Performance"; Chapter 2, "Automatic Sprinklers"; Chapter 3, "Automatic Sprinkler Systems"; and Chapter 11, "Care and Maintenance of Water-Based Extinguishing Systems."

DEFINING CORROSION

General Corrosion

Generating a universal "working definition" for MIC in fire protection is complex. And to understand the relationship of MIC and sprinkler components, general corrosion and its various causes must first be understood. One edition of *Webster's* defines corrosion as "the wearing away of materials by chemical action(s)." Another edition simply defines it as "the wearing away of material gradually." The online encyclopedia Encarta describes corrosion as "specifically being related to the gradual action of natural agents such as air or salt water on metals." All these definitions are generally true but are also very confusing to those in the fire protection industry who are looking for answers. Even definitions presented by the corrosion engineering communities, though more detailed, can at times appear somewhat contradictory and very confusing.

Bruce H. Clarke is eastern regional manager of field services and a fire protection/loss prevention trainer with Swiss Re Global Asset Protection Services.

Anthony M. Aguilera is director of loss prevention and risk management for Honeywell Aerospace.

Corrosion can occur from many biophysical reactions and be described from a multitude of scientific viewpoints. *General corrosion* typically refers to uniform corrosion that occurs on most unprotected metallic systems. This corrosion can be associated with the uniform rust layer seen on many steel structures. Besides rust from oxidation, several other types of general corrosion include stray current, uniform biological, galvanic, molten salt, dealloying, chemical, high temperature, and general carburization. And some specific nonbiological corrosion processes having adverse effects on fire protection sprinkler systems that must always be considered with MIC include oxygen, acid, and oxygen-acid corrosion.[1]

Microbiologically Influenced Corrosion

In contrast to general, or uniform, corrosion, MIC is a form of localized corrosion. Material is lost at discrete points instead of universally across an entire surface. There are several types of localized corrosion, including pitting, crevice, cratering, and filiform (Figure 15.5.1).

As with the various other types of corrosion, MIC can take many forms and affect different systems in unique ways. But, for the fire protection profession, an industry-specific definition can be developed. This definition captures both the causes and effects of this problem with several continuous generalities to avoid some of the current inaccuracies. Thus, microbiologically influenced corrosion in fire protection systems can be described as "an electrochemical corrosion process that is concentrated and accelerated by the activity of specific bacteria within a fire sprinkler system resulting in the premature failure of metallic system components."[2]

THE CORROSION PROBLEM

Concentrated and Accelerated Corrosion

All metallic systems normally begin to corrode to various degrees from the instant moisture contacts metal, which typically appears as general corrosion. By definition, in comparison, the MIC process is both concentrated and accelerated. With general corrosion, when moisture is introduced into a system, a thin layer of oxidation occurs relatively evenly throughout the pipe wall surface. This type of corrosion is typically not a significant concern in fire sprinkler systems and does not require treatment because it does not change a pipe's interior surface roughness (i.e., C-factor) unevenly. The rate of decay is also typically slow. A typical corrosion rate in sprinkler pipe is highly dependent on water quality, but with MIC, this relatively slow corrosion rate is abnormally accelerated and not evenly dispersed. The result changes a relatively smooth pipe to one with pits and valleys.

$$p = 4.52Q^{1.85}/(c^{1.85}d^{4.87})$$

where

p = Frictional resistance in psi/ft

Q = Flow in gpm

c = Frictional loss coefficient

d = Internal diameter of pipe

Although there has not been a detailed study on exactly what amount of pipe change (or changes in pipe wall roughness) are

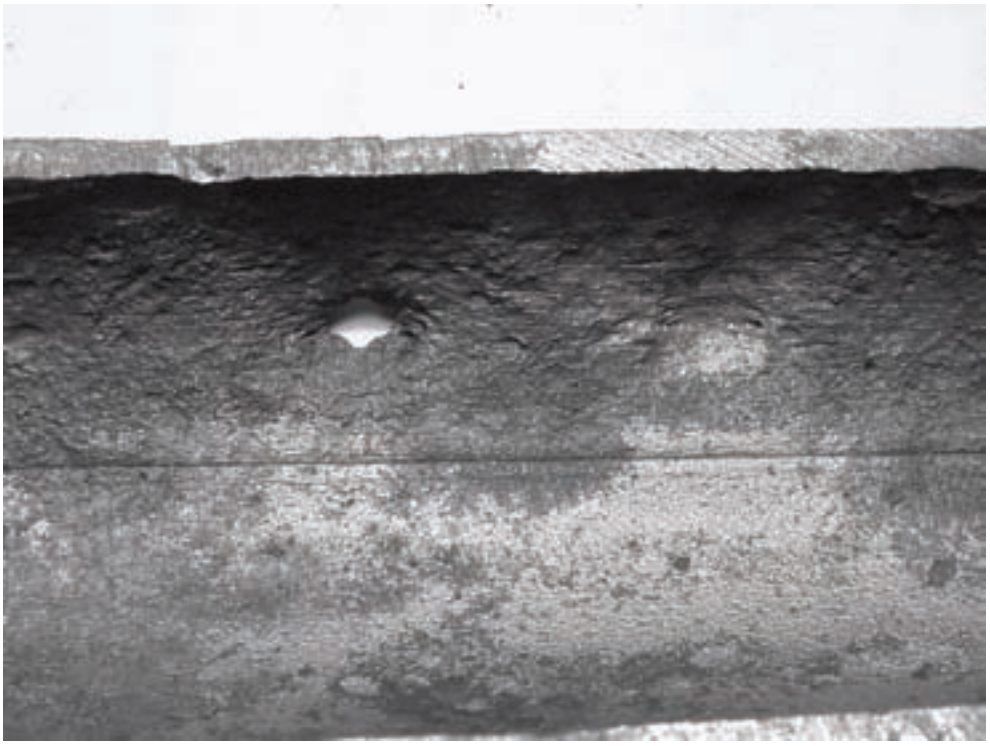

FIGURE 15.5.1 Interior Pinhole Leak

unacceptable, the Hazen-Williams formula makes several points clear:

1. Pipe surface texture is critical in sprinkler system effectiveness. With *c* based on pipe wall smoothness, any increase in roughness decreases the value of *c* and thereby increases the pressure loss in each linear foot of sprinkler pipe. Even a small amount of internal corrosion, especially in smaller main feed areas, could potentially make a system less effective in fire control.
2. Pipe diameter is a significant contributor to friction loss. Thus the smaller the pipe, the more dramatically corrosion affects friction loss and overall performance.

Although this formula is not intended to be used for nonuniform pipe surfaces, it is clear that random pockets of biological growth have the potential to affect performance. This result is especially likely if a sprinkler system has a minimum design buffer, which is regularly the case (Figure 15.5.2 and Figure 15.5.3).

MIC is the result of specific bacteria (see section on defining MIC). A multitude of bacteria is always omnipresent in all ecosystems, including the interior of sprinkler systems. Just as only a small number of bacteria on earth have the potential to cause human sickness, only a relatively small number of bacteria have the potential to cause the rapid system destruction currently linked to MIC. Thus, as defined, only a few specific bacteria concentrate and accelerate the general or uniform corrosion process.

Premature Failure

The ultimate effect of MIC in fire protection systems is the premature failure of metallic components.

Premature Failure Defined. It is clear that MIC and other related forms of corrosion cause sprinkler systems to fail prematurely. What constitutes "premature" with regard to the integrity of specific system components has not officially been defined in the industry. Long-term warranties are not typical with system components; however, with proper maintenance a sprinkler system is typically expected by the industry to last over 50 years before major repairs are required. In most cases of MIC, it has appeared that after treatment of the affected areas healthy systems can be expected to exceed this normal life expectancy.

However, as discussed, failure is a function of both integrity and function. And a system without leaks is never considered acceptable if it fails functionally (i.e., in fire control). Any time a system is in service and fails to operate as designed, it has experienced an unacceptable premature failure.

FIGURE 15.5.2 Exterior View of Pipe with No Signs of Internal Corrosion

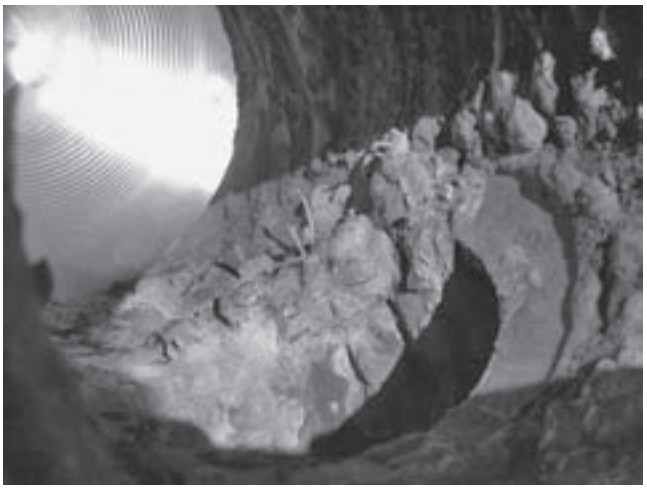

FIGURE 15.5.3 Interior View of Pipe Shown in Figure 15.5.2 with Approximately 65% Obstruction to 6 in. Tee Connection

Forms of Premature Failure. Premature failure can take two forms, both requiring individual consideration. First is the failure of a system to hold water, in other words, pinhole leaks that require component replacement (Figure 15.5.4). Leaks can cause significant damage and require immediate action. Leaks can also lead to excessive direct and indirect costs, as well as inherent risks from repeated system impairments.

In one known case, MIC-related leaks resulted in the shutdown of an aerospace manufacturer's global computing center.[3] A pinhole leak developed in a wet pipe sprinkler branch line located over the mainframe equipment of the computing center. Water from the leak not only damaged computing equipment but also resulted in over 5000 hours of lost operations time. Property damage from similar leaks at other sites has also been documented in the millions of dollars.[3,4]

The second and more concerning effect is the failure of a system to operate as designed to achieve fire control. This failure not only affects property loss but also could threaten lives. Several systems with MIC have been found with obstructed sprinkler drops, the result of debris generated as a by-product of microbial activity (called biofilm or biosludge). Many in the industry have found systems with feed mains over 60 percent obstructed from biological growth.[4,5] An analysis of corrosion

FIGURE 15.5.4 Exterior Pinhole

buildup indicates that thousands of pounds of debris can accumulate in medium-sized piping.[6] This buildup of debris presents an obvious hydraulic concern as many affected sprinkler systems today will not provide fire control as the required discharge criteria, in terms of flow and pressure, are not available due to obstruction and associated frictional pressure loss.

Extent of MIC in the Sprinkler Industry

Currently only a limited number of credible national studies on the extent of the MIC problem in the fire protection industry exist. Most data are primarily anecdotal. No detailed comparative engineering-based study on effectiveness of the various treatment options currently being marketed has been completed. Complicating this lack of data, reported MIC cases rarely have secondary analysis to differentiate MIC as a primary contributing cause over other types of corrosion involving similar symptoms. Equally important, follow-up engineering data on treatment are rarely published.

The results of MIC in other industries are well documented. The Energy and Power Research Institute has estimated that corrosion in the U.S. electric power industry costs $5 billion to $10 billion each year. Corrosion is said to be the culprit in half the forced outages each year in steam generating plants.[7] And data collected from before the 2001 U.S. power shortage showed corrosion to be the primary factor in more than 10 percent of U.S. power generation costs.[7] In the gas and nuclear industries, MIC is specifically said to account for 15 to 30 percent of corrosion-related failures.[8] And reports indicate that to prevent such problems, North American companies spend in excess of $1.5 billion per year (over $7 billion globally) on treatment chemicals to prevent microbial corrosion and fouling. Similar information, as mentioned, is not available for the fire protection industry. Although several industry groups have been attempting to compile data on this problem for several years, only two national studies have been published for the fire protection industry.[9,10] Thus, the true extent and cost of the problem are still not fully known.

In 1996, the National Fire Sprinkler Association sent out a questionnaire in its quarterly membership magazine requesting member information on sprinkler system failures that have been experienced. Results yielded approximately 40 responses from across the United States and Canada, which appeared to indicate that MIC was a "widespread problem." However, due to the reasons previously stated, the quality of analytical techniques used by respondents to confirm MIC as a cause and the lack of investigation after detection and treatment bring the results of this study into question.

The only other related studies and data compilations completed have been conducted by FM Global. In its studies, in losses involving sprinkler systems, corrosion is the fifth leading cause of system failures. This conclusion is based on a review of data from 1988 to 1997. In another study by the FM Metallurgical Laboratory between 1994 and 2000 reviewing 155 cases of sprinkler system leaks, MIC was found to be present in approximately 40 percent of cases. Details on whether the presence of MIC directly caused leaks were not indicated in all these cases.[10] In another FM study of piping field samples between 1991 and 2002, over 60 percent of these failures are attributed to MIC.[11]

Pinning the Blame

Part of the problem in obtaining detailed conclusive evidence is the complexity and cost of such investigations. This problem is also a major point of frustration with owners experiencing these types of problems. Due to the nature of electrochemical corrosion, most corrosion engineers agree that the degree to which

MIC specifically increases or contributes to general corrosion can never be conclusively determined. In fact, the complex biological interactions between bacteria and host materials are still not fully understood in many cases. There are simply too many variables and uncertainties that affect all corrosion reactions, especially those involving bacterial interactions. Thus, a percentage of blame or rate of corrosion from MIC likely cannot be numerically defined in any study. Any database generated at this point will likely list only reported cases, not confirmed cases. Thus, the best that can be achieved in the future is a regularly updated database indicating where reported cases are occurring, method of failure detection, interior condition of pipe, methods of testing, and treatment with future corrosion monitoring.

Materials Affected by MIC

Although steel sprinkler pipe is the typically observed first point of failure, sprinkler orifice caps, control valves, fittings, and supply tanks may also be subject to damage from MIC. Numerous cases of obstructive growth and pinhole leaks associated with MIC have been found within 20 feet of the discharge side of site fire pumps—an interesting phenomenon due to the velocity of waterflow at this point in the system piping. Although evidence suggests that only metallic components are susceptible to MIC, it is clear that some grades and alloys of steel are definitely more susceptible than others. As an example, certain grades of stainless steel are more susceptible than regular steel pipe, whereas others appear to show signs of resistivity. And although plastic components, such as underground water mains, are not subject to direct MIC, they are subject to the effects of biofouling or bacterial debris blockage from upstream corrosion activity.

DEFINING MIC

Oxygen Tolerance

MIC-related bacteria are classified primarily by oxygen tolerance; that is, they are aerobic or anaerobic. Aerobic bacteria require oxygen to flourish and reproduce. Anaerobic bacteria do not require oxygen to flourish and reproduce.[9] The most damaging MIC appears to take place within a highly complex community with multiple species of bacteria. This community includes not only aerobic and anaerobic bacteria but also facultative bacteria, those MIC bacteria that function in both aerobic and anaerobic environments. All three types of bacteria can play a role in the somewhat random interactions that can occur in microbiologically influenced corrosion.[12]

Metabolism

In defining MIC bacteria further, classification is not absolute and can become confusing. The most commonly used method of categorizing bacteria associated with MIC is by metabolism. These categories are basically definitions of what each bacteria type eats (or metabolizes) and excretes as a by-product. As these terms imply, where plants use photosynthesis (i.e., light) to develop energy, bacteria use chemosynthesis (i.e., eating/breathing various chemicals or minerals) to sustain life. Metabolic classifications are not universally replicated among scientists and can be somewhat confusing. A single bacteria type may fall under more than one metabolic definition. Some of the commonly referenced categories include sulfur-reducing bacteria, metal-reducing bacteria, acid-producing bacteria, iron-depositing bacteria, low-nutrient bacteria, iron-related bacteria, iron-reducing bacteria, iron-oxidizing bacteria, sulfate-oxidizing bacteria, slime-forming bacteria, and iron bacteria.[9,12–14]

Scientific Nomenclature

Finally, all bacteria (i.e., all plants and animals) can be classified by their scientific name under phylum, class, order, family, genus, and species. For example, one type of sulfate-reducing bacteria is anaerobic and metabolizes sulfate to sulfide. The sulfate-reducing bacteria group includes the genera *Desulfovibrio, Desulfobacter,* and *Desulformaculum.*[2] All are of the phylum Thiopneutes, which interestingly translates from Greek to "sulfur-breathers."

SOURCES OF MIC INFECTION

Although there are no conclusive relational studies in the fire protection industry, as noted there are growing beliefs that a sprinkler system's water supply is not the only (and possibly primary) source of bacterial infection. Bacteria capable of causing MIC are potentially present in soil, air, and cutting oils as well as water. Thus, the manufacture, shipping, storage, and flushing of system materials should be addressed in all MIC investigations. MIC does not occur only in water-filled systems. Dry pipe systems are also susceptible. Dry systems may even be more susceptible to damage than are wet systems, due to the humidified atmosphere that is created after trip testing. A trip test and subsequent drain can create the right atmospheric moisture content for some bacterial colonies to thrive. Complete drainage and the subsequent use of truly dried air or nitrogen gas appear to mitigate this problem. With regard to tubercle growth alone, dissolved oxygen content, not bacteria, may be the only considerable factor in prevention.

MIC CORROSION PROCESS

As with other forms of corrosion, MIC removes material through a series of electrochemical interactions. As such, both an electrical component and a chemical component occur with MIC. The electrical component occurs through electron transfer. Electron transfer removes pipe wall material one electron at a time. With MIC, this exact interaction is highly dependent on the specific bacteria involved. Within a sprinkler system, metallic parts become anodic in relation to the cathodic corrosion cell and surrounding water. Basic cathodic depolarization occurs as electrons are stripped away through various forms of oxidation and are pulled to an atom with another electrical potential. Although many of the complex cellular interactions of bacteria are still unclear and can vary by system, there appear to

be several somewhat universal steps in the MIC process. They are as follows:[2]

1. Bacteria enter the system, attach to metallic components, and begin to rapidly colonize and reproduce.
2. Aerobic colonies metabolize nutrients from the water and/or the metal surfaces they are attached to and, subsequently, excrete a polymer film by-product that bonds together to form crustaceous nodules called tubercles.
3. Tubercles and associated biofilms create microenvironments on the metallic material surface (under the tubercles). Tubercles are hard protective shells formed by biological activity. Tubercles typically have an open interior fluid cavity over the corrosion floor area with an approximate 3–4 pH (Figure 15.5.5).
4. The underdeposit area (i.e., under the tubercles) becomes oxygen depleted (i.e., anaerobic and anodic) in relation to the surrounding system's water or air, which remains aerobic and cathodic. Thus, electrons in the anodic metal flow to the cathode through a reduction reaction.
5. Underdeposit anaerobic bacteria metabolize pipe wall materials and excrete acids (such as acetic acid) as by-products, which are very aggressive to the carbon steels used in sprinkler piping. Relative acidity and alkalinity levels within the tubercle shells are reduced to an approximate pH of 2–4, which chemically attack the metallic component surface. On painted sprinkler piping, it is common to observe blisters where through-wall penetration has occurred. Testing of the fluid within these blisters has shown a pH of less than 3.

The described corrosion process can continue indefinitely until the aerobic and anaerobic bacteria in the system are killed. The tubercles created from bacterial colonization must also be broken down to destroy the underdeposit microenvironment. Even without bacteria in the underdeposit of a corrosion cell, the process can continue indefinitely, as the corrosion chain in its final phases is no longer reliant on their activity.

PREVENTION AND TREATMENT

References from Allied Fields

Currently, the fire protection industry has a very limited number of directly usable references supported by scientific data. However, there is excellent information on data from other industries. The National Association of Corrosion Engineers (NACE) has published multiple studies about MIC detection and treatment for many years. The American Society for Testing and Materials (ASTM) offers several publications on proper bacterial testing practices. Also the American Water Works Association (AWWA) offers standards describing the proper management of the somewhat hazardous chemicals typically used in injection devices attached to sprinkler systems for microbial control.

Fire Protection Codes and Standards

The National Fire Protection Association (NFPA) also addresses MIC. NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems,* discusses MIC treatment, inspection, and detection in some detail. NFPA 13,

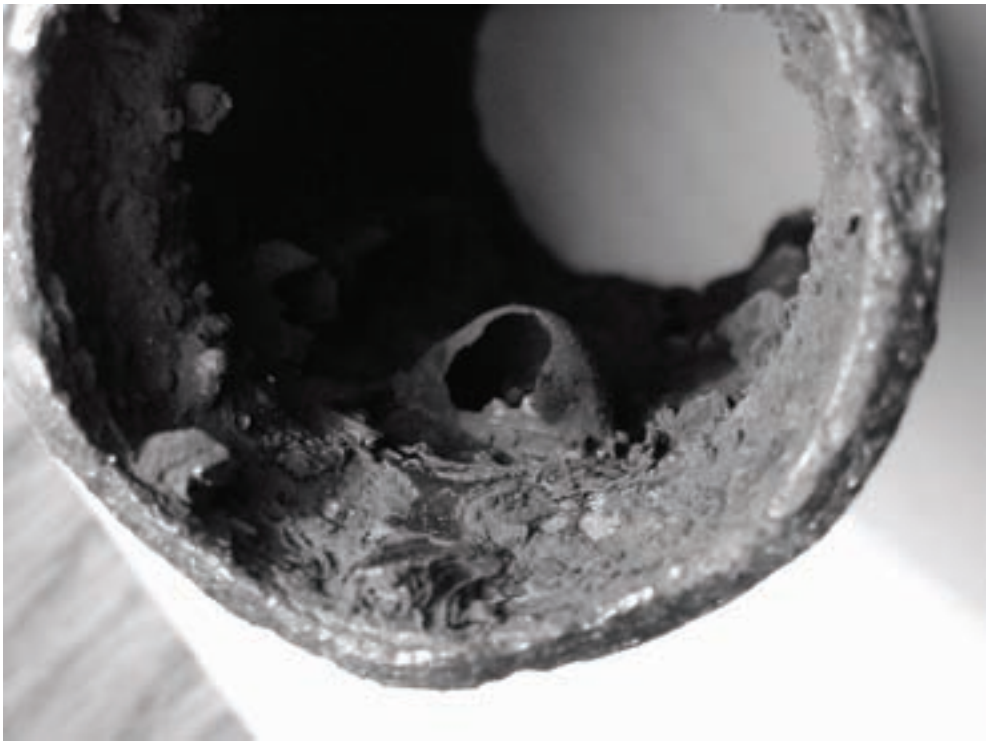

FIGURE 15.5.5 Interior Tubercle

Standard for the Installation of Sprinkler Systems, contains a requirement that provides more guidance. In covering water supply treatment, NFPA 13 states:

> Water supplies and environmental conditions shall be evaluated for the existence of microbes and conditions that contribute to microbiologically influenced corrosion (MIC). Where conditions are found that contribute to MIC, the owner(s) shall notify the sprinkler system installer and a plan shall be developed to treat the system. . . .

Although this requirement has generated curiosity, the resulting questions about effective treatment remain. NPFA 13 indicates that water supplies "shall be evaluated for the existence of microbes and conditions that contribute to microbiologically influenced corrosion (MIC)" . . . and if present or suspected . . . "a plan shall be developed to treat the system." The who, how, and when are still in debate by those addressing this issue. Who is best qualified to make the determination of when a failure is the result of MIC and if a biocidal treatment program will prevent all future failures? And how is a system best tested (i.e., with the most technical accuracy and cost-effectiveness) to confirm MIC? Almost anything requiring laboratory work can be overtested. And undertesting can lead to a false sense of security. Answers to these questions are still evolving.

Operational Considerations

As the industry continues to develop methods to treat and prevent MIC, building owners are faced with the challenge of managing associated risks to their assets and business operations. At-risk businesses should review the interdependence of various operations to identify critical locations.

Proper Diagnosis

The analysis required to properly select a course of action to address MIC is typically outside the scope of most sprinkler contractors and engineers. Thus, until treatment methods become universally proven and standardized, the most critical step in proper mitigation begins with the selection of a qualified corrosion control consultant.

With the wrong choice, a large amount of money can be spent on a problem that may not be correctable. A poor treatment choice could actually accelerate the corrosion rate and increase the affected area beyond that experienced before treatment. The company chosen to determine treatment must have detailed knowledge not only of microbial corrosion control but also of metallurgy and sprinkler system dynamics. Fire sprinkler systems have flow characteristics and concerns that are much different from other industrial processes and systems where MIC is typically addressed.

Specific Considerations for Fire Sprinkler Systems

Other industries deal with MIC in systems containing fluids that are either always static or always flowing, such as in cooling towers. Unlike sprinkler systems, dynamic systems have flow rates that are relatively constant, requiring that prescribed chemical dose rates be constant. A constant flow rate does not occur in sprinkler systems. Variable differences are seen with system drains and refills, inspector testing, and main drain tests. The dose rate for each of these flows must be considered to ensure that the chemical injection rate is always effective. Other industrial systems also have multiple points where biocidal chemicals can be injected. In contrast, sprinkler system water can realistically only be treated at system risers, backflow apparatus, or suction tanks.

Finally, it must again be stated that it is critical to understand that premature system failure can be a function of both bacterial infection and water quality that is incompatible with components. In the majority of premature system failure cases, water chemistry or poor design may be the only likely factors requiring consideration. A high bacterial count does not always indicate that MIC will occur, and conversely, a low bacterial count does not discount that MIC has occurred in the past, in a given system, and will not occur again in the near future.

Detection in Existing Systems

In existing systems suspected of being infected, the first step is to have all possible water supply sources (tank, city mains, ponds, rivers, etc.) and the interior of each system tested for bacterial levels and activity. Although current technology makes this detection easy, analysis of the results is somewhat complex. And, as previously stated, in determining treatment, bacterial detection is worthless without factoring in water quality. The laboratory used for analysis should be capable of giving conclusive details of water supply mineral and chemical levels, pipe wall deposit compositions, and type-specific bacterial counts. Multiple tests are used in these analyses from simple bacterial incubation with visual inspection to sulfur print or DNA testing. Obviously, not all tests are required or are necessarily needed. Current preferred analysis methods run the spectrum, depending on the consultant chosen. Costs for such testing can also vary widely.

Mitigation in Affected Systems

When MIC is confirmed in operational systems, the building owner is first faced with a fundamental question. Can the system be salvaged (i.e., cleaned) or does it have to be replaced? Currently, this cost/benefit decision requires further study and is not supported one way or the other by documented best practices in the fire protection industry.

Pipe cleaning is typically an option when corrosion (i.e., pitting) is not excessive. However, *excessive* is a relative term. The after-cleaning quality of the pipe must be considered, both for future longevity and system hydraulics. The resulting frictional loss from numerous pits after cleaning could affect system performance. This result, of course, is typically outside the scope of work of most corrosion control consultants. When replacement materials are chosen that are different than those of the original system, they must also be accounted for in hydraulic analysis of the posttreated system. Case studies suggest that

pipe cleaning may remove corrosion by-products that are, in effect, stopping the flow of water through existing pipe penetrations, subsequently resulting in leaks.[12] Prudence dictates that complete mitigation must include some form of treatment once pipes are cleaned.

Prevention in New Systems

In new systems, it is critical that susceptibility be determined before any systems are filled or tested with any water. If water tests are positive for MIC-related bacteria, a chemical injection system must be installed and used from the first fill. This includes hydrostatic testing and preliminary fills. The treatment methodology must also consider that water delivery of treatment chemicals might not effectively treat high spots, remote areas, or areas that trap air within the system.

If MIC is anticipated, one form of risk reduction may be to specify thicker piping in the design. Although this option only tends to buy time, it may serve as a prudent measure until universally accepted treatment methods are developed. Thicker walls buy time, not because they are less susceptible to MIC—a point on which evidence to date is inconclusive—but simply because a thicker wall has more material to corrode before a through-wall leak develops.

Another possibility in design is to remove the risk of leaks before MIC treatment is even evaluated. Areas such as those occupied by critical energized equipment can often be addressed by removing overhead sprinkler piping and limiting leak exposure through use of sidewall sprinkler coverage. Where it is not feasible to relocate large feed mains, piping can be sleeved so as not to permit potential leaks to contact energized equipment. Although these efforts provide some measure of immediate relief, they do not address the root cause or present a long-term solution to the problem.

Finally, the frequency of sprinkler and waterflow device testing must be addressed. Most agree that repeated draining and refilling of sprinkler systems can increase both biological and nonbiological forms of corrosion. Draining and refilling provide nutrients and oxygen to bacterial colonies and oxygen for general tuberculation. Some facilities have noted substantial reductions in the frequency of leaks by reducing the frequency of drain and alarm testing.

It is critical to note that once a system is filled with infected water, treatment can become exponentially more complex because any future treatment from a chemical injection system must now be effective in remote and stagnant system legs. In bacteria-positive areas, several additional water quality tests should be completed throughout the first year of service to ensure that contamination has not occurred from any other sources.

Chemical Injection

Once system components have been cleaned and sterilized or replaced, a chemical injection system must be installed to prevent recurrence. Once installed, this system will be required to be operational continuously. As with any other mechanical system, this system will require continuous preventive maintenance.

Several commercially available chemical injection systems have been specifically designed for installation on fire protection systems. Some simply use existing hardware and chemicals modified from MIC treatment in other utilities, such as cooling towers. At the time of this writing, none of the systems currently available were believed to be specifically listed or approved for use as a sprinkler system component. Although most systems appear to be effective when properly installed and maintained, reliability and effectiveness have not been time-proven when compared with other industrial system benchmarks. Past references should always be investigated with any choice.

Most injection systems currently available are designed to work with specific chemicals. These selected chemicals and dose rates are critical. Some bacteria can develop chemical resistance over time if doses are not strong enough and bacteria are not quickly killed. A small number of bacteria believed to be related to MIC (such as the genera *Bacillus* and *Clostridium*) are known to have the ability to convert to a spore state when they encounter adverse conditions that are not lethal.[2,15] Spores are impervious to penetration by most chemicals and can thus survive biocide treatments indefinitely. Although subsequent treatments may slow or stop their activity, spores will reappear if and when treatments are stopped and resume colonization. With a weak chemical attack, bacteria may also become resistant to the chemicals chosen.

As with other factors involved in treatment, the choice of chemical depends on the consultant. These chemicals generally include penetrants and biodispersants to break up the tubercles that protect underdeposit colonies, a biocide to kill the bacteria in the colonies, and a corrosion inhibitor to protect the interior surfaces of the system.

When such a system is chosen, the applicable authority having jurisdiction (AHJ) should be consulted. In addition to frictional loss concerns mentioned from changes in pipe surface roughness, increased backflow prevention hardware may be required. This could mean a pressure drop of 10 psi (0.7 bar) or more to sprinkler systems in addition to that created by pitting if cleaning is chosen. In new system designs, added alarm system contacts should also be planned to monitor injection system chemical levels, operational status, and trouble conditions such as loss of power. Many pre-engineered systems provide contact points for these signals. As with fire detection, the perceived "best choice" is at the discretion of the person choosing, and opinions on this subject are highly variable.

Unlike other industrial systems treated for MIC, several unique interactions must be considered. First, sprinkler systems are typically located directly over people. The chemicals used must therefore be nontoxic in contemplation of accidental discharge or exposure to fire fighters under fire conditions. The effect of chosen chemicals on fire fighting (i.e., heat absorption) and chemical reaction with fire (i.e., heat) also needs consideration. Second, system designs typically place water discharge (such as from an inspector's test ports) into foliage or biologically sensitive drains and dry wells. Most municipal wastewater treatment plants (to which typical drains ultimately flow) require bacterial activity to decompose waste. Too large a quantity of biocides in municipal drains could be a problem.

In conclusion, a complete toxicity review with the highest possible biocidal chemical concentration must be completed. As much as possible, these chemicals should be noncombustible, colorless, odorless, and nontoxic. These chemicals must also be nondeteriorating to rubbers and polymers such as those used on pipe couplings, sprinkler O-rings, and valves. Chemical storage should also be reviewed, as several chemicals currently in use degrade rapidly with heat and may create relatively toxic vapors.

Opinions of which chemicals are believed to be "most effective" in control vary. Choices are available from those currently used for treatment in cooling towers and boilers to specifically patented compounds for fire protection systems. Some of the more common chemicals currently in use specifically for microbial control in sprinkler systems include quaternary ammonium compounds, organosulfur compounds, bromines, carbamates, isothiazalone, phosphates, and chlorines. Sodium silicate is effectively used in bulk quantities by several municipalities as an inhibitor, but this use should be avoided for individual systems due to the potential for sprinkler plugging that overdosing can cause. At the writing of this article, no chemical can conclusively be said to be proven as the most effective. The chemical choice may greatly depend on the bacteria present and system water quality.

SUMMARY

Current testing and treatment options can be confusing. Treatment is slowly evolving and research is continuing. Several industry groups, allied groups, and insurance companies are looking at the problem and applicable solutions. Many universities, governments, and private industry groups also continue to research microbial control in general industry, as they have for the past several decades. These efforts will continue to provide improved treatment options in our industry.

As the need to address this problem draws on the industry's creativity for resolution, prudent thinking requires us to evaluate each solution's impact on overall sprinkler system integrity and performance. In light of this problem, the overwhelming value of sprinkler systems should not be regarded as tarnished or tainted. Although some with repeated MIC problems may view sprinklers as a risk to property, the reduction of risk to life and property from fire these systems provide should never be overshadowed.

affinity law, cavitation, discharge specific speed (N_d), fire pump (centrifugal), fire pump controller, fire pump (positive displacement), impeller, net positive suction head (available), net positive suction head (pump), total head (H), water hammer

This chapter covers the operating principles of stationary pumps used for fire protection, the methods of driving them, and the testing and maintenance procedures that should be followed to keep them in top operating condition.

Fire pumps are used to increase the water supply pressure available from public mains, gravity tanks, reservoirs, or other sources. The first modern fire pumps were the wheel-and-crank reciprocating-type, belt-driven pumps from mill machinery. If plant operations were stopped during a fire, the pump could not operate. At best, these pumps were inadequate.

Better water supplies became necessary as automatic sprinkler systems became more common, and mill pumps were replaced by rotary, or displacement, pumps driven by friction drive from horizontal waterwheels supplying power to the plant. As steam supplanted waterpower, the reciprocating steam pump was adopted for fire protection. For many years the Underwriter duplex, double-acting, direct-steam-driven unit was universally accepted as the "standard" fire pump.

Today, the stationary centrifugal and positive displacement fire pump is standard (Figures 15.6.1 and 15.6.2). Its compactness, reliability, easy maintenance and hydraulic characteristics, and the variety of available drivers—electric motors, steam turbines, and diesel engines—have made the Underwriter pump obsolete, although not entirely extinct.

Although the centrifugal fire pump is most widely used and is the basis for this chapter, the positive displacement fire pump is briefly defined and described.

The NFPA standard on fire pumps is NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection* (hereinafter referred to NFPA 20). Other NFPA documents that contain information on fire pumps include NFPA 11, *Standard for Low-, Medium-, and High-Expansion Foam;* NFPA 13, *Standard for the Installation of Sprinkler Systems;* NFPA 14, *Standard for the Installation of Standpipe and Hose Systems;* NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection;* NFPA 16, *Standard for the Installation of Foam-Water Sprinkler and Foam-Water Spray Systems;* NFPA 22, *Standard for Water Tanks for Private Fire Protection;* NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems* (hereinafter referred to as NFPA 25); and NFPA 750, *Standard on Water Mist Fire Protection Systems.*

For related topics, see Section 15, Chapter 7, "Fire Pump Controllers and Power Supply Arrangments for Motor-Driven Fire Pumps."

CENTRIFUGAL FIRE PUMP

An outstanding feature of a horizontal or vertical centrifugal pump is the relation of discharge to pressure at constant speed; that is, when the pressure head is increased, the discharge is reduced. With positive displacement pumps, the rated capacity can be maintained against any head if the power is adequate to operate the pump at the rated speed and if the pump, fittings, and piping can withstand the pressure.

Listed horizontal and vertical fire pumps are available with rated capacities from 25 to 5000 gpm (95 to 18 925 L/min). Pressure ratings range from 40 to 394 psi (276 to 2758 kPa) for horizontal pumps and 26 to 510 psi (517 to 3448 kPa) for vertical turbine pumps. Listed centrifugal fire pump designs include horizontal-end-suction, vertical in-line, split-case (horizontal and vertical shaft),

John D. Jensen, P.E., is president of JFP Engineering PC in Centerville, Utah. He is chair of NFPA's Technical Committee on the Installation of Stationary Pumps for Fire Protection.

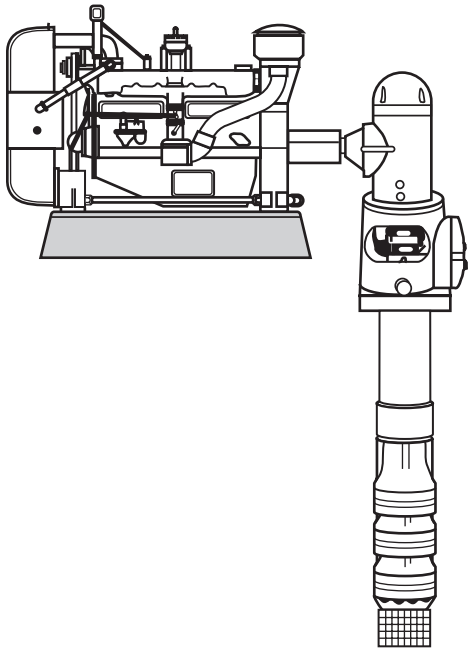

FIGURE 15.6.1 Vertical Turbine Fire Pump with a Right-Angle Gear and Engine Drive

and vertical-turbine types. Vertical turbine pumps are centrifugal pumps with one or more impellers discharging into one or more bowls and a vertical educator or column pipe that connects the bowls to the discharge head on which the pump driver may be mounted. It is anticipated that larger-capacity fire pumps will be listed in the future (Table 15.6.1).

The "size" of a horizontal centrifugal pump is generally the diameter of the discharge outlet. However, it is sometimes indicated by both suction and discharge pipe flange diameters. The size of a vertical turbine pump is the diameter of the pump bowl (see Figure 15.6.1).

POSITIVE DISPLACEMENT FIRE PUMP

Positive displacement fire pumps have been used in fire protection for many years. In fact, they were the first pump type to be used for mobile fire truck applications. Positive displacement pumps by nature are capable of high discharge pressures, something the fire service requires for many types of fire fighting.

Positive displacement, as defined by the Hydraulic Institute, essentially means that the same volume of liquid is displaced per revolution of the pumping element or rotor. Many different styles of positive displacement pumps exist; however, this short synopsis is not meant to define the wide variety of positive displacement pumps. Rather, it is intended to advise the fire protection professional that positive displacement pumps are vastly different from the more familiar centrifugal pumps.

Positive displacement pumps in general operate at lower revolutions per minute than centrifugal pumps do, can generate very high discharge pressures, and are capable of pumping a wide variety of fluids, both thin and thick.

Starting in the 1960s, gear pumps have been used to pump foam concentrate agents both on fire truck and fixed foam systems for stationary uses such as aircraft hangars, flammable liquid storage tank fire protection, and refinery process units.

Centrifugal pumps are not well suited to pumping foam concentrates because centrifugal pumps do not offer the necessary slower operating speeds, low foam agitation and shear, self-priming vapor locking, and other critical features that positive displacement pumps offer.

NFPA 20 recognizes that positive displacement pumps are suited for foam concentrate and the low-flow/high-pressure requirements of water mist systems. The 1999 edition of NFPA 20 was expanded to include an entire chapter on positive displacement pumps. Adding that chapter was necessary because of the increasing application of these types of pumps in the fire protection industry and their suitability for foam and water mist systems. The chapter has specific language that guides users and design engineers on selecting and applying a positive displacement pump for both foam and water service.

A key part of this chapter in NFPA 20 is the requirement for the positive displacement pump to be listed or approved for the intended service, meaning that the positive displacement pump must have a third-party listing and verification of performance standards whether the pump is used for foam or water service.

PRINCIPLES OF OPERATION

The two major components of a centrifugal pump are a disc, called the impeller, and the casing in which it rotates (Figure 15.6.3). It operates by converting kinetic energy to velocity and pressure energy. Power from the driver, which is an electric motor, a diesel engine, or a steam turbine, is transmitted to the pump through the shaft, rotating the impeller at high speed. The way that energy is converted varies with the type of pump. The major classes are known as radial flow and mixed flow. These pumps are identified by the direction of flow through the impeller, with reference to the axis of rotation (Figure 15.6.4).

The horizontal-shaft, single-stage, double-suction volute pump is the type most commonly applied to fire protection service and to commercial use (Figure 15.6.5). In these pumps, waterflow from the suction inlet in the casing divides and enters the impeller from each side through an opening called the "eye." Rotation of the impeller drives the water by centrifugal force from the eye to the rim and through the casing volute to the pump discharge outlet. The kinetic energy acquired by the water in its passage through the impeller is converted to pressure energy by gradual reduction of velocity in the volute.

Multistage Pumps

In order to give high pressure, two or more impellers and casings can be assembled on one shaft as a single unit, forming a multistage pump (see Figure 15.6.2). The discharge from the first stage enters the suction of the second stage, discharge from the second stage enters the suction of the third, and so on. The pump capacity is the rating in gal per min (L/min) of one stage; the pressure rating is the sum of the pressure ratings of the individual stages, minus a small head loss.

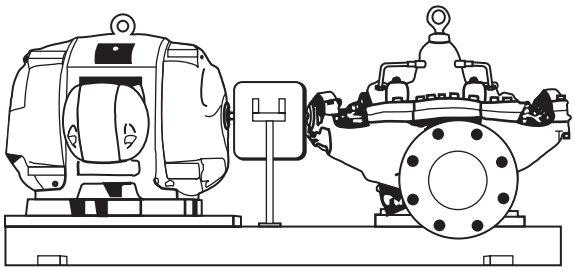

FIGURE 15.6.5 Horizontal Shaft, Single-Stage Centrifugal Pump, with Cutaway View of the Pump

High-Pressure Service Pumps

Single-stage pumps can be designed for high-pressure service by increasing the impeller diameter or the rated speed. In addition, single-stage pumps can also be installed in series to achieve the necessary pressure. In some high-rise buildings, vertical turbine pumps are installed in a subbasement and take suction from a sump pit. As shown in Table 15.6.1, these pumps are capable of developing pressures in excess of 500 psi (3448 kPa).

CHARACTERISTIC PUMP CURVES

The characteristic curves (Figure 15.6.6) of a horizontal-, centrifugal-, or vertical-turbine-type pump are as follows:

1. Total head versus discharge (ft of head or psi of pressure versus gpm)
2. Brake horsepower versus discharge
3. Efficiency versus discharge (water hp/input hp versus gpm)

Illustrated curves in Figure 15.6.6 are for a 500-gpm, 100-psi, 2000-rpm, diesel-engine-drive pump with a 14 in. impeller. Note that the shutoff point (churn pressure) is 110 psi; the maximum brake horsepower is 55; and the maximum efficiency is 75 percent at the overload point (150 percent of rated capacity). Head is 90 psi at the 65 percent minimum required at overload.

These curves assume that the pump is operated at a constant speed equal to its rated rpm (revolutions per minute). In

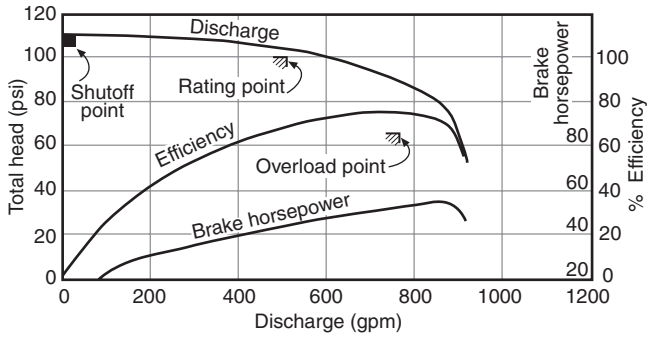

FIGURE 15.6.6 Typical Centrifugal Fire Pump Characteristic Curves

actual service, the speed of the driver varies with changes in the flow capacity.

Curves for positive displacement–type pumps are shown in Figure 15.6.7.

The flow and pressure ratings of commercial pumps are usually established on the basis of maximum efficiency and desired speed. Impellers can be designed for flat, medium, or steep head-discharge characteristics, as required for various uses. Figure 15.6.8 illustrates how the head-discharge curve is affected by the diameter of the eye, the width of the impeller, the number of vanes, and the shape or angle of the vanes.

TOTAL HEAD

The total head of a pump is the energy imparted to the liquid as it passes through the pump. It may be expressed in various units of pressure, but for fire protection it is generally given in pounds per square inch (psi) or kilopascals (kPa), or in feet (ft) or meters (m) of liquid measured vertically. The total head is calculated by subtracting the energy in the incoming liquid from the energy in the discharging liquid. The total head (H) of a pump is calculated by the formula

$$H = h_d + h_{Vd} - h_s - h_{Vs}$$

where

H = Total head (ft [m])

h_d = Discharge head (ft [m])

$h_{Vd} = \frac{Vd^2}{2g}$ = discharge velocity head (ft [m])

h_s = Total suction head (ft [m])

$h_{Vs} = \frac{Vv^2}{2g}$ = suction velocity head (ft [m])

V = Average velocity (ft/sec [m/sec])

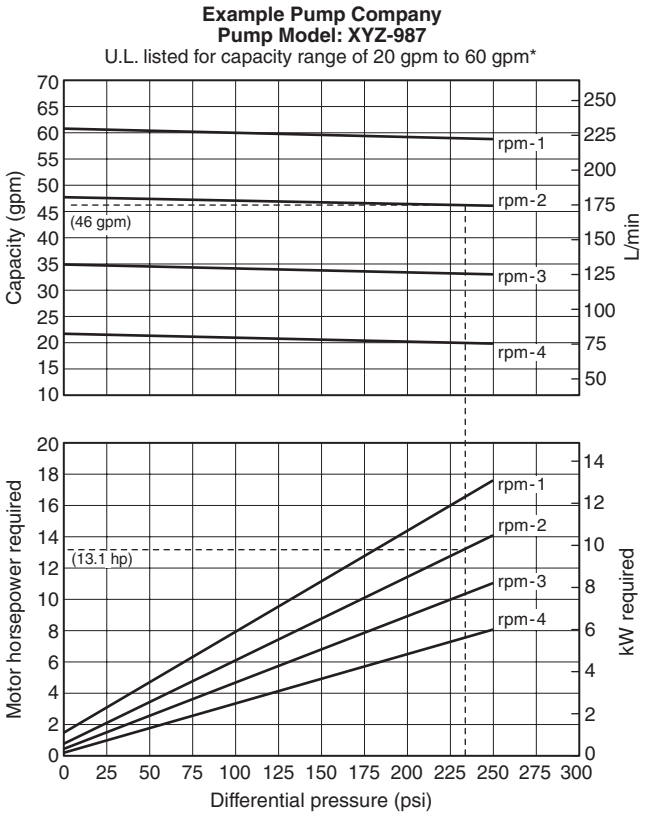
g = Acceleration due to gravity (32.2 ft/sec^2 [9.81 m/sec^2])

For a horizontal split-case pump, the individual heads (h_V) are measured at the pump discharge nozzle flange and at the suction flange (Figure 15.6.9). The heads are read from pressure gauges attached to the pump flanges. The velocity head must be calculated for the volume of liquid passing through the flanges. One expression of this relationship is

$$h_v = \frac{V^2}{2g}$$

If the flanges have the same diameters, there will be no difference between the incoming and outgoing velocity, and the calculation can be omitted.

For a vertical turbine pump, the discharge head is theoretically read at the discharge flange of the pump. Since this flange usually is inaccessible for gauge readings, a gauge is used at the discharge fitting at the top of the pump column pipe (Figure 15.6.10). The discharge pressure at the pump discharge flange therefore equals the pressure at the gauge above, plus the pressure effect of the vertical distance between



*Conforms to requirements of Chapter 8 of NFPA 20 on positive displacement foam concentrate and additive pumps.

FIGURE 15.6.7 Typical Positive Displacement Pump Characteristics Curve

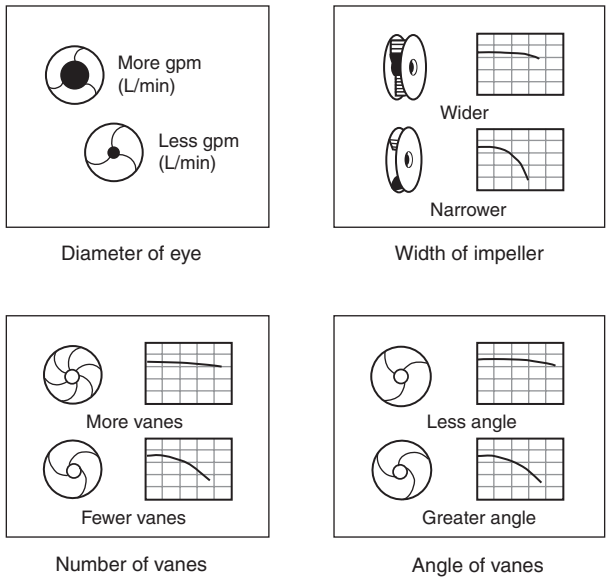


FIGURE 15.6.8 Effect of Impeller Design on Head-Discharge Curves for Fire Pumps

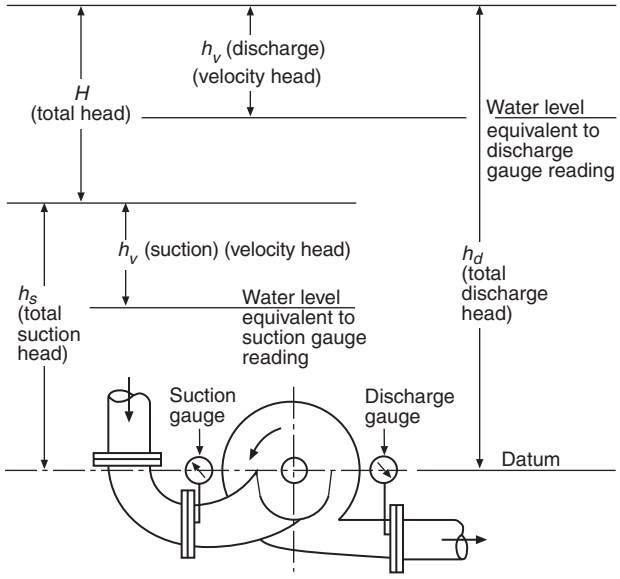

Installation with suction head above atmospheric pressure shown.

FIGURE 15.6.9 Typical Head of Horizontal Shaft Centrifugal Fire Pumps

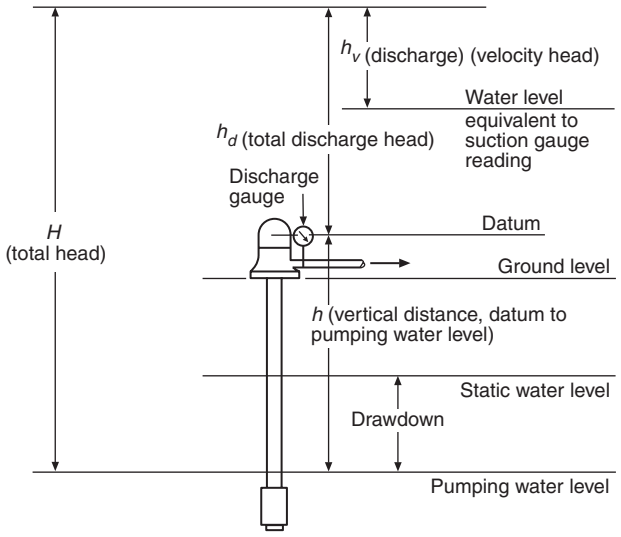

FIGURE 15.6.10 Total Head of Vertical-Turbine-Type Fire Pumps

the two points, plus the friction loss between the two points. In most cases, the friction loss is so small that it may be disregarded.

The suction head is the vertical distance from water level to the pump discharge flange. The velocity head of the incoming liquid is assumed to be zero. Hence, the formula would now take the following form:

$$H = h_d + h_{Vd} - h_s = (h_{gd} + L) + h_{Vd} - h_s$$

where

h_{gd} = Discharge gauge reading (ft [m])

L = Gauge pump flange (ft [m])

h_s = Water level when pumping to pump flange [ft (m)]

However, $L - h_s = h$, the vertical distance between the discharge gauge and water level. Therefore the formula becomes

$$H = h_{gd} + h_{Vd} + h$$

Hydraulic and power losses within the pump due to turbulence, disc friction, and shock are represented by the efficiency rating.

Total head at rated capacity is used to establish the rated head of a pump. Actually, the rated head is the amount of energy given to the water.

The total head of a vertical-turbine-type pump may also be defined as the vertical water-to-water dimension of the system in which the pump operates. However, there is a difference in the method of measuring total head. As shown in Figure 15.6.10, it is the sum of the vertical distance between water level in the well or pit, the discharge head indicated by the gauge on the pump outlet, and the velocity head at the gauge connection.

DISCHARGE SPECIFIC SPEED (N_d)

Discharge specific speed is a number relating the head, capacity, and speed of a centrifugal pump for design purposes. Actually, discharge specific speed is the revolutions per minute (rpm) of a geometrically similar impeller that will discharge 1 gpm (3.8 L/min) at 1 ft (0.3 m) total head. The formula for calculating discharge specific speed of a centrifugal pump is

$$N_d = \frac{\text{rpm} \times \text{gpm}^{1/2}}{H^{3/4}}$$

where

N_d = Specific speed number

H = Head (ft [m])

When values of head, speed, and capacity in the formula correspond to pump performance at optimum efficiency, the specific speed may be used as one measure of pump performance. Impellers designed for high heads usually have low specific speeds, and impellers designed for low heads have high specific speeds.

A pump of low specific speed will operate satisfactorily with greater suction lift than a pump of the same head and capacity with a higher specific speed. Experience shows that specific speed is a useful guide for determining maximum suction lift or minimum suction head.

Fire pumps are not allowed to take suction under lift. However, some existing installations may be encountered when a centrifugal pump is subject to lift conditions exceeding 15 ft (4.5 m), and it may be necessary to provide a larger pump at less speed. With low lift or positive head on the suction, a smaller pump operating at greater speed may be used. Abnormally high

suction lifts may seriously reduce pump capacity and efficiency or cause excessive vibration and cavitation.

NET POSITIVE SUCTION HEAD

Net positive suction head (NPSH) is the pressure head that causes liquid to flow through the suction pipe and fittings into the eye of a pump impeller. The pump itself has no ability to "lift," and the suction pressure depends on the nature of the supply.

Although not permitted, a horizontal pump being supplied from a pond, stream, open well, or uncovered reservoir, where the water level is below the pump, would have a suction head equal to atmospheric pressure minus the lift. If the water level is above the pump, as from a water main or aboveground tank, the suction head is atmospheric pressure plus static pressure.

Pressure readings at the inlet flange of a pump operating under lift are negative with respect to the gauge but positive when referred to absolute pressure—hence, the expression "net positive suction head." Absolute pressure is gauge pressure plus barometric pressure.

There are two kinds of NPSH to consider. Pump NPSH is a function of the pump design and varies with the capacity and speed of any one pump and with the designs of different pumps. Available NPSH is a function of the system in which the pump operates and can be calculated readily. Curves of NPSH versus gallons per minute usually can be obtained from pump manufacturers.

Figure 15.6.11 shows an NPSH curve for a typical fire pump. Note that the required NPSH is 10 ft at 2000 gpm and 18 ft at 3000 gpm. The shutoff point equals the churn pressure at zero flow; the overload point equals 150 percent of rated flow at 65 percent of the rated pressure.

When the water source is above the pump, available NPSH = atmospheric pressure (ft or m) + static head on suction (ft or m) – friction and fitting losses in suction piping (ft or m) – vapor pressure of liquid (ft or m). Note that the vapor pressure of water at 90°F (32°C) is 1.6 ft (0.48 m).

For any pump installation, the available system NPSH must be equal to or greater than the pump NPSH at the desired operating conditions.

CAVITATION

Cavitation is a complex phenomenon that can take place in pumps or other hydraulic equipment. As water flows through the suction pipe of a centrifugal pump and enters the eye of the impeller, the velocity increases and pressure decreases. If the pressure falls below the vapor pressure corresponding to the temperature of the water, pockets of vapor will form. When the vapor pockets in the flowing water reach a region of higher pressure, they collapse with a hammer effect, causing noise and vibration. Tests have shown that the extremely high instantaneous pressures that may be developed in this manner may pit various parts of the pump casing and impeller. Conditions may be mild or severe, and mild cavitation may occur without much noise. Severe cavitation can cause reduced efficiency and, ultimately, failure of the pump if it is not corrected.

PUMP AFFINITY LAWS

The mathematical relationships among head, capacity, brake horsepower, and impeller diameter are called the pump affinity laws. Law 1 assumes constant impeller diameter with change of speed. Law 2 assumes constant speed with change in diameter of the impeller. These laws are expressed by proportion, as follows:

Law 1

$$\frac{Q_1}{Q_2} = \frac{N_1}{N_2}, \quad \frac{H_1}{H_2} = \frac{N_1^2}{N_2^2}, \quad \frac{\text{bhp}_1}{\text{bhp}_2} = \frac{N_1^3}{N_2^3}$$

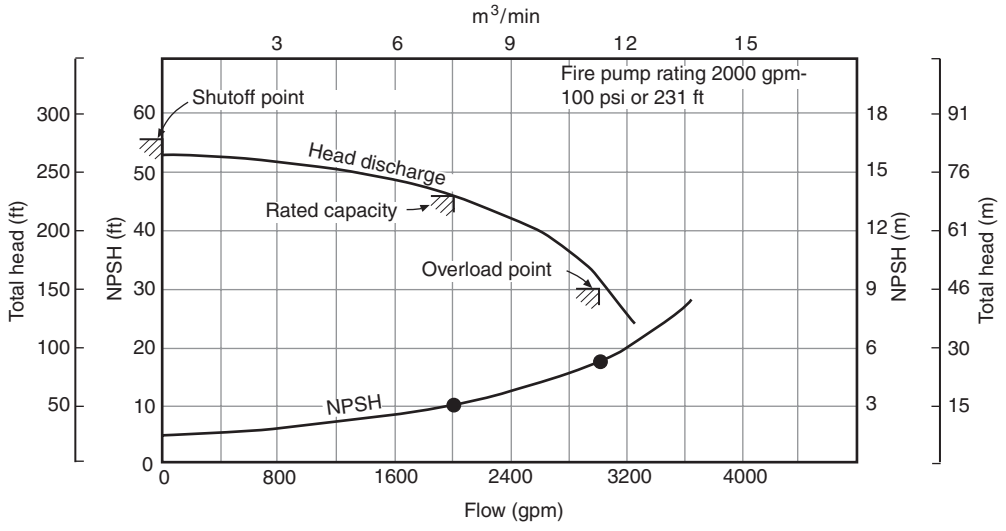

FIGURE 15.6.11 NPSH Curve of a Typical Fire Pump

Law 2

$$\frac{Q_1}{Q_2} = \frac{D_1}{D_2}, \quad \frac{H_1}{H_2} = \frac{D_1^2}{D_2^2}, \quad \frac{\text{bhp}_1}{\text{bhp}_2} = \frac{D_1^3}{D_2^3}$$

The nomenclature for the relationship is

Q = Capacity

H = Head, N = Speed

D = Impeller diameter

bhp = Brake horsepower

Thus,

Q_1 = gpm (L/min) at N_1 or D_1

Q_2 = gpm (L/min) at N_2 or D_2

H_1 = Head in ft (m) at N_1 or D_1

H_2 = Head in ft (m) at N_2 or D_2

bhp_1 = Brake horsepower (kW) at N_1 or D_1

bhp_2 = Brake horsepower (kW) at N_2 or D_2

Law 1 applies to common types of pumps, including horizontal centrifugal pumps and vertical turbine pumps. Law 2 applies to centrifugal pumps with reasonably close agreement between calculated and tested performance. Generally, pumps with low specific speeds show closer agreement than do pumps with high specific speeds.

The pump affinity laws should be applied when proposed changes in a fire pump installation would increase the speed or significantly raise the pressure of the suction supply. Greater speed would increase the power demand, and high discharge pressure might be undesirable. In some instances, it is possible to trim the impeller. This should not be done without the approval of the pump manufacturer. Likewise, when a variable pump driver is used, the pump affinity laws will apply when the rotational speed of the pump is changed to control the output head in feet (m) available.

STANDARD HEAD DISCHARGE CURVES

The shape of the standard head discharge curve of a fire pump is determined by three limiting points: the shutoff, the rating, and the overload.

Shutoff

With the pump operating at rated speed and no flow, the total head of a horizontal centrifugal pump, vertical turbine pump, or an end-suction pump at shutoff must be between 100 and 140 percent of the rated head pressure at the 100 percent flow capacity.

The shutoff point represents the maximum allowable total head pressure. Otherwise, the pump would have a rising or convex characteristic curve. Such pumps are not listed. With a convex curve, there could be two flow points for one pressure.

Rating

The curve should pass through or above the point of rated capacity and head (Figure 15.6.12).

Overload

At 150 percent of rated flow capacity, the total head pressure should not be less than 65 percent of the rated total head. The curve should pass through or above the overload point. Most fire pumps have curves with a small margin above the theoretical overload, and some models have a cavitation or "break" point in the curve just beyond overload.

HORIZONTAL-SHAFT CENTRIFUGAL FIRE PUMPS

Horizontal-shaft centrifugal fire pumps are required to be installed to operate under positive suction head. If the water supply is such that suction lift cannot be avoided, vertical turbine fire pumps should be installed. NFPA 20 does not allow the use of horizontal-centrifugal fire pumps taking suction under lift for new installations.

Types of Pump

Horizontal centrifugal fire pumps are of the split-case, vertical in-line, or end-suction type (Figures 15.6.5 and 15.6.13). The end-suction type is manufactured to ANSI specifications[1] for centrifugal pumps. In general, there are no limits on the capacities of split-case fire pumps, but the maximum rated capacity of any listed fire pump is currently 5000 gpm (18 925 L/min).

Suction Supplies from Public Mains

When streams, ponds, and other open bodies of water are used, properly screened intakes should be provided to prevent fish,

eels, and foreign material from entering the pump and the fire protection system. Some older pumps may have a foot valve such as the one shown in Figure 15.6.14. However, pumps taking suction under lift are not allowed for new installations as per NFPA 20.

Use of nonpotable water should be avoided when fire pumps discharge into a system that is also connected to public mains or to other potable supplies. Otherwise, there will be cross connections, which are restricted in some locations by federal clean water act regulations or health or water utility authorities. In those cases where cross connections cannot be avoided, listed or approved backflow prevention devices acceptable to health and water authorities are required to prevent contamination of potable water supplies. Such devices should be installed on the discharge side of the pump. Where a backflow preventer is required to be installed in the suction piping, it must be at least

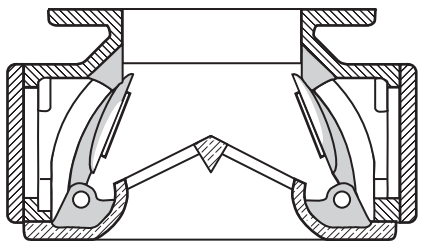

FIGURE 15.6.14 A Typical Foot Valve of Good Design Shown in the Open Position

10 pipe diameters from the suction flange of the fire pump. It is preferred, however, to locate the backflow preventer at least 50 ft (16 m) from the pump suction flange. When a diesel engine pump driver is used and the source of cooling water is connected to the pump discharge, a reduced pressure backflow preventor is required to be installed in the cooling water piping as shown in the annex to NFPA 20.

Suction Water Storage Tanks

The volume of suction storage should be sufficient to supply the pump or pumps at 150 percent of the pump's rated capacity for the required duration of the water demand. This is normally 1 to 4 hours. Aboveground, underground, or fire well tanks filled with potable water are recommended for supplying fire pumps.

Break Tanks

At locations where a direct connection between a public water supply and a private fire protection system is prohibited, either for public health or hydraulic reasons, a break tank installation may be desirable. A break tank is an automatically filled tank that provides a suction supply for a fire pump without a direct connection to a public supply (Figure 15.6.15). This is done by an actual physical break or gap between the public supply and a private protection system. Water from the public supply enters the break tank from a height above the tank's overflow outlet and falls freely to the surface of the water in the tank. A fire pump is needed to take suction from the tank, as the water is no longer under pressure from the public supply. The fire pump may be a vertical turbine, horizontal, or positive displacement type.

A separate tank may be provided for each fire pump in an installation. The flow into the tank from the public supply is controlled by an automatic fill mechanism, and since the water in the tank is considered potable, the top of the tank should be closed.

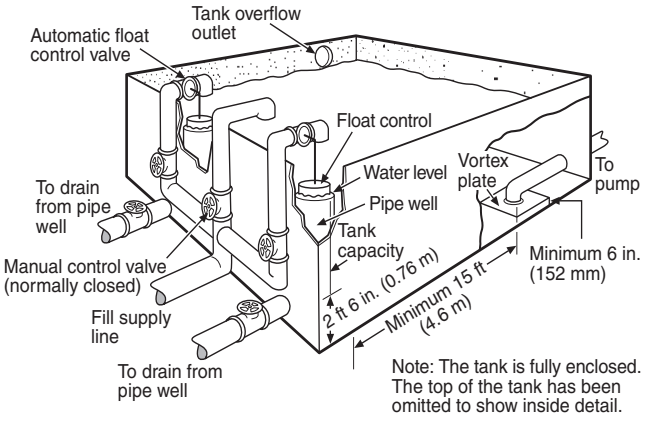

FIGURE 15.6.15 A Break Tank Used in Connection with a Fire Pump When a Direct Connection Between a Public Water Supply and a Private Fire Protection System Is Prohibited

Break tanks are less reliable than good, full-sized suction tanks, as the automatic fill mechanisms could fail. There is no NFPA standard for the design and installation of break tanks, but to the extent possible, the requirements of NFPA 22 and NFPA 20 should be used.

Booster Pumps

These are fire pumps taking suction from public water mains or industrial water systems. (In a mechanical sense, all pumps are booster pumps.) As a prelude to purchasing and installation, the available fire waterflow is obtained by conducting flow tests. The pump is sized by first conducting a flow test of the water supply and plotting the test on a water-supply graph having pressure versus volume (gpm), semi-log $N^{1.85}$ paper (SI units: 1 gpm = 3.785 L/min). The required water demand is then plotted to determine what pressure is required. The manufacturer's characteristic curves are researched to find one that adds the required pressure at a volume range of 90 percent of rated capacity to 130 percent of the rated pump capacity. The pump should be sized so that, when pumping is at 150 percent of rated (overload) capacity, the pump does not lower the water supply pressure to a gauge pressure less than 10 psi (69 kPa), or a safe point that may be determined by the local health authorities. Full overload capacity of the pump, plus the probable flow drawn from area hydrants by the fire department, are calculated, and they should not drop the gauge pressure in the water mains below 10 psi (69 kPa) or that allowed by the public health authorities. Head rating of the pump should be sufficient to meet all pipe friction in the connection plus pressure demand.

Pump Accessories

Auxiliary devices have an important bearing on the complete functioning of a pump as a fire protection water supply, and their provision or omission should never be decided solely on the basis of cost. NFPA 20 gives detailed information concerning their installation. The following items are worthy of special consideration.

Relief Valves. These are required on the pump discharge line when the operation of the pump can result in excess pressure that would exceed the pressure rating of the fire protection system. The design of this device is very critical to the proper operation of the fire protection water supply. If the pump is oversized for flow and pressure, the main relief valve should not be used to limit the pressure and discharge excess quantities of water during the normal weekly run test and annual flow test. This is of particular importance in climates where there is freezing weather for a portion of the year. In these situations the designer should look further at other pump choices and optional drivers for the pump that will limit the discharge head. A good example is a variable-speed diesel engine or electric motor listed system.

Hose Valves. Approved 2½-in. (64-mm) hose valves can be used in testing pumps and for hose stream(s) fire protection. The valves are attached to a header or manifold outside the pump room, or otherwise located to avoid water damage to the pump,

driver, and controller. The number of valves needed depends on the pump capacity. The number of 2½ in. (64 mm) outlets provided is based on a 250 gpm (946 L/min) flow per outlet. Design consideration should be made to use a fixed, listed flowmeter with water discharging back to the water source to conserve water and improve the accuracy of flow test results. When the water supply is tested, the hose valves, fire hose, and nozzles should be used for the test.

Automatic Air Release Valves. These are installed on the top of the pump casing(s) and arranged for automatic or remote-control operation. The purpose is to release trapped air in the casing and to minimize pump cavitation. An automatic air release is desirable on any pump with a casing that is normally full of water.

Circulation Relief Valves. These are installed on pumps that start automatically or by remote control. Their function is to open at slightly above rated pressure, when there is little or no discharge, so that sufficient water is discharged to prevent the water in the pump from overheating. These valves are not required on diesel-engine-driven pumps where cooling water is taken from the pump discharge.

Vertical Turbine Fire Pumps

Vertical turbine pumps were originally designed to pump water from wells. As fire pumps, they are recommended in instances where a fire well is used as the water source or the horizontal pumps would operate with suction lift. An outstanding feature of vertical pumps is their ability to operate without priming. Vertical pumps may be used to pump from streams, ponds, wet pits, wells, underground water storage tanks, cisterns, and break tanks.

Suction from wells is acceptable if the adequacy and reliability of the well has been established and the entire installation is built in conformance with NFPA 20. There is no maximum pump depth. The water level in the well is required to cover the pumping bowls to a depth required by the pump manufacturer's recommendations. If the yield from a well is too small to supply a fire pump, low-capacity, commercial well pumps can be used to fill conventional ground-level tanks or reservoirs for the fire pump supply.

A vertical fire pump assembly consists of a discharge head or right-angle gear drive, a pump column pipe and discharge fitting, an open or enclosed drive shaft, a bowl assembly containing the impellers, and a suction strainer (Figures 15.6.16 and 15.6.17). The principle of operation is comparable to that of a multistage horizontal centrifugal pump. Except for shutoff pressure, the characteristic curve is the same as it is for horizontal pumps (see Figure 15.6.12).

Vertical Turbine Barrel or Can Pump

Sometimes vertical-type multistage pumps are installed in a casing called a "barrel" or "can" for high-pressure installations (Figure 15.6.18).

Vertical pumps have the same standard capacity ratings that horizontal fire pumps have. Pressure ratings are standardized and vary by the number of bowls and diameter of the bowls.

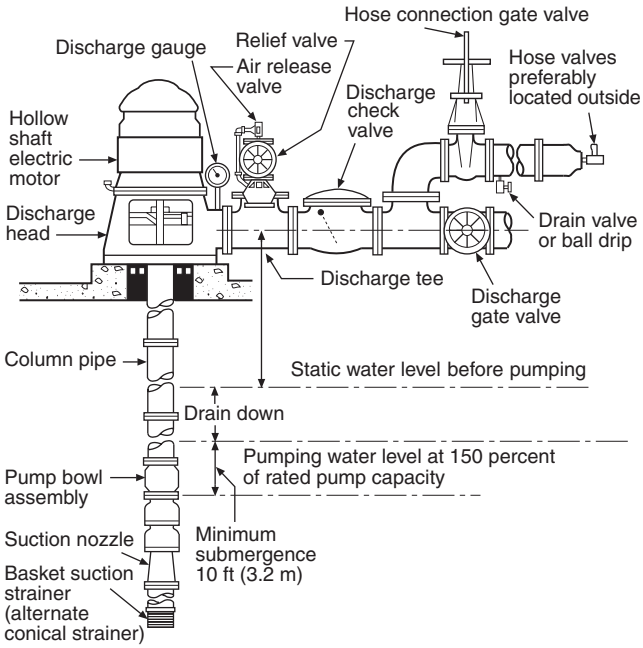

FIGURE 15.6.16 Vertical-Shaft-Turbine-Type Pump Installation in a Pit. Note: The distance between the bottom of the strainer and the bottom of the wet pit should be one-half of the pump bowl diameter but less than 12 in. (305 mm).

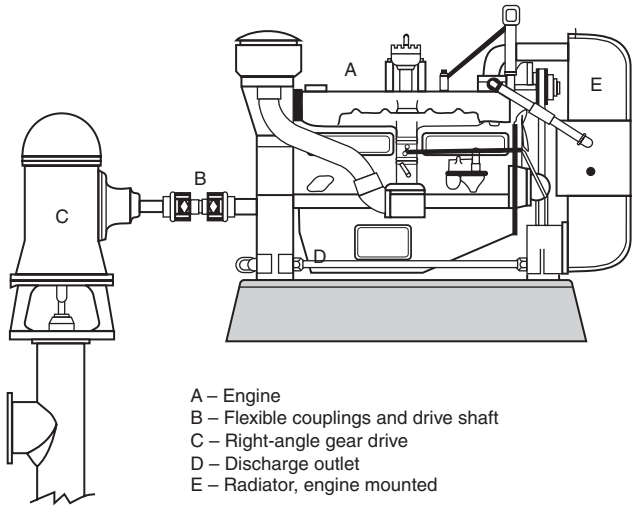

FIGURE 15.6.17 Engine-Driven Vertical Fire Pump

By changing the number of stages, or the impeller diameters, or both, the pump manufacturer can provide a specific total head at rated speed. Pressures are available up to 520 psi (3585 kPa). Vertical or horizontal mounted electric motors can be used, as well as hollow shaft motors. Diesel engines (mounted vertically or horizontally) or steam turbines can be used by means of right-angle gear heads.

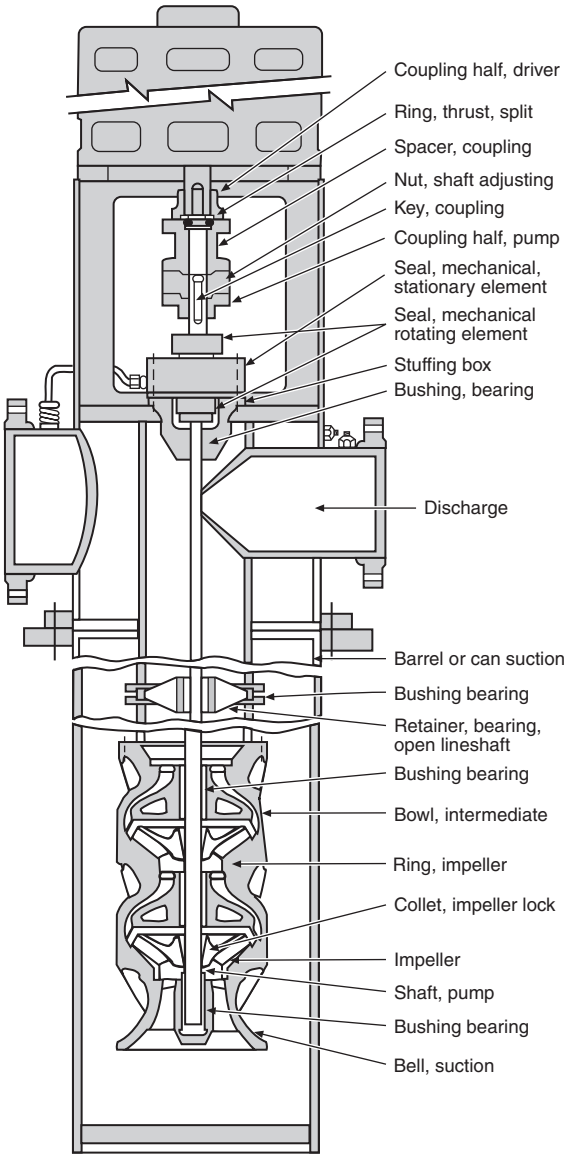

FIGURE 15.6.18 A Turbine-Type, Vertical, Multistage, Barrel or Can Pump

FIRE PUMP CAPACITY AND HEAD RATING

The capacity and pressure ratings of fire pumps must be adequate to meet flow and pressure demands consistent with water supply requirements for the property in question. Fire pumps are designed to provide their rated capacity with a safety factor built in (150 percent of rated capacity at 65 percent of rated pressure) to provide some protection in case of greater-than-expected demand at the time of a fire. The following examples show one method of how rated capacity and pressure can be determined by using the standard fire pump curve for a typical manufacturer's pump characteristic curve (see Figure 15.6.12).

EXAMPLE 1: HORIZONTAL CENTRIFUGAL PUMP The estimated water demand for sprinklers and hose streams is 1400 gpm at 90 psi. The suction supply is a ground-level storage tank, and the minimum inlet gauge pressure is 0 psi at maximum flow.

PROBLEM: Determine the required rated capacity and pressure of the pump.

SOLUTION: Solution is determined by the following steps:

1. Meet the demand of 1400 gpm with the capacity of the pump, which is 150 percent of rated capacity.
2. Thus, 1400 ÷ 150 percent = 933 gpm. The nearest standard pump rating is approximately 1000 gpm.
3. Therefore, 1400 gpm demand would be 140 percent of capacity.
4. From the manufacturer's pump characteristic curve, it is determined that, at 140 percent capacity, the total pressure is 72 percent of rated pressure.
5. Under conditions of operation, the total pressure equals the discharge pressure (90 psi) plus suction pressure (0 psi).
6. Therefore, net pressure at 1400 gpm equals 90 + 0 = 90 psi, and rated pressure at 1000 gpm = 90 ÷ 72 percent = 125 psi.

ANSWER: Pump rating should be not less than 1000 gpm at 125 psi.

EXAMPLE 2: HORIZONTAL CENTRIFUGAL PUMP (SI UNITS) The estimated water demand for a sprinkler system is 2000 L/min at a pump discharge pressure of 400 kPa. The suction supply is a well with a lift of 5 m from water surface to the pump.

PROBLEM: Determine the required rated capacity and pressure of the pump.

SOLUTION: Solution is determined by the following steps:

1. Meet the demand of 2000 L/min with the overload capacity of the pump which is 150 percent of rated capacity.
2. Thus, 2000 ÷ 150 percent = 1330 L/min. The nearest standard pump rating is approximately 1500 L/min.
3. Therefore, 2000 L/min demand would be 2000/1500 × 100 percent = 133 percent of rated capacity.
4. From the manufacturer's pump characteristic curve, it is determined that, at 133 percent capacity, the total pressure is 78 percent of rated pressure.
5. Under conditions of operation, the net pressure equals the discharge pressure (400 kPa) minus suction pressure (5 m head = 5 ÷ 9.81 kPa = 50 kPa).
6. Therefore, net pressure at 2000 L/min equals 400 + 50 = 450 kPa, and rated pressure at 1500 L/min = 450 ÷ 78 percent = 580 kPa.

ANSWER: Pump rating should be not less than 1500 L/min at 580 kPa.

EXAMPLE 3: VERTICAL TURBINE PUMP IN A WELL The estimated water demand at ground level is 1100 gpm at 100 psi.

Tests and weather records show that the aquifer, or underground water source, is reliable and adequate at all seasons. The static level is 45 ft below the surface. The draw down, or vertical distance, between the static and pumping water levels is 40 ft at 1100 gpm pumping rate.

PROBLEM: Determine the rated capacity and pressure of the pump.

SOLUTION: Solution is determined by the following steps:

1. Meet the demand of 1100 gpm with the rated capacity of the pump, which is 100 percent of rated capacity.
2. Thus, 1100 ÷ 100 percent = 1100 gpm. The nearest standard pump rating is approximately 1100 gpm.
3. Therefore, the 1100 gpm demand would be 110 percent capacity.
4. From the manufacturer's pump characteristic curve, it is determined that, at 110 percent capacity, the total pressure is 70 percent of the rated pressure.
5. At 1100 gpm, pressure demand at the surface = 100 psi.
6. Static level (ft) + drawdown level (ft) = Pumping level (ft). In the example 45 ft static water level + 40 ft drawdown level = 85 ft pumping level. Now converting ft of water to psi, 85 ft × 0.434 psi/ft = 37 psi. Determine the pumping pressure required for the example: 100 psi + 37 psi = 137 psi, and 100 psi/137 psi = 0.73 (%), and finally, 137 psi/0.73 = 188 psi.

ANSWER: The pump rating should be not less than 1000 gpm at 188 psi.

EXAMPLE 4: BOOSTER PUMP ON PUBLIC WATER CONNECTION A sprinklered building in a city has an estimated sprinkler demand of 750 gpm at 60 psi. Based on fire flow tests from nearby street hydrants, 750 gpm at 27 psi is available for sprinklers at the inlet flange of the pump. Allowance has already been made for hose streams.

PROBLEM: Determine the rated capacity and pressure of the pump.

SOLUTION: Solution is determined by the following steps:

1. Meet the demand of 750 gpm with the rated capacity of the pump, which is 100 percent of rated capacity.
2. Thus, 750 ÷ 100 percent = 750 gpm, a standard pump rating.
3. The total pressure at 100 percent capacity is 100 percent rated net pressure.
4. With positive head suction supply, the net pressure equals discharge pressure minus suction pressure; thus, at 750 gpm flow, net pressure equals 60 – 27 = 33 psi.
5. Therefore, 33 ÷100 percent = 33 psi.

ANSWER: The pump rating should be 750 gpm at 33 psi.

NFPA 20 recommends that the pump not be used at over 140 percent capacity. This leaves a small reserve as pump curves drop off sharply after 150 percent. Generally, a one size larger pump is recommended than the calculations indicate. When the pump is used above its rated capacity, the available pressure is reduced.

HORSEPOWER OF FIRE PUMPS

Before matching a driver to a pump, it is necessary to know the maximum brake horsepower demand of the pump at rated speed. This demand can be determined directly from the horsepower curve provided by the pump manufacturer. Typical fire pumps reach maximum brake horsepower between 140 and 170 percent of rated capacity.

Engine Horsepower

Engines specifically designed for use with fire pumps are rated by measuring the horsepower developed with all accessories in operation and then making some allowance for wear and tear. When equipped for fire pump driver service, an allowance of not less than 10 percent greater than the maximum brake horsepower is required by the pump under any conditions of pump load. Typical bare engines and usable horsepower curves are shown in Figure 15.6.19.

The engine manufacturer's test curves are based on barometric pressure of 29.61 in. (752 mm) Hg, which approximates 300 ft (90 m) above sea level and 77°F (25°C). The usable horsepower of a fire pump engine should be reduced for each 1000 ft (300 m) rise in altitude above 300 ft (90 m) by 3 percent for a diesel engine and 1 percent for each 10°F (5.6°C) rise above 77°F (25°C).

If the curves are not available, horsepower can be calculated by the formula (in U.S. customary units)

$$\text{bhp} = \frac{5.83QP}{10{,}000 \times E} \quad \text{or} \quad \text{bhp} = \frac{QP}{1710 \times E}$$

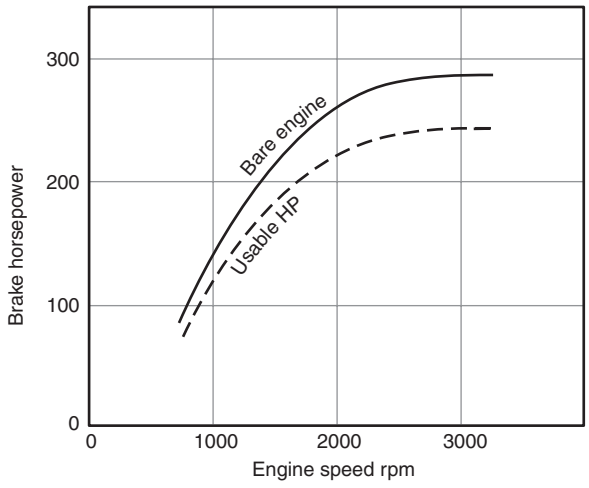

FIGURE 15.6.19 Typical Engine Horsepower Curves

where

bhp = Brake horsepower

Q = Gallons per minute

P = Total head (psi)

$$E = \text{Efficiency} = \frac{\text{Water horsepower}}{\text{Input horsepower}}$$

The efficiency at maximum brake horsepower is usually 60 to 75 percent.

PROBLEM: Find by formula the minimum horsepower needed to drive a 1000 gpm, 100 psi, 1760 rpm horizontal centrifugal fire pump.

SOLUTION: Solution is determined by the following steps:

1. Assume 65 percent efficiency at 160 percent capacity.
2. From a standard pump curve, the pressure is 55 percent at 160 percent capacity or 55 psi at 1600 gpm.
3. By formula,

$$\text{bhp} = \frac{5.83 \times 1600 \times 55}{10{,}000 \times 0.65} = 79$$

ANSWER: Not less than 79 usable brake horsepower.

IN SI UNITS.

$$\text{Output power} = \frac{0.167 Q_m P_m}{10{,}000E}$$

where

kw = Power output (kilowatts)

Q_m = Liters per minute

P_m = Total head (kPa) or net pressure

$$E = \text{Efficiency} = \frac{\text{Water power output}}{\text{Input power}}$$

PROBLEM: Find by formula the minimum power output needed to drive a 4000 L/min, 700 kPa, 1760 rpm horizontal centrifugal fire pump.

SOLUTION: Solution is determined by the following steps:

1. Assume 65 percent efficiency at 160 percent capacity.
2. From a standard pump curve, the pressure is 55 percent at 160 percent capacity or 385 kPa at 6400 L/min.
3. By formula,

$$\text{Power output} = \frac{0.167 \times 6400 \times 385}{10{,}000 \times 0.65} = 63 \text{ kW}$$

ANSWER: Not less than 63 kW output.

FIRE PUMP DRIVERS

Power for driving fire pumps is selected on the basis of reliability, adequacy, safety, and economy. The reliability of utility electric power may be judged by the record of outages and by review of the power sources and distribution layout of the system in question.

Some public utilities in metropolitan areas operate steam distribution systems. When high-pressure steam is available, it is practical to use steam turbine-driven fire pumps. Some remote industrial plants generate their own electricity using steam or hydro power, or both. Utility electric power is also used.

Diesel engines have the advantage of not being dependent on outside sources of power.

Electric Motors

Electric motors for driving fire pumps must be listed for fire pump service. These motors are designed in accordance with specifications of National Electrical Manufacturers Association (NEMA) or Electrical Manufacturers Association of Canada (EMAC). All electrical equipment and wiring in a fire pump installation is required to comply with NFPA 70, *National Electrical Code*®, Article 675.

Section 15, Chapter 7, "Fire Pump Controllers and Power Supply Arrangements for Motor-Driven Fire Pumps," provides a detailed discussion on electric motor design considerations.

Electric Motor Controllers

The fire pump controller used for an electric-driven pump is a critical component to ensure the successful operation of the pump. Such controllers are equipped with a variety of internal components to achieve this level of reliability. These components may include elements such as circuit breakers, disconnecting means, timers, and similar devices. Recently, an electric motor controller that uses a variable-speed system has been listed for use in fire pump applications. This controller is an additional tool that can be used by the designer to control the discharge head developed by a fire pump. This type of system is of particular value where the pump takes suction from a variable pressure source such as a city water supply that has a higher pressure in some seasons of the year and a very low pressure in other times of the year. It is also of value for some of the new sprinklers that require a high operating pressure to maintain a water application rate to control a fire in warehouses and high-hazard occupancies.

Section 15, Chapter 7, "Fire Pump Controllers and Power Supply Arrangements for Motor-Driven Fire Pumps," describes details for the design and selection of electric motor controllers.

Engine Controllers

Controllers are used for automatic operation of engine-driven fire pumps. The specifications for construction, location, and methods of actuation of engine controllers are the same as for electric motor controllers. Automatic controllers are equipped with manual starting and stopping switches. Diesel engine controllers are available as electric or air starting types. Unlike electric motor controllers that are available in a limited service type for less than 30 hp, all diesel engines, large or small, require the same operational features. Details on the design of the electric operated diesel engine controller are found in Section 15,

Chapter 7, "Fire Pump Controllers and Power Supply Arrangements for Motor-Driven Fire Pumps." Air-operated diesel engine controllers are required to have the same operational features as the electric controller.

Audible supervisory devices are provided to indicate low oil pressure in the lubrication systems, high engine-jacket water temperature, failure of the engine to start automatically, and shutdown from overspeed.

Steam Turbine

When adequate and reliable steam supplies are available, turbine-driven fire pumps are acceptable. Only well-built machines of good design with industrial records of proven reliability are used. Special arrangements are needed for automatic operation. Speed rating should not exceed 3600 rpm, because this is the maximum speed of listed fire pumps. Detailed requirements for steam supply, speed governors, and controls are contained in NFPA 20.

Diesel Engines

Engines that are powered by diesel fuel are used for fire pump service. Engines powered by gasoline, natural gas, or LP-gas are not recognized by NFPA 20.

In addition to NFPA 20, reference should be made to NFPA 31, *Standard for the Installation of Oil-Burning Equipment,* and NFPA 37, *Standard for the Installation and Use of Stationary Combustion Engines and Gas Turbines.* Installations should be made in conformance to local codes.

The development of unsatisfactory conditions, such as pump running, failure to start, high cooling water temperature, and low oil pressure, should be indicated by supervisory signals, not by shutting down the engine. The intent is to keep the pump operating just as long as possible. The importance of constant supervision for automatic pumps is obvious. Recently, a new operating system has been developed to control the discharge head (or pressure) from a diesel engine driven fire pump. This system operates as part of the diesel engine and not the controller like the electric motor driven fire pump. Both have the same advantage of being able to accurately control the pump discharge pressure when the suction pressure is variable or the pressure needs of a fire sprinkler system in a warehouse or high-hazard occupancy need to be maintained at a constant pressure to control a fire in the occupancy.

Cooling Systems. An adequate cooling system is vital to the reliable operation of a diesel engine. A closed pipe system with a heat exchanger and a thermally insulated manifold is the preferred cooling arrangement for a diesel engine recognized in NFPA 20. Only clean or potable water should be circulated through the engine block. Raw water is piped from the fire pump and discharged through the heat exchanger tubes to free discharge in a visible location, such as the cone of the building drain or building exterior. On some engines, the manifolds, oil coolers, and other parts are equipped with water jackets, as recommended by the engine manufacturer. Most engines require a raw waterflow of 15 to 30 gpm (57 to 114 L/min).

In cooling water systems connected to potable water systems and where an antifreeze with inhibitors is used inside of the engine block, federal clean water act regulations and local water suppliers are requiring that reduced-pressure backflow preventors be installed in the cooling water piping upstream of the heat exchanger in both the main cooling waterline and the bypass line. Details of the acceptable arrangement are found in the annex to NFPA 20.

Figure 15.6.20 shows the raw water from the fire pump entering the system through the strainer (1), which prevents sediment from entering the system, and the pressure regulator (2), which protects the heat exchanger from excessive pressure. The solenoid valve (3) is required with automatic control of the engine. The valve (4), normally closed, may be used to bypass the regulator and solenoid valve. The exhaust manifold (5) may be cooled by the clean water circulating system.

Another method of providing cooling to the diesel engine is a closed loop radiator. The radiator can be remotely installed outside of the pump room or on the engine platform. When the radiator is mounted on the engine skid, it should be arranged to pull the air across the engine and out through the radiator. The radiator is sized, according to engine manufacturer's recommendations, to remove the engine-radiated heat and to provide the internal engine cooling requirements.

Fuel Tanks. The storage tank for the diesel engine fuel is sized to contain at least an 8 hour supply. A larger capacity can be provided if facilities for prompt refilling are not available. Tank capacity is estimated by allowing 1 gal/hp. (For SI units: 1 pt = 0.473 L, and 1 gal = 3.785 L.) (See diagrams of typical fuel systems in NFPA 20.)

The fuel storage tank is required to be installed inside the fire pump room, because all listed diesel engines require fuel to be available by gravity, thereby eliminating the fuel pump on the engine. The bottom of the tank is at or above the level of the fuel injectors. This location also allows for easy inspection and maintenance of the tank.

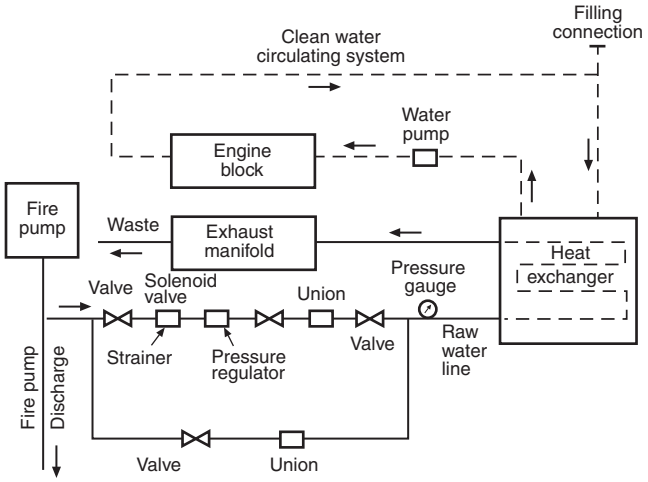

FIGURE 15.6.20 A Typical Heat-Exchanger Cooling System for an Automatically Controlled Engine-Driven Fire Pump That Does Not Require Backflow Protection

Battery Chargers. The energy source needed for automatic starting of a diesel-driven fire pump depends on a sufficient capacity from the battery system. The charges used to satisfy this requirement are specifically listed for fire pump service, and consist of rectifiers, transformers, and relays.

Batteries are provided in two banks with alternate starting cycles to increase the system reliability.

Automatic Pump Control

Most fire pump installations are arranged for automatic operation, preferably with automatic start and manual shutdown. The choice between manual and automatic shutdown depends on the specific conditions involved in a pump's installation and use. Horizontal centrifugal pumps under automatic control must always operate under a head to avoid the need for priming.

Each engine controller is equipped with a separate pressure switch and sensing line that actuate the pump unit when pressure in the water system piping drops to a preset level. Unless the normal water supply static pressure is higher than the pump starting pressure, an automatic jockey (pressure maintenance) pump must be provided to maintain pressure in the system at the higher level.

Actuation of a pump by waterflow instead of by pressure drop is desirable for certain installations, such as those in which: the opening of a moderate number of sprinklers would not drop the system pressure enough to move the pressure switch; high-hazard occupancies in which a fire would demand fire pump service without delay; combined fire protection and plant service systems where a pressure maintenance pump would be impractical; and occupancies in which pressure fluctuates so much that a stable cut-in pressure could not be obtained.

The wiring system of a pump controller includes terminals for connection of a relay to an external supervisory circuit from a sprinkler, deluge, or special fire protection system. To secure reliable pump actuation, external circuits should be installed in conformance with the following NFPA standards, depending on the nature of the signaling system:

NFPA 70, *National Electrical Code®*, Article 695
NFPA 72®, *National Fire Alarm Code®*

Circuits for remote automatic starting of fire pumps should be powered from the controller power.

FIELD ACCEPTANCE TESTS

After a new fire pump has been installed, it is required to make a performance test. Defects and faults are discovered and steps are taken to remedy them. These tests enable the purchaser to determine that the contract has been properly concluded. They also demonstrate the need for future maintenance tests.

Details of the acceptance tests are given in NFPA 20. The test demonstrates the adequacy of the pump and the ability of the pump to deliver water in accordance with its head-capacity curve. The prime mover is operated under various conditions and its performance recorded. There are provisions for electric motors, steam turbines, and diesel engines. Repeated operation of the controlling equipment is required to ensure that full operation of the unit will result from either manual or automatic operation of the controller.

Flow tests are conducted to develop the pressure-discharge characteristic curve of the pump. The procedure followed is to run the pump at three to four different flows, including shutoff (no water flowing). The rate in gallons per minute (L/min) is determined with a Pitot tube and gauge at the nozzles (preferably standard 30-in. [762-mm] long Underwriter playpipes) attached to hose lines from an outside hose-valve header. The discharge is varied by changing the number of lines, the size of nozzle tips, or both; or by using an installed waterflow meter with flow to an open source. Flow is varied by opening or closing the valve on the meter line.

The nozzles may be attached directly to outdoor headers, without hose lines, if water damage can be avoided. Disposal of test water is often a problem, and the length of hose lines depends on the drainage facilities available and the exposure to property and people.

For every flow, pressure readings are taken at the suction gauge and the discharge gauge. The revolutions per minute are also measured using a revolution counter or a tachometer, if available.

The net pressures are calculated from the pump gauge readings, and the flows in gallons per minute corresponding to the Pitot readings are obtained from discharge tables. The flow required for coolant purposes for diesel engine-driven pumps can be added to the measured flow. However, it is usually difficult to accurately measure this flow, so an estimate based on the manufacturer's recommendations may have to be used. In many cases, this flow is small enough to be considered negligible.

With the growing problems of waste water disposal, many pump installations are equipped with waterflow meters for the acceptance test and the periodic service tests. The meters should be installed in conformance with NFPA 20, in order to function properly and not interfere with the operation of the pump.

Vertical turbine fire pumps are tested in the same manner as horizontal pumps, except that there is no suction gauge. The pumping water level should be recorded at each test point.

Figure 15.6.21 presents data obtained by a typical field acceptance test of a horizontal 1500 gpm, 100 psi, 1760 rpm (5678 L/min, 689 kPa, 1760 rpm) diesel-engine-driven centrifugal pump. The net pressure and total flows are calculated from the observed data and plotted (Figure 15.6.22). The curve best

Acceptance Test for a 1500-gpm, 100-psi, 1760-rpm Fire Pump

			Hose	Streams			Corrected to 1760 rpm			
rpm	Discharge (psi)	Suction (psi)	Net (psi)*	No.	Size (in.)	Pitot Pressure (psi)	gpm*	Total*	gpm*	Net (psi)*
1700	125	+16	109	0	–	–	–	0	0	118
1695	120	+18	102	1	1¾	70	742	742	772	110
1690	110	+16	94	2	1¾	60, 60	687, 687	1374	1420	101
1686	95	+17	79	3	1¾	55, 55, 55	657, 657 657	1971	2060	85
1675	85	+16	69	4	1¾	35, 37, 48, 48	525, 540 614, 614	2293	2410	76

* Calculated from observed data.

FIGURE 15.6.21 Example of a Log for a Fire Pump Acceptance Test

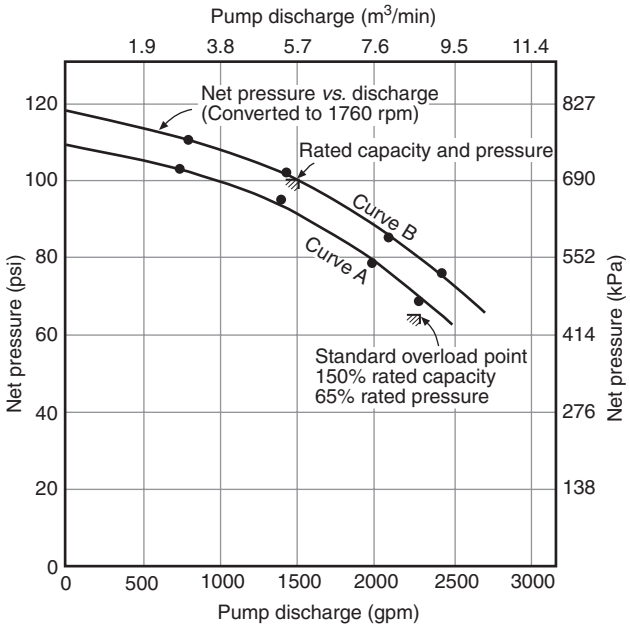

FIGURE 15.6.22 Head Capacity Curves Plotted from Data Compiled in a Fire Pump Acceptance Test

fitting the plotted points is then drawn (Curve A). In this installation, the engine governor appeared to be out of adjustment, restricting the average speed to 1689 rpm, whereas the rated speed was 1760 rpm.

Since the pump was tested at less than rated speed, the observed net pressures and flows were converted to what they would have been at the rated speed of 1760 rpm. Curve B is the characteristic curve at rated conditions. Although the rating point was barely reached, the overload point exceeded the minimum by a good margin. With the engine adjusted to operate at full speed, the pump performance would be acceptable. The following is the conversion calculation procedure that was followed.

Flow is directly proportional to rpm; net pressure is proportional to rpm.[2] For example, test flow, 1971 gpm at 1686 rpm:

$$\text{Flow at 1760 rpm} = 1971\left(\frac{1760}{1686}\right) = 2060 \text{ gpm}$$

Net pressure for 1971 gpm at 1686 rpm is 78 psi. Net pressure for 2060 gpm at 1760 rpm is

$$78\left(\frac{1760}{1686}\right)^2 = 85 \text{ psi}$$

Similar calculations can be carried out in SI units using the affinity laws mentioned previously in this chapter.

LOCATION AND HOUSING OF CENTRIFUGAL PUMPS

Fire pumps are preferably housed in buildings of fire-resistant or noncombustible construction. Even when the climate is so mild that there is no danger of freezing, sufficient enclosure is needed to protect against dirt, corrosion, and tampering. Structural separation of the pump room from other parts of a property is a requirement.

Pump rooms and power facilities should be as free as possible from exposure to fire, explosion, flood, earthquake, and windstorm damage.

Light, heat, ventilation, and floor drainage should be provided for pump rooms. A dry location above-grade is preferred. Pump rooms should be large enough to facilitate easy access to all equipment and devices for inspection, testing, and maintenance.

Fire pumps are located as close as possible to those areas where protection is most important. In some large properties, it may be necessary to have water supplies at more than one point to obtain the most favorable distribution system.

PUMP TESTS

A fire pump must be flow tested annually to ensure that the pump, driver, suction, and power supply function properly and to correct faults that may be found. The hydraulic performance of the pump is measured by a flow test, using a flow meter or hose and nozzles connected to the pump header or yard hydrants. Three points on the standard curve are checked: (1) shutoff, (2) overload (150 percent of rated capacity), and (3) at capacity rating.

Automatic operation is tested by lowering the system pressure, giving due consideration to the layout of the fire protection system, that is, pressure drop or waterflow actuation, jockey pump, and so on.

The water level of wells, ponds, and reservoirs and the condition of suction screens and intakes, above- and below-ground tanks, and so on should be carefully inspected. The history of power outages, low water, and failure of any kind that involves pump, driver, or associated equipment also should be investigated and gauge records from engine controllers recorded for future evaluation.

PUMP OPERATION AND MAINTENANCE

A fire pump can be depended on to work in an emergency only if it is properly operated and maintained. (See NFPA 25 for requirements for inspection, testing, and maintenance of these systems.) It is required that an inspection and testing program that includes written instructions and recordkeeping be implemented. It is further required to have someone at the property at all times who is designated and instructed to operate the pump and its driver. A short (30-min diesel engine; 10-min electric motor) test is required to be made each week by discharging water from some convenient outlet or recirculating through a flow meter.

Fire Alarm Interface

When a supervisory signal indicates an automatic fire pump is operating, the person responsible for the fire pump should proceed to its location immediately. The pump should be allowed to run until the emergency is over, when it may be shut

down manually. During this and every other operating period, the equipment should be checked carefully to see that it is performing properly.

To minimize too-frequent starting and stopping, an electric motor controller has a timer that keeps the motor running for at least 1 minute for each 10-hp motor rating; not less than 10 minutes is required. With electric motors, it is necessary to allow the electrical windings to cool down after starting, to minimize damage to the windings.

It is preferable with all pump drivers to permit the unit to run until it is shut down manually.

When there is more than one automatic fire pump, the controllers are arranged to operate the pumps in a predetermined sequence. The diesel engine is usually first, followed by the electric motor or second diesel engine. Control of the pump from one or more remote pushbuttons, which will start but not stop the pump, may be provided, if desired. If there is deluge valve control of an open discharge device system, the pump may be started by a drop-out relay in a closed circuit. The cooling and lubrication of a centrifugal fire pump is so dependent on water that the pump must never be run unless the pump casing is full of water. Close attention should be given to the bearings and stuffing boxes during the first few minutes of running to see that they do not heat up and need no adjustment. When water reaches the water seal, a small leak at the stuffing box glands is desirable. The suction inlet and discharge outlet pressure gauges should be read weekly to see that the inlet is not obstructed by a choked screen or partially closed valve.

With a vertical-shaft-turbine-type fire pump, the water level can be observed if suction is from a visible supply. If the pump takes suction from a well, water level testing equipment must be used. The groundwater level at the pump should be checked at the weekly test interval during the year and the drawdown should be determined during the annual 150 percent capacity test. These tests should indicate any important change in the groundwater supply.

The direction of rotation of the pump and the speed of operation should be checked each week.

Power Supply Maintenance

The source of electric power for the pump should be checked weekly. With an electric motor drive this means current supply for the motor and its auxiliary equipment. For steam turbine drive, it means the steam supply up to the control valve and the absence of condensate from supply, turbine, and exhaust. If the pump is driven by a diesel engine, there must be adequate fuel for 8 hours of operation. The batteries must be fully charged.

The starting equipment must be test-operated and its functioning carefully checked. Any evidence of a drop in voltage greater than –15 percent (nominal voltage less 15 percent) to an electric motor or a drop in steam pressure to a turbine must be investigated.

With a diesel engine drive, the crankcase oil must be replenished or renewed as needed, the oil filter and air cleaner given the necessary attention, the automatic battery charging equipment checked, and the specific gravity of battery electrolyte determined at least once a month.

RECIPROCATING STEAM FIRE PUMPS

Although no new reciprocating steam fire pumps have been installed in recent years, a few may still be in service. These fire pumps are commonly referred to as Underwriter steam fire pumps. The general features of a direct-acting duplex steam pump are shown in Figure 15.6.23. The size of the steam and exhaust ports of this type of pump is larger than it is in the general-purpose steam pump, thus permitting higher speeds. The steam supply pipe should be an independent line run from boiler to pump in such a way that it will not be damaged by fire or other hazards.

Automatic control can be provided by a pressure governor to regulate steam supply to the pump in accordance with the water pressure on the pump discharge. For successful operation, it is nearly always necessary to provide a small, automatically controlled jockey pump to maintain system pressure, control supply leakage, and avoid continuous operation of the large pump.

FIRE PUMP APPROVAL AND LISTING

NFPA standards for design and installation of various fire protection systems require the use of approved equipment, or listed equipment, or both, including fire pumps, for installations requiring them. Under the testing and listing approval system, the manufacturer is responsible for providing a listed or approved pump that will perform satisfactorily when installed in conformance with NFPA 20. Contractors or others are responsible for installing the driver-pump combination in accordance with the provisions of NFPA 20, whereas it is the customer's obligation to provide adequate data about the pump driver, power supply, water supply, location, and so on.

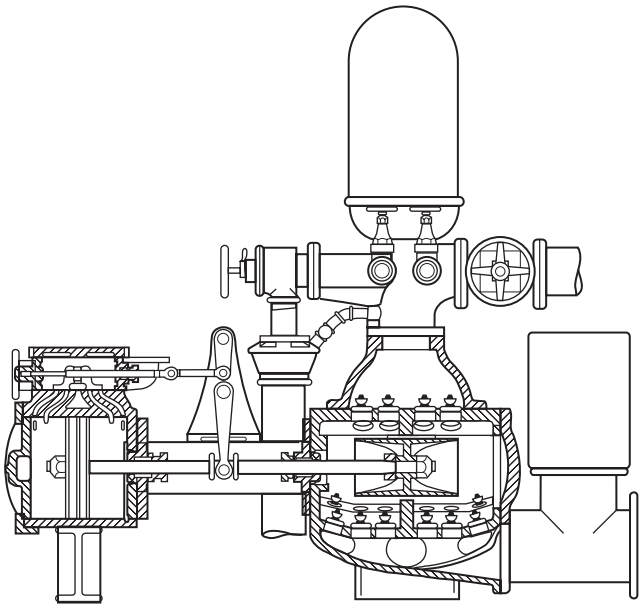

FIGURE 15.6.23 Sectional View of an Approved Duplex Steam Pump

Fire pumps are designed to provide maximum reliability and specific net head-discharge characteristics. Except for periodic inspections and tests, fire pumps are idle most of the time. Pumps for commercial use, on the other hand, are chosen for maximum efficiency and economy.

To obtain a listing of a new pump, the manufacturer submits plans and specifications to a testing agency for review and comment. After any revisions or corrections have been agreed to, arrangements are made for representatives of the testing agency involved to witness the required approval tests at the manufacturer's plant.

If the results are satisfactory, the new pumps are listed in the usual manner or with any restrictions considered desirable. It is the duty of the manufacturer to shop-test every unit sold and to furnish certified curves of head, efficiency, and brake horsepower versus discharge. The NPSH curve of the pump should be provided on request.

Many of the listed fire pumps used today are top-quality commercial units. These pumps are upgraded when necessary, trimmed, and fitted to meet all the approval requirements for fire protection.

SUMMARY

Fire pumps provide the water supply pressure, or they enhance the existing water supply pressure, for powering fire protection systems such as automatic sprinklers. This chapter described different types of fire pumps, that is, centrifugal pumps and positive displacement pumps. The chapter further discussed the principles of fire protection operation, including a discussion of the power sources that drive fire pump systems. The chapter concluded with a description of field acceptance tests and pump operation and maintenance procedures.

Chapter 7

Fire Pump Controllers and Power Supply Arrangements for Motor-Driven Fire Pumps

Revised by
James S. Nasby ❑ John R. Kovacik

Chapter Contents

Worldwide Standards for Fire Pump Controllers
Electric Power Supply Arrangements for Motor-Driven Fire Pumps
Electric Drive Controllers
Limited-Service Controllers
Full-Service Controllers
Variable Speed Electric Motor–Driven Fire Pumps
Controller Parameters
Standard Controller Components
Standard Controller Features
Nonmandatory Controller Features
Transfer Switches

Key Terms

combination controller, fire pump controller, fire pump (diesel-engine driven), fire pump (electric-motor driven), fire pump (steam-turbine driven), fire pump (variable speed), power transfer switch

Where determined to be necessary through hydraulic analysis, a fire pump is a critical component of the overall water-based fire protection system. A successful outcome to a fire incident depends on the proper operation of the fire pump or pumps because the pump generates the necessary waterflow and pressure for fire control or extinguishment. In this regard, it is not just the fire pump that is of concern. All components that enable the pump to operate must be considered and be properly designed, installed, and maintained. This chapter focuses on the electrical and control aspects of electric motor–driven fire pump installations and is specific to fire pump controllers, motors, and electrical power supply arrangements.

Specific requirements concerning the design, construction, and performance of fire pump components are covered in NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection.* NFPA 70, *National Electrical Code®*, addresses how the electrical equipment—including the wiring of the power supply, fire pump controller, fire pump motor, and ancillary circuits—are to be installed. NFPA 20 covers the commissioning (acceptance testing) of fire pump equipment, whereas NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems,* addresses the routine servicing of fire pump equipment after it has been commissioned.

This chapter is intended to assist those involved with fire pump installations with making better decisions that will lead to more reliable and successful fire protection. This chapter provides added detail and establishes a perspective for the requirements spelled out in NFPA 20, NFPA 25, and NFPA 70 as they pertain to the electrical and control aspects of fire pump installations. In the end, the fire pump installation needs to be reliable and adequate for the life of the building. If determined not to be, corrective actions need to be immediately identified and executed in order to maintain the reliability of the fire protection of the building and maintain the expected degree of property and life-safety protection.

This chapter first appeared as new Section 10, Chapter 8, in the 19th edition of the *Fire Protection Handbook.* The revision in this edition primarily incorporates the extensive changes to the power supply text and requirements of the 2007 edition of NFPA 20. This revision also recognizes the introduction of variable speed motor-driven fire pumps, their applications, and field experience.

For related topics see, Section 15, Chapter 4, "Water Supplies for Sprinkler Systems"; and Section 15, Chapter 6, "Water Distribution."

James S. Nasby is director of engineering at Master Control Systems, Inc., in Lake Bluff, Illinois.

John R. Kovacik is a principal engineer at Underwriters Laboratories Inc., in Northbrook, Illinois.

WORLDWIDE STANDARDS FOR FIRE PUMP CONTROLLERS

Fire pumps and fire pump controllers are widely used throughout the world wherever the need for water exceeds the ability of water supply systems to provide it. The style or type of fire pumps, drivers, and controllers used in North America are the type governed by NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection.* In much of the rest of the world, this type of equipment is known as either the NFPA type of fire pump installation or the North American style of fire pump installation. Although many countries have adopted other NFPA standards, such as NFPA 70, *National Electrical Code®*, only a few countries outside of the United States and Canada (e.g., Brazil, Panama, Malaysia, Korea, Indonesia, and Australia) have also adopted NFPA 20 for fire pumps. In other countries, "NFPA-style" equipment is used when North American insurance, financing, or ownership is involved. The other U.S.-based fire pump controller standards are UL 218, *Approval Standard for Fire Pump Controllers,* by Underwriters Laboratories Inc. and FM 1321/1323, *Approval Standard for Fire Pump Controllers for Electric Motor Driven and Diesel Engine Driven Fire Pumps,* by Factory Mutual (FM Global).

Outside of the United States, fire pump controllers and drivers are very different from the NFPA-style equipment. Specifically, most of Europe uses LPC-style equipment. LPC stands for the Loss Prevention Council, which is headquartered in England. The LPC's Loss Prevention Certification Board publishes a list of approved LPC equipment. The Loss Prevention Certification Board is in the process of establishing standards for diesel engines and electric motor–driven fire pump controllers, namely, LPS1236 and LPS1237, respectively. In addition, the British Standards Institute (BSI) offers standard BS 5306: Part 2, a fire pump standard in which the equipment described is similar to that in LPC-type installations. Further, a new European norm, EN 12845, on automatic sprinkler systems is now being used in certain countries. Table 15.7.1 summarizes the key salient features of these two types of fire pump equipment.

ELECTRIC POWER SUPPLY ARRANGEMENTS FOR MOTOR-DRIVEN FIRE PUMPS

The major components of a motor-driven fire pump installation include the pump, the electric motor, and the controller. Another less obvious but equally important component is the electric power supply. Because electric motors require an electric power supply to operate, the arrangement and type of electric power supply used is critical. Loss of electrical power during a fire incident would totally disable the fire protection system, which could then result in potential loss of the building. Therefore, the electric power supply is as critical as any other component of the fire pump installation.

When a fire pump operates, it must do so as intended for the length of time necessary for fire protection operations. Therefore, the electrical power supply must also remain available for this time period. Sufficient electrical capacity to start the fire pump motor and to maintain proper operating speeds once started must also be available. Additionally, the electrical supply must be of sufficient capacity for the locked rotor condition.

A locked rotor condition occurs when a rock or other object gets lodged in the fire pump between the fire pump casing and the impeller or if the pump shaft is seized (frozen) due to long periods of neglect. If the pump shaft cannot rotate freely, it will cause the motor to draw high currents, usually during the starting sequence, as the motor attempts to turn the pump shaft. This prolonged high current can cause significant damage to the electrical equipment and the motor, impairing the entire fire protection system. A prolonged locked rotor condition is not considered a normal condition.

The intent of NFPA 20 is to set higher limits on the overcurrent protection devices than what is normally allowed or required by NFPA 70 to increase the likelihood that the fire pump motor can dislodge an obstruction or free a frozen pump and allow pumping to commence or continue. For some motor starting methods, especially for emergency mechanical starting, the current required for starting the motor can reach a locked rotor condition. Various methods are employed so that the short-term high-inrush starting currents do not open the disconnecting means in the fire pump controller during pump starting.

Overall, electrical safety and preservation of electrical equipment are considered secondary objectives in NFPA 20. This philosophy is contrary to the general requirements of NFPA 70, in which requirements are written to minimize electrical hazard to buildings and occupants, reduce the likelihood of damage to electrical equipment, and decrease the possibility of ignition from overloaded electrical circuits. In this regard, NFPA 70 specifies certain safety devices to protect people and equipment from hazardous voltages and electrical currents. NFPA 20, however, which essentially pertains to the effective and continued operation of the fire pump once a fire has occurred, overrides the general safety provisions of NFPA 70. NFPA 20 considers the fire pump equipment to be sacrificial so as to provide continued water delivery for fire-fighting operations for as long as possible. The potential for damaging the motor or other equipment because of high electrical currents is not considered an appropriate reason for shutting down the fire pump and the water-based fire protection system.

The 2007 edition of NFPA 20 included significant revisions to the power supply requirements in Chapter 9. Sections 9.1, 9.2, and 9.3 were rewritten to clear up the following concerns with the existing text:

1. The portion of the power supply that must be dedicated to the fire pump installation
2. Questions on whether the normal supply arrangement is allowed to change based on provisions for backup power
3. Clarification of the requirements for using the "campus-style" arrangement
4. Questions on whether more than one backup source of power is permitted
5. Increased guidance for services over 600 volts (privately owned transformers)

In the 2007 edition, NFPA 20, Section 9.1, "General," is essentially the same as in the 2003 edition, except that a new Sec-

TABLE 15.7.1 Comparison of Fire Pump Controller Characteristics

Parameter or Attribute	*LPC*	*NFPA*
All Controllers (Both Diesel and Electric Motor Driven)		
Manual stop required (no automatic stop)	All fire pumps	All sole-source pumps
Enclosure type (protection)	IP65 (dust tight, spray resistant)	NEMA 2 (drip proof)
Usual location of pressure switch	Separate from controller	Within controller
Pressure recorder required	No	Yes
Electric Motor Drive Controllers (Low-Voltage Full-Service Controllers)		
Power for electric motor driver	Separate building circuit	Separate service or feeder
Maximum load on electric motor driver	90.9%[a]	115%
Separate isolating switch required	No	Yes
Overcurrent protection	Fuses	Circuit breaker
Overcurrent protection	200%, for 5 hr minimum	300% or less, no trip
Motor locked rotor protection timing	75% of motor burn-out time	8 to 20 sec
Emergency run manual operator required	No	Yes
Overload relays allowed	No	No
Diesel Engine Drive Controllers		
Maximum load on diesel engine driver	90.9%[a]	90.9%[a]
Overspeed shutdown	Prohibited	Mandatory
Low oil and high-temperature shutdown	Prohibited	During test only
Cranking batteries	Two	Two
Battery capacity	6 cranks each	12 cranks each
Cranking cycle times (sec)	15 sec cranking, 10 sec resting	15 sec cranking and resting
Cranking cycles	Six on one battery	Six, alternating
Emergency manual cranking	Both batteries in parallel	Either or both[b]
Test start light after a pump demand run	Required	Not required
Automatic weekly test circuit	Not required	Required
Battery charger size (for lead acid batteries)	3.5 to 7% of 10-hr capacity	Total capacity recharge of both batteries in 24 hr or less
Typical charger size for 100 amp-hour batteries	3.5 to 7 amperes	10 amperes[c]
Typical charger size for 200 amp-hour batteries	7 to 14 amperes	10 amperes[c]
Location of tachometer and speed switch	In controller	On engine

[a]Driver must be 110% of maximum pump load.
[b]Varies with the controller design (manufacturer); some have one start button, others two.
[c]Either two 10 ampere chargers or a single divided 20 ampere charger is typical.

tion 9.1.4 was added as a relocation of an existing requirement that all power supplies are to be located and arranged to protect against damage by fire from within the premises and exposing hazards. This requirement previously applied where power was supplied by a service. It now applies to all power sources. Section 9.2 was retitled "Normal Power," and Section 9.2.2 was rewritten to identify the types of power supplies that may serve as the normal source of power to the electric motor–driven fire pump. The requirements for the one allowable disconnecting means and associated overcurrent protection installed in the power supply to the fire pump controller are now covered in Section 9.2.3. Section 9.3 was retitled "Alternate Power," and Section 9.3.1 was rewritten to relocate an existing requirement that at least one alternate source of power is to be provided when the height of the structure is beyond the pumping capacity of the fire department apparatus. Since it applies to the need for alternate power, its new location is more appropriate. The types of power supplies that may serve as the alternate source of power to the electric motor–driven fire pump where reliable power cannot be obtained from a service connection or on-site power production facility are identified in Section 9.3.2.

Sources of Electric Power Supplies

The following electrical power supplies are acceptable for fire pump installations under specific conditions. As will be

described, only a reliable utility service or private power station can be used as a stand-alone individual power supply.

Utility Service. *Service* is the conductors and equipment for delivering energy from the electricity supply system to the wiring system of the premises served. Generally stated, the service is the equipment provided by the public utility used to deliver electrical power to the facility for all normal operations. Specifically, the service begins where the utility wiring stops (service point), and the service ends at the customer side of the service disconnecting means (usually the main switch or main circuit breaker). Ideally for fire pump installations, electrical power should be provided through a direct dedicated circuit to the fire pump controller from the service point as indicated in Figure 15.7.1. The connection is made from either a dedicated service or as a tap ahead of the service disconnect supplying the premises' electrical equipment. For either of these arrangements, the fire pump controller serves as the service disconnecting means. If this direct connection is not possible, other options exist and are discussed in the following section on dedicated connection of supply conductors. In general, the service equipment needs to be located and arranged to minimize the possibility of damage by fire and other hazards from both within the premises and external exposures.

On-Site Electrical Power Production Facility. On-site generation encompasses one or more prime movers and generators located on the premises that serve as the normal electric power source for the premises. In other words, the on-site generation supplies all electrical loads on the facility. This power supply is also referred to as a private power station. A prime mover is described as a mechanical device such as a turbine used to drive a generator. As with the utility service described previously, electrical power should ideally be provided via a direct dedicated circuit to the fire pump controller from the private power station, and the power generation facility needs to be located and protected to minimize the possibility of damage by fire and other hazards from within the premises and from external exposures. This equipment must be located in a separate building or in a structure cut off from the remainder of the premises. An on-site standby or emergency generator as described next cannot be considered on-site generation because its purpose is to supply emergency electrical loads only.

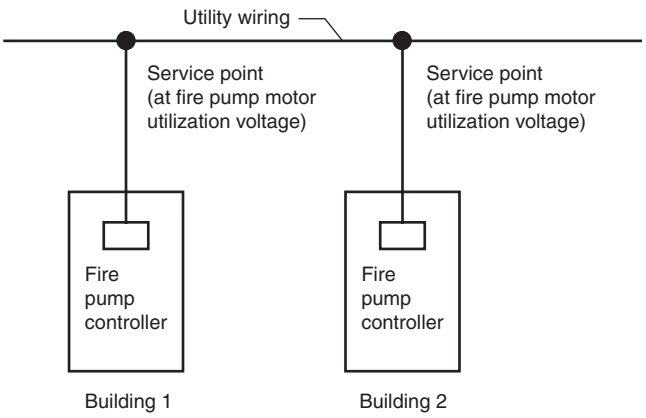

FIGURE 15.7.1 Direct Connection to Utility Service

On-Site Standby (or Emergency) Generator. Generators are considered an emergency or backup electrical power supply. Generators are not intended to serve as the normal source of power for the facility and are, therefore, not considered a private power production facility. Generators do not need to be dedicated solely to fire pump operations but must be of sufficient capacity to allow normal starting and running of the fire pump motors while supplying all other simultaneously operated loads such as elevators and emergency lighting. NFPA 110, *Standard for Emergency and Standby Power Systems,* addresses the installation of these generators.

Feeder Sources. Feeders constitute a power supply arrangement in which power is delivered from a single service point to fire pump equipment in more than one building through a nondedicated circuit. Unlike the arrangement for a utility service or private power station that requires a dedicated circuit from the service point to the fire pump equipment, feeders employ conductors from the service point to deliver power to multiple buildings. Figure 15.7.2 illustrates two feeder arrangements, one supplied from a utility service and the other supplied from a private power station.

Feeder sources are limited to multibuilding campus-style arrangements with fire pumps located at one or more buildings, where the utility service or private power station arrangement is not practicable and where the feeder arrangement is acceptable to the authority having jurisdiction (AHJ). A campus-style facility generally encompasses a considerable contiguous area. Under these circumstances, two feeder sources or a single feeder source in combination with another power supply can be considered a reliable source of electrical power. (See the section on individual sources of power supplies for additional information.)

Other Sources. Diesel engines and steam turbines can also serve as power supplies for fire pumps, although not for the electric motors. Diesel engines and steam turbines are stand-alone power supplies not requiring a backup or emergency source of power. Where diesel engines or steam turbines are used in combination with electric motor drives, they serve as an entirely redundant fire pump arrangement to the electric motor–driven fire pump. Although NFPA 20 does not require this type of arrangement, insurance companies may do so depending on the risk in question. The installation of diesel engines and steam turbines is addressed in Section 15, Chapter 6, "Water Distribution."

Individual Sources of Electric Power Supplies

The basic rule for power supply is that electrical power is to be supplied to the motor-driven fire pump by an individual stand-alone reliable source or by two or more (multiple) independent sources. Therefore, if the utility service or private power station is considered reliable, only one source is needed. If a single power supply is unreliable, then additional sources of electrical power must be provided. Additionally, regardless of the reliability of a proposed single power supply, where the height of the

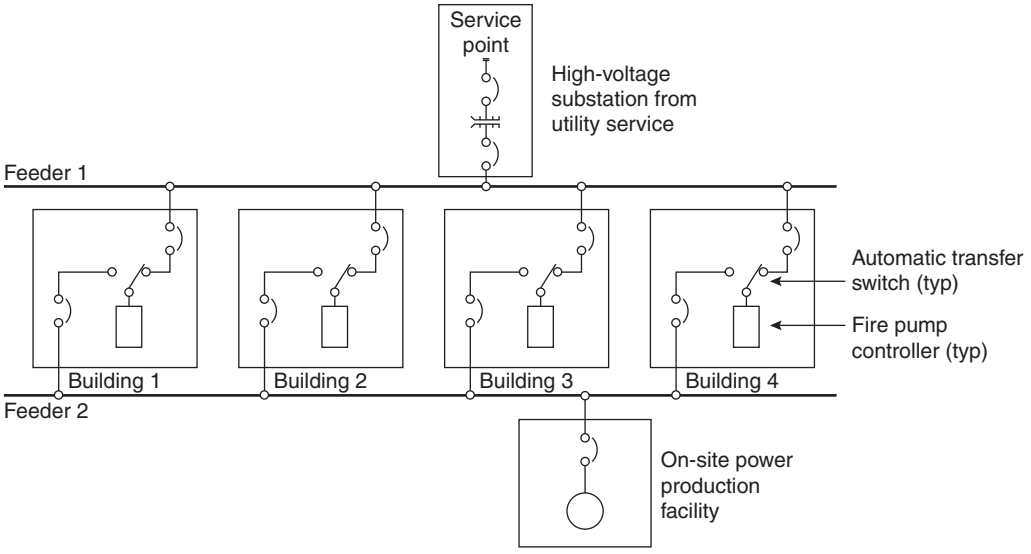

FIGURE 15.7.2 Feeder Arrangement from Two Independent Sources

building is beyond the pumping capacity of the fire department, a second source of power needs to be provided. This provision addresses the situation of the electrical power supply being inadvertently lost or intentionally disconnected during a fire, and the fire department not being able to deliver the necessary water pressure and flow to fight the fire.

Local regulations often override the requirements of NFPA 20 and usually specify additional conditions under which more than one power supply is required even if a single source is considered reliable. For example, the building code in one state requires that all fire pumps serving high-rise buildings, assembly and educational facilities with more than 300 occupants, buildings classified as hazardous occupancies, and institutional facilities in which surgical or treatment operations are conducted be provided with emergency power.

Reliability of Electrical Power Supply

Reliability of the power supply generally pertains to the availability of the power supply and how it is arranged and connected to the fire pump controller. NFPA 20 suggests that a reliable electrical power supply is one that experiences only infrequent power disruptions from environmental conditions or human interaction. This statement implies that a reliable power source can tolerate some limited interruptions and supports the notion that zero risk is unattainable. Responsibility for determining reliability of the power source in terms of its availability and whether it meets the intent of NFPA 20 rests with the AHJ.

The service owned by the public utility and a private on-site electrical power production facility are the only two electric power sources that NFPA 20 would consider to be reliable. However, local regulations and other conditions usually specify additional restrictions in this regard. In some instances, the AHJ might not consider the public utility or private power station as a reliable electrical power source for the fire pump(s) due to frequent power interruptions. For example, under the rolling power blackout conditions in California during 2000 and 2001, the single power source, the public utility, was not considered reliable and corrective action was needed for emergency power. As described previously, it is important to recognize that a private on-site power generation facility or private power station is not the same as an on-site generator.

There have always been questions as to what defines a reliable power supply. The 2003 edition of NFPA 20 first introduced annex material that provided guidance on the selection of such a power supply. The 2007 edition revised that annex material to provide more specific criteria. The Fire Pump Committee included the following guidance for determining the reliability of the power supply:

1. The source power plant has not experienced any shutdowns of longer than 4 continuous hours in the year prior to plan submittal.
2. No power outages have been experienced in the area of the protected facility that were caused by failures in the power grid that were not due to natural disasters or electric grid management failure.
3. The normal source of power is not supplied by overhead conductors outside the protected facility.
4. Only the disconnect switches and overcurrent protection devices permitted by Section 9.2.3 are installed in the normal source of power. The committee did add two requirements to the body of the standard to specify certain levels of performance that, to a certain degree, define the capability (and reliability) of the power supply. The standard now states that all power supplies shall (a) have the capacity to run the fire pump on a continuous basis and (b) comply with the voltage drop requirements of Section 9.4. These are key elements of pump performance.

The use of phase converters as part of the power supply to the fire pump motor has raised concerns regarding the reliability of such a supply. The 2007 edition of NFPA 20 added annex mate-

rial stating that "Phase converters that take single-phase power and convert it to three-phase power for the use of fire pump motors are not recommended because of the imbalance in the voltage between the phases when there is no load on the equipment. If the power utility installs phase converters in their own power transmission lines, such phase converters are outside the scope of this standard and need to be evaluated by the AHJ to determine the reliability of the electric supply." Although there are no requirements prohibiting their use, phase converters are not considered a reliable source of power and are not recommended for fire pump service.

Multiple Sources of Power

Where multiple electric power sources are provided, NFPA 20 requires that they be arranged and located so that a fire, structural failure, or operational accident that interrupts one source will not cause an interruption of the other source. Additionally, on-site standby generators must be protected to minimize the possibility of damage by fire and other hazards from within and external to the premises.

When reliable electrical power cannot be obtained from either the utility service or a private power station, a redundant or backup source of power by one of the following arrangements is required:

- Combination of two or more sources of either utility service or private power station
- Combination of on-site standby generator and either utility service or private power station
- Combination of feeders from two separate sources
- Combination of feeder source and on-site standby generator
- Diesel engine–driven or steam turbine–driven fire pump

Combination of Two or More Sources of Either Utility Service or Private Power Station. Under this arrangement, a combination of two independent utility sources, two separate private power stations, or a utility source and private power station would suffice. It is important to recognize that where two utility sources are considered, they must be independent of one another. An arrangement consisting of two separate service points from the same utility equipment would not be considered an acceptable combination of power sources.

Combination of On-Site Standby Generator and Either Utility Service or Private Power Station. In this case either the utility service or the private power station would provide power for normal operations and the standby generator would provide backup power. In the event that normal power is lost and a fire occurs, the standby generator would be available to start and operate the fire pump motor. This arrangement should not be interpreted to mean that only the standby generator should be arranged to start and operate the pump. The normal electrical power supply also needs to be sized and arranged to execute this function.

Combination of Feeders from Two Separate Sources. This arrangement is depicted in Figure 15.7.2. Feeder 1 delivers power from the utility service, and feeder 2 delivers power from the private power station. Under this arrangement, both feeder conductors constitute an independent power source because they are delivering power from two separate sources. The intent is that failure of one source will not or should not affect or cause the failure of the other source. If feeder sources were arranged such that two separate feeder conductors supplied power to a building from two separate service points from the same utility service, the feeder source would only be considered as a single unreliable power source. As previously indicated, the feeder source can only be used for multibuilding campus-style complexes where a direct connection to the utility service or a private power station is not practicable and where such an arrangement is acceptable to the AHJ.

Combination of Feeder Source and On-Site Standby Generator. This arrangement is depicted in Figure 15.7.3. The feeder connects the utility service power source to multiple buildings and each building contains a standby generator. As indicated in the previous section, the feeder source can only be used for multibuilding campus-style complexes where a direct connection to the utility service or a private power station is not practicable and where such an arrangement is acceptable to the AHJ.

Diesel Engine–Driven or Steam Turbine–Driven Fire Pump. The diesel engine or steam turbine would be redundant to the electric motor–driven pump, which in turn is supplied by the utility service or a private power station. The diesel engine or steam turbine cannot be redundant to an electric motor fire pump powered exclusively by a feeder source or an on-site generator. However, as previously discussed, where a diesel engine or steam turbine fire pump arrangement is provided, NFPA 20 permits the diesel engine or steam turbine to serve as a standalone driver not requiring any backup power supplies.

Dedicated Connection of Supply Conductors

To minimize the possibility of accidentally disconnecting the power supply to the fire pump, the power supply to the fire pump must not be disconnected when the power for the facility is disconnected. For this reason, a reliable power supply is one that contains a separate dedicated connection to the service point or a connection to the supply side of the service disconnecting means. The only exception to this general rule pertains to feeder sources in which the disconnection of power to the fire pumps is permitted under circumstances that automatically ensure the continued availability of the alternate power supply. Because feeders use a single circuit to supply several buildings, disconnecting power to the feeder at any one of a number of points would potentially cut off power to all buildings served by the feeder and, thus, their fire pumps as well. It is also strongly advised that the power circuit for any fire pump not be routed through any other building to minimize the chance of a fire in one building knocking out the fire protection in any other building(s).

The most preferred power supply arrangement is a direct connection, as illustrated in Figure 15.7.4. In this arrangement, the power supply conductors directly connect the service point

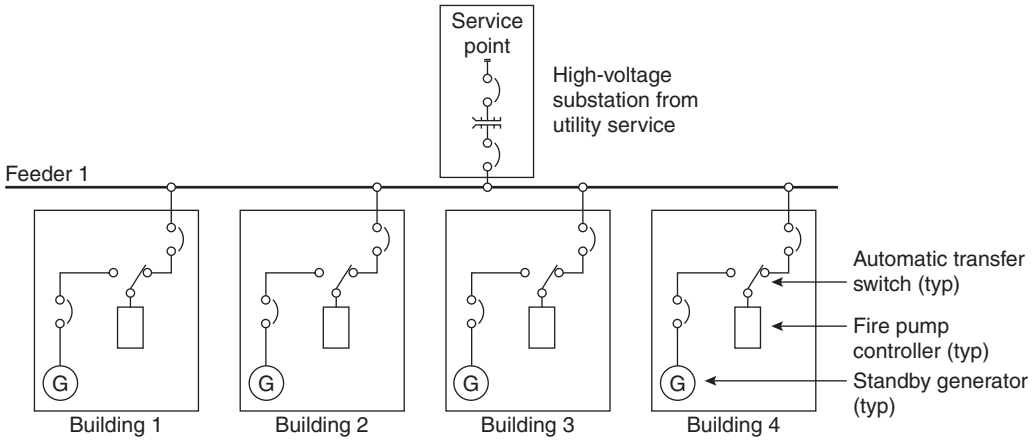

FIGURE 15.7.3 Feeder Source in Combination with an On-Site Standby Generator

or private power station to the fire pump controller or a combination fire pump controller power transfer switch, where more than one power supply is used. Under this arrangement, there is no disconnecting means or overcurrent protection device(s) other than that provided by the fire pump controller. In essence, the fire pump controller becomes the service disconnecting means and overcurrent protection device and is listed as such. Arranging the power supply in this manner minimizes the possibility that the fire department will inadvertently cut off power to the fire pump when the facility's power supply is disconnected.

NFPA 20 recommends that where anticipated risks are large and interruption for fire pump service would seriously affect protection, at least two separate circuits from the power supply to the pump room be provided. The circuits should be run by separate routes or in such a manner that failure of more than one at the same time would be only a remote possibility.

Supervised Connection of Supply Conductors

Where a utility service or private power station serves as the power supply but a direct connection from these sources is not practicable, NFPA 20 allows for two other power supply arrangements. These include a supervised connection and a connection incorporating a transformer. Note that connections for feeder sources are addressed separately later. For both arrangements, the circuits that supply electric motor–driven fire pumps must be supervised against inadvertent disconnection. The first arrangement, referred to as a supervised connection, allows for a single disconnecting means and overcurrent protective device(s) to be installed ahead of the fire pump controller, as illustrated in Figure 15.7.5. A supervised connection is allowed under specific conditions only, pertaining to selection of the overcurrent protective device, means of disconnecting power, marking of the disconnecting means and the controller, and supervision of the disconnecting means as described in the following sections.

Overcurrent Protective Device Selection. Overcurrent is any current in excess of the rated current of equipment such as the fire pump motor, or the ampacity of a conductor, and can result from overload, short circuit, or ground fault. An overload condition for an electric motor includes locked rotor in which the motor is loaded so heavily that the motor shaft cannot turn. Locked rotor can be caused when a stone or other obstruction prevents the fire pump impeller from freely rotating. The overcurrent protective device, normally a circuit breaker for fire pump applications, serves to protect the motor from destroying itself under specific overload conditions. It senses when the amount of current flowing through the supply conductors exceeds a certain value and opens the circuit.

For a supervised connection, the overcurrent protective device on the supply conductors serving the fire pump equipment must be selected or set to carry indefinitely the sum of

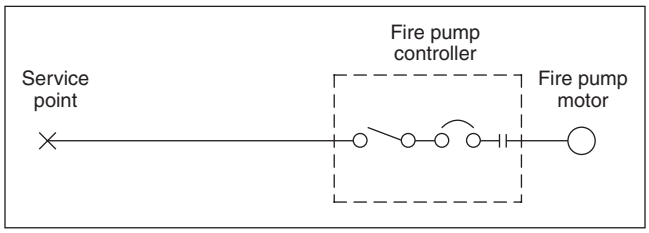

FIGURE 15.7.4 Direct Connection Between Service Point and Fire Pump Motor

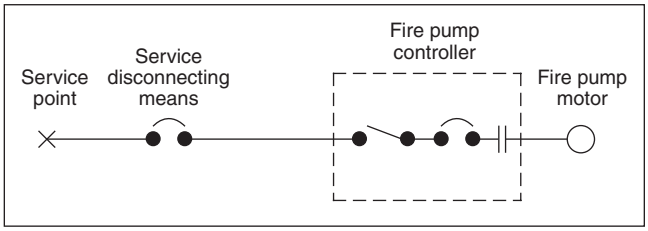

FIGURE 15.7.5 Installation of a Disconnecting Means

the locked rotor current of the fire pump motor(s), the pressure maintenance pump motor(s), and the full-load current of the associated fire pump accessory equipment when connected to this power supply. This value of overcurrent protection is set higher than that typically required for NFPA 70 for nonfire pump equipment. In other words, more current is allowed to pass through the conductors and motor, increasing the potential for equipment failure and the possibility of an additional ignition source. The reason for allowing more current to pass is to permit operation of the fire pump equipment for as long as possible during a fire. As previously indicated, the fire pump equipment is considered sacrificial and preservation of fire pump equipment is not an acceptable reason for disconnecting power to the pump equipment during a fire.

Although the overcurrent protective device is required to carry the locked rotor current indefinitely, in actuality this time period is normally limited by the disconnecting means located in the controller. When a motor is started, a large inrush current occurs and, in many cases, especially for manual (emergency mechanical) starting, is as high as that experienced during a locked rotor condition. For this reason, the overcurrent protective device must have a sufficiently high ampere rating to avoid opening the circuit on the occurrence of large but temporary inrush currents required for motor starting. In this regard, the locked rotor protection in the fire pump controller will allow for the motor to be started without disrupting the circuit. The upstream overcurrent protective device is required to hold the motor locked rotor current indefinitely to allow the fire pump controller to govern when or if the circuit is to be interrupted.

Disconnecting Means. The disconnecting means is a manually or automatically operated device that removes electrical circuits from their power supply. The disconnecting means can consist of circuit breakers for most controllers or fused switches in medium-voltage controllers. The supplemental disconnecting means permitted through a supervised connection is supplemental to the manual and automatic disconnecting means located in the fire pump controller and is intended for only periodic use. The supplemental disconnecting means must possess the following characteristics:

- Identified as suitable for use as service equipment
- Lockable in the closed position
- Located at a sufficiently remote location from other building or other fire pump source disconnecting means that inadvertent operation at the same time would be unlikely

Service equipment is the necessary equipment that connects the lead end of service conductors to the electrical circuits of a building or other structure. Service equipment usually consists of a circuit breaker(s) or fused switch(es) and their accessories and is intended to constitute the main control and cutoff of the electrical supply. Service equipment is intended to disconnect all ungrounded conductors in a building from the service-entrance conductors. The disconnecting means at any one location should not consist of more than six circuit breakers or six switches and is required to be readily accessible either outside the building or inside nearest the point of entrance of the service-entrance conductors.

Disconnect Marking. The disconnecting means must be permanently marked "Fire Pump Disconnecting Means" to make clear the purpose of the disconnecting means. The letters are to be marked at least 1 in. (25.4 mm) in height and they are to be visible without opening enclosure doors or covers.

Controller Marking. A placard must be placed adjacent to the fire pump controller stating the location of the additional disconnecting means and the location of the key if the disconnecting means is locked.

Supervision. The disconnecting means must be supervised in the closed position by one of the following methods:

- Central station, proprietary, or remote station signal device
- Local signaling service that will cause the sounding of an audible signal at a constantly attended location
- Locking of the disconnecting means in the closed position
- Sealing of the disconnecting means and approved weekly recorded inspections where the disconnecting means are located within fenced enclosures or in buildings under the control of the owner. The intent of monitoring is to ensure that if the power supply is inadvertently disconnected, corrective action can be immediately taken.

Power Supply Connection Incorporating a Transformer

Where the supply voltage differs from the utilization voltage of the fire pump motor, that is, the loaded voltage and the rated motor voltage, a transformer meeting the requirements of NFPA 70 along with a disconnecting means and overcurrent protection can be installed between the fire pump controller and the service point, as illustrated in Figure 15.7.6. Where this arrangement is employed, specific conditions pertaining to the selection of the overcurrent protective device, the means of disconnecting power, the marking of the disconnecting means and the controller, and supervision of the disconnecting means as described for a supervised connection apply. It is important to note that secondary side overcurrent protection on the transformer is not permitted.

The transformer must be dedicated to fire pump equipment unless it supplies a feeder source as described in the section on feeder arrangement. The transformer must be rated at mini-

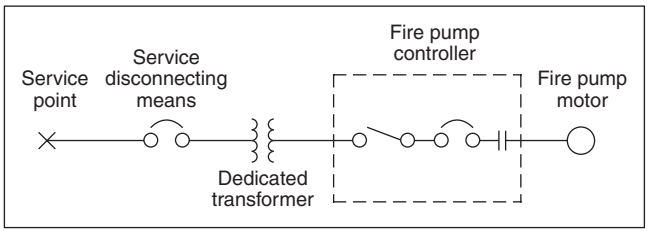

FIGURE 15.7.6 Installation of a Disconnecting Means and a Transformer

mum of 125 percent of the sum of the fire pump motor(s) and pressure maintenance pump motor loads and 100 percent of the associated fire pump accessory equipment supplied by the transformer. Note, however, that this rating is a thermal rating and that 125 percent will almost never be large enough to meet the voltage drop requirements.

The most critical limiting conditions for both the supervised connection and the transformer connection are the location of the disconnecting means that are to be remote from the other service disconnecting means and the overcurrent protection setting that is to be set to carry indefinitely the sum of the locked rotor current of the fire pump motors and the pressure maintenance pump motors, plus the full-load current of the connected fire pump accessory equipment.

Feeder Arrangement

Where feeder sources are used, the 2007 edition of NFPA 20 indicates that the overcurrent protection and the disconnecting means are to be arranged as indicated in NFPA 70 rather than that specified for a supervised connection as indicated previously. However, the 2008 edition of NFPA 70 provides no latitude in this regard and requires that the overcurrent protection and disconnecting means be arranged like that for a supervised connection. In other words, the circuit breaker on the feeder conductor needs to be set to carry indefinitely the sum of the locked rotor current of the fire pump, jockey pump, and other accessory equipment; and the disconnecting means must be suitable as service equipment, lockable in the closed position, and located at a sufficiently remote location from other building or fire pump source disconnecting means. Additionally, where more than one disconnecting means is supplied by a single feeder, the overcurrent protective device in each disconnecting means must be coordinated with all other supply side overcurrent protective devices. This requirement is to ensure that only the breaker nearest the fault or short circuit trips open.

The transformer on the feeder conductor may serve loads other than those dedicated to the fire pump. The transformer must be rated at a minimum of 125 percent of the sum of the fire pump motor(s) and pressure maintenance pump(s) motor loads and 100 percent of the remaining load supplied by the transformer, that is, all other loads served by the feeder. As described in the section on connection incorporating a transformer, the transformer will normally need to be larger to meet the voltage drop criteria.

Connection to a Power Transfer Switch

Perhaps the most complex arrangement is that of multiple power sources serving a fire pump motor. Transfer of power to the fire pump controller between the normal supply and the alternate supply, including an on-site generator, is to take place within the pump room. Figure 15.7.7 illustrates two acceptable arrangements for two power sources feeding a single fire pump motor. The combination fire pump controller/power transfer switch shown in arrangement I of Figure 15.7.7 must be listed for such fire pump service. Arrangement II of Figure 15.7.7 shows where a separately mounted power transfer switch is used. As in the case of the combination fire pump controller/power transfer switch, the separately mounted power transfer switch must be listed for fire pump service. Unless the emergency power source is an on-site generator, the disconnecting means and overcurrent protective devices shown must meet the requirements for a supervised connection as specified previously.

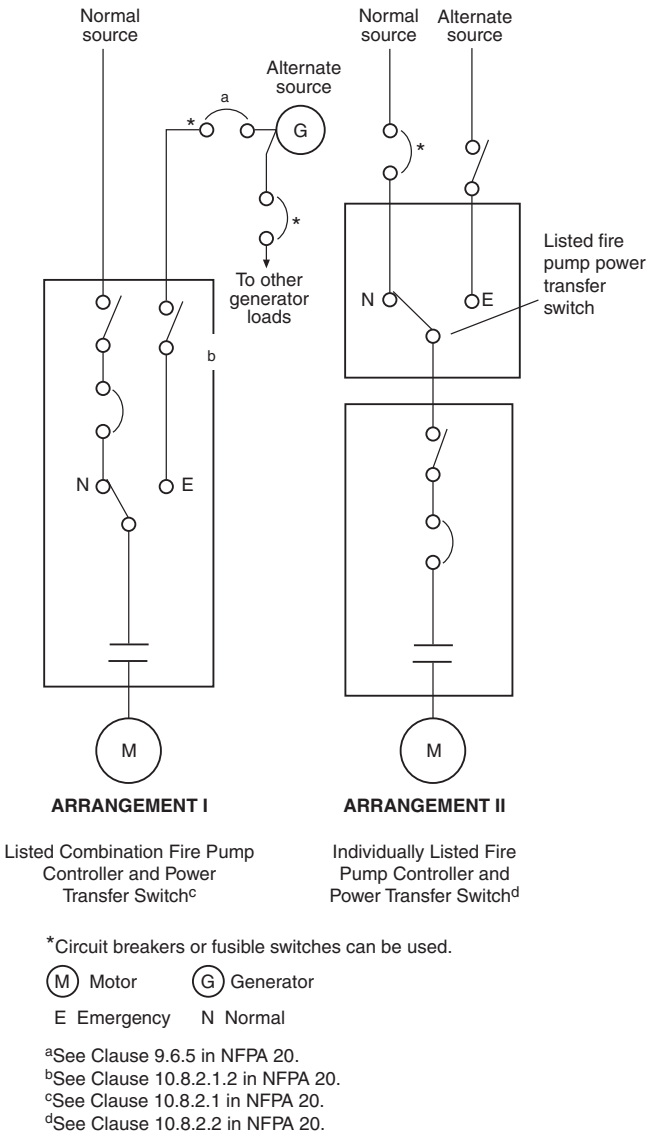

FIGURE 15.7.7 Two Acceptable Arrangements for Two Power Sources Feeding a Single Fire Pump Motor (Source: NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection,* Figure A.10.8, 2007, p. 20-75)

Physical Protection of Supply Conductors

In general, conductors feeding fire pumps and their accessories must be protected to resist possible damage by fire, structural failure, or operational accident.

Supply Conductors. These are physically routed outside buildings and installed as service-entrance conductors in accordance

with NFPA 70. If supply conductors cannot be physically routed outside buildings, they can be routed through buildings if installed under not less than 2 in. (50 mm) of concrete beneath the building, or if installed within a building in a raceway that is encased in concrete or brick not less than 2 in. (50 mm) thick. For a feeder arrangement, the requirement for protecting service conductors applies to all supply conductors on the load side of the service disconnecting means that constitute the normal source of supply to that fire pump. However, where there are multiple sources of supply with means for automatic connection from one source to the other, the requirement only applies to those conductors on the load side of the point of automatic connection between sources.

Circuit Conductors. These are on the load side of the final disconnecting means and overcurrent protective devices permitted for a supervised connection and must be kept entirely independent of all other wiring. The conductors are to supply only loads that are directly associated with the fire pump system, and they are to be protected to resist potential damage by fire, structural failure, or operational accident. They are permitted to be routed through buildings if encased in 2 in. (50 mm) of concrete, or within enclosed construction dedicated to the fire pump circuit(s) and having a minimum 2 hour fire resistance rating, or be listed electrical circuit protective systems with a minimum of 2 hour fire resistance. The 2008 *NEC* increased the fire resistance ratings from 1 to 2 hours to be consistent with *NFPA 72®, National Fire Alarm Code®,* which requires 2 hour survivability of the notification circuits and the interconnecting wiring of the fire command center.

Wiring. The installation must comply with any restriction provided in the listing of the electrical circuit protective systems used. The supply conductors located in the electrical equipment room where they originate and in the fire pump room are not required to have the minimum 2 hour fire separation or fire resistance rating, unless otherwise required by NFPA 70.

All wiring from the controllers to the pump motors needs to be rigid metal conduit, intermediate metal conduit, liquidtight flexible metal conduit, or liquid-tight flexible nonmetallic conduit Type LFNC-B or Type MI cable. Where wire connectors are used in the fire pump circuit, the connectors must also be listed. All wiring from engine controllers and batteries must be protected against mechanical injury and must be installed in accordance with the controller and engine manufacturer's instructions. See the section on motor wiring in *Pumps for Fire Protection* for more information in this regard.

The 2007 edition of NFPA 20 added a requirement addressing the use of single conductors entering the fire pump controller enclosure. The requirements addressed two concerns. Single conductors entering the fire pump controller enclosure separately could produce significant heating of the metallic enclosure due to magnetic forces. Also, certain electrical circuit protective systems could produce flammable gases that must be prevented from entering the fire pump controller enclosure. The new requirement states: "Where single conductors are used, they shall be terminated in a separate junction box" (not the fire pump controller). This permits splicing to a different wiring method that allows for all phase conductors to enter the controller through the same raceway. It also allows for the sealing of cables outside of the fire pump controller enclosure to keep flammable gases at a safe distance from the controller enclosure.

Fire Pump and Fire Pump Controller Power Transfer Switch. Although not directly pertaining to the protection of conductors, the fire pump controller and fire pump power transfer switch are not to be used as a junction box to supply other electrical equipment, including the pressure maintenance pump. Additionally, the fire pump controller and fire pump power transfer switch cannot serve any loads other than the fire pump for which it is intended. In this regard, a fire pump controller cannot serve more than one fire pump.

Buried Installation. A completely underground circuit from the service point or the private power station to the pump room is strongly recommended and should be arranged where practicable. This guideline also pertains to feeder conductors. Where such buried installation is not possible, that portion of the overhead circuit adjacent to the property served by the fire pump or to exposing properties or structures should be installed with consideration to potential damage in case of fire or other hazard. Where the pump room is part of, or in close proximity to, the property or structures that the pump is intended to protect, the conductors should be underground for some distance from the pump room.

The physical protection of the supply conductors provides a means of minimizing the impact from external exposures as well as minimizing the spread of fire as a result of overcurrent within the conductors themselves. During fire conditions, conductors from the service point or private power station are susceptible to direct impact and failure from collapsing buildings and other structural members on the facility as well as failure from direct impact by the fire. Where ignition is a result of overcurrent in the fire pump power supply conductors, the general construction arrangement described previously also serves to minimize the spread of fire.

Junction Boxes. The 2007 edition of NFPA 20 added requirements addressing the use of junction boxes for routing conductors to or from a fire pump controller. As previously mentioned, where single conductors are used to provide power to a fire pump controller, they must be terminated in a separate junction box. In addition, junction boxes are often used to terminate cables and change to some other form of wiring to the fire pump controller. The new requirements state that:

1. The mounting and installing of a junction box shall not violate the enclosure Type (NEMA) rating of the fire pump controller(s).
2. The mounting and installing of a junction box shall not violate the integrity of the fire pump controller(s) and shall not affect the Short Circuit Rating of the controller(s).
3. At a minimum, a (NEMA) Type 2, dripproof enclosure (junction box) shall be used and the enclosure shall be listed to match the fire pump controller enclosure Type rating.
4. Terminals, junction blocks, splices, and the like, when used, shall be listed.

Voltage Drop and Conductor Sizing

The voltage at the controller line terminal must not drop more than 15 percent below normal (controller-rated voltage) under motor-starting conditions. The voltage at the motor terminal must not drop more than 5 percent below the voltage rating of the motor when the motor is operating at 115 percent of the full-load current rating of the motor. (See the section on controllers for discussion of starting of motors.) This limitation does not apply for emergency-run mechanical starting, which may experience larger inrush currents.

Conductors supplying a fire pump motor(s), pressure maintenance pumps, and associated fire pump accessory equipment will have a minimum rating of 125 percent of the sum of the fire pump motor(s) and pressure maintenance motor(s) full-load currents and 100 percent of the associated fire pump accessory equipment. Conductors supplying only a fire pump motor(s) will have a minimum rating of 125 percent of the fire pump motor(s) full-load current(s).

Arrangements for an On-Site Standby Generator

An on-site generator used to supply backup power to fire pump motors needs to be of sufficient capacity to allow normal starting and running of the motor(s) driving the fire pump(s) while supplying all other simultaneously operated load(s). Generally, the generator does not need to be sized for locked rotor current if locked rotor current is not required for normal starting, such as for part winding and autotransformer starting. Where protective devices are installed in the on-site power source circuits at the generator, such devices need to be set to allow instantaneous pickup of the full pump room load. Additionally, a tap ahead of the on-site generator disconnecting means is not required as is for the connection of other power sources.

On-site standby generators are to comply with the voltage drop requirements previously discussed and are to meet the requirements of Level 1, Type 10, Class X systems of NFPA 110. The fuel capacity is to be sufficient to provide 8 hours of fire pump operation at 100 percent of the rated pump capacity in addition to the supply required for other demands. Where the generator is installed to supply power to loads in addition to one or more fire pump drivers, the fuel supply should be sized to provide adequate fuel for all connected loads for the desired duration. These connected loads can include such loads as emergency lighting, exit signage, and elevators.

Where more than one fire pump and motor are used, such as for high-rise buildings, automatic sequencing of the starting of the fire pumps is both permitted and required, as described in the following section on controllers. Starting all pumps simultaneously is not desirable from a pump performance standpoint. Additionally, this would create tremendous inrush currents and a higher voltage drop as more than one motor attempts to start.

ELECTRIC DRIVE CONTROLLERS

Controllers are devices that govern, in some predetermined manner, the starting and stopping of the fire pump driver as well as the monitoring and signaling of the starters and the condition of the fire pump unit (Figure 15.7.8). This section describes attributes of the different types of electric drive controllers and provides a broad perspective on the use of various types of controllers.

Fire Pump Controller Characteristics

Because of their intended function, fire pump controllers possess unique characteristics when compared to controllers for other types of applications. The most obvious is the limited protection of the fire pump motor and the motor circuit and components. The power path components of the controller, like the fire pump motor and power wiring circuits, are considered sacrificial. (Note that fire pump equipment is considered sacrificial because safeguards associated with other building equipment to preserve equipment do not apply. Fire-fighting operations must continue until the fire is extinguished even if the fire-fighting equipment is eventually damaged.) Controllers do not include motor overload relays and the only overload, overcurrent, or short circuit protection for the controller, motor, and wiring is provided by the fire pump controller circuit breaker. Note that the requirements differ for limited-service fire pump controllers, which use a different type of circuit breaker, and for medium-voltage controllers, which use special fuses and overcurrent sensing. Nonetheless, these controllers also sacrifice the fire pump motor and wiring similar to all other fire pump controllers.

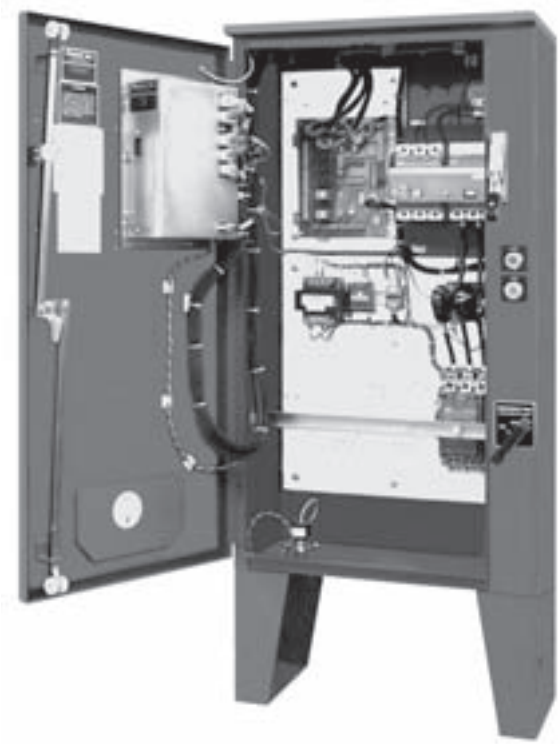

FIGURE 15.7.8 Electric Fire Pump Controller (Source: ASCO Power Technologies, Firetrol Brand Products)

Motor Overheating. The fire pump circuit breaker is not allowed to trip on currents less than 300 percent of FLA (full-load amperes), which is seven times the motor-rated heating compared with that at rated FLA. Running the motor at these high currents will overheat the motor's windings, which will damage or destroy the motor, the controller, and/or the power wiring in a fairly short time. Although not a desirable condition, operating the motor at these high currents is permissible so that fire-fighting operations can continue. This is the reason the motor, controller, and wiring are considered to be sacrificial. Nonetheless, this equipment must be protected from needless damage, stress, or destruction. It is, therefore, recommended that the motor current be monitored for overload (overcurrent) conditions. All listed controllers are available with an optional motor overcurrent alarm circuit.

Ground Fault Monitoring. Another unique characteristic is that ground fault protection is prohibited. However, ground fault monitoring is allowed. The same applies for low voltage, phase loss, phase reversal, underfrequency, and so on. Monitoring is allowed or mandated for some of these conditions, but the controller must keep the fire pump motor running under any of these conditions. The only exception is allowing the controller to protect the motor from attempting to start under a single-phase condition that would destroy the motor. In this condition it is better to protect the motor, as there is no opportunity to start a three-phase motor at rest when supplied with a single-phase power source.

Critical Path Control Circuitry. Another peculiarity of fire pump controllers is the sacrificial nature of the critical path control circuitry. The critical path or critical starting path encompasses every component and connection needed for successful starting of a fire pump. NFPA 20 mandates that the control circuitry within the controller not be protected by fuses or circuit breakers other than the controller's main motor circuit breaker.

Critical Electrical Parameters

Among other things, three electrical parameters are absolutely crucial to the successful starting and running of any fire pump motor: (1) the starting (locked rotor) voltage drop at the controller (15% maximum drop allowed), (2) the service factor (115% maximum) load current voltage drop at the motor (5% maximum allowed), and (3) the ability to start the motor without any false tripping of the fire pump breaker (in the fire pump controller) or any upstream overcurrent protection (fuses or circuit breaker). The voltage drop considerations are covered in more detail in the section on power supplies.

LIMITED-SERVICE CONTROLLERS

Fire pumps and their associated fire pump controllers come in two service types: full service and limited service. Limited-service fire pumps and controllers were introduced in the late 1940s in response to a major insurance organization request for simpler, less expensive controllers for use on smaller risks. One way of helping to assure that these units would be restricted to use on smaller risks was to impose the 30 horsepower (22 kW) maximum size limitation. The controllers are allowed to use the common "inverse time" nonadjustable circuit breaker rather than the special characteristic fire pump circuit breaker as required in full-service controllers. Typical listed limited-service controllers use thermal-magnetic-type circuit breakers. A further cost savings is accomplished by not requiring the separate isolating switch as is required in full-service controllers. In accordance with NFPA 20, these controllers are allowed only where such use is acceptable to the AHJ. Each such installation must be so approved.

Limited-service controllers must meet all of the requirements of full-service controllers with the two exceptions noted previously. By not requiring a full-service fire pump controller, the following characteristics of overcurrent protection are *not* required and are not normally found in these units: (1) they need not hold 300 percent continuously, (2) they need not meet the trip time requirements of 8 to 20 seconds at locked rotor current, and (3) they need not be adjustable. Moreover, the inverse time circuit breaker is required to be between 150 percent and 250 percent of the motor full-load current. This provides a wide range of motor locked rotor trip times. Based on commercially available and commonly used circuit breakers, the trip times can be far less than the minimum 8 second trip time and well over the 20 second maximum time required of full-service controllers. This is due to the difference in circuit breaker trip curves among different ratings, types, and manufactures of thermal-type circuit breakers and due to the motor rated full load current versus the breaker rated current.

Single-Phase Limited-Service Controllers

NFPA 20 states that limited-service controllers can be used for across-the-line starting of squirrel-cage motors of 30 horsepower or less. In some cases the motor horsepower is small enough to allow the use of single-phase motors and controllers when the use of same is approved by the AHJ. Listed controllers are available for those cases where a single-phase pump motor is adequate and where the source of supply will tolerate the starting and running currents while still meeting the voltage drop requirements of 15 percent maximum while starting and 5 percent maximum while running at 115 percent of motor full-load amperes (FLA).

Three-Phase Limited-Service Controllers

Most limited-service controllers and motors are three-phase types. The advantage of three-phase units is lower line currents for any given horsepower at a given voltage. More importantly, three-phase squirrel-cage motors are inherently more reliable than single-phase versions. This is because a single-phase motor contains a start winding in addition to the run winding and also contains a start winding cutout switch or relay to accelerate the motor. These extra components serve to reduce reliability over the simpler three-phase motors that contain none of these extra items.

Means of Starting Limited-Service Controllers

All limited-service controllers are required to be across-the-line, full-voltage, starting types only. This requirement further limits their complexity and, thus, costs. The maximum allowed horsepower limitation of 30 hp (22 kW) also limits the size of the power path components. The circuit breaker is either of the so-called E frame or F frame size. The contactors are similarly limited in size.

FULL-SERVICE CONTROLLERS

All fire pump controllers, with the exception of limited-service controllers, are known as full-service controllers solely to differentiate them from the limited-service types. All full-service controllers must be three phase since regular fire pump motors must be three-phase motors. There are no listed single-phase full-service fire pump controllers.

Low Voltage (600 Vac Maximum)

The majority of fire pump motors and controllers are of the so-called low-voltage type, in electrical power utility terminology, meaning that they are used on power sources of 600 Vac or less. Typical low-voltage power source voltages range from 120 Vac at 60 Hz or 220 Vac at 50 Hz, single phase, and up to 600 Vac, three phase.

Medium Voltage (Up to 7200 Vac)

Some installations use medium-voltage motors and controllers for convenience because the facility already has this voltage available, for example, in large mills and process plants. Another example is multibuilding campus-style sites where the power distribution is at medium voltage. Medium-voltage controllers are also used to avoid the step-down transformer, which would otherwise be needed to reduce the voltage to the range of low-voltage (600 Vac or less) controllers and motors. This transformer also requires upstream disconnect and overcurrent protection. Lastly, medium-voltage controllers are being used more often because the "service" from the power utility is increasingly at medium voltage rather than at low voltage, as was nearly universal not too many years ago.

Medium-voltage fire pump controllers differ from low-voltage controllers by one significant item: the customary fire pump circuit breaker is replaced by three special "R"-rated, medium-voltage, current-limiting motor circuit fuses and a contactor tripping circuit. The tripping circuit has the same characteristics as the circuit breaker in low-voltage controllers, namely, the 300 percent no-trip and the 8- to 20-second trip time at locked rotor (600%). The motor contactor is used to break overload currents whereas the fuses break the higher short circuit currents. Matching the controller and motor horsepower or FLA is vital to prevent false tripping of the fuses, which take considerable time to replace. Note that the NFPA 20 standard does not require the controller to be equipped with spare fuses. It only requires that the controller have a "compartment or rack" within it for the fuses and that a "spare set of fuses be kept readily available" therein by someone.

Low-Voltage, Full-Service Controller Starting

The fire pump is generally required to be connected directly to the incoming service to minimize the chance of unintentional disconnection of the fire pump power supply during a fire. However, this often results in one of two opposite conditions. The first is that the service is of very high capacity and across-the-line starting can safely be used, particularly if emergency power or alternate standby power will not be needed for the pump. In these cases, the short circuit ratings are of utmost importance. The second case is where a dedicated step-down transformer is used for the fire pump. In this case, the size of the dedicated transformer can be reduced somewhat (but not all the way down to the thermal rating) by the use of reduced inrush starting.

Where emergency power is needed and supplied by an on-site generator, the fire pump(s) is often the largest load on the genset. In these cases, the extra cost of the reduced inrush starting fire pump controller, and sometimes of the special motor, is often justified by the savings in the size and cost of the genset. Nonetheless, all fire pumps, whether or not reduced inrush starting, must be capable of starting by the use of the emergency mechanical operator. This mechanical operator is the reason that the genset must be large enough to start the pump or pumps in the ATL (across-the-line) full-voltage starting mode while supplying all other simultaneously operated load(s). This can result in an increase in the size of the genset even though the 15 percent maximum starting current voltage drop under motor-starting conditions is waived for this method of starting. Table 15.7.2 summarizes the various types of starting methods.

Across-the-Line (ATL or Direct-on-Line) Starting

Across-the-line starting mode is the simplest and most common form of fire pump motor starting. ATL starting is also the least expensive, making it the logical choice where the electrical supply or supplies are adequate for the high- inrush (600%) currents that are incurred by this method. This method also produces the highest starting torque, namely, the motor's full-rated starting torque, ignoring any voltage drop. Both NFPA 20 and the *NEC* require that the voltage drop during starting must not exceed 15 percent of the controller's rated voltage at the controller inlet (line) terminals. It is important to note that this requirement applies to any and all sources feeding the controller. With combination transfer switch fire pump controller units, this requirement applies to both of the two input source line terminals and requires a fairly "stiff" power source. Long power wiring runs will cause additional voltage drop, requiring less voltage drop from the source, and must be taken into account to ensure that the voltage drop during pump starting does not exceed the 15 percent limit. This also applies to a genset or to a transformer used to supply a fire pump.

The reason for the maximum drop of 15 percent during starting is based on the fire pump controller contactor and control circuit operating voltages. These components typically have a specified operating voltage of 85 percent of rated nominal voltage. An unloaded power line will usually be at or above the rated voltage. However, as soon as the motor contactor closes, the

Note: Refer to section on reduced voltage starting for details.
[a]The three- and four-step methods are basically two steps (accelerate and run) with the third and fourth steps being transition steps.
[b]Also called ATL or *direct-on-line.* Motor power factor taken as 40%. Other values shown are due to the effects of the controller.
[c]Part-winding parameters vary with the motor. Starting amps and KVA vary from around 60% to 70%; starting torque from around 45% to 50%. The motor can start a fully loaded pump if it has no large torque dip or cusp. See the text discussion on part-winding starting for details.
[d]Part-winding motors must be wound specifically for this service. Some motors may not accelerate to full speed in the starting mode. See Note (c).
[e]Figures are for tap set at 65%, which yields a motor voltage of 65% of line (main) voltage.
[f]The dual figures are for starting and transition. The transition values are to finish accelerating a fully loaded pump. Examples include deluge or open systems, restarting a fully loaded pump after a power failure or interruption, and failure of another pump feeding the same system.
[g]Ignores the momentary transition resistor loads.
[h]Varies with pump load and particular soft starter used. Values shown are for a fully loaded pump and are typical only.
[i]The 46% starting amps and KVA figures include the autotransformer exciting current.

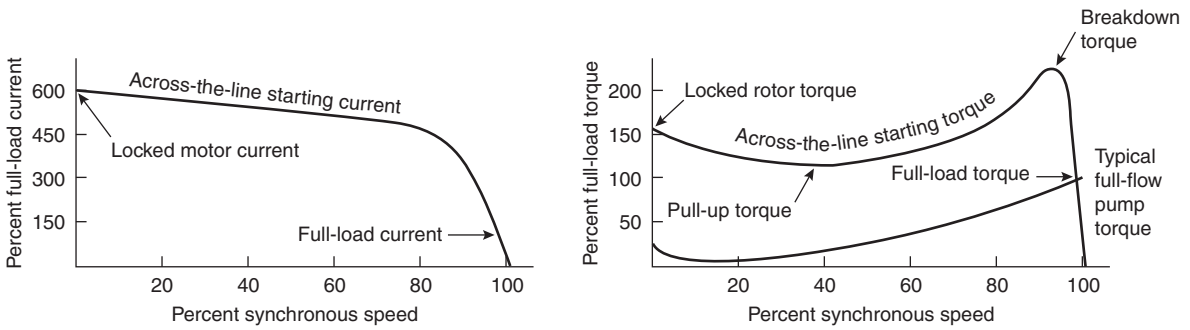
motor locked rotor impedance is applied to the power source, which will always cause some amount of voltage drop. If this voltage drop exceeds the maximum allowed 15 percent value, the motor contactor or other control components may not have enough voltage to remain closed and may cause disconnection of the motor, which will cause highly destructive rapid cycling (chattering) of the motor contactor and will cause the controller breaker to trip and/or damage or destroy the contactor(s) and/or the motor or pump coupling.

Given adequate voltage, the ATL motor torque will be more than adequate to start a fully loaded fire pump under any conditions of ultimate pressure and flow that comply with NFPA 20. NFPA 20 requires that the motor current in any phase not exceed 115 percent of FLA under *any* condition of pump load or voltage imbalance. This requirement determines the minimum size motor (horsepower) needed for a given pump. When this motor size requirement is met and given that the line voltage is 85 percent or more of rated voltage during starting (no more than a 15% drop), the motor torque will easily be able to accelerate the pump to full rated speed, regardless of the pump hydraulic load. Figure 15.7.9 illustrates the voltage curve for ATL starting versus the pump curve.

The first torque shown on the curve in Figure 15.7.9 is the locked rotor torque, also known as the motor's stall torque. This is the amount of torque that the motor will deliver to "break away" a frozen, stiff, or stuck pump. The second torque shown is the so-called pull-up torque. This is the minimum motor torque in the acceleration (starting) region. The torque curve from this point increases, as does the pump torque requirements. The motor torque, however, is always greater than the required pump torque by a wide margin, about twice what is needed. The third torque shown is the so-called breakdown torque, which is the border between the motor's starting torque region and its running torque region. The final torque shown is the full-flow pump torque, which must be less than the motor's rated full-load (plus service factor) torque. When this condition is not met, the motor current will likely exceed the maximum allowed 115 percent FLA current and the motor will likely overheat. Finally, it is important to note that the motor's starting torque (i.e., all three previously named torques) is proportional to the square of the voltage applied to the motor during starting.

Reduced Voltage Starting

All reduced inrush starting types are of the reduced voltage type, the reduced current type, or both. However, the reduced voltage types also reduce the motor's starting current, since in the starting region, the motor's current draw is proportional to the voltage applied to it. This relationship is the opposite of the case



(a) Starting current vs. motor speed for ATL starting

(b) Motor starting torque and pump torque curves for ATL starting

FIGURE 15.7.9 ATL Motor Starting Characteristics for a Typical 75 hp, 4 pole, Nema B, Code G Motor: (a) Starting Current vs. Motor Speed for ATL Starting, and (b) Motor Starting Torque and Pump Torque Curves

in the motor's running region, where the motor draws more current when given less voltage in order to draw enough electrical power to produce the required mechanical power.

The comments regarding voltage drop are just as important for reduced controllers as they are for across-the-line controllers, if not more so. All reduced voltage controllers have more contactors and control components than do ATL controllers, so they are more prone to the relay dropout and contactor chattering problems. An additional, and more likely, mode of failure exists, whereby the accelerate timer may not time out or operate, which then leaves the controller and motor in the accelerate mode indefinitely. This will cause motor overheating, depending on the motor (pump) load, which will ultimately lead to motor burnout followed by tripping of the controller circuit breaker, usually after the motor has been damaged or destroyed. The controller will likely also suffer varying degrees of damage, depending on its type and other factors.

The usual purpose of reduced inrush type of controllers is to reduce the starting current, which makes it easier to meet the 15 percent maximum allowed starting current voltage drop. Another reason that they are often used is to reduce the required size of an alternate (backup) source genset needed to meet the voltage drop requirements. Reduced inrush controllers are sometimes also used, especially soft start type controllers, to reduce the hydraulic surge on pump starting and/or to reduce the water hammer that can occur on pump shutdown when the pump check valve closes. Even so, these systems must still be able to start the motor in the full-voltage ATL mode, using the emergency mechanical operator, which is required of *every* fire pump controller type, without causing any blown fuses (where used) or any tripped circuit breakers, either upstream of the controller (if used) or the controller's circuit breaker. In either case, the sizing requirement for upstream circuit protection, where used, remains the same, namely, that any upstream protection must meet the NFPA 20 (and *NEC*) requirements for holding (carrying), indefinitely, the sum of the fire pump(s) locked rotor current(s) plus all other connected loads, except for the alternate (emergency) source side, if used.

Part Winding Starting. This method of starting requires motors to have two windings operating in parallel for running *and* to be manufactured and labeled as suitable for part winding. As a result, the applications for this starting type are somewhat limited, especially at the higher voltages, which often need the motor windings connected in series rather than in parallel for running.

Part winding starting is a reduced current type of starting because only half of the motor's windings are energized during starting, which nearly doubles the motor load impedance and nearly halves the motor current. Due to magnetic effects, the actual starting current is about 65 percent of the rated locked rotor current, which yields a starting current of around 390 percent of FLA. The stall torque is close to 50 percent of nominal because full voltage is delivered to one-half of the motor's windings. However, there does exist a "cusp," or torque dip, during acceleration, usually at one-half of the rated speed of the motor.

At the end of the acceleration period, which is limited to 10 seconds, the second motor contactor closes to energize the second set of motor windings, which then supplies the motor with its full running power, making this starting type a "two-step" starting means. It is also of the closed transition type because power is never interrupted or disconnected from the motor starting windings. This starting method has the same power factor as the motor itself during acceleration of around 40 percent (0.40 power factor) as it does not add to or change the motor's impedance other than using only half of the motor windings. Thus, this method is usable for starting from a genset for dual-source installations, but it is not the best method. Other methods have lower starting power (kilowatt) demands.

Primary Resistor Starting. Primary resistor starting has long been used to reduce the starting (inrush) current of fire pump controllers. It is a reduced voltage starting method because three resistors, or sets of resistors, are inserted in series with the motor during the starting (accelerating) period. The usual value used is 65 percent, which is the voltage supplied to the motor (at stall). The other 35 percent of the voltage is dropped vectorially across the three resistors, which are in each of the incoming lines. The motor torque follows the square of the voltage law, yielding a stall torque around 42 percent of rated stall torque. Meanwhile, the starting current is reduced to 65 percent of locked rotor amperes (LRA) or around 390 percent of FLA. At the end of the

acceleration period, the main motor contactor bypasses the resistors to apply full-line voltage to the motor, which makes this starting type a two-step starting means. It is also of the closed transition type because power is never interrupted or disconnected from the motor. This starting method can be used with any fire pump motor, including three-lead motors. This starting method changes the starting power factor to a higher value than the motor's own power factor because the resistors represent a unity (100%) power factor load. All other starting methods have a lower starting power (kilowatt) demand.

For economic reasons, the resistors need to provide only a 5 second acceleration period. As a result, this is the only reduced starting type limited to less than the otherwise maximum allowed 10 second acceleration period. Normal controller construction includes venting the cabinet that houses the resistors due to the large amount of heat generated during starting (around 130 kW for a 100 horsepower motor).

Primary Reactor Starting. Primary reactor starting has also long been used to reduce the starting (inrush) current of fire pump controllers. It is a reduced voltage starting method because a saturable reactor is inserted in series with the motor during the starting (accelerating) period. The reactors have multiple voltage taps, but the usual value used is 65 percent, which is the voltage supplied to the motor (at stall) with the other 35 percent of the voltage being vectorially dropped across the reactor coils. The result is a stall torque around 42 percent of rated stall torque. Meanwhile, the starting current is reduced to 65 percent of LRA or around 390 percent of FLA. On the 65 percent tap with 42 percent of the motor torque available for starting, the motor will normally accelerate a pump even if it is fully loaded. This is particularly true because the accelerate timer can be set for the full allowed maximum time of 10 seconds, as the reactors must be capable of 15 seconds of accelerate time, which also makes this method a very robust reduced inrush starting method.

At the end of the acceleration period, the main motor contactor bypasses the starting reactor coils to apply full-line voltage to the motor making this starting type a two-step starting means. It is also of the closed transition type because power is never interrupted or disconnected from the motor. This starting method can be used with any motor, including three-lead motors.

The reactor has a very low power factor (less than 5%) and, therefore, has very little heat dissipation. As a result, no venting is required for these controllers, and so any cabinet construction type can be had. This low power factor leads to a combined value lower than the motor's own power factor. As a result, the size (horsepower and kilowatts) of the genset can be basically the same for either reactor or autotransformer starting.

Wye-Delta (Star-Delta)—Open Transition Starting. Like part winding starting, wye-delta (also known as star-delta) starting changes the motor windings to affect the reduced inrush starting. A detailed description of the characteristics of these motors appears in the book *Pumps for Fire Protection Systems.* These motors must be of the so-called delta run type, meaning that the windings are meant to be connected in delta (end to end) while running. Both ends of each winding coil must be brought out to the motor junction box for external connection to allow the windings to be connected in the wye (star) configuration for starting.

Although wye-delta starting gives the largest current reduction, it also produces the least starting torque. The starting torque follows the square law for the coils, which have only 58 percent of their rated current, and so the motor delivers only 33 percent of rated starting torque. Although useful for unloaded motors, such as unloaded chiller compressors, or loads that are small compared to the motor horsepower, this starting method will *not* accelerate a loaded centrifugal pump up to speed if the pump horsepower demand is anywhere close to the motor's rated horsepower. It often will not have enough torque to accelerate a pump at shutoff (churn), especially with high-speed pumps, which typically have a higher churn horsepower load. If the motor is not up to speed during the acceleration period, the motor will have to finish accelerating the load (pump) after the acceleration period when it is in the full-voltage (delta) configuration. Unfortunately, this situation will also result in normal starting currents of near locked rotor (LRA) until the pump (motor) is up to speed. The resulting characteristic is sometimes called delayed across-the-line starting.

As the voltage applied to the windings is less than normal rated voltage, the wye-delta method of starting is of the reduced voltage type, although the voltage reduction takes place entirely within the motor. In operation, the controller uses three motor contactors, typically designated as M1, M2, and Y. Initially contactors M1 and Y close to connect the motor coils in the wye configuration for acceleration. At the end of the acceleration period the controller opens the wye contactor. As one end of each winding is now open, the motor is deenergized at this point and loses some of its speed. After some delay, the second main motor contactor (M2) connects these open ends of the motor windings to the respective incoming lines. This is the full-voltage, delta-configuration running mode. This delay is anywhere from a few milliseconds up to a full second, depending on the controller design. Any delay longer than the minimum of a few milliseconds will result in motor deceleration and high starting (accelerating) currents when the motor is reenergized at full voltage in the delta running configuration.

This method, therefore, is a three-step starting method. Because the motor windings are deenergized for at least some period of time, this is also known as an open transition starting means, referring to the conditions of the windings (open circuited) prior to the instant of reconnection to full-line voltage.

In addition to possibly incurring full ATL starting currents, there may also be a brief, but very high, current spike at the instant of transition to full voltage due to the open transition method of switching the motor windings. This spike occurs when the motor magnetic vector phase angle differs from that of the line (mains) voltage when the M2 contactor closes. The greater the phase angle difference, the greater will be the current spike, which can be up to 18 times FLA (1800%). The magnitude of the transient will be higher on larger or stiffer power sources. This spike can cause undesired tripping of the circuit breaker when it occurs. This current spike is worse if the motor does reach full speed during the acceleration period,

because the back electromotive force (EMF) (generated voltage) is a function of the motor speed—hence, the conundrum. If the motor does not reach full speed, it will draw ATL starting currents, after the transition, for as long as it takes the motor to reach full speed. In the opposite case where the motor does reach full speed, the motor's back EMF can cause large transition spikes and cause unintended circuit breaker tripping sooner or later.

Three methods have been used to mitigate this current spike condition. The first is to turn down the accelerate timer to a short interval (a few seconds or less) so that the motor does not have time to come up to full speed. The second method is to add a delay to the transition period to allow the motor magnetic field and, hence, its back EMF to decay. Although these measures will reduce the spike, they will also allow the motor to lose much of its speed. The results are full ATL starting currents and no benefit from reduced inrush starting. Either of these methods amounts to a delayed ATL starting of the motor.

The third method is to make the transition rapidly and also control the direction of the winding vector angle change. The idea is to have the vector angle fall back rather than jump ahead and, thus, serve to cancel the effect of the motor slowdown phase angle shift. This requires the use of a controller with a built-in leading phase monitor and means for changing the closing (transition) phase angle from lagging to leading.

Like ATL and part winding starting, this method has the same power factor as does the motor during acceleration, that is, around 40 percent (0.40 power factor) because it only changes the voltage applied to the motor windings. This method is of only limited use for starting from a genset for dual-source installations because the motor will not likely be up to speed during the acceleration period. As a result, the genset will necessarily have to attempt to produce across-the-line starting currents for at least some amount of time.

Wye-Delta (Star-Delta)—Closed Transition Starting. Closed transition wye-delta (star-delta) starting has the same starting characteristics as the open transition wye-delta starting method. The main difference between closed transition and open transition wye-delta starting is the reduction of the transition transient (spike) current. The starting current is the same, and the starting torque is the same (33%) for either open or closed transition wye-delta starting. This, again, is not enough torque to fully accelerate most loaded pumps.

During acceleration, this method is the same as the open transition starting method and is, therefore, also of the reduced voltage type. In operation, the controller uses four rather than three motor contactors. Initially, the motor windings are connected together in wye as with the open transition starting. At the end of the acceleration period, a transition (S) contactor closes to connect one end of each of three transition resistors to the line power, which briefly puts the three resistors in wye in parallel with the motor windings. A short time later, the Y contactor opens, which places the motor windings in series with the resistors. The resistors allow the line voltage to pull the motor magnetic vector to that of the line voltage phase angle or close to it. At the end of this time, the second main motor contactor (M2) short circuits the resistors and, thus, connects the ends of the motor windings to the respective incoming lines, which is the full-voltage, delta running mode.

As a result, this method is four-step starting. The motor windings are never deenergized at any time, making a closed transition starting means. As with the open transition starting, if the motor has not reached full speed during the acceleration period, the motor will finish accelerating in the across-the-line (full-voltage) mode with resulting ATL starting currents for the duration of the acceleration period. It also has the same starting power factor as the open transition starting; that is, around 40 percent (0.40 power factor) or the same as the motor itself.

This method also has the same limitations as open delta when used with a genset for dual source installations. As the motor may not be up to speed, the genset will have to attempt to produce ATL starting currents for some period of time. If the genset is not sized to produce these starting currents, the resulting voltage drop may cause contactor chattering and ultimately controller and/or motor damage or destruction.

Soft Start (SCR) Starting. Soft start starting is a newer method of motor starting. Basically, it varies the voltage fed to the motor over the acceleration period and, thus, affects the starting current and, therefore, the starting torque. The usual case is to start with a lower voltage and increase (ramp up) the voltage to the full-line voltage during the acceleration period. Because the acceleration period is limited by code to a maximum of 10 seconds, this period is usually selected for the voltage ramp-up time and, thus, the motor acceleration period. In addition to soft start starting, all listed fire pump controllers using this scheme also offer the so-called soft stop deceleration when the pump is no longer needed. Because the voltage to the motor is being controlled, this method of starting is the reduced voltage type.

Soft start starters are specified and used for one of two reasons, if not both: (1) for reduced inrush starting and (2) for hydraulic reasons, mainly to reduce pressure and/or flow surges during start-up, and/or to reduce the water hammer or hydraulic shock that can occur during pump shutdown when the pump check valve closes (slams shut).

The soft starter operates in a manner similar to a large variable transformer. The motor is usually started with around 30 to 40 percent of the rated voltage (the so-called ramp start voltage) and yields an initial starting torque of 9 to 16 percent, which assures no sudden acceleration. The voltage then ramps up, usually in a linear fashion. The motor torque still follows the square of the voltage law and, therefore, the motor torque builds up as the square of the applied voltage. After the voltage has reached 100 percent (or within 10 seconds), the main motor contactor closes to bypass the soft starter. This operation reduces the heat buildup in the controller that would occur if the soft starter continued to supply the motor running current. This starting method is a two-step starting type; however, the distinction is minor because the motor should already be at full voltage by the time the main motor contactor closes. Since the motor is at no time deenergized during or after the starting (accelerate) cycle, this starting method is of the closed transition starting type. This main motor contactor also provides for the required emergency mechanical starting of the fire pump motor. Some designs also employ an isolating (start) contactor to shield the

soft start starter from line voltage transients while in the standby mode. Some also employ a mode switch to allow the unit to work in an across-the-line mode for start-up (commissioning) or emergency automatic fire protection.

Because the voltage varies over time in a continuous fashion, both the motor torque and starting current draw also vary over time. One estimate gives an accelerate time of around 7 seconds for a fully loaded (full-flow) pump with a peak starting current of around 400 percent and an estimate of around 3 seconds and peak current of around 300 percent for an unloaded (no-flow) pump.

The soft stop shutdown cycle is basically the reverse of the starting cycle. To stop the pump, the controller first opens (deenergizes) the main motor contactor (M) with the soft starter SCRs set to 100 percent (full voltage). The soft starter then ramps the voltage down. Some designs incorporate a delay or pedestal dwell time as part of the stopping sequence. Designs employing an isolating (start) contactor open (deenergize) same at the end of the ramp-down time to isolate the soft starter from line transients.

Because the motor voltage is both nonlinear and time variant, the circuit power factor is not constant. It remains inductive because the motor itself is inductive. The power factor is the same as that of the motor when the SCRs are fully on (full voltage to the motor), around 40 percent (0.40 power factor). The motor will "appear" more inductive at lower voltages due to the delayed conduction angle. When these starters are used with gensets, the gensets must be sized conservatively as the starting current cannot be easily determined without analyzing the motor, starter, and pump dynamics during starting under full pump load. In any case, the worst case size needed would be that needed for across-the-line starting.

Autotransformer Starting. Autotransformer starting has also long been used for reduced (inrush) starting of fire pump controllers. It too is a reduced voltage starting method. The transformer is of the autotransformer type, which is about half the size of a normal isolated winding-type transformer. The autotransformer has multiple voltage taps, but the usual value used is the 65 percent tap, which is the voltage supplied to the motor (at stall) and gives a stall torque of around 42 percent of the rated stall torque. Meanwhile, the starting current is reduced to around 46 percent of LRA or around 270 percent of FLA when the autotransformer exciting (saturation) current is accounted for.

During acceleration, a Y contactor connects the autotransformer low side terminals together, and a start contactor(s) connects the top of the autotransformer windings to line power. The motor connects directly to the autotransformer's voltage reduction taps. At the end of the acceleration period, the controller disconnects (opens) the autotransformer wye connection, which is the second step. During this brief step, the autotransformer acts as a saturable reactor (series impedance) similar to the primary reactor starting method. Finally, after a fraction of a second, the main motor contactor (M) short circuits the top of the transformer windings to apply full voltage to the motor, which makes this method a three-step starting means. This method is also of the closed transition type since power is never interrupted or disconnected from the motor. This starting method can be used with any motor including three-lead motors.

Like the saturable reactor, the autotransformer is actually overdesigned because it too must be designed for 15 second acceleration periods to meet NFPA 20 requirements. As the maximum allowed acceleration period is only 10 seconds, this method is also a very robust reduced starting method and results in very low stress and temperature rise of components.

The autotransformer preserves the motor's 40 percent starting power factor during acceleration as it does not add to or change the motor's impedance but merely increases its magnitude to reduce the starting current. This characteristic makes it advantageous for starting from a genset for dual-source installations as it is least demanding of genset power and, therefore, size. Therefore, it is on a par with primary reactor starting on a power (kilowatt) size basis; however, it reduces the current further. This current reduction is an advantage when long power lines separate the genset from the fire pump or in remote areas or other areas where current reduction is as important or more important than starting power reduction. Like primary reactor starting, this method also has very little heat dissipation during starting. As a result, no venting is required for these controllers. Thus, one can have any cabinet construction type. Also, like the reactor case, multiple starting rarely causes the autotransformer to be more than slightly warm.

Medium- (High-) Voltage Full-Service Controller Starting

Across-the-Line (ATL or Direct-on-Line) Starting. This starting method is electrically the same as the low-voltage ATL starting method. The difference in controller construction relates to the fact that all currently listed medium-voltage fire pump controllers use vacuum contactors for the main motor contactor. Also, Class R motor circuit fuses are used in place of the fire pump circuit breaker used in low-voltage controllers. The motor locked rotor protection is provided by deenergizing the motor contactor instead of tripping the circuit breaker in low-voltage units. Further, additional safety interlocking is used due to the dangerous amount of electrical energy available. Some controllers use triple safety interlocking. First, the isolating switch is interlocked with the main contactor (M) in a two-way fashion so that the isolating switch may neither be opened nor closed while the contactor is closed. Second, the high-voltage door is interlocked with the isolating switch so that it cannot be opened if the isolating switch is closed. Third, the isolating switch cannot be closed if the high-voltage door is open. Some designs also interlock access to the incoming wiring (bus bar) compartment to the high-voltage door and also electrically interlock the control transformer(s) to allow for low-voltage testing of control circuitry. Another difference with medium-voltage controllers is that the interrupting and short circuit ratings are given in MVA (megavolt-amperes) rather than in symmetrical amperes.

Primary Reactor Starting. The primary reactor starting method has the same motor starting characteristics as the low-voltage counterpart. The controller construction differs slightly

in the way the two motor contactors are connected. The run contactor and the reactor are connected to the output of the main contactor to allow the full safety interlocking of the main contactor to provide full safety for the second (run) contactor, the reactor, and all other medium-voltage components and wiring. Because there are two contactors used to run the motor at full voltage, there are also two emergency mechanical manual operator handles, providing the added benefit of reduced inrush starting even when the manual operators are used. The main contactor operator is actuated first, and when the motor is up to speed or within 10 seconds, the second run contactor operator is actuated.

Neutral Reactor Starting. This method is a variation of the primary reactor starting method, except that the reactor is moved from the line (primary) side of the motor to the wye point (neutral) of the motor, which must be of the six-lead wye-wound type. The operation and characteristics are otherwise identical to those in the primary reactor starting method. The advantage of this method is that the reactor is not subjected to full-line voltage. This method is used for controllers rated above 5000 V.

Autotransformer. This starting method is also electrically comparable with its low-voltage counterpart. All electrical characteristics and type descriptions are the same as for the low-voltage equivalent with the previously stated differences for medium-voltage controllers.

VARIABLE SPEED ELECTRIC MOTOR–DRIVEN FIRE PUMPS

This section summarizes a significant change occurring in fire pump technology by outlining the availability, application, and installation of variable speed fire pumps (Figures 15.7.10 and 15.7.11) and controllers. More specifically, this section covers (1) the relevant changes to the fire pump standard, (2) the state of the art, including a brief history, (3) example installations, (4) the equipment involved including controller features and functions, (5) application needs, and (6) hydraulic considerations, particularly system time constants. This type of fire pump operation is new and requires both additional and innovative design and application considerations. As a result, certain sections are both detailed and exhaustive where needed to avoid incomplete information.

The section also describes how the 2007 edition of NFPA 20 affects variable speed fire pumps.

Update on NFPA 20

Although variable speed pumps have been used for a number of years in pumping applications such as process pumps and domestic booster pumps, the 2003 edition of NFPA 20 contains the first mention of variable speed fire pumps. That edition added both diesel engine–driven and electric motor–driven variable speed fire pumps. With the exception of wound rotor manually controlled fire pumps in New York City, variable speed fire pumps have not heretofore been used in stationary fire pump applications.

FIGURE 15.7.10 Closed Door View of Model ECV-250-46, 250 hp, Single-Source, Variable Speed Source Fire Pump Controller in NEMA 12 Enclosure with Air-to-Air Heat Exchanger (Source: Master Control Systems, Inc.)

Prior to the 2003 edition of NFPA 20, fire pumps were considered to be constant speed units. Although designed to run at a fixed speed under normal conditions, traditional diesel-driven fire pumps have always been considered variable speed drivers since the engine speed can exceed normal rated running speed should certain failures occur. The only pressure control allowed was the required pressure relief valves to prevent an overspeed occurrence from damaging the sprinkler system due to excessive pressure. As such, from a sprinkler design standpoint, diesel-driven pumps are considered to be constant speed systems.

The initial considerations of variable speed systems to *actively* control system pressures were incorporated into the 2003 edition of NFPA 20 and constituted the first recognition of variable speed fire pump systems, both diesel engine–driven and electric motor–driven fire pump systems. Another significant change in the 2003 edition of NFPA 20 in this regard is the prohibition of the use of main relief valves for "normal" system pressure control. They are only allowed for the purpose of preventing system damage during *abnormal* conditions. Both variable speed diesel drivers and electric motor drive variable speed controllers use active feedback control to regulate the pump discharge pressure. Active feedback control makes use of mechanical or electrical (electronic) means to compare the pump output pressure against a preset desired (set point) pressure and adjust the speed of the driver up or down as needed in order to

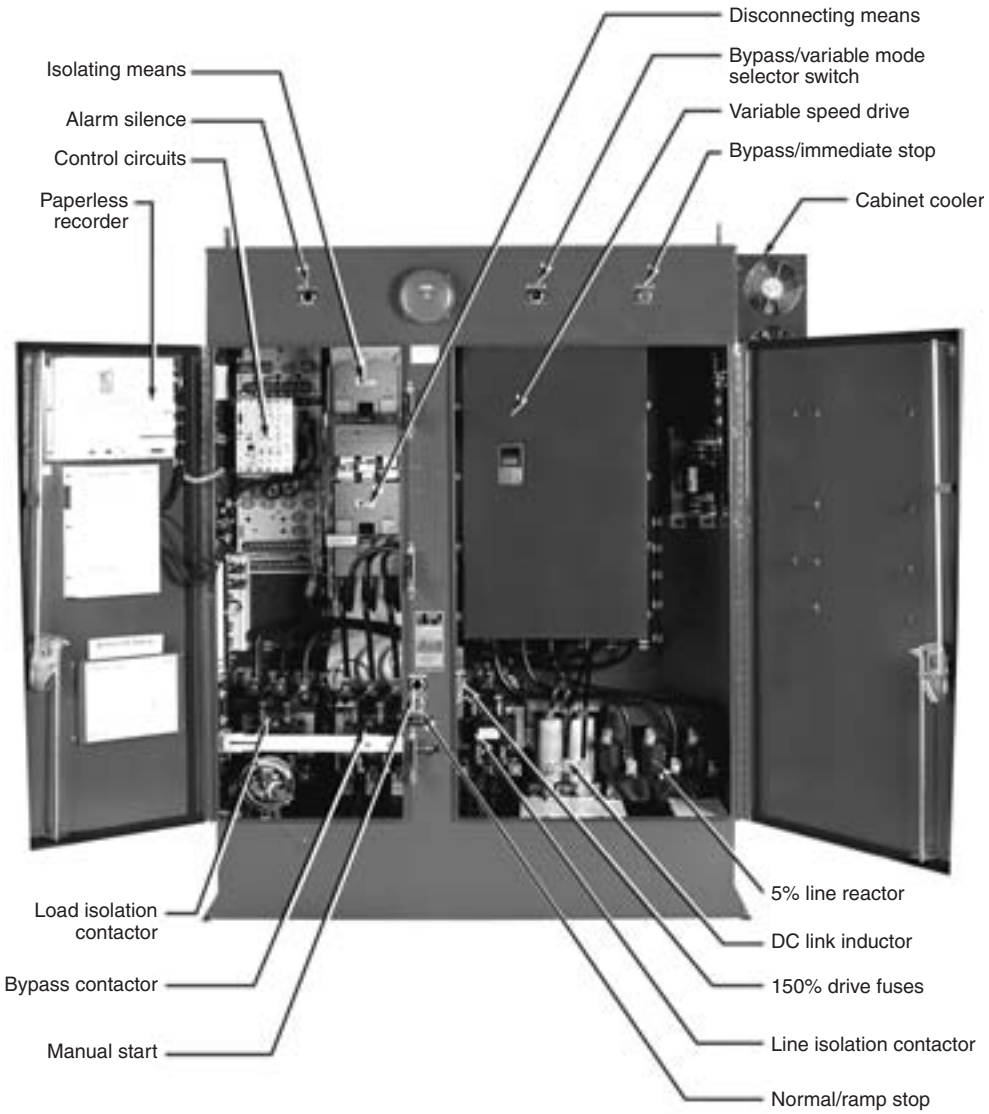


FIGURE 15.7.11 Open Door Flagged View of Model ECV-250-46, 250 hp Single-Source, Variable Speed Source Fire Pump Controller (Source: Master Control Systems, Inc.)

match the pump output pressure to the desired set point value. In operation, a difference value between the actual output pressure and the set point pressure is created and amplified and used to control the speed of the driver to minimize the magnitude of said error signal. Accordingly, they are able to limit system pressures to safe values or provide a source of closely regulated pressure or both. The feedback control scheme tends to maintain the pump output pressure close to the desired set point value and, thus, compensate for suction pressure variations, suction side friction losses, and pump curve variations over the full range of output flow (gpm) rates.

Finally, the 2007 edition of NFPA 20 established a significant body of requirements for variable speed motor drive fire pump controllers that is delineated next. Much of this work was done by two task groups, namely, an NFPA 20 Variable Speed task group and a NEMA Variable Speed Controller task group. The 2007 edition also establishes requirements for break tanks, which are another means of dealing with pressure variations in the suction supply.

State of the Art, Variable Speed Electric Motor–Driven Fire Pump Controllers

The first UL-listed variable speed electric drive fire pump controller was available in 2003. The balance of this section presents an overview description of the unit, a brief history of its application, and application examples.

Controller Overview. All compliant variable speed controllers consist of both a full-service fire pump controller and a separate variable speed controller section. There are two main operating modes for these controllers, namely, the variable speed mode

and the bypass mode. In the bypass mode, the unit operates as a fixed full-speed, full-service fire pump controller. These controllers may be either the single power source type or the dual power source combination transfer switch and fire pump controller type. The normal operating mode for these units is the variable speed mode. In this mode, the controller compares the system pressure to a previously set desired value, that is, the pressure set point, and adjusts the speed of the pump to produce the desired system pressure. Typical pressure regulation accuracy is better than one-tenth of 1 psi. For example, with a system set to 140 psi (9.6 bar), the variable speed controller will produce a pump output pressure within 0.1 psi of the desired 140 psi (9.6 bar) set point pressure over the full range of rated pump flow. The same is true whether the set point is 70 psi (4.8 bar), 175 psi (12 bar), or any pressure within the capability of the pump involved.

The bypass path is used for full-speed pump testing, commissioning, and servicing. It is also used on failure of the variable speed portion of the controller. The bypass mode can be manually selected by a manual mode switch, although the controller will automatically revert to the full-speed bypass mode should the variable speed portion either fail to operate or fail to meet system pressure requirements. The starting means in the bypass mode may be either full voltage or reduced voltage starting types. These are used to reduce the size of the genset required where emergency power is utilized. Reduced inrush starting controllers installed to date are either of the primary reactor or the soft start types. Since the bypass path constitutes a complete full-service fire pump controller, it includes an emergency mechanical operator. Since this feature connects the pump motor directly to the power source, its use always causes the pump to run at full speed.

In the variable speed mode, the controller makes use of a variable frequency drive (VFD) to control the voltage and frequency fed to the fire pump motor. In this way, the unit controls both the speed and torque of the motor. All units currently in service also incorporate both soft starting (ramp-up) and soft stopping (ramp-down) operation. In this mode of operation, the controller ramps up the motor (pump) speed to a preset idle speed, typically two-thirds of rated speed. At this speed, the pump pressure produced is around 44 percent of rated pressure boost since the pump pressure gain is related to the square of the pump rpm (revolutions per minute). At this low-boost pressure the pump normally does not produce any flow if the system is pressurized. If the system pressure is below the controller set point pressure, the controller will continue to accelerate the pump to the speed required to meet the set point pressure. If need be, the controller will accelerate the pump all the way up to full speed in order to cause the pump to produce the desired pressure. If and when the pump does achieve the desired set point pressure, the controller maintains the pump at that speed. If necessary, the controller will adjust the motor speed up or down in order to maintain the pressure at the desired set point value.

A main relief valve is required if the fire pump can exceed the system rated pressure when operating at full speed, at churn (shut off), and with the maximum anticipated suction pressure. This requirement is important since the pump will operate at full speed in the bypass mode, including the emergency mechanical operator mode of operation.

Application History. Designing fire sprinkler systems has become a challenge for a number of reasons, including the following:

1. Higher pressure demand at the top of high-rise buildings, typically 100 psi (6.9 bar) at the roof hydrants
2. Varying suction pressures, especially when dual water supplies are required (municipal and tank)
3. Need to limit maximum pressures to 175 psi (12 bar) component ratings to avoid the cost of higher pressure components
4. Need to limit pressure at certain types of sprinklers, such as large drop sprinklers, to avoid exceeding their operating ratings or degrading their performance
5. Requirement for backflow preventers in most systems
6. Various pressure drops that occur with large orifice sprinklers and increasing waterflow, including pump curve, suction piping friction loss, and discharge piping friction loss
7. Dual water supply requirements (tank and municipal) that are required in some jurisdictions

In the past, because of these design constraints, some designers and installers have made use of active pressure control means by the use of a so-called "main relief valve." However, these were prohibited with the 2003 edition of NFPA 20. The other hydraulic means sometimes used to control pressure are main or riser pressure regulating or pressure reducing valves (PRVs). The latter are different from those used to control the pressure of fire water on a given floor of a high-rise building, where allowed by local code. However, variable speed fire pumps or break tanks are now being used for the purpose of pressure control.

The first variable speed fire pumps were motor-driven units commissioned in spring 2004. They have since been used in numerous fire sprinkler systems and also in dual-use systems. Some examples of dedicated fire sprinkler system applications include (1) airport parking garages, (2) college housing midrise buildings that have been retrofitted with full sprinkler coverage, (3) a 1.8 million ft^2 (167,200 m^2) distribution center, (4) a municipal courthouse, (5) high-rise condominium buildings, and (6) a three-zone, high-rise commercial office building, among others. These particular units are all booster pumps taking suction from city water mains.

Dual-purpose applications in service include (1) combination domestic (potable) water and fire water pumps (four booster pumps) for a very large shopping center, (2) dual-purpose process water and fire water for a multibuilding commercial and residential complex where the process water is used for heat pumps for both cooling and heating, and (3) triple-purpose domestic water, fire water, and water tower fill pump with three distinct operating modes for a multibuilding medical housing complex.

Most of these units are combination transfer switch units, which are also reduced voltage starting in the bypass mode (Figure 15.7.12) since emergency power is from an on-site genset. A few units are single-source type but receive emergency power as part of the site power distribution. Units in service vary in size

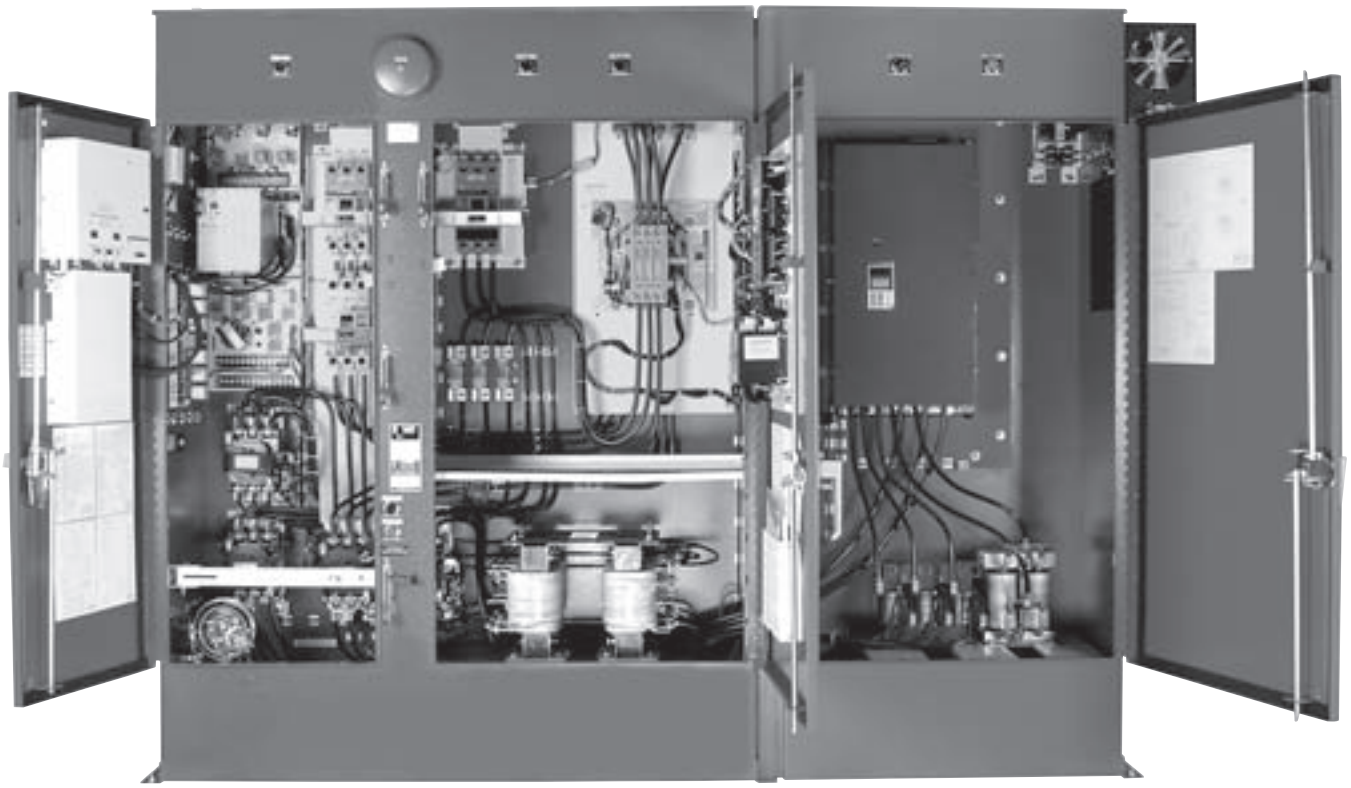

FIGURE 15.7.12 Open Door View of Model ECVRT-125-46, 125 hp, Dual-Source, Variable Speed Fire Pump Controller with Reduced Inrush (Primary Reactor) Starting in Bypass Mode (Source: Master Control Systems, Inc.)

from 30 hp to 300 hp. As to pump types currently in operation, one unit is a vertical pump taking suction from a below-the-floor reservoir. Several are vertical in-line pumps; two are vertical deep well pumps; and the remainder are horizontal split-case pumps. One of the deep well pumps is of the water-lubricated type since the water is potable. Water-lubricated vertical pumps require special considerations to assure adequate lubrication water is supplied in time and also maintained under worst-case conditions.

Application Example—The Triple-Purpose Pump. The previously mentioned triple-purpose pump is a vertical deep well pump that uses the water tower for backup domestic and fire water. For filling the tower, the controller is started remotely by the site building management system, which also controls the speed of this pump in this mode. The speed is controlled to less than full-pump output flow to provide for optimum water treatment (chlorination, etc.). The pump can also be started remotely by the complex fire alarm system, in which case the controller accelerates the pump to full speed. If the controller pressure switch trips, which is the third operating mode, the controller accelerates the pump to full speed unless it detects that the tower is full. In this system the pressure cannot exceed 80 psi (5.5 bar) on a continual basis since that is the pressure that will overflow the tower.

Application Example—The Dual-Purpose Pump. The dual-purpose process water and fire water system is also a vertical deep well pump. In this system, a second well pump provides a backup source of water. It also shares the duty of providing the water since this system operates on a 24 hour, seven day basis. The two pumps alternate duty on a weekly basis and also operate in a so-called duplex mode of operation. In this mode, if the running pump controller (lead pump) ramps its pump to near full speed (97% of full speed), it will call for the reserve pump (lag pump) to start and ramp up to its idle speed. If the reserve pump needs to accelerate above its preset idle speed to meet the pressure demand, it signals the lead pump to lock to full speed so that the lag pump can take over the job of regulating system pressure. In this way only one controller is regulating the system pressure rather than having two competing for the job. If and when the reserve pump drops back down to idle speed, it unlocks the primary (lead) pump controller so that it can resume the job of regulating system pressure. If the reserve (lag) pump remains at idle for a predetermined length of time, it ramps the pump down to around one-third rated speed and then stops it.

Since the controllers operate independently, either will accelerate to full speed if the system pressure cannot be satisfied in the normal manner. This way, failure of one controller does not inhibit the operation of the other. No central pressure control is involved since both pumps and controllers operate independently other than causing the other pump to start or to lock the other pump to full speed. This system operates at around 140 psi (9.6 bar). Since both wells are within 20 ft (6.1 m) of a major river, there is no chance of depleting either. The two wells are

separated from one another by some distance in order to keep them independent of one another.

Application Example—A Four-Pump System. The four pumps at the major shopping center mentioned earlier operate in a triplex mode where one, two, or three pumps operate as system flow demands. In this system, two 30 hp (22 kW) pumps serve as the lead and second pump to supply domestic water demands and also fire water if the demand is not too great. The third pump is a 60 hp (45 kW) unit and is capable of supplying needed fire water. The fourth pump is also 60 hp (45 kW) and serves as a backup for the third pump. It takes over the duty of the third pump if that pump or its motor or controller fails. The triplex operation is similar to the duplex operation described previously. The lead pump starts upon pressure drop sufficient to trip its pressure switch or via a remote start input signal from the site fire alarm system. It regulates the system pressure needs (around 95 psi [6.6 bar]) unless the system demand causes it to ramp up to near full speed. In that event, it signals the second 30 hp (22 kW) pump to start and accelerate to its idle speed. If pump 2 needs to accelerate above its idle speed, it locks the lead pump to full speed and takes over regulating the system. If the second pump accelerates to near full speed, it signals the third pump (60 hp [45 kW]) to start and accelerate to its idle speed. Similarly, if pump 3 accelerates above idle speed, it locks pump 2 to full speed and takes over the job of pressure regulation. If pump 3 fails, pump 4 takes over and shuts down pump 3 to keep from overloading the genset if the system is running under emergency power.

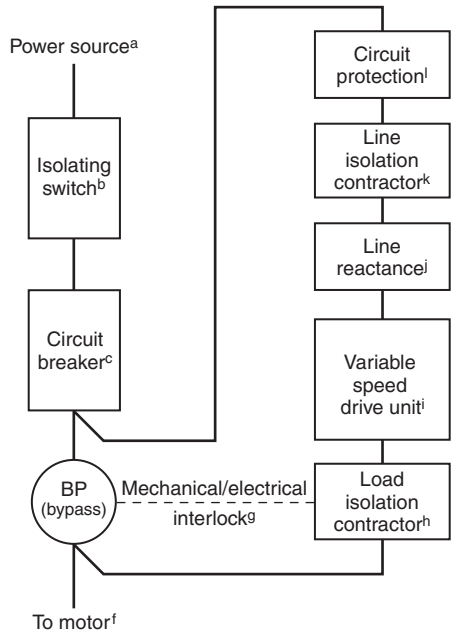
If and when the system flow demand diminishes sufficiently, the pump controllers reverse the described operation as follows. If the lag pump (pump 3) decelerates down to idle speed, it unlocks pump 2 so that pump 2 can take over pressure regulation. If pump 3 remains at idle for the automatic stop interval, or if the minimum run time has elapsed and if the idle stop delay has also elapsed, controller 3 shuts down pump 3. If the system demand drops down enough for pump 2 to reduce to its idle speed, it unlocks pump 1 (lead pump) to take over the system pressure regulation. If and when all timers are satisfied, controller 2 will shut down pump 2. Since there is no central control, failure of one controller will not affect the operation of the others. Like the duplex system, these units are equipped with sequential starting as required by NFPA 20 to prevent all three pumps from starting simultaneously. Although this situation will not normally occur when the controllers are in the variable speed mode, it would happen if they are in the bypass mode if not equipped with the required sequential starting feature. This system also has a commercial domestic pumping system, but in the event of a power failure, the variable speed fire pumps will take over the job of providing the shopping center with domestic water as well as fire water if needed. These multipurpose units already have tens of thousands of hours of accumulated variable speed operating (running) time.

Equipment Description

The equipment and functions described hereinafter are those required by the 2007 edition of NFPA 20. The primary emphasis in NFPA 20 is that the variable speed path and the bypass path are both reliable and robust and also are as independent of one another as possible. This philosophy is to protect the integrity and independence of the bypass path to the fullest extent practical. In this way, variable speed controllers can be more reliable than a traditional fire pump controller if, as required, two conditions are met: (1) the design and construction of the bypass path is not diminished in any way from that of any other full-service fire pump controller, and (2) the variable speed path does nothing to diminish or potentially damage the controller bypass path. These two conditions being met yields a full-service fire pump controller with a redundant variable speed path. It is also desirable for said variable speed path (Figure 15.7.13) to also be reliable and robust as is expected from any fire pump controller to provide a reliable source of fire water at the expected controlled pressure.

Controller Equipment Features

In order for active pressure control to be achieved in a reliable and robust manner, certain unique functions are also required of the controller. The major functions are delineated next.



[a]See Section 9.2 in NFPA 20.
[b]See Clause 10.4.2 in NFPA 20.
[c]See Clauses 10.4.3 and 10.4.4 in NFPA 20.
[d]See Clause 10.4.5 in NFPA 20.
[e]See Clause 10.5.3.2 in NFPA 20.
[f]See Clause 9.5.1.3 in NFPA 20.
[g]See Clause10.10.3.3 in NFPA 20.
[h]See Clause 10.10.4 in NFPA 20.
[i]See Clause 10.10.1.1 in NFPA 20.
[j]See Clauses 10.10.6.1 and 10.10.6.2 in NFPA 20.
[k]See Clause 10.10.4 in NFPA 20.
[l]See Clause 10.10.5 in NFPA 20.

FIGURE 15.7.13 Variable Speed, Pressure-Limiting Control (Source: NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection,* Figure A.10.10, 2007, p. 20-75)

Control and Alarm Elements. The major control and alarm elements of controller equipment include the following:

- Separate pressure switch for controller start and stop control and for use by the pressure bypass timer
- A low-pressure timer to automatically switch the controller into the bypass mode if the controller pressure switch remains tripped too long
- Separate and independent pressure sensing for the VFD (also known as a VSD, variable speed drive) or ASD (adjustable speed drive) speed control
- A manual mode control switch to allow operation in the full-speed bypass mode or the normal variable speed mode
- Alarm light and remote contacts to indicate drive (VFD) failure detected
- Drive failure timer to automatically switch the controller into the bypass mode on detection of a failure of the VFD
- Alarm light and remote contacts to indicate controller in bypass mode

Power, Isolation, and Circuit Protection. The major power, isolation, and circuit protection elements of controller equipment include the following:

- Full horsepower rated isolating contactor to keep the VFD powered down until needed. The purpose of this contactor is to prolong the life of the VFD and also to avoid VFD capacitor overvoltage shutdown due to power line surges, spikes, or overvoltage when the controller and pump are on standby (not running).
- Full horsepower rated VFD output motor (load) contactor to isolate the VFD from the bypass path.
- Full horsepower rated bypass contactor as part of the controller bypass path. This contactor is also operated by the emergency mechanical operator (see Figures 15.7.11 and 15.7.13). These last two contactors are both electrically and mechanically interlocked to prevent backfeeding line power to the VFD when the controller is operating in the bypass mode. Backfeeding would damage the VFD and probably cause the fire pump circuit breaker to trip and would disable the bypass path, leaving the fire pump inoperable.
- Circuit protection (fuses or circuit breaker) to isolate the VFD power path on circuit or component failure. This protection is set to trip at a value and time that will avoid tripping the controller fire pump circuit breaker, and thus leave the controller bypass path intact.
- A 5 percent or better line reactor to reduce harmonic currents within and upstream of the controller. This reactor also reduces harmonic currents within the VFD and protects the VFD rectifiers and capacitors from line voltage spikes and transients. Most importantly, it reduces the likelihood of VFD overvoltage shutdown due to these same spikes and transients.

System-Related Elements. The major system-related elements of controller equipment include the following:

- Alarm light and remote contacts to indicate that the system pressure is exceeding the VFD set point. This can be caused by a failure within the controller or by other pumps pressurizing the system.
- The means to control the system pressure in view of the multiple hydraulic, electrical, and mechanical time constants involved. This control is needed for successful and stable controller operations and requires the use of a full 3 term PID (proportional-integral-derivative) process controller or, at least a 2 term PI controller with suitable means to adjust and adapt to the conditions and requirements of the installation. This degree of control is needed to yield both stable operation and timely adjustment of the pump speed to give prompt response to changes in the system demand (flow) or suction pressure variations or both. Time constants are discussed later in this section.
  - The settings required for all of the preceding elements must both be lockable and also be marked and visible for service personnel.
  - For multiple variable speed pump installations, no common pressure control is allowed. Each controller must sense and control pressure independently to avoid a single point of failure in multiple-pump installations.

Additional Considerations. The controller equipment must be designed with the following requirements in mind:

- The controller must be able to deal with the heat given off by the VFD unit, which is typically 2 to 3 percent of the motor horsepower rating and is similar to the amount of heat given off by the motor itself. Better controllers do this without pulling air through the controller. This method requires an isolated means of cooling and keeps the inside of both the controller and the sensitive control portions of the VFD unit free from dirt, dust, and moisture that would otherwise occur in vented units.
- The VFD must be rated for the type of pump involved. Positive displacement pumps require a VFD unit with a higher current rating than that needed for centrifugal pumps for a given horsepower. Centrifugal pumps present a variable torque load to the pump motor, which reduces the power needed from the VFD as compared to positive displacement pumps because these present a load whose torque is relatively constant over speed.
- The controller must be designed to take care to avoid causing excessive currents when switching modes, particularly from variable speed mode to the bypass mode. This can be done with a motor restart delay of a few seconds to allow any motor magnetic flux and resultant back EMF (voltage) to decay to safe values before connecting said motor to the power source, especially if the bypass mode incorporated full-voltage (across-the-line) starting.
- There are a number of additional design considerations (Figure 15.7.14 and 15.7.15) that, if properly accounted for and manufactured, can further enhance the ability of these units to deal with various field conditions in a forgiving and robust manner.

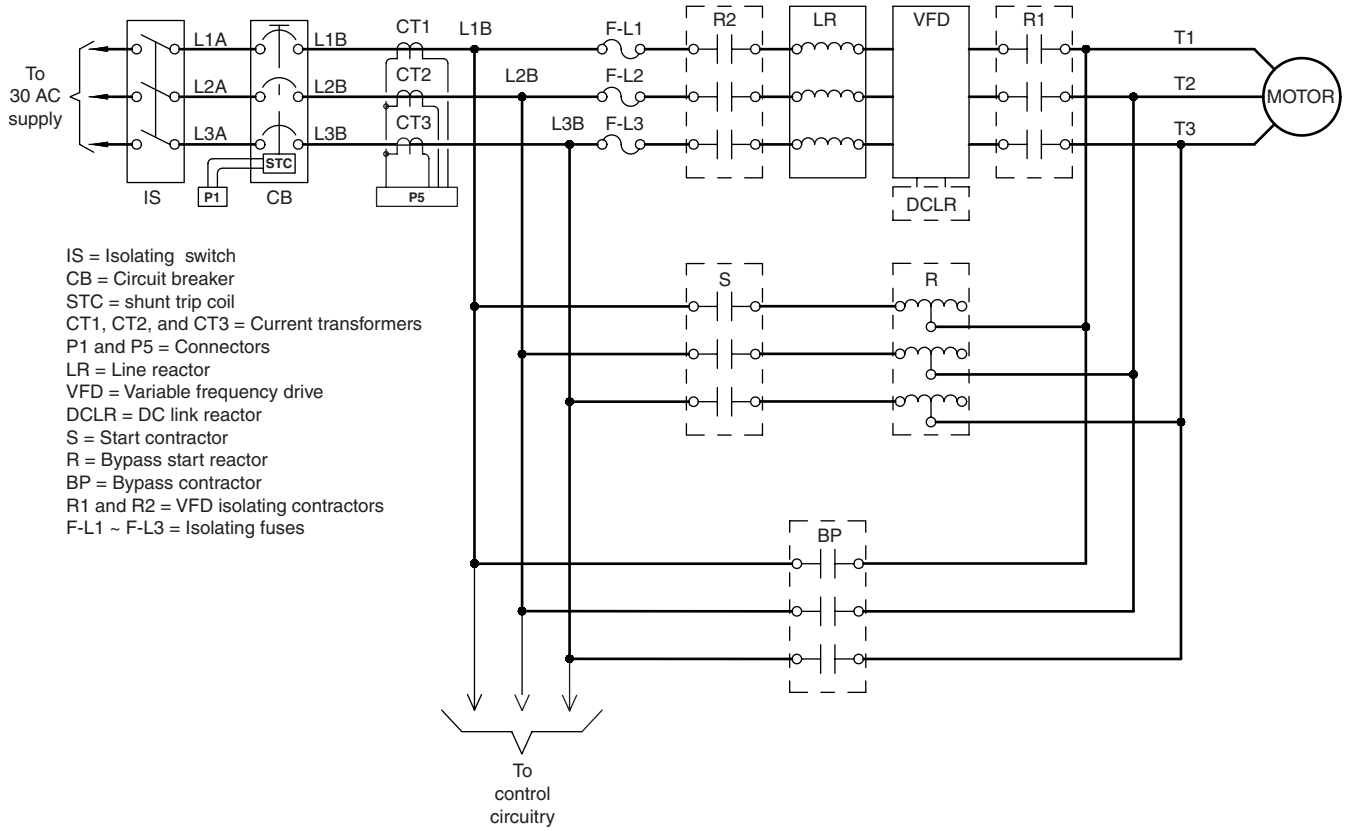

FIGURE 15.7.15 Variable Speed Fire Pump Controller with Reduced Inrush Starting in Bypass Mode (Source: Master Control Systems, Inc.)

Special Application-Related Controller Requirements. The controller equipment must be designed to meet the following application-related requirements:

- Where motor wiring distance exceeds manufacturer's ratings, a motor dV/dT (spike) filter or a load reactor must be incorporated into the controller to reduce motor voltage spikes to a safe and tolerable level.
- Skip frequencies may be required to be programmed into the VFD for vertical pumps. Application requirements are discussed later.
- Special enclosures such as NEMA 12 (UL Type 12) or better. Special enclosures will likely require upgrading the VFD cooling means or equipment.
- Additional door interlocking is needed where multiple bay controllers are involved for safety.

Functions

Certain new functions are required of these controllers, either by code (NFPA 20) or otherwise for successful operation. These include:

1. *Bypass mode lock-on.* When either the drive failure or the low-pressure timers time out to switch the controller automatically to the bypass mode of operation, the controller must lock onto that mode until manually shut down. Although the controller may be equipped with an automatic stop feature, that feature is not allowed to stop a pump running in the bypass mode. This lock-on also prevents the controller from switching modes back and forth between variable and full-speed bypass operation. Once in bypass, the controller must both stay in that mode and also not cause the pump to stop. The requirement is necessary as the bypass mode of operation represents a fallback either due to a failure or due to the manual mode switch being manually set to bypass. The controller must not interfere with this mode of operation since it is presumed that the variable speed mode has experienced a failure.

2. *Two stop push buttons.* These provide both normal ramp-down stopping and emergency instant pump stopping. The emergency stop push button is also the method of stopping the pump if it is running in the bypass mode.

3. *Coordination of start and stop pressures of the controller pressure switch with the VFD set point pressure for proper operation of the controller.* This coordination is needed whether the controller is set for manual stop or for automatic stop operation.

4. *Automatic stop based on VFD operating frequency.* The controller must not stop itself automatically if there is a requirement for water (fire water still being delivered). This means that the system pressure must both be at or above the pressure set point and that the pump running is no longer needed.

Operating Sequence

The description that follows briefly outlines normal controller and pump operation for a single fire pump. For proper operation, the VFD pressure set point is set to a value above the controller pressure switch reset (stop) set point.

Normal Operation—Variable Speed Mode—Automatic Pressure Loss Start. The following steps outline normal controller and pump operation:

1. Controller pressure switch trips (contacts close) to signal a pressure loss (pressure drop) pump demand.
2. The two VFD contactors (line side and load side) close to energize the VFD and to connect it to the motor.
3. The drive failure timer (DFT) begins timing.
4. The low-pressure timer (LPT) also begins timing.
5. If the VFD is healthy, it sends a "Drive Ready" signal that stops the DFT timer.
6. The VFD accelerates the motor to its set idle speed and continues to ramp up the motor speed sufficiently to cause the pump to raise the system pressure high enough to reset the controller pressure switch, which stops the LPT timer.
7. The VFD controls the motor in a closed loop mode (feedback) using the PID or PI process controller to maintain and regulate the system pressure at the programmed VFD pressure set point.
8. The VFD promptly responds to changes in water demand to adjust the motor and pump speed without excessive pressure overshoot or excessive delay to prevent excessive pressure drop.
9. Likewise, the VFD responds suitably to changes in pump supply (suction) pressure changes.
10. The VFD adjusts the pump speed to bring the pressure to within 1 psi (0.07 bar) of the desired pressure set point under stable demand (flow) conditions.
11. If and when the system demand drops to either low or no-flow conditions, the VFD throttles back the pump speed to that needed to just maintain the desired pressure. This is typically around two-thirds of pump rated speed resulting in a pressure boost of around 44 percent of rated boost, which will be too low to flow any water under normal conditions.

12a. The pump remains at this speed if the controller is set for manual stop, or

12b. The VFD signals the automatic stop timer that no water is being delivered. If the minimum run time has already occurred, the controller stops the pump. If not, it keeps the pump at idle speed until the minimum run timer is satisfied (times out), and then it stops the pump.

13. This leaves the controller and pump in the normal standby mode.

Normal Operation—Variable Speed Mode—Remote Deluge Valve Start Demand or Remote Momentary (Remote Start Push-Button) Demand. The following steps outline normal controller and pump operation:

1. The controller starts the motor as previously.
2. If there is no demand for water, the pump remains at the pressure maintenance speed.
   a. If started from a remote momentary (push-button) demand, the controller continues to run the pump at the low pressure maintenance speed until manually shut down.
   b. If started from a remote deluge (static) demand and depending on the controller type, the unit will remain run-

ning at low speed or stop after the minimum run timer times out if arranged for automatic stop.

3. If a demand for water occurs during the time that the pump is running, the VFD will accelerate the pump as needed. The controller will not shut the pump down even if or when the automatic stop time occurs in units set for automatic stop.

Normal Operation—Variable Speed Mode (Local Start Push-Button Demand). The following steps outline normal controller and pump operation:

1. The controller starts the motor as previously.
2. If there is no demand for water, the pump remains at the pressure maintenance speed.
3. The unit will remain running at low speed, or if a demand for water occurs, the VFD will accelerate the pump as needed. The controller will not stop the pump since it was started locally (manually).

Manually Set Bypass Mode (Mode Switch Set to Bypass). In this mode, the fire pump controller acts as a nonvariable speed (full-speed) full-service fire pump controller except as follows:

1. On a pressure loss demand (controller pressure switch trip), the controller starts the pump motor and runs it at full-line voltage and frequency to cause the motor to run at full rated speed. The controller continues to run until manually stopped regardless of whether it is equipped for automatic stop and regardless of whether the controller pressure switch is reset.
2. On a remote deluge start pump demand signal, the controller starts and runs the pump until manually stopped as in the preceding exception.
3. On a remote momentary demand (remote push button), the controller starts and runs the pump until manually stopped as in the first exception.

Abnormal Operation. The following steps outline abnormal controller and pump operation:

1. If the drive fault timer (DFT) times out, the controller begins its switch to bypass sequence. It will:
   a. Deenergize both VFD contactors to isolate both the VFD and the pump motor.
   b. Pause for the motor restart time (a few seconds) to allow motor flux to decay to reduce the motor back EMF (voltage) to a safe level.
   c. Restart the pump motor in the bypass full-speed mode.
   d. Continue running the pump at full speed until stopped manually.
2. If the low-pressure timer (LPT) timer times out, the controller will begin the switch to bypass sequence as above.
3. If the controller pressure switch recloses any time during variable speed running operation:
   a. The controller ramps the pump motor up to full speed, if not already there.
   b. The low-pressure timer (LPT) begins timing.
   c. If the pressure climbs high enough to reset the pressure switch, the LPT timer resets and the drive continues normal variable speed operation.
   d. If the LPT times out, the controller begins the switch to bypass sequence as above.
4. Should a fault in the motor occur during variable speed running, the VFD will normally shut down the motor since the output current from the VFD is limited to safe values.
5. If a fault occurs in the VFD input circuitry or if the VFD otherwise begins to draw excessive current, one of the following events occurs:
   a. The VFD branch (path) circuit protection (fuses or circuit breaker) trips to prevent the main fire pump circuit breaker from tripping.
   b. The drive fault timer begins timing and causes the controller to initiate the switch to bypass sequence.
   c. Since the motor is stopped, the pressure will likely drop enough to trip the controller pressure switch, which will start the low-pressure timer and subsequently cause the controller to initiate the switch to bypass sequence.
6. If the line voltage has spikes, transients, or voltage surges of sufficient magnitude, it will cause the VFD, if running, to go into its "overvoltage" shutdown mode. Better-quality VFD units, including all variable speed fire pump controllers installed as of this writing, will tolerate up to 800 Vdc on the capacitors before shutting down the VFD. This is 18 percent higher than the nominal 680 Vdc (480 × 1.414) on a 480 Vac system. In the event that the VFD goes into its overvoltage shutdown mode:
   a. The VFD will stop the motor and clear the drive ready signal.
   b. When the drive fault timer (DFT) times out, the controller begins its switch to bypass sequence as above.
   c. In the process, the VFD is disconnected from the power source and will reset the overvoltage shutdown mode. If not damaged by the overvoltage condition, it will be available for service on the next pump demand.
   d. The unit switches to bypass until manually shut down.

Application Considerations

For a variable speed fire pump installation to be successful (reliable and robust), certain unique requirements of the installation are needed. At a minimum, they include the following:

1. Adequate ventilation is required. The controller mounting must be per the manufacturer's instructions so as to not block controller ventilation requirements.
2. The pump room or pump house must be adequately cooled or ventilated to prevent heat from both the controller and the motor from exceeding the maximum allowed controller-rated ambient temperature.
3. The motor wiring length must not exceed the manufacturer's rating to avoid excessive motor voltage spikes that can damage the motor insulation.
4. As with other fire pumps, the motor must be a NEMA Design B, Starting Code G.

5. The motor must be suitable for and labeled for use with a variable speed drive (e.g., it must be marked as an inverter duty motor).
6. The motor-rated horsepower may not be exceeded. It is not allowed to use the motor into its service factor. The maximum allowed motor running current is 1.0 times the motor nameplate full-load current (FLA), not 1.15 times.
7. The pump and motor must be rigidly coupled to prevent motor torque oscillations.
8. For horizontal pumps, the pump and motor must be properly grouted for the same reason.
9. A relief valve is required for emergency and manual full-speed operation if the pump can exceed the system pressure rating when running at full speed and at churn.
10. For vertical turbine pumps, all resonant frequencies (or speeds) up to full speed must be known and programmed into the controller. These are skip frequency(s).
11. For water-lubricated pumps specify minimum speed and maximum allowed acceleration time to said speed, if applicable. Also specify the minimum idle speed needed to keep the top bearing wet at the lowest anticipated well-water level.

Basic Hydraulic System Considerations

Feedback Control Theory. With the availability of variable speed fire pumps, the system designer can now design for the worst-case low suction pressure and maximum pump demand factors and not have to worry about how high the pressure rises during low-flow or no-flow conditions, such as occur during pump testing. Note that actively controlling pressure implies the use of a feedback control system, which is the case with either diesel engine or electric motor–driven systems. This operation is always the case whether these systems are referred to as pressure limiting or not. The control of pump discharge pressure occurs by way of sensing the pressure at the pump discharge, comparing it to a set reference value, the "set point pressure," and using the difference, either positive or negative, to increase or decrease the speed of the pump driver in order to bring the pump pressure up to or down to the desired set point value as other system parameters vary, such as system flow and suction pressure.

Feedback System Control Gain. The gain of the system determines how close the controlled variable comes to the desired set point value. In the case of variable speed electric motor–driven controllers, the gain should always be high enough to allow controlling pump discharge pressure to within 0.1 psi (6.9 mbar) of the desired set point value. However, if the gain is too high, the system may not converge on the desired final value (set point value) in a smooth manner. Too much gain can lead to either overshoot or oscillation and unstable operation. These problems will not occur with properly set and operating PID or PI feedback controller.

System Time Constants. Every feedback control system has one or more time constants—the time that it takes for such a system to settle to within 37 percent of its ultimate value. A hydraulic system, such as a fire sprinkler system, may be either an open system or a closed system.

Open Systems. An open system is one that is open to the atmosphere somewhere. Typical are sprinkler systems fed from elevated tanks or towers. System pressure is determined by gravity and the height of the water in the tower or tank. These can have long time constants. Several seconds is not unusual. The longest time constants on one multibuilding medical housing campus measured 20 to 24 seconds along with several shorter ones.

Closed Systems. Most building fire sprinkler systems are closed, meaning that system pressure is maintained by means other than gravity. In hydraulic systems, the system time constant is dependent on a number of variables, but the two primary variables are the size of the system and the amount of air in the system. Pressure in these systems is maintained by a pressure maintenance pump, also called "Jockey Pump" or "make-up pump," whose start and stop pressures are coordinated with the churn pressure of the fire pump. The size of the system determines how many tons of water are entrained within the system. The amount of air trapped in the system determines both the amount of stored energy in the system and the overall system time constant. Specifically, with very little trapped air, the system time constant can be very short, even less than 1 second. This case can occur in high-rise buildings when the air has been bled out of the branch piping. On the other hand, large factory or warehouse buildings often have a large amount of trapped air in the system and, therefore, have long time constants.

Multiple Time Constants. Sprinkler systems may have numerous branches, each of which will have varying amounts of trapped air. These several branches will, therefore, have varying time constants. Most important is the time constant of the system as viewed from the variable speed fire pump. In systems with multiple buildings and multiple underground loops, there can be several time constants due to varying sizes of subsystems (buildings) and varying amounts of trapped air (Figure 15.7.16).

Hydraulic Versus Electrical Time Constants. A second source of multiple time constants is the variable speed pump itself. When the pump is off, the system will have a main (fundamental) time constant or resonant point. When the pump is turned on or is accelerating, it can cause a different, usually shorter, time constant, since it is acting as a forcing function in feedback theory terms. Also, the motor and controller times are under the control of both the VFD set parameters as well as the PID set parameters. These time constants are important only while the system check valve is open, meaning when the pump is delivering water.

Other Applications. Time constant considerations will be different for other systems but must still be considered for stable and responsive system operation. Examples of these other systems are agent pumps (foam agent, etc.) and water mist systems. Some of these employ positive displacement pumps that also require the use of unloader valves during motor starting.

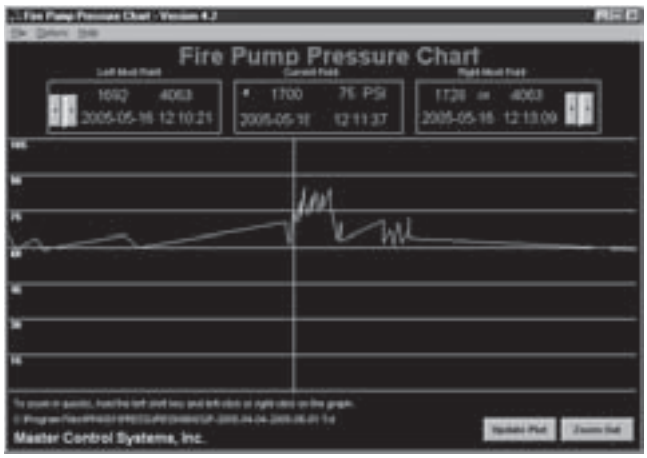

FIGURE 15.7.16 Screen Shot of Pressure Plot Showing Several Different System Time Constants (Source: Master Control Systems, Inc.)

CONTROLLER PARAMETERS

It is paramount that the fire pump installation and the fire pump package (pump, motor, and controller) be coordinated. Any mismatch can result in a nonfunctional package that will have to be corrected or replaced. Worse yet, the mismatch can result in an installation that appears to work but is unreliable. This situation may not be discovered until the pump is needed for fire suppression. Finally, since substantial fault currents and voltages exist, miscoordination can and does result in unsafe installations.

Nameplate Parameters

Voltage. The controller's parameters must match the incoming power and the motor that it will be controlling. The line voltage must be the same as the controller-rated voltage and the motor-rated voltage. Special care must be taken for part winding and wye-delta (star-delta) starting controllers to determine that the intended motor is rated for the respective type of starting at the intended voltage. This is especially true of dual-voltage (series/parallel) motors.

Frequency. The controller-rated frequency must match that of the incoming power (mains). To be specific, 60 Hz controllers will not be reliable when used at 50 Hz and vice versa, unless the controller is designed, rated, marked, and listed for such dual-frequency service. Most controller components that operate at the line frequency are affected by the applied frequency in one of two ways. First, 60 Hz components used at 50 Hz at the same voltage will draw more current due to the reduced inductive impedance (reactance) at the lower frequency and will thus run hotter and possibly overheat. The second, and often the more important, effect occurs with AC-powered relays, contactors, timers, and so forth. When used at a higher frequency than intended, such as with a 50 Hz coil used at 60 Hz, the coil will have a lower inrush (pickup or pull-in) current. Such use will result in lower pull-in force, which may not be adequate under normal or low-line voltage conditions. Note that some devices are rated, and labeled, for such dual-frequency use because they have been designed, tested, and listed under both frequencies.

Horsepower or Motor Kilowatt Rating. The controller components are sized for a specific maximum motor FLA and service factor. Applying a larger-than-rated motor voids the controller listings, invalidates the design, and usually voids the controller warranty. It is also dangerous and unreliable, especially when the unit is needed to deliver water at full flow for any length of time. The use of a smaller-than-rated motor must be approved by the controller manufacturer to assure proper coordination because the sizing of the circuit breaker shunt trip unit (for the motor locked rotor protection) covers only limited ranges of motor FLA.

Short Circuit Rating

Every fire pump controller has a labeled short circuit current rating in accordance with NFPA 20. The current is given in either symmetrical amperes (A) or in symmetrical kiloamperes (kA) where 1 kA is 1000 A. As detailed in NFPA 20, these ratings are established by the listing agencies Underwriter's Laboratories (UL) and Factory Mutual (FM) by way of testing, which is often destructive. The testing affirms that the equipment can both withstand the rated short circuit current and that the equipment can safely interrupt said short circuit currents. In order to pass the test, the equipment may not become a shock hazard or a fire hazard. NFPA 20 also makes it clear that to determine the suitability of the controller, the short circuit current availability of the power source supplying the controller must be determined. This determination requires a short circuit study. A controller rated at 30,000 A is an entirely unknown variable if connected to a power source capable of delivering more than 30,000 A. If the controller short circuit rating is exceeded, the equipment may become a fire or shock hazard during or after a short circuit event. It is important to note that the interrupting capacity rating of the circuit breaker (and/or isolating switch) inside of the controller is not the rating of the controller. These two different ratings should never be confused or used interchangeably.

With dual-power sources, two short circuit ratings are involved and must be coordinated with the alternate (emergency) power source (genset, other utility, etc.), namely, the interrupt capacity rating and maximum allowed ampere size upstream circuit breaker. See the section on power transfer switches for details.

STANDARD CONTROLLER COMPONENTS

Certain elements are common to all or most fire pump controllers.

Nameplate

A listed electric motor–driven fire pump controller must bear a ratings nameplate that gives the important electrical parameters, including operating voltage, motor horsepower or ampere

rating, or both, the minimum operating temperature, and the enclosure type, among other parameters. The ratings also include the required short circuit rating. UL listing and FM approval marks are also required.

Isolating Switch

An isolating switch is required and is present on all controllers except on limited-service controllers. These are sized to have an ampere rating at least 115 percent of the full-load current rating of the motor and/or be horsepower rated at not less than the motor horsepower. An isolating switch is not necessarily a load break rated switch. If the isolating switch is not mechanically interlocked with the controller circuit breaker, a warning label must also be present to warn of operating (opening or closing) the isolating switch if the circuit breaker is closed. This is because the isolating switch is not required to be rated or tested for closing on to or interrupting faults.

Circuit Breaker (Disconnecting Means)

The fire pump circuit breaker serves several purposes. It is an important and integral part of the controller short circuit design and rating. It must safely interrupt fault currents up to the rated short circuit rating of the controller. In many, if not most, modern designs, both the isolating switch and the circuit breaker are of the molded case construction and share the task of clearing high fault (heavy short circuit) currents between the two devices. The circuit breaker is required to be rated at 115 percent or more of the motor FLA. The circuit breaker will have an interrupt capacity rating. However, this rating is not the same as the controller short circuit rating. It may be either higher or lower than the circuit breaker's interrupt capacity rating. Note that medium-voltage fire pump controllers use current-limiting, R-rated motor circuit fuses instead of a circuit breaker for this fault-clearing function.

Motor Locked Rotor Overcurrent Protection

Modern controllers use a separate current sensing trip unit in conjunction with a shunt trip solenoid, which is part of the circuit breaker. The circuit breaker itself is usually a molded case switch with a shunt trip solenoid. The trip unit senses the motor current flowing and compares it with the desired tripping curve characteristics. The two points that define the breaker trip characteristic curve are the 300 percent no-trip value and the 8 to 20 second trip time at 600 percent of the motor FLA. These trip units have setting switches to select a range of motor FLA values for the motor being used. Using a trip setting higher than the motor FLA value is more likely to result in a motor that will burn out before the trip unit can open the circuit breaker. If the trip unit setting is lower than the motor FLA, the circuit breaker is more likely to trip prematurely. Trip units with smaller ranges (more settings) are able to provide more precise motor protection.

Limited-service controllers are allowed to have a wider range of motor protection by allowing the use of thermal circuit breakers. Medium-voltage controllers use the trip unit to deenergize the motor contactor to take the motor off-line under overload conditions up to and including locked rotor. The contactors are tested for this duty to UL 347 on high-voltage industrial control equipment.

Motor Contactor(s)

The main motor contactor(s) takes the place of a motor starter in conventional combination motor controllers. There is no motor overload relay. Motor tripping is accomplished by opening the circuit breaker. The number and purpose of contactors vary with the controller starting type, as illustrated in Table 15.7.3.

Pressure Switch

An automatic controller of the pressure-actuated type will be equipped with a pressure-actuated switch. The pressure switch is required to have independent high and low set point adjustable settings. This pressure switch has traditionally been a Bourdon tube type pressure switch, although pressure transducers, along with amplifier circuitry, are used in some designs instead, especially in those jurisdictions where products incorporating mercury are prohibited. This switch has been a hermetically sealed mercury "tilt bottle" type of pressure switch, which protects the contacts from atmospheric and environmental conditions.

The pressure switch settings are normally determined by the hydraulic design of the installation and by the AHJ over the installation. The setting of the start and stop pressure of every fire and jockey pump in a system is of vital importance. The settings need to be correct for the fire protection system (the fire sprinkler system) to function correctly and deliver the required amount of water or agent. Moreover, incorrect settings can damage the system by either overpressure or excessive water surging, either of which can damage an underground piping system (loop).

Start and Stop Push Buttons

Every controller has a manual "Start" push button known as the manual electric control at controller. Operation of the "Start" push button locks the controller into a running condition. If the controller is of the reduced inrush starting type, the starting will be in the reduced inrush starting mode. In most controller de-

TABLE 15.7.3 Summary of Number of Motor Contactors Versus Starting Type for Fixed and Variable Speed

Starting Type	*Number of Contactors*
ATL	1
Part winding	2
Primary resistance	2
Primary reactor	2
Wye-delta open transition	3
Wye-delta closed transition	4
Soft start	2[a]
Auto transformer	3
Variable speed	At least 3[b]

[a]Three for soft start if an isolating (start) contactor is provided.
[b]Depending on which bypass starting method is used.

signs, the "Stop" push button will stop the pump regardless of whether or not a demand still exists. If there is still a demand, the pump will restart when the "Stop" button is released.

Emergency-Run Mechanical Control at Controller

The emergency mechanical operator will start the pump motor by physically closing the main motor contactor M or both of the two main motor contactors (typically M1 and M2). As a result, the motor is started at full voltage. Most low-voltage controllers have an electrical assist mechanism to avoid undue contact erosion due to arcing or welding of the contacts because of slow opening or slow closing of the contactor.

Emergency Stopping

With low-voltage, single-source (nontransfer switch) controllers, emergency stopping of the pump can always be accomplished by opening the controller circuit breaker. This operation allows stopping of the motor in case there are one or more welded contacts in the motor contactor(s). This method of stopping will still work if a dual-source (transfer switch) controller is running on the normal source. Some dual-source controllers (the so-called dual-utility controllers) have two circuit breakers, allowing emergency stopping of the motor regardless of which source it is connected to.

In medium-voltage controllers, it is the motor contactor that must always break the motor circuit. The only exception is when a controller is equipped with a suitably rated disconnect switch in lieu of the usual isolating switch. As noted earlier, the motor circuit fuses interrupt the motor current only during a high-current short circuit. These fuses are coordinated with the motor size and the other power path components. Therefore, the "Stop" push button serves as both the normal and the emergency stopping means.

Surge Arrester

The surge arrester offers mixed benefits. The purpose of the surge arrester is to protect the fire pump controller from line surges, mainly lightning surges, although no secondary equipment (nonutility equipment) will survive a direct lightning hit on its incoming lines. The surges in question are induced surges caused by capacitive or inductive coupling from a nearby lightning strike rather than a direct strike. When a surge does occur, it will find the path of least resistance. This will be equipment or wiring devices having the weakest dielectric strength (voltage withstand). The purpose of surge arresters is to absorb this surge energy before it can cause damage to equipment or wiring devices. Equipment having the highest voltage withstand will not conduct the surge energy since other equipment and/or equipment having arresters will do that job instead. Equipment having a high enough voltage withstand will thus be unaffected by such surges.

For lightning arresters to be effective, they need to be sized in accordance with the energy available versus their ability to absorb said energy. Basically, they should be sized in accordance with the upstream impedance, which limits the energy. Arresters are rated on how large of a current surge they can absorb and how often they can absorb the same. When an arrester absorbs more than this rated energy, its leakage current (follow-on current) can be high enough to destroy it, even if a first surge or a repeated surge does not. This can be immediate or may be delayed due to a condition known as thermal runaway. This condition occurs when the self-heating caused by leakage current leads to internal heating faster than the heat can be dissipated. Suitably rated and well-designed arrester equipment is available. However, the cost and size prevent their widespread use inside fire pump controllers as standard equipment. They are sometimes installed in parallel with fire pump controllers. Because of this hazard, some designs mount the arresters "out of sight" for personnel safety. Some designs also provide fuses to protect the equipment from damage due to blown arresters.

STANDARD CONTROLLER FEATURES

The description of certain standard features of electric drive fire pump controllers follows. The list is not exhaustive. For a complete list, see NFPA 20.

Devices and Controls

Locks. Most or all listed controllers have, or should have, a lockable cabinet. The means may be by way of padlock hasps, a lockable door handle(s), key-lockable handle(s), or separate key lock(s). If the pressure switch is a Mercoid Bourdon tube type, its setting knobs are lockable or can be sealed with a seal wire. Most or all controllers have isolating switch or circuit breaker operator handles that can be locked on or off. The "On" position is used to lock the unit in the standby fire protection mode, whereas the "Off" position is used as a lockout for servicing.

Interlocks. Most listed controllers have an interlock between the cabinet door(s) and the isolating switch operator mechanism or handle. This interlock prevents opening of the door while the isolating switch is in the "On" position (unit energized). The interlock also prevents closing of the isolating switch while the door is still open. These interlocks are important because the controllers operate at lethal voltages. They are also very important for controllers that are connected to high-fault power supplies. These controllers are very unforgiving of accidental short circuits. It is also most important to be sure that the door is closed before energizing the unit, especially when closing the circuit breaker. Should a pump demand exist and a short circuit exist, there will be venting of ionized gases in one or more of the power devices. This can cause explosive pressures within the controller. If the controller door(s) is not closed and latched, serious injury can occur. This is also the reason for greater emphasis on short circuit availability and controller short circuit rating coordination. Medium-voltage controllers have additional interlocking between the motor contactor and the isolating switch and the high-voltage door.

External Operators. All listed electric fire pump controllers have an emergency mechanical operator. Low-voltage controllers also have a circuit breaker operator. Medium-voltage

controllers have an isolating switch operator in lieu of the circuit breaker operator. Full-service low-voltage controllers have either two operators or one combined operator for the isolating switch and the circuit breaker. The required external operators are shown in Table 15.7.4.

Manual Electrical Control. All listed controllers have, as a minimum, the required "Start" and "Stop" push buttons. Controllers have circuitry that keeps the pump running if started from the local "Start" push button independent of an automatic stop (minimum run timer) circuit. The same applies for a remote lockout or remote shutdown circuit. Because the pump was started manually and locally, it should not be stopped automatically or remotely.

Pressure Loss Starting. Controllers used for pressurized systems also have the pressure switch described previously.

Remote Starting. When controllers are used for an unpressurized system, a deluge system, or a monitor nozzle system, the controller must be equipped with a remote start option circuit. The controller might not be equipped with a pressure switch. These units are actuated by the opening of a remote (external) contact, such as from a deluge valve contact, a fire or smoke alarm relay contact, or a remote or central station push-button contact, among others, to signal the controller to start. Some systems are a combination of both pressurized and deluge type sprinklers. For these systems, the controller has both a pressure switch and a remote start option circuit.

Accelerate Time. Reduced inrush (reduced current) type of controllers have one or more means to set the accelerate time. Most, but not all, are adjustable. In addition, primary resistor, primary reactor, and autotransformer controllers have two or more taps for setting the motor starting voltage. Similarly, soft start controllers have various adjustments for setting the voltage and time parameters.

Input Signals

All electric fire pump controllers have power inlet terminals for the motor power circuit. Dual-source controllers have two such inputs. A second (or third) power source is sometimes also supplied to a controller equipped with certain options. This additional source is the so-called supervisory power supply, usually a 115 Vac (at 60 Hz) or 220 Vac (at 50 Hz) branch circuit. It is used for a supervisory power loss start circuit option for a so-called built-in alarm set circuit option.

TABLE 15.7.4 External Operators

Controller Type	Controller Voltage	
	Low Voltage	*Medium Voltage*
Limited service	Circuit breaker operator only	(not applicable)
Full service	Circuit breaker operator and isolating switch operator	Isolating switch operator only

All automatic controllers have at least one pump demand input to signal the controller to start the fire pump. The most common is a pressure sense line fitting that connects to the controller's internal pressure switch. Other inputs include the aforementioned remote start circuit. Some controllers have separate remote start inputs, either as standard equipment or as optional equipment, one specifically for deluge or fire alarm contacts and the other specifically for remote start push-button contacts. Some designs use circuitry to keep the automatic stop circuitry from canceling the latter demand as it is initiated manually.

A controller may also have an input for a remote stop or lockout signal, either as standard equipment or as optional equipment. This input signal is sometimes used to keep a second pump from starting unless a first pump has failed to start.

Controllers can also have other inputs, usually for alarm, monitoring, or supervising purposes. Some of these are described in the section on alarms and indications.

Output Signals

The main output from an electric fire pump controller is the motor power, which comes from the main motor contactor(s) as described previously. Controllers may also be equipped (as standard or optional equipment) with auxiliary control power output at the same voltage levels as those described for supervisory power input. This power is often used as one of the power inputs to a remote alarm set (alarm panel). In jurisdictions that allow or mandate low-suction shutdown, this auxiliary power may be used as one source of power for a low-suction shutdown panel. This source of power is usually limited to a current of 1 A or less and is normally protected by a fuse or circuit breaker to prevent damage to the controller's control power transformer because this is often in the critical starting path of the controller.

Controllers used in multiple-zone installations (the so-called high-zone and low-zone installations) have an output signal from the high-zone controller(s) to signal the lower-zone pumps to start in order to supply water to the higher-zone pump suction inlets. The low-zone controller(s) have inputs, such as remote start, to accept the start signals from the high-zone controller(s). See the section on high-zone delay for pumps in series.

All controllers must be equipped with a minimum of three output alarm contacts, for motor (or pump) running, power available (or power failure or phase loss), and phase sequence reversed (or phase reversal). Dual-source (transfer switch) controllers must also supply two additional output alarm contacts: one to indicate when the transfer switch is in the emergency (alternate) source position and the other to indicate when the emergency isolating switch is opened. Various controller options supply additional contacts for alarm, monitoring, or supervisory purposes. Some of these are described next.

Alarms and Indications

All electric fire pump controllers must have at least two indicator pilot lights (visible indicators). One is used to indicate

that power is available in all phases at the line terminals of the contactor(s). The other is used to indicate a phase reversal of the power source to which the line terminals of the motor contactor are connected. Controllers may also have an optional motor (pump) running signal light, among others.

When the pump room is not constantly attended, alarms must be provided "at a point of constant attendance." In the absence of such an attendant, the mandatory three (or five for dual-source controllers) alarm contacts should be connected to either an on-site alarm set installed at a point of constant attendance (switchboard, security post, etc.) or an off-site monitoring location such as a central watch or alarm service. Not monitoring the alarm contacts results in degraded fire protection because pump failure conditions go unheeded and uncorrected for some period of time. Similarly, a pump running condition should always cause someone to be in attendance at the pump to watch for problems. More importantly, a pump running alarm might be due to the pump responding to an actual fire condition. Such a condition should always initiate a course of action that includes immediate attendance at the fire pump to monitor its operation and possibly allow for intervention in the event of trouble with the pump, motor, or controller.

All electric controllers must also signal an alarm condition if a single-phase condition occurs, whether or not the motor is running. This condition may be either annunciated as separate light and alarm contacts or it may be combined with the power available/phase loss alarm light and contacts.

Strictly speaking, only the loss of phase open or closed contact is required. However, all listed controllers provide both open and closed contacts. Since these contacts operate in opposition, they can signal power failure (phase loss) and power available conditions.

Dual-source controllers (combination transfer switch fire pump controllers) require additional alarms related to the transfer switch itself. These are a pilot light and contacts to indicate when the transfer switch is in the normal source position and when it is in the emergency (alternate) source position. The same is required to indicate when the emergency source side isolating switch is open as well as a local audible alarm for this indication. These units also require contacts to initiate genset starting when the alternate source is a standby generator set. The required alarms for electric fire pump controllers are given in Table 15.7.5.

TABLE 15.7.5 Required Alarms for Single- and Dual-Source (Transfer Switch) Controllers

Alarm	*Contacts*	*Visible*	*Audible*
All Fire Pump Controllers			
Power available	Yes	Yes	Optional
Motor (pump) running	Yes	Optional	Optional
Phase sequence reversed	Yes	Yes	Optional
All Variable Speed Controllers			
Drive failure (variable speed drive failed)	Optional	Yes	Optional
Bypass mode (full speed running)	Optional	Yes	Optional
Overpressure (115% of set pressure)	Optional	Yes	Optional
Dual-Source Controllers or Power Transfer Switches			
Transfer switch in normal position	Optional	Yes	Optional
Transfer switch in emergency position	Yes	Yes	Optional*
Emergency isolating switch open	Yes	Yes	Yes

*Some controllers provide this audible alarm as standard in addition to the emergency isolating switch open audible alarm.

High-Zone Delay for Pumps in Series

In high-rise buildings, a lower-zone pump is often used to supply suction pressure to the next or higher-zone pump. This arrangement is usually done when more than one pump is needed to supply the required head (psi pressure). When the suction of one pump is supplied directly from the discharge of another pump, the pumps are considered to be in series.

Each pump supplying pressure to another pump must be arranged to start before the pump it supplies. The starting requirement prevents the higher-zone pump from running dry or cavitating. When only two zones are involved, a demand for the high-zone pump causes the high-zone controller to send a demand signal to the lower-zone pump before energizing the high-zone pump motor. The delay is required to be between 5 and 10 seconds, which allows the lower-zone pump to come up to speed and supply water to the high-zone pump. In practice, the high-zone controller merely delays the actuation of the motor contactor(s) for a fixed delay time (5 to 10 seconds), while sending the demand (start) signal to the low-zone controller. The high-zone controller should impose this start delay for every demand source to avoid cavitation or dry running. This delay interval is usually known as the high-zone delay.

In case of more than two zones, all the higher-zone pumps must delay starting their motors while sending a start signal to the lower-zone pump controller. In the case of three zones, when the highest-zone controller receives a demand signal, it sends the demand signal to the middle-zone pump remote start input while delaying the start of the high-zone motor by 10 to 20 seconds. The middle-zone controller likewise sends a demand signal to the low-zone pump controller. The low-zone controller starts its pump motor immediately and supplies suction pressure to the middle-zone pump. In 5 to 10 seconds, the middle-zone controller starts its pump motor and supplies suction pressure to the high-zone pump. In 10 to 20 seconds the third- (highest-) zone pump starts to provide discharge (system) pressure.

Failure of a leading motor to start must not prevent subsequent pumps from starting. This requirement is accomplished with the aforementioned delay scheme because the high- or higher-zone pumps will start unconditionally after their set time delay, regardless of the state of other pumps. This scheme is followed with the intent that the high(er)-zone pumps will still

have enough suction pressure to provide at least some pressure and flow.

Sequence Starting for Pumps in Parallel

When pumps feed a common system or manifold, they are considered to be pumps in parallel. This scheme is usually implemented when more than one pump is needed to supply the required flow or when the added reliability of having more than one pump is desired. Although electric motor–driven pumps are used in parallel, many applications for parallel pumps for increased flow capacity (gal/min) use diesel drives.

Controllers for each unit of multiple-pump units must incorporate a sequential timing device to prevent any one motor from starting simultaneously with any other motor. There are two main reasons for this requirement. One is to prevent excessive load on the electrical systems from simultaneous starting of pumps. The other is to reduce the stress on the associated piping system. In these installations, the controllers are equipped with a sequence start timer, which inhibits pump starting during the delay period. The delays are set in the required 5 to 10 second intervals, although the first unit need not have any delay in most applications. At the end of the time interval, the controller in question will start the pump regardless of whether previous pumps have started or not. The only exception is controllers that reset if the demand signal ceases during the timing interval.

Control of Pumps in Series and Parallel

Some installations use two fire pumps in each zone in order to provide a backup pump in case the primary pump fails. In a three-zone installation, there is a total of six pumps. Where emergency (alternate) power is required, the controllers are sometimes interlocked to prevent both motors in any zone from starting to avoid overloading the alternate power source genset. One scheme uses a combination of failure to start, motor overload, or power failure signals from the primary pump to lock it out and pass the demand signal to the low-zone pump. When motor current exceeds a fixed percentage (e.g., 15%) a motor running signal is sent to the backup pump to lock it out. The backup pump is equipped with sequence start delay in order to allow the primary pump to start.

High-Pressure Wet Parts (Plumbing, Pressure Switch, and Recorder)

Most listed controllers are rated at 275 to 300 psi (19 to 21 bar) working pressure and use 300 psi (21 bar) full-scale pressure-sensing elements (pressure switches or pressure transducers and pressure recorders, where used). Pressure switches suitable for higher-pressure applications are available for use with these systems. The pressure switch and pressure recorder are the most delicate devices with regard to overpressure.

Stainless Steel Wet Parts (Plumbing, Pressure Switch, and Pressure Recorder)

Although more common with diesel drive fire pump controllers, this feature is needed when the pump takes suction from seawater or other brackish or corrosive water sources. The book *Pumps for Fire Protection Systems* provides additional detail in this regard.

NONMANDATORY CONTROLLER FEATURES

Listed electric fire pump controllers are available with a great number of options, features, and modifications. Some of these affect controller or pump operation and/or functionality. Some provide additional information (indications or readings) or additional protection for the equipment or the installation. Others modify the construction of the controller itself. The following paragraphs describe some of the options that affect pump operation and/or reliability of operation.

Motor Burnout Protection

Motor Overload Alarm. A motor overload alarm is one of the best ways to provide increased fire pump reliability, if properly used and monitored. This feature is available as an option with most listed controllers. Because the code prohibits the usual overload relay in the interest of keeping the flow of water running during a fire, the motor is subject to damage or destruction by any number of overload or overcurrent conditions. Although no overload relay or protection is allowed by code, other than that provided by the controller circuit breaker, an overload alarm feature is allowed. This alarm will warn of an overloaded motor due to pump problems, a low line voltage condition, a controller stuck in the accelerate mode for any reason, a single-phase condition, or a damaged or degraded motor.

Single-Phase Start Protection. All electric fire pump motors and controllers are three phase except for a small number of limited-service controllers and pumps. Attempting to start a three-phase pump with only single-phase power will cause the motor to draw starting currents until it is destroyed, until the fire pump circuit breaker trips, or often both. Fortunately, all electric fire pump controllers inherently protect the motor from starting during a single-phase condition on two of the incoming lines, namely, the lines that are used to supply control power to the motor contactor(s). Some designs also complete the protection by providing single-phase motor start protection on the third phase as well. This difference is seen during wide-area single-phase events. Note that the fire pumps will attempt to start after the jockey pump or pumps trip off-line due to the same single-phase condition.

Motor Restart Delay. If a running motor is briefly taken off-line and then reconnected (restarted), a very high transient can occur, depending on the phase angle difference between the motor's back EMF voltage and the line voltage to which it is reconnected. This phenomenon is the same as that described in the preceding section on wye-delta controllers, but it can be worse as the motor will have full-line voltage rather than the smaller 57 percent wye-mode voltage. This can cause a false trip of the circuit breaker, which takes the pump off-line until someone manually resets the fire pump circuit breaker or possibly the

upstream (service) breaker or replaces the fuses. To prevent this situation, some controllers are equipped with a restart delay as standard equipment, which operates by sensing when the motor contactors drop out (deenergize). The circuit then inhibits the contactors from reenergizing for a few seconds, which is enough time to allow the motor magnetic flux, and the resultant motor back EMF voltage, to decay to a safe value. After the delay period, the restart delay circuit allows the controller to restart the motor and also resets itself to be ready for the next motor interruption.

Exterior Measurement Means. The exterior measurement means facilitates reading controller (motor) voltages and currents from outside the controller. This means addresses personnel safety since both lethal voltages are always present and very high and dangerous short circuit fault currents are available. The best personnel protection against this danger is for the controller door to be securely closed and latched. This measurement means also provides an easy way to monitor the health of the installation and its power source if adequate records are kept of the motor running voltage and current readings during the weekly test running.

Alarms and Other Signals

As previously mentioned, additional alarm inputs and/or outputs are available as optional equipment in these controllers. Some of the more commonly used additional signals and alarms follow. The terms *pump room* and *pump house* are used interchangeably.

Sensor (Input) Signals. Some of the commonly used sensor (input) signals include the following:

- Low pump room temperature (freeze alert)
- Low reservoir temperature (freeze alert)
- Low suction pressure
- Low reservoir level
- Reservoir empty
- Relief valve open
- Flow meter on

Output Signals. Some of the commonly used output signals include the following:

- Motor overload (amperes exceed 115% of FLA) alarm
- Failure to start (within time limit) alarm
- AC volts low alarm (precise detector)
- Load shed signal (transfer switch units)
- Communications options, including telephone dialer to a remote location or pocket pager or cell phone, network reporting, Internet access, or wide area access

Other Selected Options

Automatic Weekly Test Start. Although required in all diesel fire pump controllers, this option is seldom specified in electric drive controllers. NFPA 25 now requires weekly rather than monthly test starting of these pumps. This feature can aid in meeting this requirement, although NFPA 25 does require the weekly test to be attended by qualified operating personnel. Note that electric drive pumps must be equipped with circulation relief valves in order to provide enough waterflow to keep the pump from overheating due to running at churn (shutoff).

Failure to Start. This alarm is a complement to the pump running alarm as it indicates that the pump should be running but is not. This alarm is of utmost importance during a fire.

Built-In Alarm Set. This option provides an audible alarm (bell, horn, etc.) for the standard alarms listed in the section on alarms. It uses a separate source of power—supervisory power—for this function. This option also includes a means of silencing the audible alarm.

Control Power Loss Start. In some high-risk applications, this option starts the pump in the event of internal control power loss. This feature overcomes the inaction that would ensue when a pump demand occurs.

Supervisory Power Loss Start. Supervisory power loss start is an older method of annunciating loss of supervisory power by way of the motor running alarm. Better methods provide two sources of power or battery backup or dial-up communications to monitor and alarm a loss of supervisory power.

Built-In Recording and/or Telemetry. Most controllers are available with built-in pressure recorders of the paper chart, strip chart, or paperless variety. Some units also record alarms and/or other parameters. Some units allow local or remote data access because they can transmit said data on command or on occurrence via various network communications media.

Environmental, Construction, and Other Treatment Options and Modifications

Controller Enclosure (Cabinet) Space Heaters (Strip Heaters). High moisture, especially condensation, is ruinous to electrical and electronic equipment. This condition occurs when the equipment is subjected to either damp atmospheres or varying temperatures (hot in daytime and cool at night). Cabinet heaters help avoid this condensation or excessive moisture. Some designs use heaters that are operated at one-half of their rated voltage, which reduces the temperature of the heater and increases its life. Also, some designs control the heater by use of a humidistat rather than a thermostat, which is more efficient because the purpose of the heaters is to control humidity. Designs that leave the heaters on continuously are outmoded and wasteful of energy.

Motor Heaters. Controllers may be equipped with pilot contacts to enable the motor heater or, depending on the wattage, the slave contactor for the motor heater. This contact will be closed except during motor running.

Controller Enclosure (Cabinet) Construction. NFPA 20 requires a minimum enclosure construction of NEMA Type 2 (UL Type 2), which is rated as and suitable for indoor use only and

is dripproof only. Note that this is the minimum requirement. NFPA 20 also requires that the "fire pump, driver, and controller" be protected against possible interruption of service through damage caused by "any adverse conditions." A NEMA 2 enclosure rating only "provides a degree of protection against limited amounts of falling water and dirt." They are tested for water dripping from the downward vertical direction only. They do not necessarily provide any degree of splash, spray, or water impingement from any of the numerous possible sources of pressurized water within the pump room, especially when the pump room is equipped with fire sprinklers. Also, NEMA 2 enclosures are not necessarily dustproof. The enclosure types described in Table 15.7.6 provide better protection than the standard NEMA 2 rating.

Another enclosure that is also available is the so-called NEMA 3R rated enclosure. It is rated for outdoor use for rain protection. This construction is typically the kind used for outdoor disconnect switches, such as on air conditioning units and outdoor advertising signs. It is basically a variation of NEMA 1 construction and it specifically allows water to enter the enclosure and accumulate within it, although the water is not allowed to wet electrical parts or accumulate to the level of the lowest electrical live part. This construction offers only limited protection of the controller since moisture can enter and accumulate therein. In some cases, the manufacturer builds a NEMA 3R enclosure similar to a NEMA 4 enclosure instead.

TABLE 15.7.6 Enclosure Types

Enclosure Type[a]	*Location*	*Protection*
NEMA 12	Indoor	Dripping water and dust (was splash and oil resistant)
NEMA 13	Indoor	Spraying water (and oil) and dust
NEMA 3	Outdoor	Rain, dust, and ice
NEMA 4	Outdoor	Rain, dust, ice, splashing, and hose-directed water (hose-tight)
NEMA 4XA	Outdoor	Same as NEMA 4, but corrosion resistant (special paint finish)
NEMA 4XB	Outdoor	Same as NEMA 4, but also corrosion resistant of type 304 stainless steel[b]
NEMA 4XC	Outdoor	Same as NEMA 4, but also corrosion resistant of type 316 stainless steel
NEMA 4XCL	Outdoor	Same as NEMA 4XC, but type 316 low-carbon stainless steel

[a]Differences exist between exact definitions and testing methods. The NEMA 4XA, 4XB, 4XC, and 4XCL designations are unofficial and are for reference only. These enclosures are considered as 4X.

[b]The 400 series of stainless steels (such as type 403) is magnetic and does not offer nearly the level of corrosion protection that the nonmagnetic 300 series of stainless steels offers.

The current requirements for raceway terminations for fire pump controllers address the problem of the fire pump controller Type rating being compromised by (1) the use of improperly rated conduit hubs and fittings and (2) field modifications made to the controller enclosure not endorsed by the controller manufacturer.

Current requirements for raceway terminations state the following:

1. Listed conduit hubs shall be used to terminate raceway (conduit) to the fire pump controller.
2. The (NEMA) Type rating of the conduit hub(s) shall be at least equal to that of the fire pump controller.
3. The installation instructions of the manufacturer of the fire pump controller shall be followed.
4. No alterations to the fire pump controller other than conduit entry per the *NEC* shall be allowed.

Other Approvals. To comply with NFPA 20, these controllers are all listed for fire service. Although other possibilities exist, they are all UL listed and almost all are also FM Global approved. Some equipment is available with "CE" (compliance with European norms) compliance certification. Note that these European norms (compliance requirements standards) are widely adopted equipment safety standards within and throughout the European Economic Community.

Electromagnetic Compatibility (EMC). Microprocessor-controlled equipment can and does radiate a certain amount of high-frequency noise. It is also susceptible to disruption by nearby portable radio equipment. Another approval available from some manufacturers is UL EMC certification of compliance (conformance) to standards covering electromagnetic radiation and other electrical disturbances such as transients, surges, and dropouts. The EMC standard used to access conformance (conformity) requires a two-way evaluation, meaning that the equipment is both tested for immunity (susceptibility) from these influences as well as tested and evaluated for emissions (radiation) of deleterious energy. Both radiated and line (power mains) conducted energy are evaluated.

TRANSFER SWITCHES

Where more than one source of electric power supply is needed, a power transfer switch is required to connect the power supplies to the controller. Some combinations use more than one such switch. The following section discusses other considerations and requirements regarding these switches.

There are two different methods of incorporating a power transfer switch. The first includes a listed combination fire pump controller and power transfer switch. The second includes an individually listed fire pump controller and power transfer switch. It is specifically required that both types of transfer switches be listed for electric motor–driven fire pump service. An ordinary listed transfer switch is neither adequate nor permitted. Fire pump transfer switches are also examined and tested to the requirements of UL 1008.

Combination Transfer Switch Fire Pump Controllers

Combination controller-transfer switch units are more common and provide for control of the pump motor and for the switching of the electric power supplies. These units are commonly called dual-source controllers (Figure 15.7.7).

Limited-Service Combination Units. As with single-source controllers (nontransfer switch controllers), these units are also available as listed and approved complete units. Most listed units can be used as service-entrance equipment. These units feature the same controller functions described in the section on limited-service controllers. They also provide all the required features of the power transfer switch as are required of full-service units. These units are subject to the same 30 hp (22 kW) limitation as their single-source counterparts.

Full-Service Combination Units. Full-service dual-source units are available as listed equipment in roughly the same variety as listed single-source controllers. They are available in the same starting types (ATL and reduced inrush starting) and in the same low-voltage ranges and horsepower ranges. Note that listed medium-voltage combination units are not available as of this writing. The listing criteria for these units examines their coordination, identification, location, interwiring, and interlocking requirements. Specifically, these units are examined against UL standards UL 1008 (transfer switches), UL 508 (industrial control equipment), UL 218 (fire pump controllers), and FM Standard FM-1321/1323 (fire pump controllers). The following discussion centers on those items that are not found in single-source controllers or that were not previously covered.

Short Circuit Ratings. The nameplate parameters of voltage, frequency, horsepower (or motor kilowatt) rating, and service factor are covered in the section on controllers. Short circuit ratings require additional concern with these transfer switch units as two sources of power are involved, which require two separate short circuit ratings. Also note that the controller normal side short circuit rating is the same as was discussed in the section on controllers. The emergency (alternate) source side will normally have both a short circuit rating and a maximum allowed size rating for the upstream circuit breaker.

When the alternate source of power is provided by a second utility power source, NFPA 20 requires an emergency side circuit breaker meeting the same requirements as the normal side (or single-source) fire pump circuit breaker. The emergency side nameplate short circuit ratings will give the required maximum short circuit rating of this (alternate utility side) power source in the same manner as the required normal side rating.

The more common case of a second power source is a standby generator. An emergency side circuit breaker is not required for smaller gensets. In the absence of this emergency side circuit breaker, the controller must show both the emergency side short circuit rating and maximum size (ampere) rating or rating of the upstream circuit breaker. This maximum upstream fuse or breaker size rating (restriction) is based on the tested and listed short circuit ratings of the transfer switch, which are based on the upstream device that limits and finally interrupts the fault current. Like the controller itself, the transfer switch short circuit ratings are also established by testing. This testing uses a maximum size breaker (or fuses) to limit the fault current that the transfer switch will be subject to and is capable of handling. Larger-frame-size circuit breakers (or fuses) will allow more fault current to pass compared to a comparable but smaller-frame-size breaker or fuse. This is why the use of a larger than rated breaker violates the transfer switch short circuit ratings. On the other hand, if the circuit breaker or fuses are too small, they may trip or blow prematurely, disabling emergency power to the fire pump. The result of either condition is an installation that is unreliable and unsafe to both personnel and property. Note that although upstream fuses are allowed and used, circuit breakers eliminate the need to search for replacement fuses, and also they avoid the problem of incorrect replacement fuses being used.

In general, standard controllers have emergency side short circuit ratings that are lower than the normal side ratings on any particular unit. They also vary with horsepower because the size of the internal transfer switch varies with horsepower. Larger switches have higher short circuit ratings and abilities. Some units use so-called self-protecting switches for the emergency side isolating switch, and, as a result, rate both sides with the same short circuit ratings. This is possible as they have been examined and/or tested to meet the short circuit and interrupting requirements in order to be so rated. For the same reason, the upstream breaker size restriction may no longer apply.

Additional Parameters. The following issues should be considered:

- *Normal side voltage sensors.* The transfer switch is required to transfer to the alternate source if the voltage in any phase falls below 85 percent of the motor's rated voltage. All listed controllers have a means to adjust the transfer voltage(s).
- *Phase reversal.* When a phase reversal of the normal source occurs, the transfer switch must initiate a transfer to emergency (by simulating a normal source power failure). Some designs use the controller's usual phase reversal circuitry on the load side of the transfer switch, whereas others use two separate sensors for the purpose.
- *Emergency side voltage and frequency.* The transfer switch is inhibited from transferring unless and until the genset output voltage has reached suitable voltage and frequency levels. This is usually monitored in only one phase of the emergency source to reduce costs.
- *Second utility (emergency side) three-phase voltage sensors.* If the unit is designed for dual utility application, the single-phase voltage/frequency sensor is replaced by three-phase sensing like that used on the normal source side.
- *Genset start signal (transfer) delay.* An adjustable delay is usually set for a few seconds to prevent nuisance starting of the genset on short duration power glitches (dropouts).
- *Retransfer delay.* Another adjustable delay is used to delay retransfer from the alternate power source to the normal source

until the normal source is stabilized (see NFPA 20). This is typically set to 30 minutes or so to avoid transferring back to the normal source while it is still experiencing outages, dropouts, or single-phase events, as is typical during a lightning storm. Retransfer delay also prevents problems caused when the genset runs for a short period of time.

Standard Components. The following issues should be considered:

- *Barriered or separate compartment.* It is important that faults occurring in the normal source compartment not be allowed to propagate into the emergency compartment and vice versa. This consideration is more critical at voltages above 240 Vac because the resulting arcs are more difficult to extinguish and more ionized gases are created. Besides being highly destructive, these ionized gases are highly conductive and are a means of fault propagation.
- *Emergency source isolating switch.* In these controllers, the other isolating switch is known as the normal source isolating switch. This emergency side isolating switch must be equipped with means to prevent starting of the emergency source generator from this controller if this isolating switch is open. This means, however, does not prevent starting of the genset from other means. This isolating switch must also be supervised both locally and remotely, which is usually done with multiple pilot switch or limit switch contacts actuated by the isolating switch or its mechanism.
- *Manual (mechanical) transfer.* A means for safe manual (nonelectrical) operation of the power transfer switch must be provided. This manual means need not be externally operable. At present, no listed units are externally operable. Thus, the controller door(s) must be opened to manually transfer the switch. As most standard transfer switches are not rated for manual switching under load, it is important that they be deenergized by opening both isolating switches before attempting a manual transfer. Both the normal and the emergency isolating switches must be opened to completely deenergize the power sources before attempting a manual mechanical transfer. Not following the prescribed procedure is a distinct safety hazard, especially if a short circuit is involved.
- *Push buttons.* Transfer switch controllers have a test push button to simulate a loss of normal source power. Although not specifically required, most or all listed controllers also have a bypass push button to retransfer the transfer switch back to the normal position. Note, however, that this retransfer is predicated on having suitable normal source power present. This bypass push button bypasses the retransfer delay timer, which is often set for around 30 minutes.
- *Other items.* The required controls (push buttons), lights, alarms, and remote alarm contacts are covered in the section on controllers.

Standard Features. The primary standard features have been discussed in the sections on standard equipment or important and other parameters. These include voltage and frequency sensors, phase reversal sensing, transfer and retransfer delays, and the genset start signal. Also required is a means to prevent higher-than-normal inrush currents when transferring the fire pump motor from one source to the other. These are the same high transient (spike) currents that can occur if a spinning motor is transferred to a source whose phase angle differs significantly from that of the motor's back EMF voltage. This is the same phenomenon described in the section on controllers (under restart delay and wye-delta open transition starting). The usual method to prevent such transient currents is for the transfer switch to signal the controller to shut down the motor for a few seconds while inhibiting transfer of the transfer switch. This is to allow enough time for the motor magnetic flux to decay to a safe level.

Another means that can be used is the so-called program neutral type of transfer switch. Rather than switching immediately from one source to another, the transfer switch has an in-between (neutral) open position in which the load is not connected to either source. In operation, the switch first moves to this in-between (neutral) position and dwells there for a few seconds. At the end of this delay, the switch completes its travel to the other power source.

A third method is sometimes specified for these controllers for this same purpose. It is the so-called in-phase monitor circuit available from transfer switch suppliers. This scheme is highly variable in fire pump installations. It should not be used without one of the other schemes for controlling transient currents. The variables are due to several factors. The first one is the low-inertia nature of centrifugal pumps, which causes very rapid spin down when power is interrupted. The second variable is the fact that there can be a permanent difference of phase angle between the two sources such as with a dual utility, even though the phase sequence (rotational sense) can still be correct. For example, one source can be described as having phases A-B-C whereas the other might be B-C-A or C-A-B. These last two phases are 120° apart from the first and from each other. The third factor is that the transfer may be due to a phase reversal.

Other Features of Combination Controllers. Another standard feature can include an emergency source circuit breaker. As stated earlier, where the alternate (emergency) source is another utility source (i.e., a second utility), the controller must have a second circuit breaker and locked rotor overcurrent protection the same as the normal source side of the controller. Its emergency isolating switch must meet all the requirements of the normal source isolating switch. In certain installations, the alternate source is on-site generation from large gensets such as those used with "emergency bus" type installations. Moreover, the emergency bus may be normally fed by more than one source through one or more transfer switches, is usually normally "hot" (energized), and usually fed by a utility source in the normal or standby condition. This is another reason for having an emergency side (second) circuit breaker in the controller in these installations, because this utility source may be capable of high-fault currents. In any case, the controller emergency side short circuit rating must be suitable for the sources to which it is or to which it can be connected, particularly when a combination of upstream transfer switches may ultimately connect to a utility source of power.

Nonmandatory Features. Some transfer switch controller combinations have a mechanical interlock between the normal source isolating switch and the emergency source isolating switch. This interlocking prevents the emergency source side switch from closing if the normal source side switch is still open. This prevents false or inadvertent starting of the genset due to lack of power on the normal source side circuitry. Similarly, the normal side switch cannot be opened until the emergency switch is also opened. The transfer switch and genset can still be tested in these designs by opening the normal side circuit breaker.

The following issues should be considered:

- *Engine "overrun" (cooldown) timer.* All listed controllers have either an optional or a standard engine overrun timer. This timer keeps the start signal to the genset asserted after the transfer switch has retransferred back to the normal source. The purpose is to allow the engine to cool down with no load applied to its generator, which, therefore, allows the engine to run unloaded. This timer is typically set for 10 to 30 minutes.
- *Load shed contacts.* Load shed contacts are used to signal another load to disconnect from the genset in order to provide enough power and current to start the fire pump. These contacts are usually maintained for the entire time that the fire pump runs. In other cases, the contacts are momentary to unload the genset enough to start the fire pump but then allow some loads to reconnect to the genset. This scheme may also include delaying the start of the fire pump for up to 10 seconds to allow time for the shed loads to disconnect.
- *Higher short circuit ratings.* All listed controllers are available in higher short circuit ratings on the emergency source side as well as on the normal source side.
- *Emergency side circuit breaker.* Even when not mandatory, this option provides better protection for the fire pump motor. It may also be used in conjunction with higher short circuit ratings on the emergency source side, particularly when used with higher-capacity gensets or on high-capacity emergency bus systems.
- *Other options and modifications.* Other optional equipment or features are available from the various listed controller manufacturers. Oversized transfer switches are sometimes requested for higher reliability and/or higher short circuit ratings. Sometimes transfer switches from a specific manufacturer are specified and supplied to coordinate with other transfer switches used in a facility or building. Also, some transfer switches are supplied with communication ports to allow communication of status information with so-called building automation systems, telemetry systems, or remote monitoring and alarm recording systems. Additional or other nonstandard alarm and signal contacts and/or alarm lights are also available.

Individual Power Transfer Switch and Fire Pump Controllers

Individual power transfer switch and fire pump controller units consist of a listed single-source (nontransfer switch) fire pump controller and a listed fire pump power transfer switch (see Figure 15.7.7). As previously stated, both the transfer switch and fire pump controller must be listed for fire protection service. It should be noted that not all UL-listed transfer switches are listed for fire service.

Much of the section on combination controllers also applies to these separate transfer switches. This section will detail different and/or additional requirements for installations using separate transfer switches. These are also known as upstream transfer switch installations.

Location. The transfer of power to the fire pump controller between the normal supply and the alternate supply must take place within the pump room. Hence, the fire pump transfer switch must be installed in the same pump room or pump house as the fire pump controller to which it is connected.

Number of Switches Required. If alternate power is required for one or more fire pumps, each fire pump controller requires its own dedicated transfer switch. More than one fire pump (controller) cannot be fed from a single transfer switch.

Coordination of Short Circuit Current Ratings. The same considerations regarding short circuit ratings for the combination controller transfer switch also apply to the separate transfer switch. Here, however, neither the manufacturers of the controller nor the transfer switch provide the coordination.

NFPA 20 requires an isolating switch, or service disconnect, where required, ahead of the normal input terminals of the transfer switch. This requirement will be the case for any transfer switch unless the service device, usually a circuit breaker, is supplied as part of the transfer switch and the transfer switch is rated, listed, and labeled as service entrance equipment. If this circuit breaker is not provided, an upstream device must be supplied. It must meet, among other things, the 600 percent rule that requires that any such overcurrent protective device be selected or set to carry indefinitely the sum of the locked rotor current of the fire pump motor plus any additional connected loads. This requirement is a very important limitation to the transfer switch short circuit rating since its size must not exceed the maximum upstream device size qualification of the transfer switch short circuit rating.

With separate transfer switches, this rating will apply to both incoming sides, normal and emergency, unless circuit breakers are supplied as part of the transfer switch. As a result, the coordination may be missing or incorrect. A dangerous and unreliable situation then ensues. For specifics, see NFPA 20 and NFPA 70.

The transfer switch must be sized at 115 percent of the motor FLA current. However, the transfer switch will most likely have to be larger in order to meet the maximum size rating of the upstream circuit breaker (or fuse).

The matter is further complicated by the listed transfer switch manufacturers typically having two or three different short circuit device rating charts. Typical is (1) the any breaker or the any molded case breaker rating, (2) the specific breaker or coordinated breaker ratings, and (3) the fuse category, which is usually of a particular type (class) of fuse.

Coordination of Phase Reversal Switching. The transfer switch is required to switch to emergency power on reversal of

the normal source power. This phase reversal sensing circuitry should be included as part of the transfer switch. Either two such circuits are needed, or else one such circuit should be on the load side of the transfer switch.

Coordination of Alternate Source Isolating Switch. When the alternate power source is a second utility, another upstream service and overcurrent device like the one described previously is required and must also meet the 600 percent sizing rules. Otherwise, for the more typical genset alternate power source installations, an emergency side isolating switch is required. Again, due to cost, such a switch is not standard equipment on all listed fire pump transfer switches. It must either be ordered as an option with the switch or purchased and installed separately. In any case, the switch must meet the following requirements:

- It must be lockable in the "On" position. Note, incidentally, that all listed enclosed isolating or safety switches can be locked in the "Off" position, but not all of them are capable of being locked in the "On" position.
- A placard with large (1.0 in. [25.4 mm]) lettering must be affixed to the outside of this switch reading "Fire Pump Isolating Switch."
- Another placard must be mounted in the pump room "adjacent to the fire pump controller," stating the location of this switch and the location of the key for unlocking it.
- The isolating switch must be supervised to indicate when it is not closed. Four methods are allowed and listed in the standard.
- The supervision must operate an audible and visual (alarm light) on the transfer switch and also at a remote point where required.
- Contacts to interlock with the transfer switch engine start contacts are required to prevent signaling the genset to start if this isolating switch is open.

Alarm Circuits. The transfer switch will usually have at least one set of position-indicating remote alarm contacts as standard. It may or may not have the position-indicating lights as standard. It will not likely have the isolating switch alarm light and contacts unless it is ordered with an isolating switch as part of the transfer switch.

Generator Start Circuit Override. The transfer switch will normally have the engine start contacts as standard equipment. However, it will not normally have the engine start override (lockout) means, unless it is ordered with an isolating switch option. These contacts are needed to prevent undesired and/or unexpected starting of the genset by this transfer switch when the isolating switch (wherever it is located) is opened. Note, however, that other transfer switches can and will start the genset.

Higher-Than-Normal Inrush Currents. A means must be provided to prevent higher-than-normal inrush currents when transferring the fire pump motor from one source to the other. As discussed in the section on combination units, there are currently three methods used for this purpose. The momentary motor shutdown method requires signaling circuitry (contacts) wired from the transfer switch to the fire pump controller, properly equipped, to momentarily shut down the fire pump motor.

Checklist. All the following should be verified for each installation. The following is usually supplied:

- NEMA 2 enclosure as a minimum
- The manual (mechanical) transfer means
- The three normal side voltage sensors
- The alternate side single-phase voltage and frequency sensor (for genset applications)
- The manual (mechanical) transfer means
- The two position indicator lights
- The engine start delay timer and the retransfer delay timer
- The engine start contacts
- The test (transfer) switch (push button)

The following may not be supplied as standard equipment:

- Three-phase voltage sensing on the alternate source side for dual (second) utility jobs
- The normal side service disconnect and overcurrent protection fuses or breaker
- A second service-entrance device for dual-utility jobs
- The emergency side isolating switch
- The ability to lock the emergency side, isolating switch in the "on" position
- An external fire pump isolating switch placard
- A placard next to the controller giving the location of this isolating switch
- Supervision of the isolating switch by one of the four means given
- Contacts to interlock with the engine start contacts
- Audible and visible alarm to indicate isolating switch open
- Isolating switch contacts for remote alarm
- Means to prevent higher-than-normal motor inrush currents
- Phase reversal sensing and transfer circuitry

Finally, the coordination of both the normal source side and the alternate source side short circuit ratings must be performed by someone. This coordination must include (1) any upstream protective device(s), (2) the transfer switch, (3) the fire pump controller, and (4) the available short circuit current. Unfortunately, miscoordination may not be discovered until it is uncovered during an inspection; worse yet, miscoordination may not be discovered even then. Installations that are not coordinated for proper short circuit protection are more likely to be unreliable and unsafe from a personnel and fire hazard standpoint.

SUMMARY

Fire pumps are critical to fire protection systems because they generate the necessary waterflow and pressure needed for fire control and extinguishment. It is especially true where more than one pump must be relied on for proper system operation. Therefore, the components that go into fire pumps are equally important and must be properly designed, installed, and main-

tained. This chapter presented information on fire pump components, specifically on the electric power supply and control aspects of motor-driven fire pump installations.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on the fire pump controllers and power supply arrangements for motor-driven fire pumps discussed in this chapter. SECTION 16

Water-Based Fire Suppression Equipment

Christian Dubay

16.1 Principles of Automatic Sprinkler System Performance
16.2 Automatic Sprinklers
16.3 Automatic Sprinkler Systems
16.4 Hanging and Bracing of Water-Based Systems
16.5 Sprinkler Systems for Storage Facilities
16.6 Residential Sprinkler Systems
16.7 Ultra-High-Speed Water Spray Systems
16.8 Water Mist Fire Suppression Systems
16.9 Water Spray Protection
16.10 Standpipe and Hose Systems
16.11 Care and Maintenance of Water-Based Extinguishing Systems

The eleven chapters in Section 16 of the *Fire Protection Handbook*® review water-based fire suppression equipment. Water-based fire suppression was perhaps the first fire protection technology and has evolved to become a widely used mainstay of fire protection.

Chapter 1, "Principles of Automatic Sprinkler System Performance," describes the thermal response, water distribution, and spray cooling characteristics of sprinklers and distinguishes between fire control and fire suppression by sprinklers.

Chapter 2, "Automatic Sprinklers," presents the operating principles, temperature ratings, and water discharge characteristics of automatic sprinklers and describes types of sprinklers. In a similar vein, Chapter 3, "Automatic Sprinkler Systems," covers topics such as system components and materials, installation requirements, and design considerations, as well as plans, calculations, and system acceptance.

Chapter 4, "Hanging and Bracing of Water-Based Systems," considers hangers, hanger installation, earthquake bracing, and joint restraint of underground piping.

Chapter 5, "Sprinkler Systems for Storage Facilities," begins with a discussion of commodity classification and storage arrangement, height, and clearance. It then discusses sprinkler systems and associated design factors unique to storage operations.

Automatic sprinkler systems were first developed for and are still predominantly used in nonresidential occupancies. By contrast, Chapter 6, "Residential Sprinkler Systems," describes specialized technology for residential sprinkler systems, residential sprinkler standards, residential sprinkler experience, and incentives for more widespread use of residential sprinklers.

The section next turns to two highly specialized types of systems. Chapter 7, "Ultra-High-Speed Water Spray Systems," introduces types of systems that are available for explosion protection, including squib-actuated systems, pilot-actuated systems, and portable systems. The use of water mist fire suppression, discussed in Chapter 8, "Water Mist Fire Suppression Systems," came about as a result of requirements for sprinklers on passenger ships and the search for alternatives to ozone-depleting halocarbons. The chapter provides details on the components, types of systems, calculation methods for single and twin fluid systems, pump selection and application of positive displacement pumps, and maintenance issues.

Chapter 9, "Water Spray Protection," covers the uses and applications of water spray systems for fire suppression, control, and extinguishment and describes the components of spray systems and the specialized uses of the systems. The primary distinction between a water spray and a sprinkler system is that of specific coverage versus general area coverage. Water spray systems have typically been provided to protect a specific piece of equipment with surface coverage.

Chapter 10, "Standpipe and Hose Systems," describes design and installation considerations, commissioning, and fire department operations using standpipe systems. Outside hose systems are also reviewed.

Christian Dubay, P.E., is NFPA's vice-president, codes and standards, and chief engineer.

The section concludes with treatment of system inspection and maintenance. Chapter 11, "Care and Maintenance of Water-Based Extinguishing Systems," covers the activities that are central to system reliability. Among other topics, the chapter covers sources of obstruction in sprinkler system pipes and methods for flushing and cleaning them, as well as sprinkler leakage and water damage.

Thermal Response of Sprinklers
Water Distribution and Spray Cooling Characteristics of Sprinklers
Interaction of Sprinkler Distribution and Burning Fuel
Fire Control by Sprinklers
Fire Suppression by Sprinklers
Recent Developments

Key Terms

actual delivered density (ADD), automatic sprinkler system, convective heat flow, density/area curve, heat release rate, required delivered density (RDD), spray pattern, sprinkler sensitivity, thermal response, water distribution

Most fire sprinkler systems are designed so that each individual sprinkler can react to heat from a fire, operating to distribute water over the source of that heat. The complex nature of the interaction of fire and sprinklers historically has prevented an analytical approach to sprinkler system design, but today there is a growing appreciation for measuring the performance characteristics of sprinklers and for using those characteristics in new combinations to achieve specific fire protection goals. The characteristics include thermal response, water distribution, and fire suppression and control capability.

This chapter discusses the response, distribution, and fire-extinguishing characteristics of automatic sprinkler systems and the mechanisms by which it is believed that those characteristics work together for successful sprinkler system performance.

See also Section 2, Chapter 7, "Theory of Fire Extinguishment," and other chapters in Section 16, particularly Chapter 2, "Automatic Sprinklers"; and Chapter 6, "Residential Sprinkler Systems."

THERMAL RESPONSE OF SPRINKLERS

Although it is possible to equip sprinkler systems with elaborate detection systems intended to recognize other fire products or signatures, it is heat detection that serves as the basis of sprinkler system response. Therefore, a basic understanding of heat production and movement in a fire is an important first step in an analysis of the way fire sprinkler systems work.

Convective Heat Flow in Fires

Since combustion is an exothermic process, burning fuels produce heat. Even smoldering fires produce heat, although the level of heat can be so low as to be ineffective in actuating thermal detectors. However, smoldering fires generally develop to a flaming stage before producing untenable room conditions. Once the fire reaches the flaming stage, the heat release rate of the fire will grow in a manner related to the nature of the fuel and its arrangement, the ventilation conditions, and other factors.

Heat is released from a fire in several forms: radiation, conduction, and convection. It has been determined that convective heat transfer is most important in activating sprinklers.[1] Convective heat transfer involves heat transfer through a circulating medium, which, in the case of fire sprinklers, is the room air. The air heated by the fire rises in a plume, entraining other room air as it rises. When the plume hits the ceiling, it generally splits to produce a ceiling gas jet (Figure 16.1.1). The thickness of this ceiling jet flow is approximately 5 to 12 percent of the height of the ceiling above the fire source, with the maximum temperature and velocity occurring 1 percent of the distance from

Russell P. Fleming, P.E., is executive vice-president for the National Fire Sprinkler Association, Inc., in Patterson, New York. He has served on more than a dozen different NFPA technical committees, including the Technical Correlating Committee on Automatic Sprinklers.

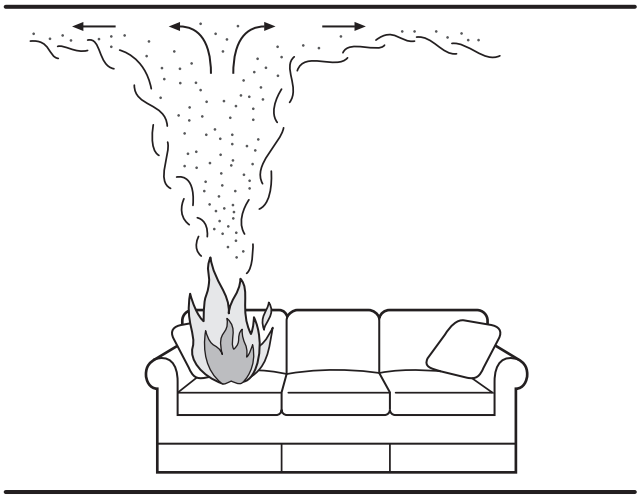

FIGURE 16.1.1 Plume-Ceiling Interaction

the ceiling to the fire source.[2] The heat-sensing elements of sprinklers within this ceiling jet are then heated by conduction of the heat from the air.

Quantifying Sprinkler Sensitivity

Tremendous effort has been made in recent years to quantify the thermal sensitivity of sprinklers and other heat-actuated detectors. This effort is aimed at making it possible to use analytical methods to predict the time of sprinkler response.

Several terms have come into use as part of this process. One is the time constant τ (tau), which is a measure of the thermal sensitivity of a body and is defined as:

$$\tau = \frac{mc}{h_c a}$$

where

m = Mass of the body

c = Specific heat of the body

h_c = Convective heat transfer coefficient

a = Area of the body exposed to gas flow

The time constant has units of seconds but cannot be determined readily for any specific body due to difficulties in estimating the convective heat transfer coefficient. This term varies with the velocity of the gases that pass by the body. As a result, the time constant is measured using a plunge test apparatus, first developed for use with sprinklers in 1976.[3] This apparatus generally consists of a circulating air oven with a known air temperature and velocity (Figure 16.1.2). The air temperature is set well above the nominal operating temperature of the sprinkler. At time $t = 0$, a sprinkler is "plunged" into the heated air. The amount of time it takes for the sprinkler to operate is recorded and is presumed to be the time necessary for the sprinkler operating mechanism to move from room temperature to the nominal operating temperature.

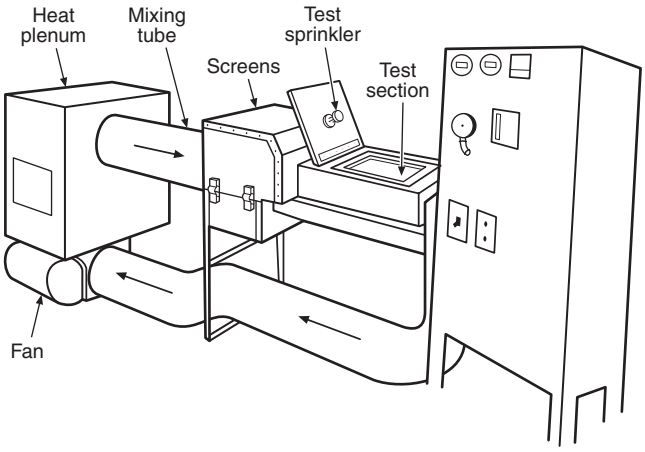

FIGURE 16.1.2 Sprinkler Plunge Test Apparatus

The use of the plunge test permits determination of the time constant, because it provides two data points with regard to the sensitivity of a sprinkler. It is known that the sprinkler was at ambient room temperature, T_a, at $t = 0$, and it is known that the sprinkler reached its nominal operating temperature, T_L, at time $t = t_{act}$, the time of sprinkler activation. Based on the known shape of the curve by which a body takes on or loses heat to its environment, the time constant can be determined. Under plunge test conditions, involving a constant environmental temperature, the time constant is effectively the amount of time that would be needed for the body to move 62.8 percent of the way to the temperature of its heated environment (Figure 16.1.3). In an environment in which the temperature is constantly increasing, the time constant is the amount of time by which the body lags behind its environment after some initial period of time equal to approximately four times the time constant (Figure 16.1.4).

Due to the fact that the time constant varies with the velocity at which it is measured, it is not a particularly useful term. Researchers at Factory Mutual Research Coporation (now FM Global) therefore developed a new term, "response time index" (RTI), as a measure of sprinkler sensitivity independent of velocity.[4] The researchers observed that the convective heat transfer coefficient of blunt bodies in cross-flows was roughly

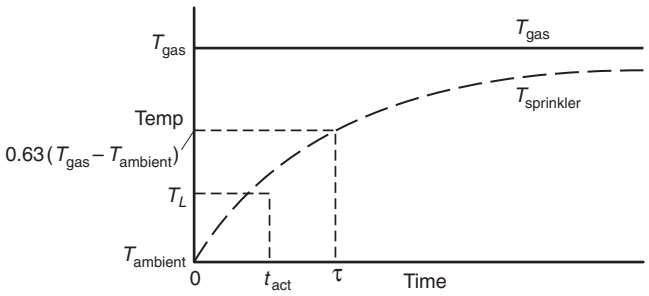

FIGURE 16.1.3 Representation of Time Constant τ for Constant Temperature Condition

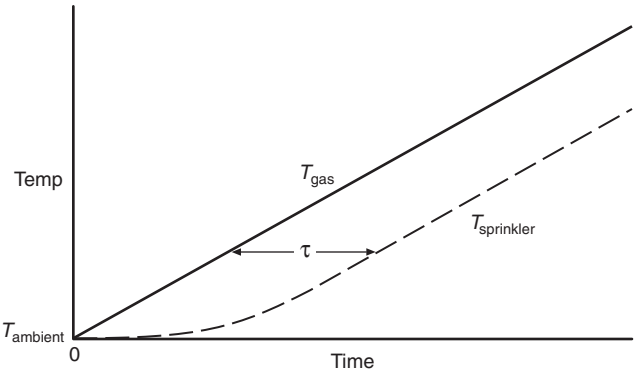

FIGURE 16.1.4 Representation of Time Constant τ for Constantly Increasing Temperature Condition

proportional to the square root of the velocity of those flows. This meant that the time constant is roughly proportional to the inverse of the square root of flow velocity. By multiplying the time constant by the square root of its corresponding velocity, they could eliminate the effects of the convective heat transfer coefficient's dependence on flow velocity:

$$\text{RTI} = \tau u^{1/2} = \text{A constant}$$

It should be noted that, depending on the units of velocity used, the actual units of RTI are either $m^{1/2}sec^{1/2}$ or $ft^{1/2}sec^{1/2}$. U.S. customary RTI values are 1.81 times the equivalent metric RTI values.

Laboratory determination of the RTIs of various devices has permitted the development of computer programs that predict the operating time of heat detectors and sprinklers based on the heat release history of a fire in conjunction with the ceiling height and radial distance of the detector or sprinkler from the fire.[5] These programs must be used with caution, since they represent only a rough correlation to actual conditions. It should also be noted that they are not appropriate for use with sprinklers following the start of water discharge.

The models of sprinkler sensitivity have recently been modified to account for conduction losses from the sprinkler operating mechanism to the sprinkler frame, fittings, and water in the adjacent piping. These new complexities are not taken into account by the original computer models.

The importance of conduction losses was established in 1986 sprinkler industry test work comparing various sprinklers.[6] These tests showed that the apparent RTI of some sprinklers increased at low velocities, particularly for sprinklers with high conductivity between the sprinkler operating mechanism and the sprinkler body. For example, Figure 16.1.5 shows response time indexes as a function of velocity.[6] In Figure 16.1.5, sprinklers D-P and D-S represent specific models of standard pendent and sidewall sprinklers, A and MA represent quick-response, flush-type pendent and sidewall sprinklers, and FR represents a specific quick-response sprinkler model with conventional frame arms.

Although it might seem beneficial to seek to control the conduction effect to maintain a constant RTI, the tests also demonstrated that the phenomenon could be helpful in preventing

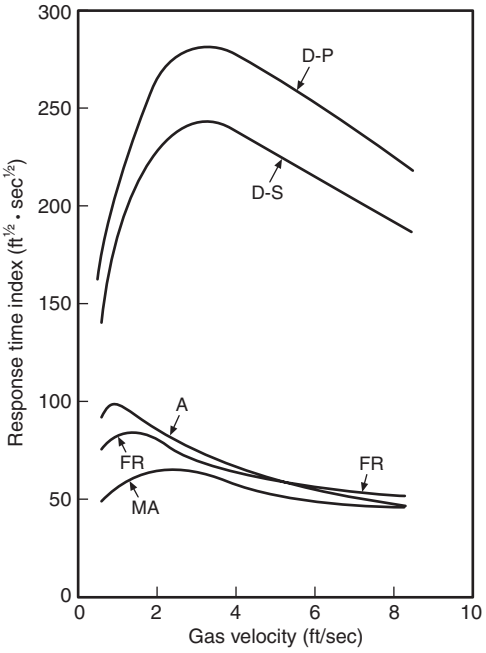

FIGURE 16.1.5 Response Time Indexes as a Function of Velocity (Courtesy of Tyco Fire & Building Products)

excessive sprinkler operations, since velocities tend to decrease with distance from the fire.

Following those tests, the FMRC researchers reviewed the original thermal response model and RTI concept and the plunge test devised for measuring RTI. They then introduced a modified model that incorporated a conductive heat loss factor.[7]

Additional testing using the plunge test apparatus yields a value for *C,* the conductivity factor. For purposes of using computer models to estimate the time of sprinkler activation, a value of "virtual RTI" can be calculated as:

$$\text{RTI}_v = \frac{\text{RTI}}{1 + C/u^{1/2}}$$

The virtual RTI can be used successfully whenever the gas velocity is fairly constant or does not change rapidly with time. With the exception of small turbulent fluctuations, this is usually the case with actual fires.

The revised model assumes that the sprinkler fitting is essentially at ambient temperature and that the conductive heat loss rate is proportional to the temperature rise of the sprinkler operating element. Experimental programs have demonstrated the accuracy of the revised model.

WATER DISTRIBUTION AND SPRAY COOLING CHARACTERISTICS OF SPRINKLERS

Relatively little can be accomplished from a design engineering standpoint with regard to the specific spray patterns produced by sprinklers. The distribution pattern of most types of sprinklers is tested only for overall coverage under specific geometric

conditions. At present, there is no method of predicting the actual amount of water that will be delivered to a specific unit of floor area under actual fire conditions, especially since spray patterns vary with water discharge pressures.

Figure 16.1.6 demonstrates the variability of the spray pattern of a typical pendent spray sprinkler with a nominal orifice coefficient of K = 5.6 (K_m = 80) when discharged under non-fire conditions at selected pressures. A 7 psi (0.5 bar) operating pressure is considered minimum by NFPA 13, *Standard for the Installation of Sprinkler Systems*. At that minimum pressure, the extent of the spray pattern roughly approximates that of the maximum light-hazard spacing permitted by NFPA 13, when the sprinkler is located 8 ft (2.4 m) above the floor. The spray pattern enlarges as the operating pressure is increased to about 70 psi (4.8 bar), then begins to contract at higher pressures, becoming more elliptical in shape at the upper end of the allowable pressure range. Within the wetting area, the water application rates vary considerably, such that the concept of an average density over the coverage area of a sprinkler provides only the roughest approximation of the amount of water that might actually be reaching a particular unit of floor area.

Some studies have been made of individual droplet size and motion. For geometrically similar sprinklers, the median droplet diameter in the sprinkler spray has been found to be inversely proportional to the one-third power of water pressure and directly proportional to the two-thirds power of sprinkler orifice diameter,[8] such that:

$$d_m \propto \frac{D^{2/3}}{\rho^{1/3}} \propto \frac{D^2}{Q^{2/3}}$$

where

d_m = Median droplet diameter

D = Orifice diameter

ρ = Pressure

Q = Rate of waterflow

Total droplet surface area is proportional to the total water discharge rate, divided by the median droplet diameter

$$A_s \propto Q / d_m$$

where A_s is the total droplet surface area.

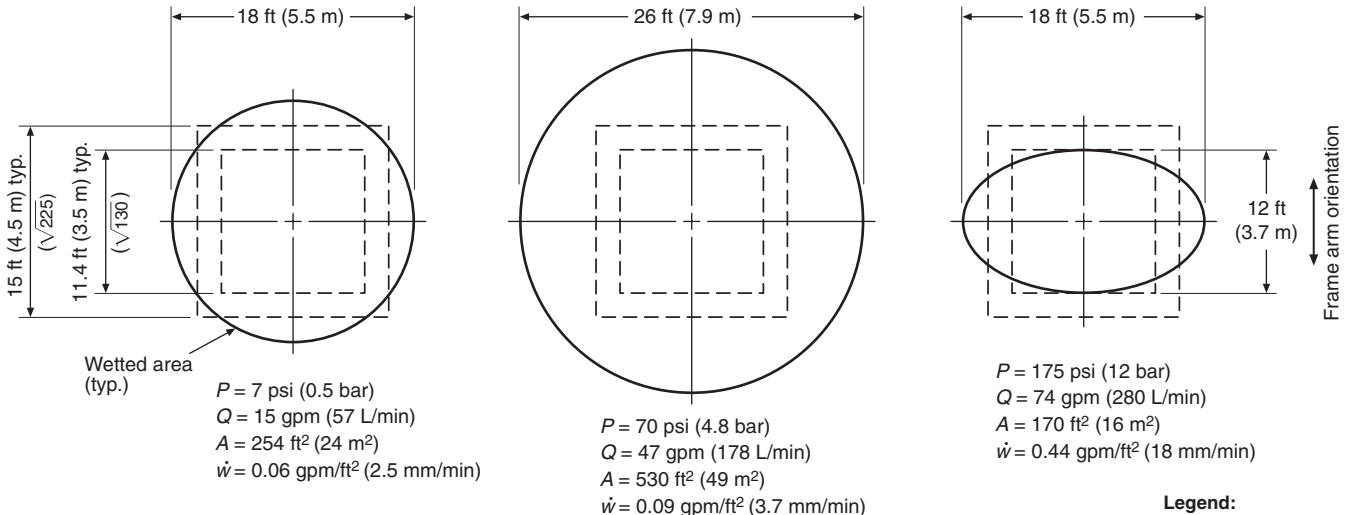
Combining these relationships, it can be seen that:

$$A_s \propto (Q^3 \rho D^{-2})^{1/3}$$

The heat absorption rate of a sprinkler spray can be expected to depend on the total surface area of the water droplets, A_s, and the temperature of the ceiling gas layer in excess of the droplet temperature. The total cooling ability of a sprinkler also depends on the depth of the ceiling jet or smoke layer through which the droplets pass.

INTERACTION OF SPRINKLER DISTRIBUTION AND BURNING FUEL

Sprinklers can be effective against fires in a number of ways. One of the most efficient, in terms of use of water, is simply through the cooling effects of the water spray. The production of a mist of fine water droplets can cause significant cooling, which reduces the radiative feedback to the fire below that which is needed to sustain combustion. In addition, the evaporation of water droplets can produce steam with a volume more than 1700 times that of the water and can deprive the fire of needed oxygen. This combination of "spray cooling" and "smothering," although efficient, has its limitations. It generally works well only if the fire is contained within an unventilated enclosure.[9]



Notes:
1. The sprinkler is mounted 8 ft (2.4 m) above the floor.
2. The smaller dashed square indicates the tributary area of the sprinkler at maximum uniform ordinary-hazard spacing, per NFPA 13.
3. The larger dashed square indicates the tributary area of the sprinkler at maximum uniform light-hazard spacing, per NFPA 13.

Legend:
P = pressure
Q = flow
A = area
$\dot{w}$ = average density over wetted area

FIGURE 16.1.6 Spray Pattern (Floor Level) Versus Discharge Pressure

The greatest efficiency is in the smallest enclosures, since almost all water droplets can be evaporated by contact with enclosing surfaces, and smothering is enhanced.[10]

In 1955, Nash and Rasbash[10] reviewed extensive tests of manual water extinguishment of fully developed room fires and suggested that there is a minimum "critical rate" of water application below which the fire cannot be extinguished. With increased rate of water application above the critical rate, the time needed to control or extinguish the fire falls rapidly. With further increases in the rate of water application, the time to extinguish diminishes more slowly (Figure 16.1.7).[10] Under the best of conditions, fires in model rooms could be extinguished with scanned jets or sprays with about 1 (imperial) gal per 1000 ft^3 (4.5 L/28.4 m^3) of room volume. It was found that a fixed spray with a medium degree of ventilation could extinguish the fire with about 2 (imperial) gal per 1000 ft^3 (9 L/28 m^3) of room volume.

Automatic sprinklers, of course, are expected to operate before total room involvement. To some extent, this makes their job more difficult, since the sprinkler spray is not readily evaporated to steam.

In a large, open, or well-ventilated area, a strong fire can create updrafts that sweep away the small droplets, making them ineffective. For this reason, traditional sprinkler system design is based on the idea of distributing a variety of droplet sizes over the burning fuel area to maintain relatively low ceiling temperatures while controlling or extinguishing the fire.

FIRE CONTROL BY SPRINKLERS

The traditional method by which sprinkler systems control fires currently is being termed the "fire control" approach. This method anticipates that a certain number of sprinklers will be opened surrounding the fire area. Although the sprinklers immediately over the fire may not be able to actually extinguish the fire, they will work with other open sprinklers to cool the atmosphere and to prevent sprinklers outside the general vicinity of the fire from operating. In the meantime, the open sprinklers outside the immediate fire area also can be expected to prewet adjacent combustibles, helping to prevent the spread of fire.

Figure 16.1.8 represents the fire control condition that can be achieved by sprinklers. In this steady-state condition, two separate energy balances must take place. At the level of the fuel, the water reaching the fire must be capable of reducing the burning rate to the point at which, in combination with the prewetting of adjacent combustibles that has taken place, the fire will not spread to additional fuel. Simultaneously, at the ceiling level, the cooling effect of the water spray from open sprinklers must be sufficient to absorb the heat of the fire plume so as to prevent additional sprinklers from operating and to maintain temperatures below those that would result in structural damage to the building.

In the fire control condition, the area over which sprinklers open generally exceeds the maximum area of the fire. The appendix of NFPA 13 provides typical examples of relative sizes of damaged areas of the test array and sprinkler operating areas (Table 16.1.1).

With sprinklers operating in the fire control mode, the central fuel package is eventually depleted and the fire is extinguished. For fire control by sprinklers, the heat release rate of the fire over time can be characterized, as shown in Figure 16.1.9.

Various studies have been made of the water application rate needed to extinguish or control fires in fully ventilated

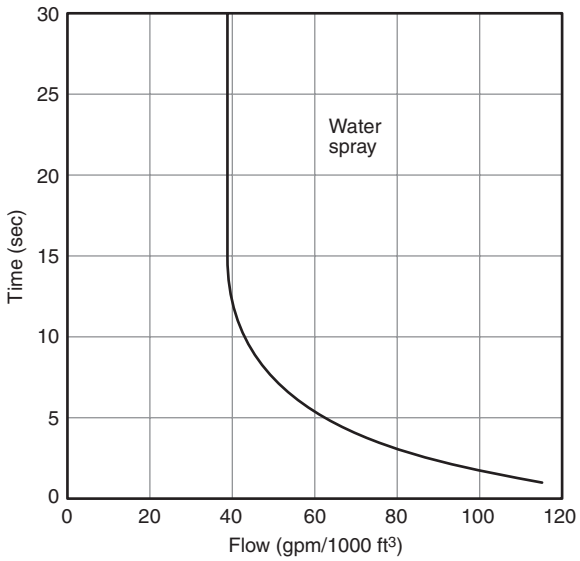


FIGURE 16.1.7 Time to Extinguish Fire in Model Room at Various Flows. For S.I. units: 1 gpm = 3.785 L/min; 1 ft^3 = 0.0283 m^3.

areas, both on simple surfaces and in complex fuel arrangements. The critical rate for wood appears to be between 0.0022 and 0.0044 gpm/ft^2 (0.09 and 0.18 mm/min), increasing to a degree with preburn.[11] For some plastic surfaces, the critical rate appears to be in the range of 0.02 to 0.065 gpm/ft^2 (0.82 and 2.67 mm/min), higher with external radiation.[12] These values are per unit of burning surface area, not floor area, and are determined under laboratory conditions.

For realistic fuel arrangements, the unit surface area of burning combustibles can be many multiples of the unit floor area protected by sprinklers. British fire tests have indicated that, for midsize wood cribs, water applied through impinging jet nozzles at rates less than 0.275 gpm/ft^2 (11.2 mm/min) of unit surface area had little effect on the actual burning zone.[13] The tests also indicated that application rates as low as 0.0625 gpm/ft^2 (2.56 mm/min) of unit surface area were found to be sufficient to limit flame spread within the crib.

Density/Area Curves

The density/area curves that form the basis of standard sprinkler system design can be considered to reflect historical experience with the fire control concept. Although most fires are extinguished or contained by only a few sprinklers, the more troublesome deep-seated fires historically have opened more sprinklers and justifiably have influenced the standards writers. System design criteria must address a reasonably worst-case situation.

The first edition of NFPA 13, published in 1896, contained simple pipe schedules that limited the maximum number of sprinklers that could be fed through each size of pipe. Combined with a minimum supply pressure of 25 psi (1.7 bar) at the highest line of sprinklers, the pipe schedule was expected to adequately provide water to at least 15 sprinklers.

The pipe schedule for sprinkler systems was altered many times, and the concept of different pipe schedules for various "hazards" was instituted with the development of "Class B" (later to become light-hazard) criteria in 1930 and the development of an extra-hazard pipe schedule in 1940.

The use of hydraulic calculation methods for fire sprinkler systems actually started in 1929, with the first formal compilation of Hazen-Williams friction loss tables and other hydraulic data in 1931.[14] NFPA 13 first addressed hydraulic calculations in its 1955 edition, but the use of such calculations was limited essentially to deluge system and water spray applications until the inclusion of density/area criteria in the 1972 edition of the standard. NFPA 231C, *Rack Storage of Materials,* the first standard developed based on fire test data, was adopted in 1971, and 1972 saw the insertion of density/area curves into NFPA 231, *Standard for General Storage,* although basic criteria had appeared as early as 1965. Density/area curves from NFPA 231 and 231C were merged into NFPA 13 beginning with the 1999 edition. The density/area curves in NFPA 13 were modified significantly in 1974 and again in 1991 as part of an overall reorganization and simplification of the standard. As developed in 1974, the curves reflect the hydraulic capability of pipe schedule designs that had proved satisfactory in nearly a century of experience.

The merging of ordinary-hazard groups 2 and 3 in the 1991 edition of NFPA 13 created a system design point of 0.2 gpm/ft^2 (8.1 mm/min) over 1500 ft^2 (135 m^2) for a hazard that could essentially be considered the processing and display of ordinary combustibles. This relates well to the historical development and use of the standard sprinkler system. The 1991 density/area curves are shown in Figure 16.1.10.

The density/area curves have traditionally provided some flexibility in system pipe sizing. Under provisions of NFPA 13, meeting any point on the appropriate curve is acceptable. This permits the use of higher densities over smaller areas or lower densities over larger areas. Higher densities with smaller areas will generally result in larger branch-line piping but lower main sizes and lower overall water supply requirements. For this reason, a high-density, small-area point is often selected as the most economical.

Modifications to the density/area curves have traditionally been made to reflect special conditions. The use of high-temperature sprinklers, where permitted for fast-developing fires, is expected to help limit the area over which sprinklers operate. The delay in water delivery resulting from the use of a dry-pipe system is expected to open additional sprinklers prior to the onset of fire control, necessitating a larger sprinkler design area.

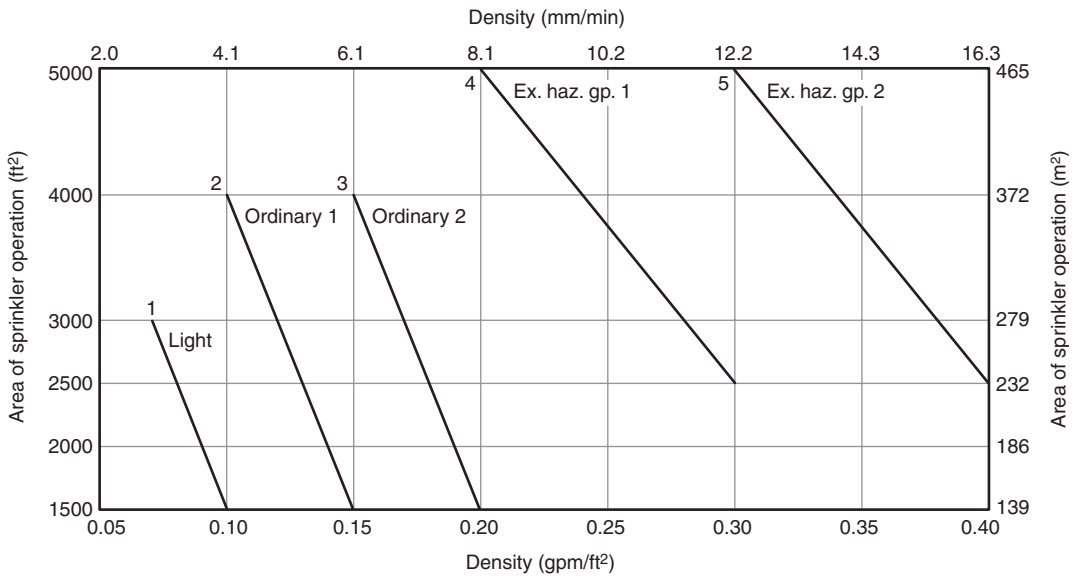

FIGURE 16.1.10 Density/Area Curves

Beginning with the 1996 edition of NFPA 13, a decrease in design area was permitted based on ceiling height with the use of quick-response sprinklers in wet-pipe systems in light and ordinary hazard occupancies. Although the faster actuation of quick-response sprinklers is expected to more quickly establish the conditions for fire control, the real basis for the area reduction is the recognition that ceiling height plays a major role in the fire control performance of sprinklers. Higher ceilings permit fires to grow larger prior to actuation of sprinklers. As far back as 1967, it was found that the size of the fire at the time of sprinkler operation increased with the square of ceiling height when the fire was located directly beneath a sprinkler and linearly with ceiling height when the fire was offset 5 ft (1.5 m) horizontally from the sprinkler.[13] The 1996 edition of NFPA 13 also introduced a corresponding design area increase for ceilings with slopes exceeding 2 in 12, based on modeling studies that showed operating patterns of sprinklers could be irregular under such conditions, causing larger numbers of sprinklers to operate.[15]

Tests conducted in 1998 suggested that fire control of high-challenge storage fires is better achieved through the use of larger orifice sprinklers. When standard orifice sprinklers were used to provide high-application densities, it was theorized that misting of the sprinkler discharge due to the high operating pressures reduced the effectiveness of the water spray in controlling the fire, allowing substantial fire damage despite the operation of few sprinklers.[16] For this reason, beginning with the 1999 edition of NFPA 13, minimum orifice sizes were specified for spray sprinklers protecting general storage, rack storage, rubber tire storage, roll paper storage, and baled cotton storage. For design densities of 0.34 gpm/ft^2 (13.9 mm/min) or less, standard-response sprinklers with a nominal orifice coefficient of K = 8.0 (K_m = 115) or larger must be used. For design densities exceeding 0.34 gpm/ft^2 (13.9 mm/min), standard-response sprinklers with a nominal orifice coefficient of K = 11.2 (K_m = 160) or larger and that are specifically listed for storage applications must be used.

Compartmentation and Fire Control

It has been observed in a number of test programs that walls tend to assist the sprinkler system in the control mode by limiting the number of sprinklers that can operate. If a fire takes place near a wall, the total number of sprinklers that operate will tend to be reduced by the fact that presumed "outer ring" sprinklers are not available on at least one side.

This will tend to conserve water for the operating sprinklers, resulting in higher application rates and earlier achievement of the fire control energy balances. Carried to an extreme, it is the benefit of walls that is recognized in the "room design method" permitted by NFPA 13 as an alternate to the area/density method.

However, one might ask how the same amount of heat can be absorbed by fewer operating sprinklers. In other words, if those fringe sprinklers are not available to operate and absorb some of the heat from the fire plume, doesn't that same heat flow back across the room in the other direction and simply open more sprinklers on the opposite side?

Two factors argue against this. One is that, unless the fire is almost exactly along the wall, it will entrain the same amount of air as a centered fire, producing the same amount of ceiling jet gases. However, the wall will prevent it from breaking into an axisymmetric ceiling jet, and the resulting ceiling jet or smoke layer will be thicker. The thicker smoke layer actually will permit more cooling to take place from the discharge of each sprinkler, since the path of each droplet through the layer is longer.

The other factor is that the spray cooling ability of each sprinkler is enhanced at higher pressures. Cooling depends on droplet surface area, which is increased with flow and with the

production of smaller-diameter droplets, both of which result from higher pressures. With fewer sprinklers operating in the vicinity of the fire, higher water supply pressures are available and more cooling takes place.

FIRE SUPPRESSION BY SPRINKLERS

Recent years have seen the development of new types of sprinklers that purport not only to control a fire but also to actively suppress the fire. To achieve fire suppression, water must be delivered by sprinklers to the burning fuel surface in sufficient quantity to disrupt the combustion process, knocking down the rate of heat release and preventing fire regrowth (Figure 16.1.11). If suppression is achieved at an early stage of the fire, only the sprinklers immediately over the fire area are expected to operate.

For this reason, the term "early suppression" has been developed. Today the term is being used both as the name for a concept and for a particular type of sprinkler. The concept is that fast response of sprinklers can produce an advantage in a fire if the response is accompanied by an effective discharge density—that is, a sprinkler spray capable of fighting its way down through the fire plume in sufficient quantities to suppress the burning fuel package.

The first sprinkler to include the term in its name, the early suppression fast-response (ESFR) sprinkler, was developed to apply the concept to a particular class of fire: protection of high-rack storage of FMRC's standardized plastic commodity, using ceiling sprinklers only. As part of the ESFR development program, FMRC researchers created new terms to investigate and to define the early suppression phenomenon: RDD and ADD.

Required Delivered Density

Required delivered density (RDD) is the minimum rate of water application that, if delivered to the top of the fuel package, is capable of providing early suppression. For the purposes of FMRC's ESFR program, early suppression was, in turn, defined as a sustained knockdown of the fire sufficient to prevent the operation of sprinklers beyond the initial ring.

Specialized test apparatus was developed by FMRC researchers to measure RDD. The apparatus consists of a series of perforated pipes suspended over the burning fuel package that are capable of spreading a fairly uniform water distribution directly over the top of the fuel, such that the water does not have to fight its way down through the fire plume (Figure 16.1.12). The pipes and fuel are all positioned below the fire products collector, a large calorimeter that collects all fire gases and determines the total rate of heat release of the fire as a function of time. The water application is initiated at a time simulating the operation of sprinklers, based on an assumed sprinkler location, sensitivity, and temperature rating. The heat release history generated while the water fights the fire can then be used to predict the operation of sprinklers beyond the first ring, based on their presumed location with respect to the fire.

Figure 16.1.13 shows the results of several RDD tests for a particular fuel package. Suppression can be considered to occur when the heat release rate of the fire is quickly knocked down and is prevented from resurging.

With regard to the standard plastic commodity stored in racks, FMRC confirmed that a relationship existed between RDD and height of storage (Table 16.1.2).

Under the sponsorship of the National Fire Protection Research Foundation, there has been an attempt to extend the early suppression concept to sprinkler protection of ordinary hazards.

Prior freeburn testing had been performed to determine the heat release histories of selected fuel packages. Among the fuel

TABLE 16.1.2 Standard Plastic Commodity—RDD Determination

Fast Response Sprinklers—30 ft (9.1 m) Racks	Storage Height in Racks		RDD Determination	
	ft	*m*	*gpm/ft²*	*mm/min*
3 tiers	15	4.6	0.35	14.4
4 tiers	20	6.1	0.45	18.5
5 tiers	25	7.6	0.65	26.7

packages tested were the upholstered furniture corner scenario used during the development of the residential sprinkler and a 6.7-ft (2.0-m) high storage configuration of the standardized plastic commodity in corrugated cardboard cartons that was used in the ESFR sprinkler program. Nineteen RDD tests were conducted by Underwriters Laboratories Inc. under the foundation's sponsorship to compare the relative suppressibilities of the two different fuel packages.[17,18]

In the freeburn testing, both these fuel packages were found to produce a total heat release history that could be approximated by an "ultrafast *t*-squared" fire, with a maximum heat release rate of about 5 MW. This refers to a standardized curve in which heat release grows proportionally to the square of time (Figure 16.1.14).

The specific water application rates needed to provide early suppression are still under study. However, it was observed clearly that the densities required for suppression of the plastic commodity were considerably higher than those required for the upholstered furniture for the same size fires. The tests conclusively demonstrated that some fuel packages are more easily

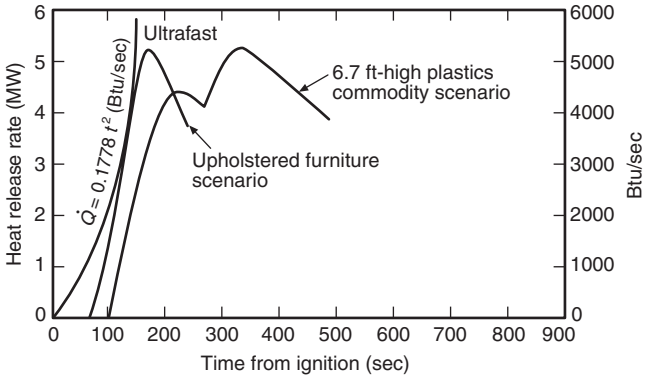

FIGURE 16.1.14 Comparison of Fire Growth Rates for Selected Fuel Packages and the "Ultrafast" t^2 Fire. For SI units: 1 ft = 0.305 m; 1 Btu = 0.055 kJ.

suppressed than others, even if their heat release rate histories appear to be similar.

Actual Delivered Density

Actual delivered density (ADD) is the actual rate of water application that a particular configuration of flowing sprinklers is capable of delivering to the top of a fuel package, depending on the strength of the upward fire plume.

The ADD measuring apparatus consists of a series of collection pans situated over a gas burner (Figure 16.1.15). The 0.5 m^2 pans simulate the top of a storage array and measure the rate at which each such area receives water from any particular configuration of flowing sprinklers. The gas burner is used to produce upward fire plume forces through the simulated flue spaces between the pans. In this manner, the ability of the flowing sprinkler(s) to deliver water to the fuel package can be checked against a wide range of fire strength conditions, simulating different points in the fire history. Typically, ADD decreases as the fire gets larger.

Since the water spray distribution of a sprinkler is not uniform, the collection pans collect different quantities of water during an ADD test. The development of ADD values from test results is accomplished using a probability distribution identified by, and named for, W. Weibull of Sweden. It was first applied to the distribution of liquid droplet sizes in 1951.[19] Using the Weibull distribution, the pan collections of each sprinkler spray acting through a fire plume of a given strength are fitted to a probability curve with a characteristic or average ADD θ and a uniformity value (*b*). The higher the uniformity value, the more likely it is that a characteristic ADD θ higher than the RDD will suppress the fire, since the needed water is being distributed in usable fashion.

The uniformity factor affects the basic shape of the probability distribution curve. Figures 16.1.16 and 16.1.17 indicate the relative effects of changing the scale parameter θ and the uniformity parameter *b* on the frequency distribution of the statistical model. These computer-generated figures demonstrate the superior ability of larger water droplets to penetrate the fire plume when a large fire is located directly below a sprinkler.

FIGURE 16.1.15 ADD Measuring Apparatus for Rack Storage (© 2008 FM Global. Reprinted with permission. All rights reserved.)

The variable x represents any given measurement. Typically, the ADD uniformity values range from about 1 to 7. A uniformity value of infinity would represent a perfectly uniform distribution.

The probability concept can also be applied to RDD data. A uniformity value b can be determined despite the fact that the RDD is measured in a test using the special water applicator intended to provide fairly uniform distribution. A "characteristic" RDD can be calculated as:

$$\theta_{RDD} = \frac{\text{RDD (proposed)}}{(1/b)!}$$

The probability distribution concept can also be used to rank the relative suppression capability of sprinklers. If ADD measurements are taken for three prototype sprinklers under the same fire, spacing, and flow conditions, and values of characteristic ADD and uniformity are found for each, the probability that each sprinkler will meet or exceed the characteristic RDD at any selected point on the fuel surface can be calculated from the relationship:

$$P(\text{ADD} \geq \theta_{RDD}) = \exp\left[-\left(\frac{\theta_{RDD}}{\theta_{ADD}}\right) b^{\text{ADD}}\right]$$

RECENT DEVELOPMENTS

The preceding discussion shows that the present understanding of the theory of fire sprinkler performance is incomplete. For some aspects of sprinkler system performance, such as thermal response and the hydraulics of water delivery, research has led to a good understanding of the mechanisms at work. On the other hand, the science of understanding how the water is dis-

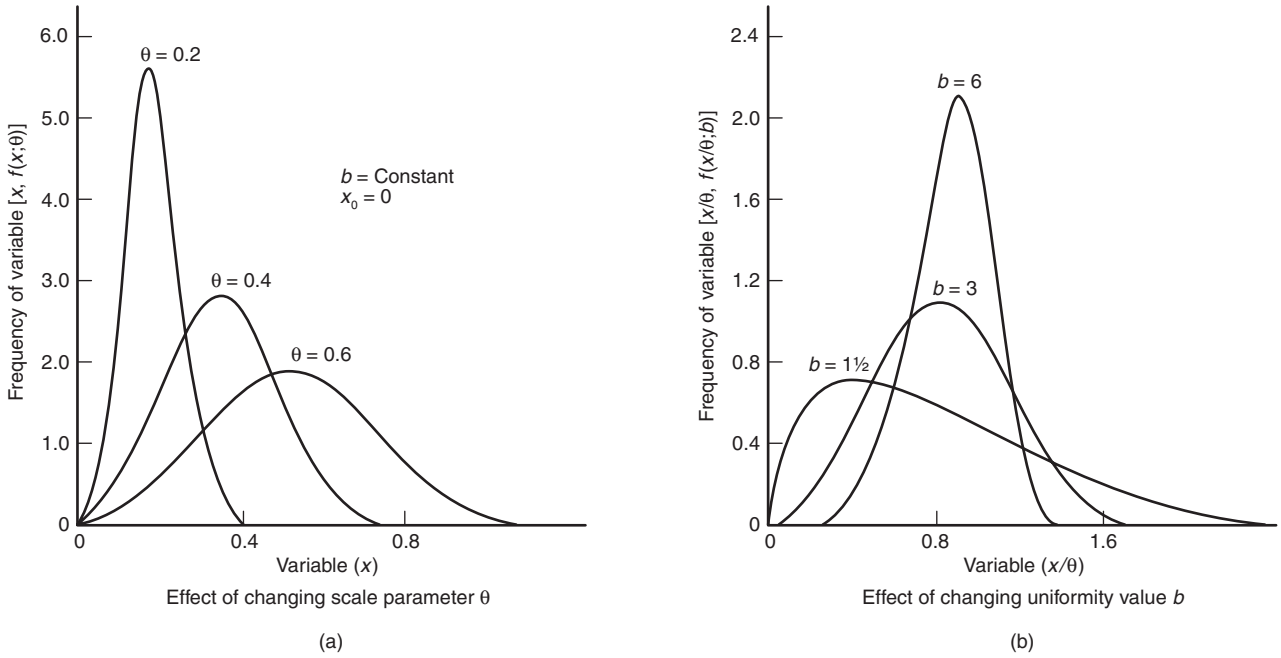

FIGURE 16.1.16 Effect of Changing (a) Scale Parameter θ; (b) Uniformity Value b

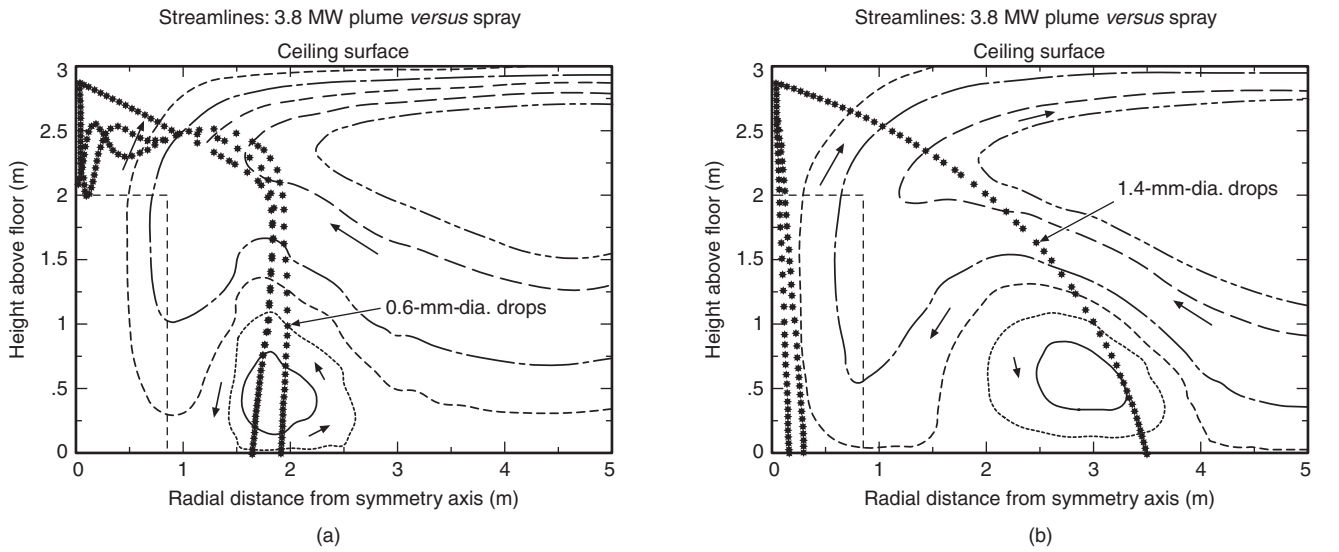

FIGURE 16.1.17 (a) Drops (0.6-mm diameter) Swept Away by the Upward Plume Velocities; (b) 1.4-mm Diameter Drops Following Their Trajectories.[19] For U.S. units: 1 in. = 25.4 mm; 1 ft = 0.305 m.

tributed remains very weak. Almost all the advances made in mathematical modeling of sprinkler performance in the past 25 years deal only with the time up to which the sprinkler starts to put water on the fire.

Research in the 1980s at FMRC, funded partly through the National Institute of Standards and Technology (NIST), began the effort of using computers to analyze the complex interactions between water droplet sprays and the gas flows induced by a building fire.[20] The work was based on very simplified assumptions, with the presumed fire located directly under a single sprinkler producing droplets of uniform size in a few specific directions (see Figure 16.1.17).

Continuing advances in computational fluid dynamics led to NIST efforts to model sprinkler response and suppression as part of a study of the interaction of sprinklers, vents, and draft curtains.[21] The NIST sprinkler/spray interaction model, now part of the Fire Dynamics Simulator, is currently accessible to practitioners through the NIST website at http://www.bfrl.nist.gov. However, potential users should be cautioned that there is still no accepted mechanism for measuring and characterizing sprinkler droplet size and distribution. Until such a mechanism is developed and validated, results of sprinkler system suppression modeling will be considered suspect. Recent work suggests that the suppression modeling problem is made even more difficult by the fact that the presence of water droplets tends to widen the fire plume and slow the upward velocity of the plume.[22]

SUMMARY

Automatic sprinkler systems are an effective means to control fires in enclosed areas, and in recent years models have been developed to perform early fire suppression. Continued improvements in design will require a greater understanding of the scientific principles involved in sprinkler performance. Whereas the thermal response and hydraulic mechanisms of sprinklers are well understood, the properties of water distribution are more complex and difficult to measure. Future advances in the fire suppression and control capability of automatic sprinkler systems will be the result of additional research based on computer analysis.

Standard Spray Sprinklers
Water Discharge
Sprinklers for Special Service Conditions

Key Terms

automatic sprinkler system, deflector, early suppression fast response (ESFR) sprinkler, flush-type sprinkler, K-factor, large drop sprinkler, pendent sprinkler, recessed sprinkler, sidewall sprinkler, standard spray sprinkler, upright sprinkler

Automatic sprinklers are thermosensitive devices designed to react at predetermined temperatures by automatically releasing a stream of water and distributing it in specified patterns and quantities over designated areas. The automatic distribution of water is intended to extinguish a fire or to prevent its spread in the event that the initial fire is out of reach of the sprinkler's discharge or is of a type that cannot be extinguished by water discharged from sprinklers. The water is fed to the sprinklers through a system of piping, ordinarily overhead, with the sprinklers placed at intervals along the pipes.

This chapter covers the operating principles, including operating temperatures, of the various types of automatic sprinklers currently available and describes their construction in some detail. Sprinklers for special service conditions are also covered.

The National Fire Protection Association (NFPA) does not have standards that cover the manufacture of sprinklers. However, NFPA does maintain many fire protection standards (most important of which is NFPA 13, *Standard for the Installation of Sprinkler Systems,* hereinafter referred to as NFPA 13) that only allow sprinklers listed by reputable product evaluation organizations to be used in sprinkler systems. Listing of sprinklers in a national organization's listing service is an indication that the sprinklers have been scrutinized for their reliability and compliance with the organization's test criteria for sprinklers.

For related topics, see Section 16, Chapter 1, "Principles of Automatic Sprinkler System Performance"; and Section 16, Chapter 3, "Automatic Sprinkler Systems."

SPRINKLER HISTORY

Since they were introduced in the latter part of the nineteenth century, the performance and reliability of automatic sprinklers have been improved continually through experience and the efforts of manufacturers and testing organizations.

In 1952 and 1953, a new sprinkler was developed with a more efficient umbrella-shaped spray pattern. This "spray sprinkler" became the standard sprinkler in 1958 for use in conformance with NFPA 13; sprinklers of the older design became known as "old-style" or "conventional" sprinklers. Redesign of the deflector was the principal feature of the new standard sprinklers.

Due to the development of many new types of sprinklers during the 1980s, it became questionable whether any single type of sprinkler could be considered standard in the future. As such, the term *spray sprinkler* was brought back into use with the 1991 edition of NFPA 13. This also conforms better to internationally accepted terminology.

OPERATING PRINCIPLES OF AUTOMATIC SPRINKLERS

In order to appreciate the ruggedness, mechanical simplicity, reliability in operation, and freedom from premature operation of an automatic sprinkler, a familiarity with the basic principles of its design, construction, and operation is necessary.

Kenneth E. Isman, P.E., is vice-president of engineering for the National Fire Sprinkler Association, Patterson, New York. He currently serves on relevant NFPA technical committees, including the Committee on Sprinkler System Installation Criteria.

Operating Elements

Under normal conditions, the discharge of water from an automatic sprinkler is restrained by a cap or valve held tightly against the orifice by a system of levers and links or other releasing devices pressing down on the cap and anchored firmly by struts on the sprinkler.

Fusible Sprinklers. A common fusible-style automatic sprinkler operates when a metal alloy of predetermined melting point fuses. Various combinations of levers, struts, and links or other soldered members are used to reduce the force acting on the solder so that the sprinkler will be held closed with the smallest practical amount of metal and solder. This construction minimizes the time of operation by reducing the mass of fusible metal to be heated.

The solders used with automatic sprinklers are alloys of optimum fusibility composed principally of tin, lead, cadmium, and bismuth; all have sharply defined melting points. Alloys of two or more metals may have a melting point that is lower than that of the individual metal with the lower melting point. The mixture of two or more metals that gives the lowest melting point possible is called a "eutectic" alloy.

Bulb Sprinklers. A second style of operating element uses a frangible bulb (Figure 16.2.1). The small bulb, usually of glass, contains a liquid that does not completely fill the bulb, leaving a small air bubble trapped in it. As heat expands the liquid, the bubble is compressed and finally absorbed by the liquid. Once the bubble disappears, the pressure rises substantially, and the bulb shatters, releasing the valve cap. The exact operating temperature is regulated by adjusting the amount of liquid and the size of the bubble when the bulb is sealed.

Sprinkler Dynamics. Figure 16.2.2 shows how the mechanical force exists in a solder-type link-and-lever-style automatic sprinkler. The construction shown is diagrammatic and does not represent any particular sprinkler.

The mechanical force normally exerted on the top of the cap or valve is many times that developed by the water pressure below, so that the possibility of leakage, even from water hammer or exceptionally high water pressure, is practically

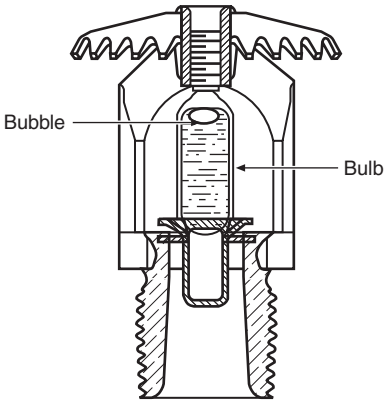

FIGURE 16.2.1 Grinnell Quartzoid, Issue D

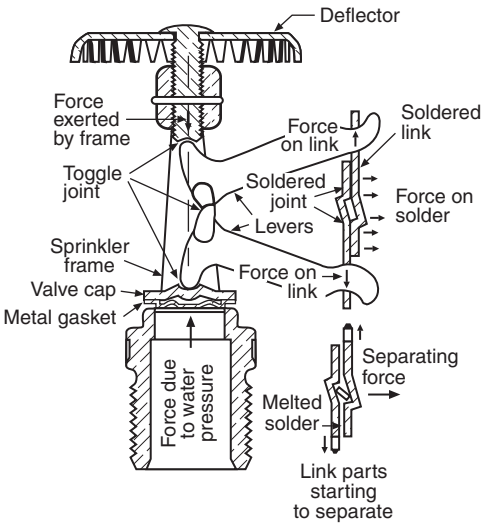

FIGURE 16.2.2 Representative Arrangement of a Solder-Type Link-and-Lever Automatic Sprinkler

eliminated. The mechanical force in a link-and-lever sprinkler is produced by tension in the sprinkler frame, usually created by tightening the screw that holds the deflector down against the toggle joint formed by the levers. This pressure is applied against the valve or cap, but the line of force is not direct. The eccentricity of the loading permits a leveraged reduction of the force, first by the toggle effect of the two levers, and second by the mechanism of the link parts. The force resisted by the solder is made relatively low because solder of the composition needed to give the desired operating temperatures is subject to cold flow under high stress. The sprinkler frame or other parts usually possess a degree of elasticity to provide the energy that produces a positive, sharp release of the operating parts.

Sprinklers illustrated in Figure 16.2.3 use modifications of the common link-and-lever construction, some of which employ solder under compression, tension, and shear.

To ensure that cold flow will not be a problem, the laboratories that test and list sprinklers use statistical methods to simulate long-term loading of heat-responsive elements. Statistical methods are also employed to ensure that the crush strength of glass bulbs is sufficiently higher than the frame loads that will be applied to the bulbs.

Deflector Design

Attached to the frame of the sprinkler is a deflector or distributor against which the stream of water is directed and converted into a spray designed to cover or protect a certain area. The amount of water discharged depends on the flowing water pressure and the size of the sprinkler orifice. A flowing pressure of 7 psi (48 kPa) is generally considered a minimum for development of a reasonable spray pattern. At this pressure, a sprinkler having a nominal ½ in. (12.7 mm) orifice (K = 5.6, or, in metric units, $K_m = 80$) will discharge approximately 15 gpm (58 L/min). (See Spray Sprinklers with Different Orifice Sizes in this chapter for the definition of K-factor.) At the same 7 psi

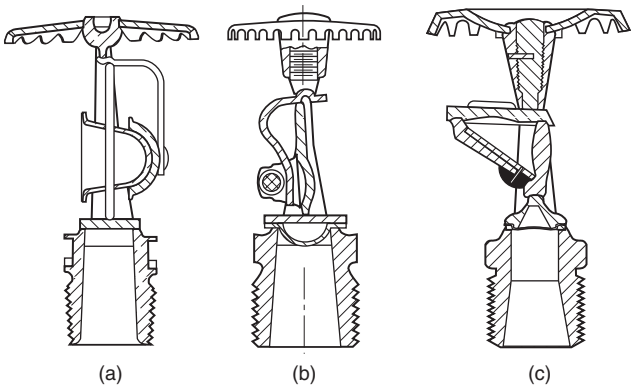

FIGURE 16.2.3 Some Modifications of the Common Link-and-Lever Construction: (a) Grinnell F950 Duraspeed, (b) Reliable Model G, and (c) Firematic Type S

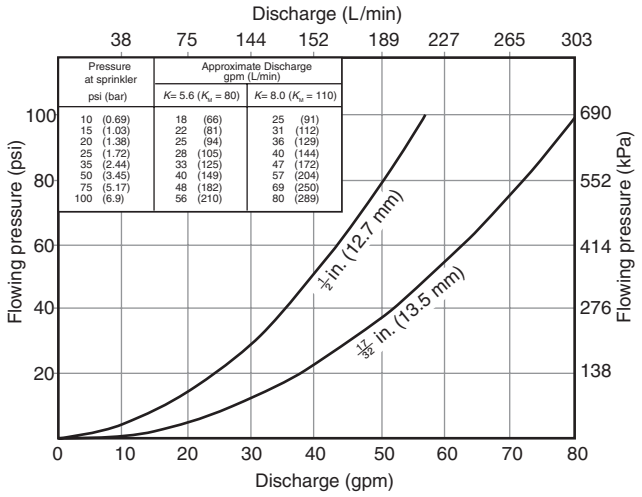

FIGURE 16.2.4 Water Discharge Rates of Typical Nominal K = 5.6 (K_m = 80) and K = 8.0 (K_m = 110) Automatic Sprinklers

(48 kPa) pressure, a nominal 17⁄32 in. (13.5 mm) orifice (K = 8.0, or, in metric units, K_m = 110) sprinkler will discharge approximately 21 gpm (79 L/min). (See Figure 16.2.4 for the quantity of water discharged at various water pressures.)

In order to have even the minimum flowing pressure at sprinklers that are remote from the point of water supply, especially when a number of sprinklers are operating simultaneously, water supply pressures in the range of 30 to 100 psi (316 to 690 kPa) are customarily provided. Hydraulically calculated systems are designed around the normally available water supply volume and pressure.

The distribution of water from a sprinkler is not expected to be axisymmetric, particularly because sprinkler frame arms obstruct the spray pattern and the serrated edges of the deflector create a "fingering" effect. A contour plot of the flow pattern of a pendent spray sprinkler is shown in Figure 16.2.5.[1]

Because the distribution of water from sprinklers is a complex phenomenon, the testing laboratories have fairly broad requirements in this area. For upright and pendent spray sprinklers, for example, Underwriters Laboratories Inc. (UL) requires a turntable test to "fingerprint" the spray pattern. For a sprinkler with an orifice of K = 5.6 (K_m = 80) or K = 8 (K_m = 110), water distribution is not permitted outside a 16-ft (4.9-m) diameter circle in a horizontal plane 4 ft (1.2 m) below the sprinkler when operating at minimum pressure. A separate "16 pan" distribution test checks the ability of four flowing sprinklers to cover the area between them with their overlapping spray patterns. Factory Mutual Research Corporation (FMRC) applies an additional six-sprinkler flow test, which looks at the area covered between two adjacent sprinklers.

TEMPERATURE RATINGS OF AUTOMATIC SPRINKLERS

Automatic sprinklers have various temperature ratings that are based on the need to make sure that sprinklers do not operate when exposed to natural heat sources that are not a fire (Table 16.2.1). In order to make sure that sprinklers will open at the proper temperature, a sample sprinkler is immersed in a liquid

TABLE 16.2.1 Temperature Ratings, Classifications, and Color Codings

Maximum Ceiling Temperature		Temperature Rating				
°F	*°C*	*°F*	*°C*	*Temperature Classification*	*Color Code*	*Glass Bulb Colors*
100	38	135–170	57–77	Ordinary	Uncolored or black	Orange or red
150	66	175–225	79–107	Intermediate	White	Yellow or green
225	107	250–300	121–149	High	Blue	Blue
300	149	325–375	163–191	Extra high	Red	Purple
375	191	400–475	204–246	Very extra high	Green	Black
475	246	500–575	260–302	Ultra high	Orange	Black
625	329	650	343	Ultra high	Orange	Black

FIGURE 16.2.5 Pendent Spray Sprinkler and Flow Contours

and the temperature of the liquid is raised very slowly until the sprinkler operates.

The temperature rating of all fusible-element-style automatic sprinklers is stamped on the soldered link. For bulb sprinklers, the temperature rating must be stamped or cast on some visible part. Color codes are also used for glass bulbs and for frame arms of fusible-element sprinklers.

The recommended maximum room temperature is restricted for both bulbs and fusible-element sprinklers. This restriction is because solder begins to lose its strength somewhat below its actual melting point. Premature operation of a solder sprinkler usually depends on the extent to which the normal room temperature is exceeded, the duration of the excessive temperature, and the load on the operating parts of the sprinkler. Although glass bulb sprinklers do not lose strength at temperatures close to their operating temperatures, using them at such temperatures can result in continuous loss and reforming of the air bubble, which creates stresses on the bulb.

The general rule of not using sprinklers of ordinary (135 to 170°F [57 to 77°C]) temperature rating where temperatures exceed 100°F (38°C) is necessary to provide a margin of safety. General practices regarding the use of automatic sprinklers of higher than the ordinary rating are given in Tables 16.2.2 and 16.2.3. Sprinklers of ordinary temperature rating can be used inside buildings and other places where they are not subject to direct sun rays, except in monitors and in blind attics without ventilation, under metal or tile roofs, near or above heat sources, or in confined spaces where normal temperatures may be exceeded.

When there is doubt as to maximum temperatures at sprinkler locations, maximum reading thermometers should be used and the temperature determined under conditions that would show the highest readings to be expected.

Sprinklers with high temperature ratings are often used in place of ordinary-rated sprinklers in situations where a high rate of heat release can be anticipated. The sprinklers rated for higher temperatures may have the advantage of reducing the number of sprinklers that would otherwise operate outside the fire area.

Automatic sprinklers may require a longer time period to operate when exposed to a slowly developing fire as opposed to the high heat release of a rapidly developing fire. They are designed to operate quickly enough to control a fire and prevent its spread.

The speed of operation depends on the physical properties of the sprinkler's mechanism. The time involved to operate depends, among other factors, on the shape, size, and mass

TABLE 16.2.2 Temperature Ratings of Sprinklers Based on Distance from Heat Sources

Type of Heat Condition	*Ordinary Degree Rating*	*Intermediate Degree Rating*	*High Degree Rating*
(a) Heating ducts			
1. Above	More than 2 ft 6 in.	2 ft 6 in. or less	
2. Side and below	More than 1 ft 0 in.	1 ft 0 in. or less	
3. Diffuser	Any distance except as shown under Intermediate Degree Rating column	*Downward discharge:* Cylinder with 1 ft 0 in. radius from edge extending 1 ft 0 in. below and 2 ft 6 in. above *Horizontal discharge:* Semicylinder with 2 ft 6 in. radius in direction of flow extending 1 ft 0 in. below and 2 ft 6 in. above	
(b) Unit heater			
1. Horizontal discharge		*Discharge side:* 7 ft 0 in. to 20 ft 0 in. radius pie-shaped cylinder extending 7 ft 0 in. above and 2 ft 0 in. below heater; also 7 ft 0 in. radius cylinder more than 7 ft 0 in. above unit heater	7 ft 0 in. radius cylinder extending 7 ft 0 in. above and 2 ft 0 in. below unit heater
2. Vertical downward discharge		7 ft 0 in. radius cylinder extending upward from an elevation 7 ft 0 in. above unit heater	7 ft 0 in. radius cylinder extending from the top of the unit heater to an elevation 7 ft 0 in. above unit heater
(c) Steam mains (uncovered)			
1. Above	More than 2 ft 6 in.	2 ft 6 in. or less	
2. Side and below	More than 1 ft 0 in.	1 ft 0 in. or less	
3. Blowoff valve	More than 7 ft 0 in.		7 ft 0 in. or less

of the thermosensitive mechanism; the temperature differential between the surrounding atmosphere and the operating temperature of the sprinkler; and the velocity of the heated fire gases past the sprinkler operating element.

In cases where extreme speed of operation is necessary owing to the likelihood of a rapidly developing and spreading fire as, for example, in explosives manufacturing, the practice is to use deluge systems incorporating open sprinklers. These systems can be activated by heat detectors, special detection systems using infrared or ultraviolet light detection, smoke detection, or other means to open a valve and quickly allow water to enter the system and discharge through the open sprinklers. In cases where extremely fast response is required, the sprinkler piping is prefilled with water up to the open sprinklers, which are equipped with blow-off plugs or caps. This system is sometimes referred to as a "hot" deluge system.

STANDARD SPRAY SPRINKLERS

Standard spray sprinklers are generally similar in appearance to old-style sprinklers and use the same style frame and linkage or other release mechanism. The essential difference is in the deflector; seemingly minor differences in deflector design make major differences in discharge characteristics. Several representative standard spray sprinklers are illustrated in Figure 16.2.6. Clockwise from upper left is a fusible link-and-lever style (Reliable Issue C); a perforated heat-collector style, which is a variation of the link-and-lever style (Grinnell F950 Duraspeed); a center-strut style with solder under compression (Chemetron Stargard Model H); and a frangible-bulb style (Viking Model M).

On the assumption that discharging water against the ceiling was essential to fire extinguishment, early research on automatic sprinklers was largely concerned with securing reasonably uniform distribution of water over the area protected by one sprinkler and with wetting the ceiling. Later research showed that more effective extinguishment and a larger area of coverage could be secured by directing all the water downward and horizontally. Research further showed that, with this pattern, discharge is effective even in controlling fires on the ceiling above the sprinklers because of the improved cooling effect of the spray, better high-level water distribution, and decreased exposure to the ceiling because of more effective direct discharge of water on burning materials below.[2]

The design of the deflector causes the solid stream of water issuing from the orifice of a standard sprinkler to break up to form an umbrella-shaped spray. The pattern is roughly that of a half-sphere filled with spray.

Standard spray sprinklers are made for installation in an upright or pendent position and must be installed in the position for which they are designed. (Note the difference in design of the deflectors shown in Figure 16.2.7.) It is customary to replace old-style sprinklers with spray sprinklers in existing installations, although NFPA 13 permits replacing old-style sprinklers with similar devices. Some manufacturers, however, have discontinued producing old-style sprinklers.

Several manufacturers developed a double deflector as their first design for use as standard spray upright sprinklers. A typical double deflector is shown in Figure 16.2.8. Such sprinklers are no longer manufactured but, if previously listed, are as acceptable as the currently approved upright spray sprinklers with a one-piece deflector.

FIGURE 16.2.6 Standard Spray Sprinklers Showing the Various Arrangements of Releasing Mechanisms

WATER DISCHARGE

The general patterns of water discharge from the old-style and from the standard spray sprinklers are shown in Figures 16.2.9 and 16.2.10, respectively.

FIGURE 16.2.7 Listed Sprinkler Showing Upright (Right) and Pendent (Left) Models of the Same Issue (Reliable Model G)

FIGURE 16.2.8 Standard Upright Spray Sprinkler with Double Deflector

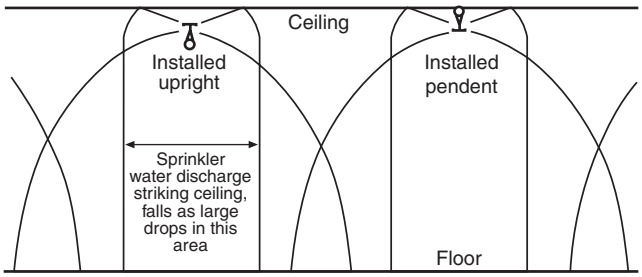

FIGURE 16.2.9 Principal Distribution Pattern of Water from Old-Style/Conventional Sprinklers

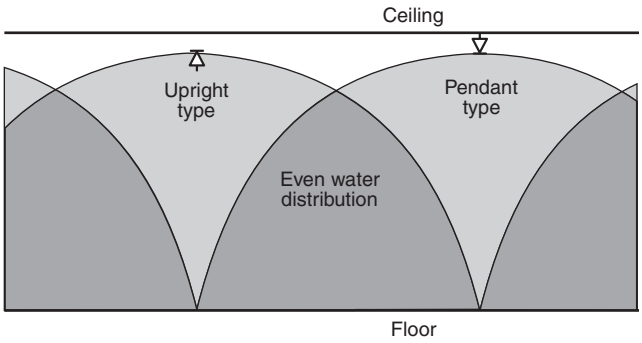

FIGURE 16.2.10 Principal Distribution Pattern of Water from Standard Spray Sprinklers

The water distribution characteristics of sidewall automatic sprinklers, picker trunk sprinklers, window sprinklers, and cornice sprinklers are described later in this chapter. The rate of water discharge from a sprinkler follows hydraulic laws and depends on the size of the orifice or nozzle and on the water pressure. Approximate rates of discharge at different pressures may be obtained from the plotted curve or from the table given in Figure 16.2.4.

Sprinklers discharging water through smaller or larger orifices are discussed later in this chapter. With similar forms of sprinkler nozzles and at the same water pressure, the discharge from these styles of sprinklers is approximately proportional to the nominal size of the orifice.

To obtain acceptance or approval of their sprinklers, manufacturers submit them to fire-testing organizations. After extensive tests and verification of the manufacturer's ability to manufacture the product properly, sprinklers found satisfactory are listed. Acceptance of a sprinkler by inspection departments or other regulatory agencies is based on such a listing.

Standard spray sprinklers are designed to be installed and operated in their proper position—that is, upright or pendent, as sometimes indicated by a stamping on the deflector bearing the appropriate word or the letters SSU (spray sprinkler upright) or SSP (spray sprinkler pendent).

Recessed Sprinklers

A recessed sprinkler is a type of ceiling sprinkler in which part or most of the body of the sprinkler, other than the part that connects to the piping, is mounted in a recessed housing. Its operation is similar to that of a standard pendent sprinkler (Figure 16.2.11).

Flush-Type Sprinklers

A typical flush-style sprinkler is shown in Figure 16.2.12. This style of sprinkler is used where appearance is considered to be

FIGURE 16.10.11 Central Model H Recessed Sprinkler

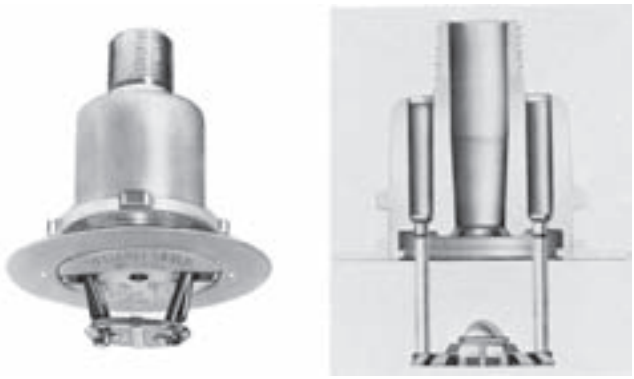

FIGURE 16.2.12 Flush-Style Ceiling Sprinkler (Reliable Model B)

of prime importance. (The diagram at the right shows the sprinkler after operation.) The special design of this type of ceiling sprinkler allows a minimum projection of the working parts of the sprinkler below the ceiling in which it is installed without adversely affecting the heat sensitivity or the pattern of water distribution.

In an effort to provide sprinkler protection in low-risk occupancies where aesthetics are important, sprinklers have been designed that attractively blend with the ceiling. Only the ceiling plate and thermosensitive assembly are visible from the floor when these sprinklers are installed. When a fire occurs and the thermosensitive element operates, the deflector drops to a position below the ceiling and water discharge commences.

Concealed Sprinklers

A concealed sprinkler is a type of ceiling sprinkler whose entire body, including the operating mechanism, is above its concealing cover plate. When a fire occurs, the cover plate drops, exposing the thermosensitive assembly. The subsequent operation of the thermosensitive assembly initiates discharge (Figure 16.2.13).

Ornamental Sprinklers

Ornamental sprinklers are automatic sprinklers that have been decorated by plating or enameling to give desired surface finishes. Ornamentation or special decorative design must not affect the operation or the water distribution unfavorably. Listed styles of ornamental sprinklers are for pendent installation in accordance with NFPA 13 (Figure 16.2.14). Such decorative coatings can be applied only by the manufacturer of the device.

Dry Pendent and Dry Upright Sprinklers

Dry pendent, dry upright, and dry-horizontal-sidewall sprinklers are used to provide sprinkler protection in unheated areas, such as freezers, where individual sprinklers are supplied from a wet-pipe system outside the unheated area. Dry pendent sprinklers must also be used on all dry-pipe systems where it is desirable to install pendent sprinklers.

A seal is provided at the entrance of the dry sprinkler to prevent water from entering until the sprinkler operates. The heat-sensitive operating mechanisms are adaptations of those used with automatic standard sprinklers.

See Figure 16.2.15 for an example of a dry pendent automatic sprinkler. When the ambient temperature rises beyond the operating temperature of the soldered link, the solder melts and the link plates separate on roller key. Levers held in place by a deflector screw are released, and the fixed tension of the frame, acting as a spring, ejects the levers and link parts clear of the sprinkler. Because the inner tube, which also serves as a discharge orifice, is no longer held in place by the levers, it moves to a predetermined position. With the support of the inner tube eliminated, the elements forming the watertight seal at the piping inlet pass through the inner tube and away from the sprinkler, allowing water to flow through the unobstructed waterway and strike the deflector, which distributes it in a spray pattern comparable to that of a ½ in. (12.7 mm) standard sprinkler. Shown is Reliable's Model C Dry Pendent. Other manufacturers have similar arrangements of proprietary equipment for dry-type sprinklers.

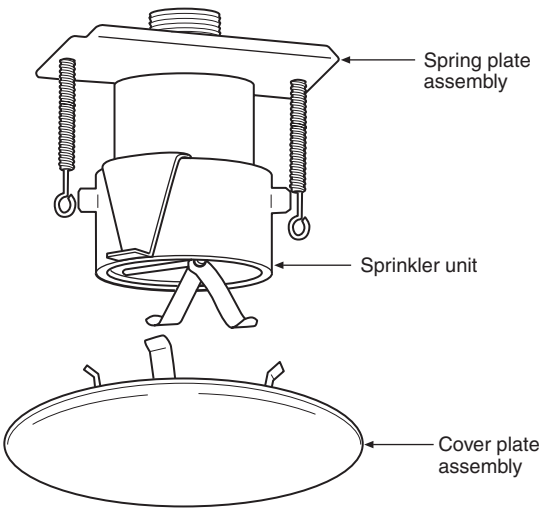

FIGURE 16.2.13 Concealed Ceiling Sprinkler (Stargard Model G)

FIGURE 16.2.14 Prussag SFH Glass-Bulb-Style Decorative Sprinkler

SPRINKLERS FOR SPECIAL SERVICE CONDITIONS

The sprinkler system using listed upright or pendent spray sprinklers is adaptable to a wide variety of conditions. However, there

FIGURE 16.2.15 Representative Dry Pendent Automatic Sprinkler

are situations for which special styles of sprinklers and special sprinkler arrangements are suited. In some cases, such as with sidewall sprinklers, special patterns of water distribution are necessary; in others, unusual ambient temperatures or corrosive atmospheres call for special design or construction features.

Residential Sprinklers

Residential sprinklers are sprinklers that have been specifically listed for use in residential occupancies. These fast-response sprinklers have special low-mass fusible links or bulbs that make the time of temperature actuation much less than that of a sprinkler with a conventional operating element.

Residential sprinklers also have different discharge characteristics than spray sprinklers. They are required to throw water within 18 in. (457 mm) of the ceiling. This high-wall wetting pattern, along with the faster response, helps the residential sprinkler control or suppress typical residential fires with flows much lower than standard spray sprinklers.

Because of the life safety aspects of fast response, these sprinklers can be used in a variety of residential occupancies. Where a conventional system installed according to the provisions of NFPA 13 might not be as practical, such as in a single-family dwelling or a low-rise residential property, NFPA 13D, *Standard for the Installation of Sprinkler Systems in One- and Two-Family Dwellings and Manufactured Homes,* and NFPA 13R, *Standard for the Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height,* may be used. These standards have been developed specifically around the life safety capabilities of the residential sprinkler. A representative residential sprinkler is shown in Figure 16.2.16. (Residential sprinkler installations are discussed in detail in Section 16, Chapter 6, "Residential Sprinkler Systems.")

Large Drop Sprinklers

Large drop sprinklers are special sprinklers with a nominal K-factor of 11.2 ($K_m = 160$). (Nominal K-factors for standard ½ in. [12.7 mm] sprinklers are 5.6 [$K_m = 80$].) The deflector of a large drop sprinkler is specially designed and, combined with the greater discharge, produces large drops of such size and velocity as to enable the spray to penetrate strong updrafts generated by high-challenge fires. The special requirements for large drop sprinklers are found throughout NFPA 13 and are organized by subject category. These special requirements supersede the density/area requirements used for standard spray sprinklers. A representative large drop sprinkler is shown in Figure 16.2.17.

On/Off Sprinklers

On/off sprinklers have two separate operating mechanisms. The first is very similar to a standard sprinkler link. The second is a heat-operated valve or snap disk. When a fire occurs, both operating mechanisms sense the rise in temperature and open up. After the environment around the sprinkler cools, the secondary valve or snap disk senses the drop in pressure and automatically closes, stopping the flow of water. If the fire has not been suppressed and grows again, the secondary valve or snap disk reopens allowing water to flow.

Once an on/off sprinkler has activated, it does need to be replaced. The secondary valve or snap disk will not completely seal the valve and may leak. After activation, the sprinkler may also not be able to handle the surge pressures that might occur in the system.

Currently, no manufacturer makes an on/off sprinkler, but they have been described here because they have been manufactured in the past.

Sprinklers for Corrosive Conditions

Measures have been developed to protect automatic sprinklers from corrosive conditions, and testing organizations have studied the value of each method. A complete covering of wax that has a melting point slightly below the temperature at which the sprinkler operates is the protective coating most commonly used. A lead coating for the body of the sprinkler and the levers in combination with wax for protecting fusible elements is also common. Traditional coatings include wax only (Figure 16.2.18), asphalt only, lead only, wax over lead, and asphalt over lead. In recent years, sprinklers have been listed with enamel, polyester, and Teflon® coatings. Stainless steel sprinklers are available from some manufacturers. Other coatings are also available and should be selected on the basis of the expected environment.

Whatever the protective measures taken, they must not delay the operation of the sprinkler, nor interfere with the

FIGURE 16.2.16 Representative Residential Sprinkler

FIGURE 16.2.17 Representative Large Drop Sprinkler

FIGURE 16.2.19 Representative Selection of Listed Sidewall Sprinklers Showing Various Shapes of Deflectors

release of operating parts, nor significantly alter the pattern of water distribution. As with decorative sprinklers, these coatings may also be applied only by the manufacturer.

Sidewall Sprinklers

Sidewall sprinklers have the components of standard sprinklers except for a special deflector, which discharges most of the water toward one side in a pattern somewhat resembling one-quarter of a sphere. A small proportion of the discharge wets the wall behind the sprinkler. Located and mounted either vertically or horizontally along the junction between a ceiling and wall, sidewall sprinklers provide protection adequate for light-hazard occupancies, such as hotel lobbies, dining rooms, and executive offices. Some sidewall sprinklers have been tested and listed for use in ordinary-hazard occupancies.

Sidewall sprinklers are generally used where pipe would be difficult to install in a ceiling. This concern might be the case with certain types of ceiling construction or in retrofit situations in which the building owner does not want to disturb asbestos above an existing ceiling. Sidewall sprinklers are also sometimes used where the space above a ceiling is subjected to cold temperatures in order to keep the sprinkler pipe in a heated space in the wall, rather than in the ceiling space where freezing conditions could be encountered.

The directional character of the discharge from sidewall sprinklers makes them applicable to occasional special protection problems. They may be installed to give discharge in any desired direction.

Figure 16.2.19 shows typical sidewall sprinklers. Selection has been made to show the different shapes of a variety of deflectors. Many vertically mounted sidewall sprinklers may be installed in either the pendent or upright position.

Extended Coverage Sidewall Sprinklers

Extended coverage sidewall sprinklers are used in the horizontal position. They have larger areas of coverage than the areas of coverage allowed for standard sidewall sprinklers. They may be used in light-hazard occupancies, particularly in hotels and similar occupancies where a sprinkler system can be installed in an existing building without having piping exposed in living areas, which could be objectionable aesthetically.

The water pressure required to obtain the greater coverage is specified in the listings for the sprinklers and is greater than that required for standard sidewall sprinklers. Installation requirements are also a part of the listing.

An extended coverage sidewall sprinkler with a conventional link release is shown in Figure 16.2.20.

Open Sprinklers

Automatic sprinklers from which the valve cap and heat-responsive elements have been omitted are used in deluge sprinkler systems where the water supply is controlled by an automatic water control valve actuated independently of the automatic sprinklers (Figure 16.2.21). The water distribution pattern and the density of the discharge are designed to be appropriate for the hazard to be protected.

Small- and Large-Orifice Sprinklers

The terms *small orifice* and *large orifice* are used to describe sprinklers with orifice sizes other than ½ in. (K = 5.6). Automatic sprinklers having a water discharge rate greater or less than that of a standard K = 5.6 (K_m = 80) orifice sprinkler operating at the same pressure have characteristics desirable in protecting certain occupancies. High-discharge, large-orifice sprinklers operating at discharge densities of 0.45 gpm/ft^2 (18 [L/min]/m^2) and greater provide a quantity discharge not available from nominal

FIGURE 16.2.20 Representative Extended Coverage Sidewall Sprinkler

FIGURE 16.2.21 Standard Upright Sprinkler with Its Operating Elements Removed

FIGURE 16.2.22 Representative K = 4.2 (K_m = 60) Sprinkler in the Pendent Position

K = 5.6 (K_m = 80) orifice sprinklers. The pattern of the water discharge from small- and large-orifice sprinklers is similar to that of the standard K = 5.6 (K_m = 80) sprinkler.

Whenever sprinklers are replaced, care must be taken to replace them with the proper styles. Replacement of sprinklers with others of the correct orifice size is critical in hydraulically calculated systems.

Spray Sprinklers with Different Orifice Sizes

For many years, sprinklers have been manufactured with different orifice sizes to achieve different flows at available pressures. The smaller the orifice size, the lower the flow that will discharge from the sprinkler when it opens. The characteristic used for measuring the size of the orifice is called the K-factor, and it represents the mathematical constant relating the flow from the sprinkler at the available pressure as indicated in the following formula:

$$Q = K\sqrt{P}$$

where

Q = Flow in gpm (L/min)

K = Flow constant

P = Pressure in psi (bar)

The K-factor is constant for any given sprinkler, only changing with the diameter and shape of the orifice and waterway leading to the point where water gets discharged from the sprinkler. The standard spray sprinkler developed in the late 1950s had a K-factor in English units of 5.6. In metric units, this sprinkler has a K-factor of 80. Sprinklers with K-factors of 5.6 are still very commonly used.

Sprinklers with orifice sizes smaller than the standard K-factor of 5.6 are available when the designer wishes to restrict the flow into a space (Figure 16.2.22). Typically, this happens where a sprinkler protects a relatively small room, where the density can be achieved at a relatively small pressure. NFPA 13 allows the smaller orifice sprinklers to be used in light-hazard occupancies. The K-factors range from K = 1.4 (K_m = 20) to K = 4.2 (K_m = 60). Where the K-factor is less than 2.8 (K_m = 40), a strainer needs to be installed near the water supply to catch the sediment that might plug a sprinkler with a very small orifice.

Table 16.2.4 shows the various orifice sizes for the sprinklers smaller than the standard K = 5.6 (K_m = 80) sprinkler.

Sprinklers with orifice sizes larger than the standard K = 5.6 (K_m = 80) are available when the designer wishes to get larger flows from the sprinkler at the same pressure (Figure 16.2.23). Another way of looking at the advantages of these sprinklers is that the designer can get the required flow from the sprinkler at a lower pressure.

Sprinklers with larger orifice sizes tend to produce better size water droplets with better droplet momentum than K = 5.6 (K_m = 80) orifice size sprinklers. These larger orifice sprinklers are better at fighting high-challenge fires such as those in storage occupancies, where the water droplets from the sprinklers need to overcome the momentum of the fire plume in order to achieve fire control or suppression. For this reason, starting with the 1999 edition of NFPA 13, restrictions on the use of K = 5.6 (K_m = 80) and K = 8.0 (K_m = 110) sprinklers have been put in place. For storage occupancies, the K = 5.6 (K_m = 80) and K = 8.0 (K_m = 110) sprinklers can be used only where the design density necessary for fire control is relatively small. Table 16.2.5 summarizes the various orifice sizes for the sprinklers larger than the standard K = 5.6 (K_m = 80) sprinkler.

28.0	400	500

Discharge characteristics of various large- and small-orifice sprinklers are given in Table 16.2.6.

Picker Trunk Sprinklers

Picker trunk automatic sprinklers have a small, smooth deflector that aids in reducing collections of lint and fiber on the sprinklers when they are placed inside ducts or enclosures where moving air carries such foreign materials in suspension. Freedom from obstruction and a general breakup of the water stream are of more importance than any specific pattern of distribution (Figure 16.2.24).

Intermediate-Level Sprinklers

Intermediate-level sprinklers, also referred to as in-rack sprinklers, have large discs (shields) designed to protect the thermosensitive assembly from the spray of sprinklers suspended at higher levels. Without the protective shields, the impinging

water could cool the thermosensitive element and retard sprinkler operation. Both upright and pendent intermediate-level sprinklers are listed by testing organizations (Figure 16.2.25).

ESFR Sprinklers

The early suppression fast response (ESFR) sprinkler was developed in the late 1980s and came into widespread use starting in the 1990s for storage occupancies. The ESFR sprinkler was developed to provide fire suppression for high-challenge storage occupancies, usually without the use of in-rack sprinklers. Whereas most sprinklers are designed to provide fire control (and achieve fire suppression as a by-product of good design and extra safety factors), the ESFR sprinkler is designed specifically to provide fire suppression. Although the ESFR sprinkler has many advantages, it does not work for all types of buildings and ceiling construction, so architects and building owners need to make sure that the building and potential obstructions at the ceiling are closely coordinated with the sprinkler installation. Figure 16.2.26 compares an ESFR sprinkler to a standard K = 5.6 (K_m = 80) spray sprinkler.

Specific Application Control Mode Sprinklers

The specific application control mode sprinkler was developed in the beginning of the twenty-first century to provide more effective fire control of high-challenge storage occupancies, usually without in-rack sprinklers. The specific application control mode sprinkler produces good-quality water droplets with high mass and velocity. The combination of mass and velocity creates water droplets with sufficient momentum to penetrate the fire plumes developed by many storage commodities. Although this sprinkler provides improved protection over standard spray sprinklers, it still is considered a control mode sprinkler, meaning it is designed to control the fire, but may achieve suppression in some circumstances. It is not designed to promise suppression in all cases. Being the newest of the sprinklers developed for storage protection, the types of occupancies that can be protected with this sprinkler are constantly changing. Check with the manufacturer to see whether additional approvals have been developed. Figure 16.2.27 shows an example of a specific application control mode sprinkler.

SUMMARY

The purpose of an automatic sprinkler system is to extinguish a fire or prevent its spread by automatically releasing a stream of water and distributing it over the protected area. The sprinklers

FIGURE 16.2.26 K = 14 (K_m = 200) ESFR Sprinkler (Left) Compared to K = 5.6 (K_m = 80) Standard Spray Sprinkler (Right) (Source: Victaulic® is a registered trademark of Victaulic Company)

are fed water through a system of piping and are triggered by predetermined temperatures. Several different types of sprinkler systems have evolved over the years since their introduction in the latter half of the nineteenth century. The type of automatic sprinkler system installed and the settings used depend on many factors, including the purpose of the building (whether residential or commercial) and aesthetic considerations. As fire protection devices, automatic sprinklers have been found to be rugged, mechanically simple, reliable in operation, and generally free from premature operation.

The first document published by NFPA, in 1896, provided the initial set of standardized rules for automatic sprinkler systems. The document was awkwardly titled *Rules and Regulations of the National Board of Fire Underwriters for Sprinkler Equipments, Automatic and Open Systems as Recommended by the National Fire Protection Association.* This NFPA document evolved to be NFPA 13, *Standard for the Installation of Sprinkler Systems*.

NFPA 13 provides standardized rules for the design, installation, and acceptance testing of sprinkler systems. Various options are presented for achieving effective sprinkler system performance, including among other considerations the selection of system components such as sprinklers, valves, and piping materials, as well as the determination of the fire hazard to be protected against and the calculation of system discharge rates.

The fundamental principles and assumptions about sprinkler systems have remained fairly consistent over the past century. However, the past 30 years have witnessed significant developments regarding the performance and effectiveness of sprinkler systems in providing life safety and property protection. Although the modern-day version of NFPA 13 is an expansion of the early principles of sprinkler system protection, it includes a much broader scope and addresses the application of many new technologies.

This chapter provides an introduction and overview to the fundamentals of automatic sprinkler systems and describes how the current edition of NFPA 13 has evolved to address a number of situations. The benefits of sprinklers are discussed followed by a review of current rules and practices that are associated with these systems.

Properly designed, installed, and maintained systems are a key element of many fire protection plans integral to modern building design and construction. Suppression, detection, and compartmentation are key safety features that allow buildings of a certain height or area to be constructed. A proper understanding of what sprinkler systems can and cannot do by those designing, installing, and approving such systems is critical to the overall effectiveness of the system.

DEVELOPMENT OF AUTOMATIC SPRINKLERS

A sprinkler is a thermosensitive device that is designed to discharge a certain amount of water in a certain pattern, is only activated when a fire generates a sufficient quantity of heat, and will control or suppress the fire once it has activated. NFPA 13 identifies and defines various types of sprinklers.

Roland Huggins, P.E., is vice-president of engineering and technical services at the American Fire Sprinkler Association and a member of the NFPA Standards Council.

Water is distributed to each sprinkler in the system through a series of specially sized pipes or tubes. Control valves are installed on the system to manually shut off waterflow to all or a portion of the system piping and the sprinklers.

The earliest sprinkler systems consisted of steel pipe networks with drilled holes or perforations provided along the length of pipe. This type of system often involved the use of a manually operated water supply. If the fire occurred when the building was not occupied, the system would be of little or no benefit. Additionally, the piping for these systems was often corroded, the holes were often plugged, and the water discharge from the pipe could generously be described as poor.

A derivative of the perforated pipe involved attachment of an open sprinkler device to the pipe. This improved the water distribution pattern of the system, but concerns with human intervention and corrosion remained.

The concept of employing a heat-actuated device dates back to approximately 1860. However, it was not until 1875 that Henry Parmelee incorporated this concept into a fire sprinkler device. The Parmelee sprinkler is credited as the first "automatic" sprinkler. Although the device was crude when compared to modern sprinklers, it established a specific water distribution pattern that was effective and efficient in controlling a fire. Figure 16.3.1 illustrates the discharge pattern from a Parmelee Number 3 sprinkler. The sprinkler consisted of a brass cap soldered over a perforated distributor and was designed to screw onto a nipple. Figure 16.3.2 shows a cross-sectional view of the Parmelee No. 3 sprinkler.

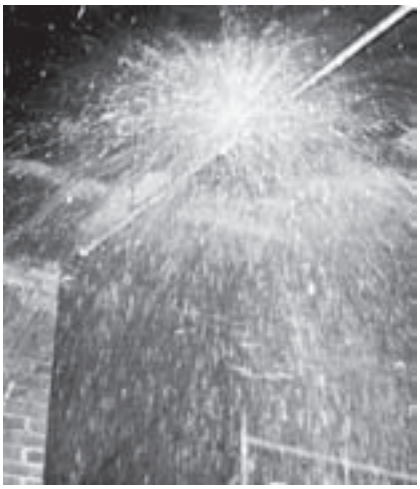

FIGURE 16.3.1 Discharge of an Early Automatic Sprinkler

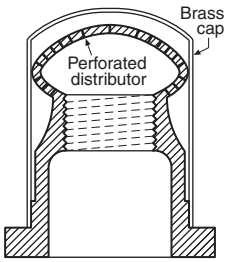

FIGURE 16.3.2 Cross-Sectional View of the Parmelee No. 3 Sprinkler

Other variations of the Parmelee sprinkler soon followed, and each one had a unique shape or form. Some of the sprinklers available when the 1896 edition of NFPA 13 was published include Neracher (Figure 16.3.3), National Manufacturing Company (Figure 16.3.4), New Grinnell (Figure 16.3.5), and Kane (Figure 16.3.6).

The introduction of these new automatic sprinkler devices that did not require human intervention to initiate waterflow prompted greater acceptance and use of sprinkler systems for factories and storage facilities.

VALUE OF AUTOMATIC SPRINKLER PROTECTION

The insurance industry in combination with the Industrial Revolution in the United States can be credited for promulgating and

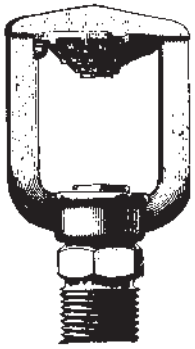

FIGURE 16.3.3 Neracher Sprinkler

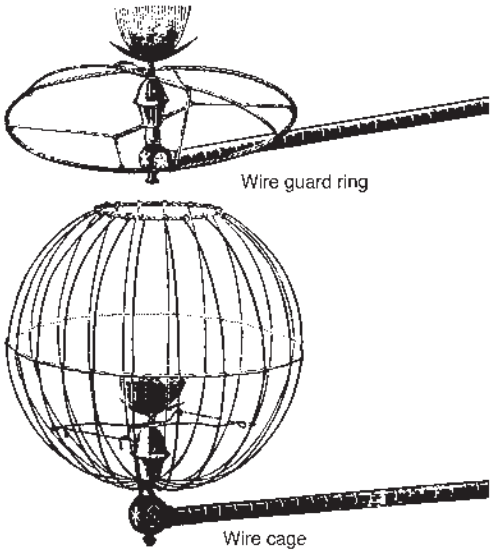

FIGURE 16.3.4 National Manufacturing Company Sprinkler

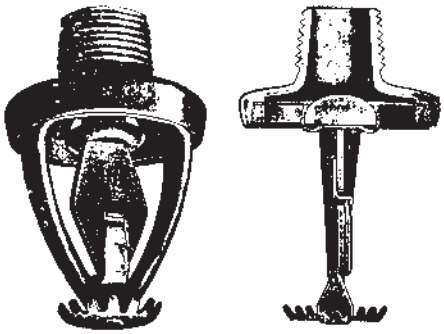

FIGURE 16.3.5 New Grinnell Sprinkler

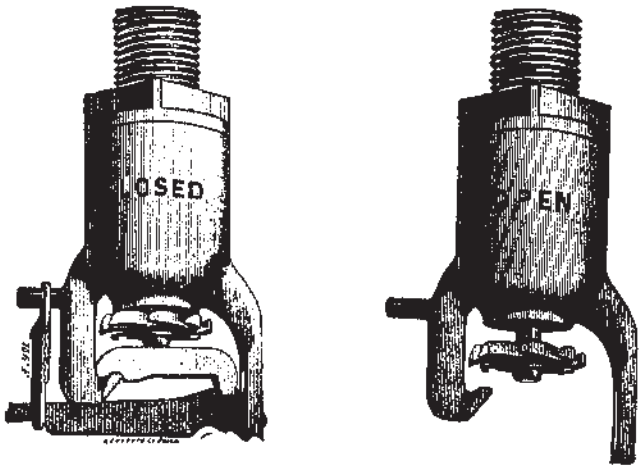

FIGURE 16.3.6 Kane Sprinkler

expanding the use of sprinkler systems. Initial system use was justified by the acute reduction in property loss that was evident in fires involving sprinkler systems when compared to those fire events in which no sprinkler systems were installed.

Because of their immediate recognition as greatly improving property protection risks, high-value facilities such as warehouses and industrial manufacturing facilities were particularly high-priority settings for protection by automatic sprinkler systems. This distinction could even mean the difference between a company staying in business versus not being able to recover from a fire and going out of business.

Although sprinklers were not immediately recognized for their life safety benefits, a trend indicating reductions in fire-related deaths in which sprinkler systems were present became apparent. Large-area, high-rise, high-value, and dense population structures soon became primary facilities where sprinkler systems would be of benefit.

Life Safety Benefits

The life safety benefit of sprinklers is intuitive since sprinkler discharge suppresses or controls a fire, thereby diminishing the threat to the occupants. Additionally, the operation of the sprinkler system sounds an alarm, warning building occupants of a fire condition. Although early sprinkler system designs focused primarily on property protection, the systems did improve the overall life safety features of the building. Current technology provides for numerous types of systems, some of which specifically focus on life safety with property protection as a secondary objective. The residential sprinkler system falls into this category. Section 16, Chapter 6, "Residential Sprinkler Systems," provides information on the development of the residential sprinkler. Although limited to residential occupancies, since its introduction to the marketplace in 1980, the application of the residential sprinkler has been expanded from use in single-family homes to high-rise occupancies such as hotels and apartments. NFPA *101*®, *Life Safety Code*®, and other building codes recognize the life safety benefits of sprinkler systems. Extended travel distances, reductions in rated wall assemblies, and interior finish materials with higher flame-spread ratings are permitted when sprinklers are present. NFPA *101* also mandates sprinkler systems in buildings that fit the high-rise category, as well as those buildings where evacuation of the occupants is impractical, such as health care facilities and some types of nursing homes.

Up until 1970, NFPA maintained a database on the performance and effectiveness of sprinkler systems. Unfortunately, collection of this type of information was discontinued when the data became skewed toward those instances in which large numbers of sprinklers tended to operate or in which the dollar losses were quite large. Such data appeared to indicate that sprinklers were only of marginal value and were not as effective as they actually were. Although substantial dollar losses can occur because of fires in sprinklered buildings, these large losses in sprinklered buildings represent a small percentage of overall fire losses. Furthermore, the majority of devastating fires in sprinklered buildings can usually be attributed to some type of human error, such as failure to maintain the system, rather than a mechanical failure of the system itself.

Even the skewed data, however, showed that a substantial number of fires in sprinklered buildings are controlled or even extinguished with the operation of only one or two sprinklers. Many more of these sprinkler successes control fires with such minimal damage that they are not reported to a fire department or insurance company. It is hoped another data collection program can be instituted in the future with the widespread use of central station alarm systems and the fact that most of today's sprinkler systems are equipped with some type of automatic alarm feature. However, at the time of this writing no formal efforts have been initiated.

Data Sources

Other data sources exist that provide some perspective on the number of sprinklers that operate in certain types of fires. The fewer the number of sprinklers that operate, the more likely that the fire is controlled by the sprinkler system. As previously indicated, the data suggest that a small number of sprinklers tend to control most fires.

NFPA's Fire Analysis and Research Division produces an annual report entitled *U.S. Experience with Sprinklers and Other Fire Extinguishing Equipment.* Table 16.3.1, based on Table 6 of that report, provides information on the number of

TABLE 16.3.1 Number of Sprinklers Operating in Structure Fires Where Sprinklers Were Present and Operated, 1999–2002 Structure Fires (Excluding Confined Fires) Reported in NFIRS Version 5.0 to U.S. Fire Departments

A. By Type of Sprinkler System

Number of Sprinklers Operating	*Wet Pipe (%)*	*Dry Pipe (%)*	*Other Type Sprinkler (%)*
1	65	41	55
2 or fewer	81	56	72
3 or fewer	88	65	83
4 or fewer	91	73	92
5 or fewer	93	77	92
6 or fewer	94	80	96
7 or fewer	95	80	100
8 or fewer	95	82	100
9 or fewer	96	83	100
10 or fewer	97	86	100

Note: These are fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. Wet pipe systems outnumbered dry pipe systems 7 to 1. Wet pipe systems outnumbered "other type sprinkler" systems by nearly 30 to 1. However, 38 percent of the incidents had type of sprinkler system unreported. Percentages are based on fires where sprinklers were reported present and operating and there was reported information on number of sprinklers operating.

Source: Rohr, K., *U.S. Experience with Sprinklers and Other Fire Extinguishing Equipment,* Table 6, National Fire Protection Association, Quincy, MA, Aug. 2005.

sprinklers operating in structure fires. The report discusses the benefits of automatic sprinklers and provides comparisons of fires in sprinklered and nonsprinklered buildings.

One of the most compelling points made in the NFPA report is the life safety benefits of sprinkler systems. The following statements are taken directly from the 2005 report:

> NFPA has no record of a fire killing more than two people in a completely sprinklered building where the system was properly operating, except in an explosion or flash fire or where industrial fire brigade members or employees were killed during fire suppression operations.

Another statement that is directed at specific occupancies indicates that:

> NFPA has no record of a fire killing more than two people in a completely sprinklered public assembly, educational, institutional, or residential building where the system was properly operating.

The Fire Analysis and Research report indicates that when fatalities do occur in sprinklered buildings, the victims tend to be in close proximity to the fire or intimate with ignition. In other cases, the victim was incapacitated or otherwise incapable of self-preservation.

The "Fire Watch" column in the *NFPA Journal* usually summarizes one or two stories about sprinkler system performance during a fire. In addition, the information collection process through the National Fire Incident Reporting System (NFIRS), NFPA's data collection survey, and insurance summaries all indicate that sprinklers are a very effective means to reduce fire fatalities and damage. The Fire Analysis and Research report summarizes these data as indicating that sprinklers reduce the chances of dying if fire occurs and the average property damage per fire by one-third to two-thirds.

Because of their effectiveness, various building codes, insurance regulations, and local laws require sprinkler systems in numerous types of buildings. If properly designed, installed, and maintained, sprinkler systems remain among the best options for providing cost-effective life safety and property protection.

FINANCIAL IMPLICATIONS OF SPRINKLER SYSTEM INSTALLATIONS

A number of devastating fires have been investigated by NFPA over the years. In nearly every one of these incidents, findings indicate that the lack of a properly functioning automatic sprinkler system was a key factor in the accelerated rate of fire growth and spread.

When a fire occurs, a certain degree of damage to building contents and the building are expected. These property losses are tangible and can be measured in direct financial terms. However, a somewhat less tangible impact of a fire can be business interruption, which not only affects the business owner and the long-term viability of the enterprise but also the employees and local community. Catastrophic losses to large employers deteriorate the local tax base affecting community services.

Another undesirable outcome of a fire in financial terms can be impending lawsuits in which litigation expenses and judgments can be severe and, when they occur, can exceed other combined direct and indirect losses. This is especially true when a loss of life has occurred. Financial aspects of lawsuits, although typically not a key consideration to most building owners or business owners, can devastate a company, its employees, and ultimately the local community.

Automatic sprinkler systems are designed to operate during the early stages of fire development and minimize the fire's overall impact. In addition, most systems are provided with an electrically supervised waterflow alarm that can automatically notify the fire department when the sprinkler system operates. Although many systems will suppress or even extinguish a fire, it is anticipated that in most cases the fire department or fire brigade will completely extinguish a fire.

Contrary to some Hollywood portrayals and public perceptions of sprinkler system activation in which all sprinklers in a building appear to operate at once, only those sprinklers that are in close proximity to the fire will operate. As previously shown in Table 16.3.1, a relatively small number of sprinklers tend to operate in most fires. Because only those sprinklers near a fire operate, considerably less water damage occurs during a fire when a sprinkler system is present. Where sprinkler systems are not present, fire damage and the magnitude of damage from

master streams and other fire-fighting operations are typically more extensive, often considerably.

Nonetheless, water damage and inadvertent system discharge often concern building owners. Reports that cite collateral water damage as larger than the fire damage encourage a misleading comparison. For instance, some news accounts have been selectively prepared, indicating that the fire damage was limited to $1000 whereas the collateral water damage from sprinklers was perhaps $1500. No mention is made about the total value of the contents and the building; no mention is made about no one being injured; and no mention is made of the fatalities that did not occur.

Although inadvertent discharge of water from system piping, valves, or a sprinkler is rare, it can occur. To minimize this possibility, NFPA 13 controls system components to ensure integrity of the system. In addition, NFPA 13 governs a number of methods and techniques that help to protect against such problems. Quality control of installation practices and procedures is also an important consideration. Special materials and methods are specified for use in corrosive atmospheres, areas subject to freezing, and for systems installed in areas requiring seismic protection.

Some Incentives for Sprinklers

The major incentive for installing sprinkler systems can be directed toward the system's inherent highly effective and cost-efficient life safety and property protection features. However, direct financial benefits can also be realized by property owners. Many insurance carriers offer reduced premiums for fully sprinklered facilities. In addition, the cost of sprinkler system design and installation can often be amortized over the life of the building.

Although sprinkler systems are mandatory in many types of buildings, most building codes permit certain construction modifications when systems are installed. These modifications include increases to building heights and areas, reductions to fire-resistance ratings for partitions, and reductions in physical separations between adjacent structures. These changes often offset the cost of the sprinkler system.

Installing sprinkler systems in existing buildings also greatly improves overall fire and life safety and offsets previous fire protection concerns. Although installing sprinklers after building construction has been completed is more costly, laws mandating sprinkler systems on a retroactive basis usually allow for the installation to be phased over time. This permits building owners to coordinate the installation with other building upgrades and renovations.

STANDARDS FOR INSTALLING SPRINKLERS

NFPA 13, *Standard for the Installation of Sprinkler Systems,* is the principal document that addresses the design and installation of sprinkler systems. Although considered by some to be a variation of a plumbing system, they are not. Sprinkler systems are unique systems requiring specialized knowledge for their proper design, installation, and maintenance.

NFPA 13 is categorized as a standard and, therefore, specifies the rules and other information necessary for the proper design, layout, and installation of sprinkler systems. NFPA 13 does not specify the types of facilities or buildings in which sprinkler systems are required. This requirement is addressed by building codes, NFPA *101,* and other regulations.

In 1999, NFPA 13 underwent a major expansion and restructuring. Although still containing requirements concerning water supply, allowable materials and components, sprinkler placement and location, discharge criteria, working plans and calculation procedures, the document's scope has been greatly expanded to include sprinkler system information from over 40 other NFPA codes and standards. This extracted information, though, is still controlled by the original technical committee and is simply copied in NFPA 13.

Effective with the 1999 edition, all requirements pertaining to the design and installation of automatic sprinkler systems were, to the extent possible, centralized in NFPA 13. The scope of NFPA 13 was expanded to include sprinkler system design and installation requirements for storage facilities, formerly located in the NFPA 231 series of documents (NFPA 231 was titled *Standard for General Storage*). The design and installation requirements for underground piping and private fire service mains from NFPA 24, *Standard for the Installation of Private Fire Service Mains and Their Appurtenances,* were also included.

The 1999 edition incorporated sprinkler system information copied from other NFPA standards to assist NFPA 13 users with the design and installation of automatic sprinkler systems for hazards and facilities not previously addressed by NFPA 13. Sprinkler system information from over 40 NFPA codes, standards, and recommended practices is cited in NFPA 13. For example, sprinkler system information specific to solvent extraction plans, laboratories using chemicals, and fixed guideway transit systems, among others, are included. The 2002 edition improved the ability to find this extracted information by incorporating it into one chapter. NFPA 13 continues to expand and refine criteria. Another change made in the 2002 edition was a restructuring of the hanging and bracing chapter. Restructuring continued into the 2007 edition where the presentation of the storage criteria was divided into nine chapters.

A number of assumptions have been employed in the writing of NFPA 13 to achieve an acceptable level of life safety and property protection while maintaining costs. For instance, the standard anticipates a single fire source, that is, no multiple ignitions in the building while the sprinkler system is operating. Nor does NFPA 13 address the likelihood of a fire occurring in one space area as opposed to another area. NFPA 13 treats the likelihood of a fire occurring in any given space on an equal footing regardless of the actual probabilities of ignition. For these reasons, the fundamental design principal that only a certain number of operating sprinklers are needed to control a given fire exists. In other words, it is only those sprinklers in the general vicinity of the fire that are expected to operate and discharge water.

A fundamental premise about buildings also serves as a basis for NFPA 13 criteria. Effective system design is a direct function of the building contents and the fire hazard associated with the contents. Building construction materials do not impact

the assigned discharge density. For example, a building of concrete construction does not receive any special preference when compared to a building of wood construction. The use and associated hazard of the contents of the building need to receive primary consideration when initiating a sprinkler system design. The structure does play a significant role in defining the type of allowed sprinklers, the minimum area of coverage, minimum starting pressure, and other installation criteria. For instance, an attic is a light-hazard occupancy but the area of coverage can be as low as 120 ft^2 (11.1 m^2) instead of the possible 400 ft^2 (37.2 m^2), as well as having a minimum starting pressure of 20 psi (1.4 bar) instead of the usual 7 psi (0.5 bar).

Although NFPA 13 serves as the primary resource for sprinkler system design and installation around the world, other documents also address sprinkler systems. Many of these documents fall within NFPA's fire codes set and address sprinkler system protection for specific hazards, building uses, and safety objectives. For example, NFPA 30, *Flammable and Combustible Liquids Code,* addresses the storage of flammable and combustible liquids; NFPA 851, *Recommended Practice for Fire Protection for Hydroelectric Generating Plants,* addresses hydroelectric generating plants; and NFPA *101* addresses the use of a sprinkler system solely for life safety purposes. Starting with the 1999 edition of NFPA 13, other NFPA documents that deal with sprinkler system design and installation are specifically referenced. In addition to NFPA's documents, local and national building codes may also address sprinkler system design and installation to some degree. Other nations and some insurance companies also maintain their own sprinkler system rules.

Terminology

Because of the complexity associated with the various aspects of sprinkler system design and installation, NFPA 13 defines various terms to establish a degree of consistency and uniformity. Some of the more prevalent terms are paraphrased here.

The most fundamental term, *sprinkler system,* is described as a combination of underground and overhead piping that is connected to an automatic water supply. The piping is specially sized or hydraulically designed with that portion of the piping within the building generally located overhead. Sprinklers are attached to the overhead piping in a systematic pattern and a valve controlling each riser is located either directly on the system riser or in the supply piping. The system is usually activated by heat from a fire and discharges water over the fire area. A device actuating an alarm when the system operates is located on the system riser. Figure 16.3.7 illustrates various aboveground and buried components that can comprise a fire sprinkler system. Note that the rules addressing fire pumps and water storage tanks can be found in NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection,* and NFPA 22, *Standard for Water Tanks for Private Fire Protection,* respectively. The criteria from NFPA 24 is repeated in NFPA 13.

System Types

Most sprinkler systems fall within one of four categories. These include (1) wet pipe, (2) dry pipe, (3) preaction, and (4) deluge with the wet pipe being the most common. The need to use one type of system rather than another depends on the environmental conditions in which the system will be used and the nature of the space being protected.

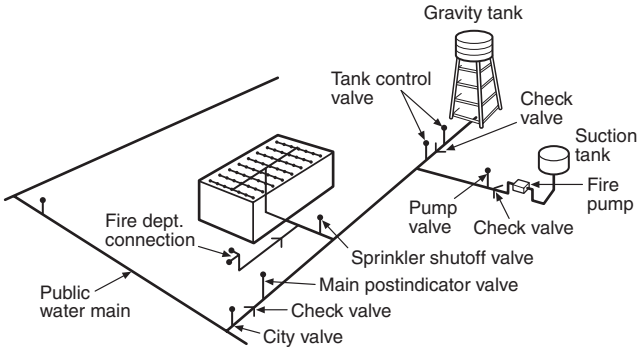

FIGURE 16.3.7 Hypothetical Sprinkler System Installation Illustrating Various Water Supply Sources and System Attachments

Wet Pipe System. This type of system is the preferred, most reliable option. It is also the easiest to design and install and the simplest to maintain. Wet pipe systems contain water under pressure at all times and utilize a series of closed sprinklers. When a fire occurs and produces a sufficient amount of heat to activate one or more sprinklers, because an automatic water supply is mandated, water immediately discharges from the open sprinklers. Wet pipe systems should be the first choice of designers and installers because they are more inherently reliable and less costly to maintain. However, wet pipe systems should not be considered when temperatures to which the system could be exposed fall below 40°F (4°C). Figure 16.3.8 illustrates a basic wet pipe system.

Dry Pipe System. These systems should only be used when system components will be exposed to temperatures below 40°F (4°C). System piping contains no water prior to system activation but rather is charged with air or nitrogen under pressure. These systems experience more internal corrosion than a wet pipe system due to moisture in the air and constant replenishment of oxygen. A dry pipe valve holds back the water supply and serves as the water/air interface. Most listed dry pipe valves act on a pressure differential principle, in which the surface area of the valve face on the air side is greater than the surface area on the water side. Figure 16.3.9 shows a typical dry pipe valve. There are also many dry pipe valves that use a latching mechanism and a pressure differential.

If a fire occurs and a sufficient amount of heat is generated, one or more sprinklers operate, causing system air pressure to drop. Once the air pressure falls below a predetermined level, the dry pipe valve opens, allowing water to flow through the system to the open sprinklers. Dry pipe systems are more complex than wet pipe systems. They require a reliable air supply source and, because of the delay associated with water delivery from

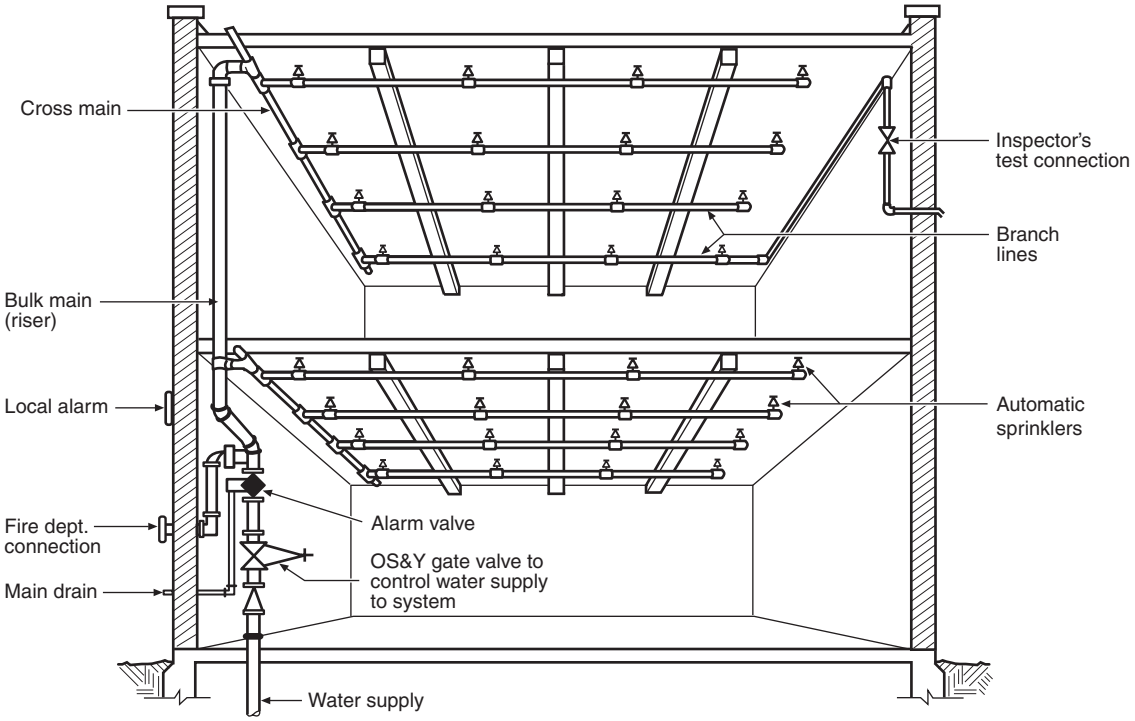

FIGURE 16.3.8 Basic Components of a Wet Pipe Sprinkler System

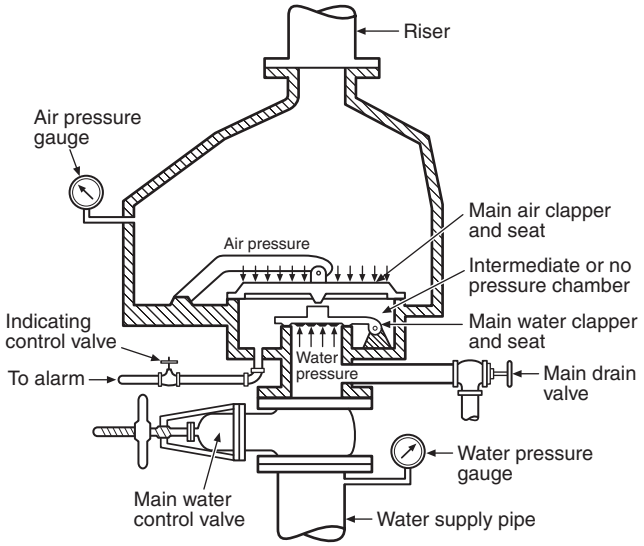

FIGURE 16.3.9 Typical Dry Pipe Valve

the dry pipe valve to the open sprinklers, are subject to certain design limitations. These limitations can include restriction of system size, the need for additional components such as accelerators, and the need for a larger design area due to an increase in the number of anticipated operating sprinklers.

In addition to serving as stand-alone systems, dry pipe systems can comprise a subsystem of a larger wet pipe system in which small coolers and loading docks need to be protected. Figure 16.3.10 illustrates a hypothetical dry pipe system.

Preaction System. Similar to a dry pipe system, a standard or single-interlock preaction system piping is charged with air under pressure rather than water. However, the air pressure associated with preaction systems is generally less than that for dry pipe systems. It also experiences a greater amount of internal corrosion. The water supply is held back by means of a preaction valve. The system is equipped with a supplemental detection system. Operation of the detection system allows the preaction valve to automatically open and admit water into the pipe network. Water will not discharge from the system until a fire has generated a sufficient quantity of heat to cause operation of one or more sprinklers. In essence, the system appears as a wet pipe system once the preaction valve operates. Figure 16.3.11 shows a typical preaction system.

Air pressure maintained in the piping is used to monitor the integrity of the pipe. If the pipe develops a leak, the air pressure will drop and an alarm will sound, indicating a low air-pressure condition. Because water is held back with a preaction valve rather than a dry pipe valve, water will not flow into the system until the supplemental fire detection system operates, signaling the preaction valve to open. The preaction valve stays in its normal position until the detection system is activated.

A variation of the single-interlock preaction system is the double-interlock preaction system. The double-interlock system has characteristics of both the single-interlock system and the dry pipe system. For water to enter the system piping both the

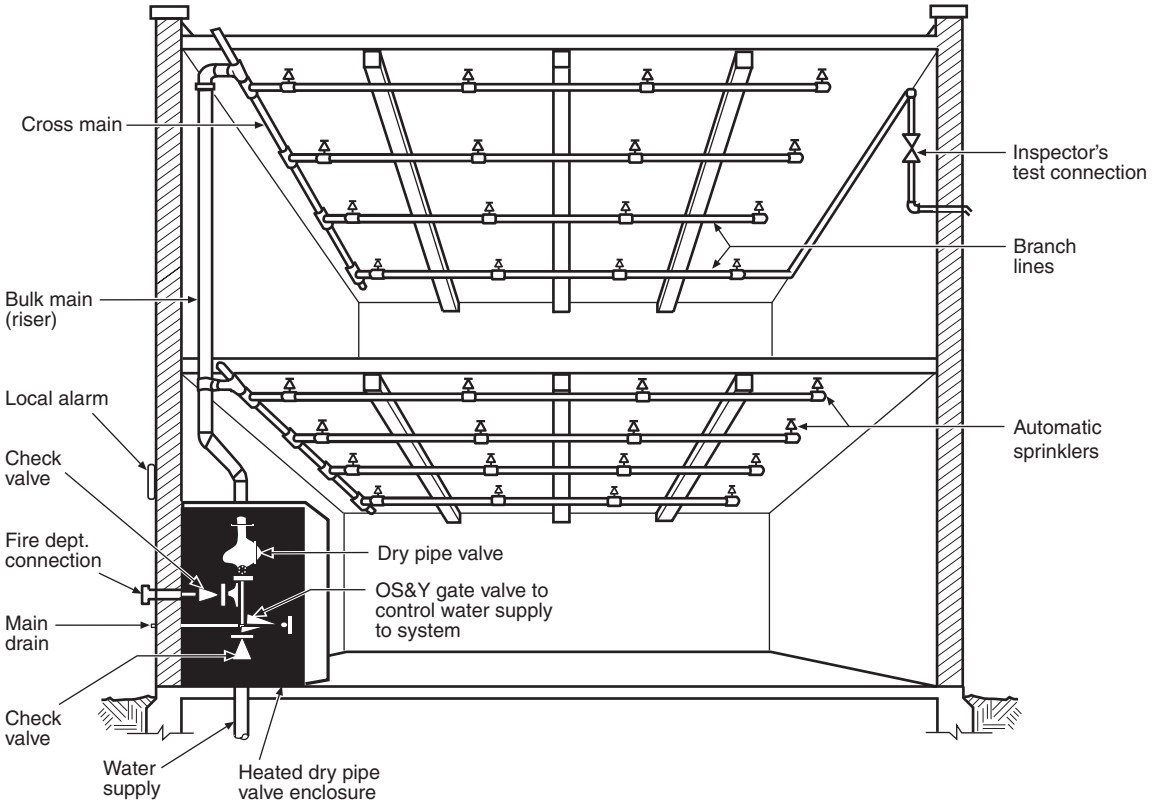

FIGURE 16.3.10 Hypothetical Dry Pipe System

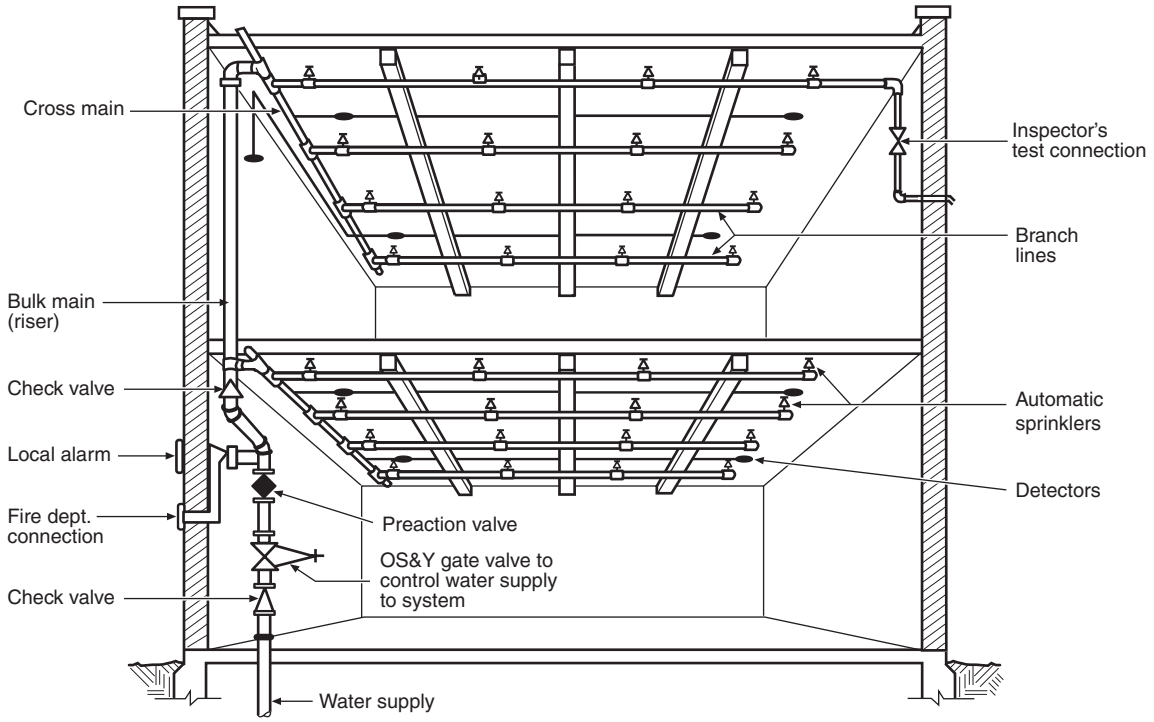

FIGURE 16.3.11 Typical Preaction Sprinkler System

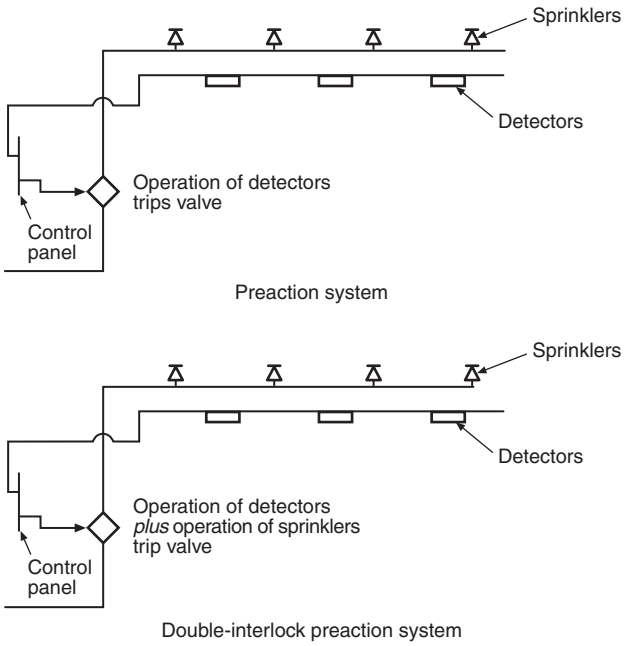

FIGURE 16.3.12 Comparison of Operating Features for the Types of Preaction Systems

supplemental detection system and the sprinklers on the system must operate. Figure 16.3.12 illustrates the double-interlock arrangement. Another variation of a preaction system is the non-interlock system in which either activation of the supplemental detection system or a sprinkler initiates waterflow through the system. Preaction systems are typically found in spaces containing computer or communications equipment, museums, and other facilities where inadvertent water leakage from system piping is of major concern. The double-interlock system is most common in deep-freeze facilities where accidental valve operation can result in the almost immediate freezing and damage of system piping.

Deluge Systems. Deluge systems, as the name implies, deliver large quantities of water over specified areas in a relatively short period of time. These systems are used to protect against rapidly growing and spreading fires. Sprinklers used in a deluge system do not contain thermally sensitive operating elements and are referred to as open sprinklers. A deluge valve controls the system water supply and is activated by a supplemental fire detection system. Because open sprinklers are employed, system piping is at atmospheric pressure. As water reaches each sprinkler in the system, it is immediately discharged from the system.

The nature of this system makes it appropriate for facilities in which significant amounts of highly combustible materials are present. The system is also used for situations in which thermal damage is likely to occur in a relatively short period of time. Aircraft hangars are one area of application of deluge systems. Figure 16.3.13 shows a typical deluge system.

Other Systems. Several variations to each one of these four basic systems exist. One such system is the antifreeze system that is essentially a wet pipe system with a certain amount of antifreeze concentrate added to provide a degree of protection

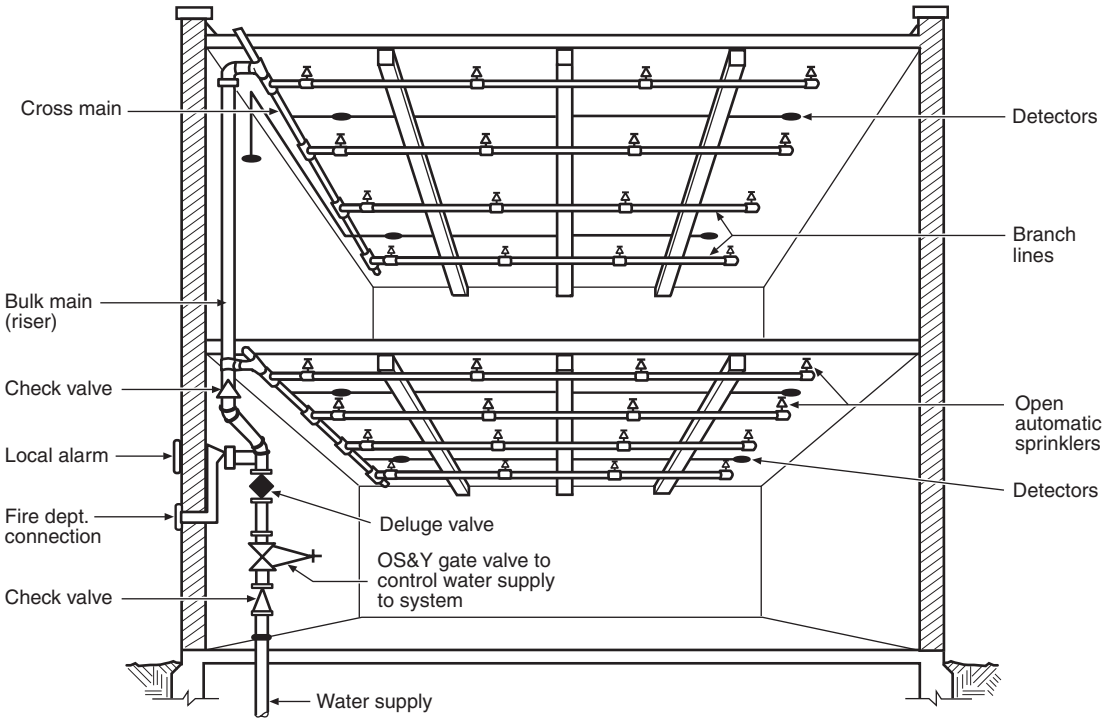

FIGURE 16.3.13 Deluge System

against freezing. Because of the cost associated with these systems, antifreeze systems are usually used to protect smaller spaces exposed to cold temperatures such as outside loading docks or exterior canopies. There has been an increased use of antifreeze for large systems protecting freezers with early suppression fast-response (ESFR) sprinklers. NFPA 13 specifies which types of antifreeze can be used and the percentage of concentrate needed.

Design Objectives

In general terms of property protection, sprinkler systems are typically designed to achieve fire control, although certain types of sprinklers allow for fire suppression to be attained in certain storage arrangements. Fire control can be described as limiting the fire size by decreasing the rate of heat release and prewetting adjacent combustibles, while maintaining ceiling gas temperatures so as to avoid structural damage. Fire suppression can be described as a sharp reduction in the heat release rate to a point at which regrowth is not possible as a result of the application of large quantities of water through the fire plume to the surface of the burning fuel. Figure 16.3.14 provides a graphical representation of these phenomena in terms of the rate of heat release as a function of time.

Where property protection is a secondary objective, options for designing systems targeted principally at life safety within the room of fire origin exist for certain types of facilities. Because property protection is typically more difficult to achieve than is life safety, more cost-effective systems can be considered, but it must be recognized that these systems might not provide the same degree of property protection in all circumstances. Systems targeted for life safety employ residential sprinklers that are intended to maintain a tenable environment in the room of fire origin. The use of residential sprinklers is limited to residential-type facilities. Since their development in the mid-1980s, building codes and NFPA *101* have mandated the use of residential sprinklers or quick-response sprinklers in apartments, hotels, and patient care rooms in health care environments. Both property protection and a higher level of life safety can be provided where facilities are protected throughout in accordance with NFPA 13 and quick-response sprinklers are used.

Occupancy Hazard Classification

To a large degree, the occupancy hazard classifications form the basis of the design and installation criteria of NFPA 13. The occupancy hazards provide a convenient means of categorizing the fuel loads and fire severity associated with certain building operations. The classifications also present a relationship between the burning characteristics of these fuels and the ability of a sprinkler system to control the associated types of fires. The likelihood of ignition is not considered in the occupancy classifications.

NFPA 13 defines three fundamental hazard levels: (1) light hazard, (2) ordinary hazard, and (3) extra hazard. These are defined in a subjective manner and generally focus on the heat release rate and the quantity of combustible fuel. The ordinary-hazard and extra-hazard categories are both subdivided into Group 1 and Group 2 categories. Larger quantities of fuel are typically present in the respective Group 2 categories. As previously stated, the properties of the contents in the building rather than the materials of construction of the building determine the classification. An extensive list of examples of various buildings is placed in the annex of NFPA 13. Defining the hazard is, thus, the first step in selecting and designing the system.

Some examples of occupancies in each of these classifications are as follows:

Light Hazard

- Office buildings
- Schools

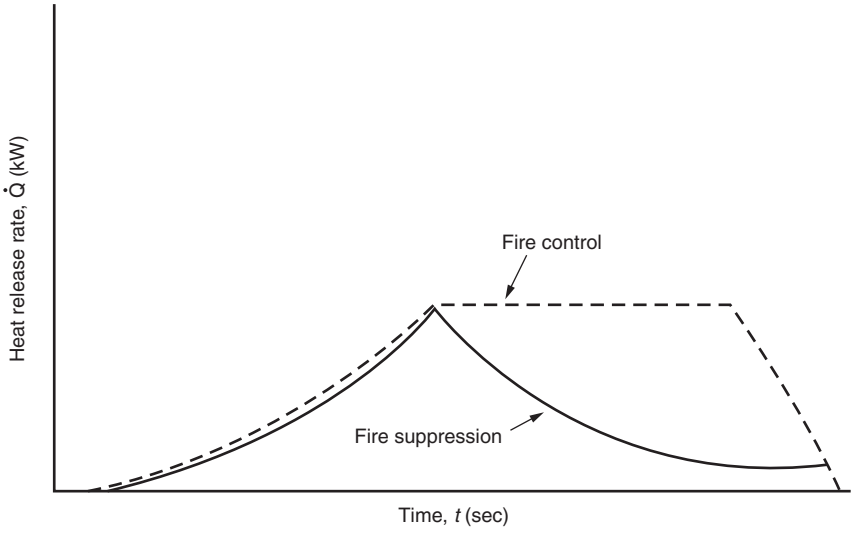

FIGURE 16.3.14 Simplified Fire Control/Fire Suppression Analogy

- Residential occupancies
- Public assembly

Ordinary Hazard

- Canneries (Group 1)
- Electronics plants (Group 1)
- Restaurant service areas (Group 1)
- Dry cleaners (Group 2)
- Library—large stack rooms (Group 2)
- Repair garages (Group 2)
- Wood product assembly (Group 2)

Extra Hazard

- Combustible fluid use area (Group 1)
- Printing that uses inks with flashpoints below 100°F (38°C) (Group 1)
- Upholstering with plastic foams (Group 1)
- Flammable liquids spraying (Group 2)
- Manufactured home assembly (Group 2)
- Plastics processing (Group 2)

Although the occupancy hazard classifications in NFPA 13 address a large majority of building operations, they are not all-encompassing. Certain building operations fall outside the scope of the occupancy hazard classifications and must be treated differently. One such instance includes storage facilities. Where large amounts of materials are stored in a building, the associated fire hazard of the contents in terms of determining appropriate sprinkler system protection is described through commodity classifications. Section 16, Chapter 5, "Sprinkler Systems for Storage Facilities," provides more information in this regard. A similar situation also holds true where flammable and combustible liquids are stored. NFPA 30 provides more information in this regard. Additionally, NFPA 13 further identifies those building operations that require special consideration in terms of either sprinkler system design or installation.

Ceiling Construction

Ceiling construction in terms of the depth, spacing, and openness of the structural and other members affects a sprinkler's activation time and discharge pattern and, therefore, must be considered when placing and positioning sprinklers throughout the building. A sprinkler's allowable area of coverage and the distance below the ceiling will be affected by the ceiling construction classification.

NFPA 13 considers two types of ceiling construction: (1) obstructed and (2) unobstructed. Obstructed construction includes ceiling members that can substantially impede heat flow or water distribution in such a manner that the ability of the sprinkler to suppress or control the fire can be more easily compromised. Under unobstructed construction, ceiling members have less of an impact on sprinkler activation and discharge pattern. NFPA 13 defines unobstructed construction as follows:

- Openings in the member must be at least 70 percent of the cross-sectional area.
- Depth of the member does not exceed the smallest dimension of the openings.
- The members are spaced more than 7 ft 6 in. (2.3 m) on center.

Figure 16.3.15 illustrates an example of obstructed and unobstructed general construction. Within the unobstructed ceiling types, there is a subcategory called smooth ceilings. Some sprinklers, such as the sidewall type, are restricted to just smooth ceilings.

SYSTEM COMPONENTS AND MATERIALS

Maintaining integrity and reliability of a sprinkler system is accomplished in a number of ways. This includes restricting the types and quality of materials and components that comprise the system. As a general rule, NFPA 13 requires that almost all system components, such as sprinklers, valves, and pipe hangers, be listed. While specifically defined by NFPA 13, being listed implies that the equipment and materials to be used on the system have been evaluated by a third party for their intended purpose and marked as such.

Sprinklers

Sprinklers must be listed, and only new sprinklers are permitted for use. Various types of sprinklers are available on the worldwide market. Table 16.3.2 identifies certain sprinkler characteristics. One of these characteristics is the K-factor, which describes the size and angle for the inlet of the sprinkler's orifice (Table 16.3.3). Although sprinklers can be used to protect against various types of fire hazards as classified by NFPA 13, it must be recognized that there might be limitations on the use of a given sprinkler. For example, sprinklers with a K-factor smaller than 5.6 are limited to light-hazard occupancies. Additionally,

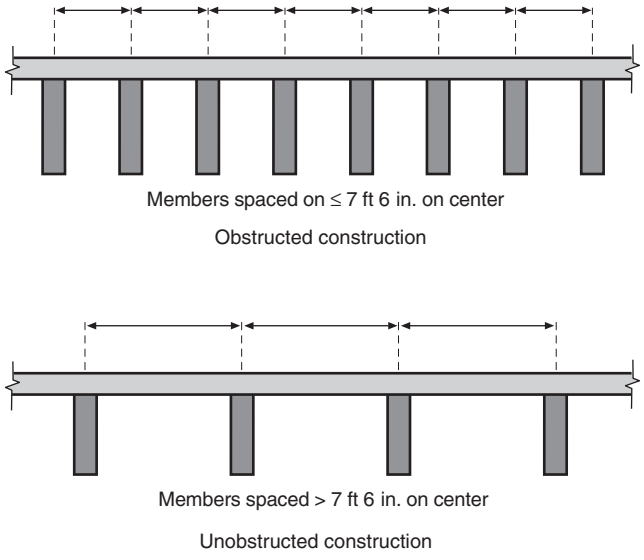

FIGURE 16.3.15 (Top) Obstructed Construction, (Bottom) Unobstructed Construction

the type of system, such as dry pipe, can require the use of a minimum K-factor value.

The 5.6 K-factor or ½-inch (12.7-mm) orifice sprinkler is considered the standard orifice sprinkler and generally serves as a benchmark against which to compare the discharge of other sprinklers. Sprinklers with K-factors less than 5.6 have traditionally been considered small orifice sprinklers. Sprinklers with K-factors larger than 5.6 traditionally have been referred to as large, extra large, and very extra large orifice sprinklers. However, the current trend is to develop sprinklers with larger and larger K-factors, the largest currently at 25. Thus, the terms *large orifice* and *extra large orifice* have lost their meaning and are no longer used.

Sprinklers must also satisfy other criteria concerning thread type and marking. Sprinkler manufacturers and listing laboratories are bound to some degree to the limits of NFPA 13. For example, a sprinkler with a K-factor of 14 cannot have a ½ in. (12.7 mm) NPT thread. Restrictions on thread type and orifice diameter are imposed on larger sprinklers because of the poor hydraulic features associated with flowing large quantities of water through a relatively small opening.

Another feature of the sprinkler that is governed by NFPA 13 is the temperature rating, as indicated in Table 16.3.4. The first column indicates the maximum ambient temperature to which the sprinkler is expected to be exposed. As the expected ambient temperature increases, sprinklers with higher temperature ratings need to be used. For example, where the ambient temperature during any given day can be expected to exceed 100°F, such as a non-air-conditioned warehouse in one of the southern states, ordinary temperature rated sprinklers cannot be used. For the most part, sprinklers with higher temperature ratings, such as ultrahigh, are intended for use around process equipment that generates substantial amounts of heat.

Although the general provisions outlined in Table 16.3.4 apply in most situations, there are additional situations in which higher temperature ratings are necessary. The installation rules in NFPA 13 govern these situations and identify conditions in which higher temperature rated sprinklers are needed, such as under skylights.

As noted in Table 16.3.4, sprinklers are color coded to facilitate the identification of the temperature rating. Eutectic metal or solder-type sprinklers use the color scheme in the next to last column, whereas glass-bulb sprinklers use the color scheme in the last column. The liquid in a glass-bulb sprinkler is basically a low-boiling-point alcohol. An air bubble within the glass bulb

TABLE 16.3.4 Temperature Ratings, Classifications, and Color Codings

Maximum Ceiling Temperature		Temperature Rating				
°F	°C	°F	°C	*Temperature Classification*	*Color Code*	*Glass Bulb Colors*
100	38	135–170	57–77	Ordinary	Uncolored or black	Orange or red
150	66	175–225	79–107	Intermediate	White	Yellow or green
225	107	250–300	121–149	High	Blue	Blue
300	149	325–375	163–191	Extra high	Red	Purple
375	191	400–475	204–246	Very extra high	Green	Black
475	246	500–575	260–302	Ultrahigh	Orange	Black
625	329	650	343	Ultrahigh	Orange	Black

Source: NFPA 13, *Standard for the Installation of Sprinkler Systems.*

is volume controlled to achieve a certain temperature rating. The larger the bubble, the higher the operating temperature. The liquid is dyed the appropriate color to correspond to the color code system in the table. Selection of the correct temperature rating for the environment is critical to ensure that sprinklers will not operate during nonfire conditions.

Sprinklers can be manufactured with special coatings to improve their corrosion resistance or aesthetic qualities. Sprinklers installed in corrosive atmospheres can be lead- or wax-coated or made of stainless steel to provide protection against premature corrosion. Sprinklers with special finish coatings are also available and can enhance the architectural features of a space. The choice of coating can be restricted by the type of sprinkler. For instance, quick-response sprinklers cannot be wax-coated.

In both the case of listed corrosion-resistant sprinklers and sprinklers with special decorative finishes, such finishes may only be applied by the manufacturer. Under no circumstance can sprinklers be "field coated" with any type of material. Sprinklers that have been coated or painted must be replaced. Such coatings may impair the spray pattern of the sprinkler or they may react with some functional part of the sprinkler assembly, such as the operating element or the Teflon® seal, which is used to seat the orifice cap on the orifice.

Pipe and Tube

A number of piping materials are acceptable for use in sprinkler systems. Steel, copper, and nonmetallic pipe materials are currently addressed by NFPA 13. These pipe materials must meet certain pipe manufacturing standards, certain listing requirements, or both. Limiting the types of pipe that are acceptable for use will increase reliability of not only the system installation, but it will also ensure the integrity of the system piping during a fire. In addition to identifying the type of pipe materials that can be used, NFPA 13 also specifies how the pipe is to be joined.

Steel Pipe. Steel pipe has been a viable option for use in sprinkler systems since the first edition of NFPA 13, published in 1896. Steel pipe of at least schedule 10 wall thickness manufactured in compliance with certain ASTM (American Society for Testing and Materials) standards as specified by NFPA 13 and summarized in Table 16.3.5 is not required to be listed. However, this does not preclude a manufacturer from having steel pipe specifically listed for fire protection service.

Copper Tube. Copper tube was first discussed as an optional material for sprinkler systems in 1954. Concern over the failure of solder materials or the brazing materials used to join the copper tube was expressed as being a potential failure point of the system during a fire. Joint research by the listing laboratories and the Copper Development Association addressed those concerns, and recommendations were made to restrict the types of brazing material and solder materials. Table 16.3.6 indicates the relevant standards for both copper tube and the joining materials. Copper tube systems have been installed in a large number of buildings. Some notable buildings with copper systems are the Trans-America building in San Francisco, the Monterey Aquarium, and the Library of Congress.

Nonmetallic Pipe. NFPA 13 previously identified two types of plastic pipe for use in sprinkler systems. Polybutylene (PB)

pipe was first listed for use in systems in NFPA 13D, *Standard for the Installation of Sprinkler Systems in One- and Two-Family Dwellings and Manufactured Homes,* in 1984. An obvious concern with plastic pipe is failure when exposed to fire and even its possible contribution to fire growth. This concern was addressed by requiring the pipe to be installed behind a protective membrane. Such a protective barrier would shield the pipe from direct heat exposure. The exposing temperature would be expected to be substantially decreased, since the operating sprinkler would be controlling the fire. Although PB pipe can still be used for sprinkler systems, since April 1996, the resin used to manufacture the pipe is no longer available. All reference to polybutylene pipe was removed from the 2007 edition of NFPA 13.

A second type of nonmetallic pipe, chlorinated polyvinyl chloride (CPVC), was introduced in 1986. CPVC pipe was listed for use in systems complying with NFPA 13D and for systems complying with NFPA 13 for light-hazard occupancies.

CPVC piping materials must be manufactured in accordance with the piping standard in ASTM F442 *and* must be specifically listed for use in automatic sprinkler systems. The listing criteria include a number of conditions and restrictions. Some of these conditions are as follows:

- Limited for use in systems that comply with NFPA 13D; NFPA 13R, *Standard for the Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height;* and NFPA 13 (light-hazard occupancies only)
- Can be used in all wet pipe systems but limited for dry pipe and preaction systems
- Must be installed behind a thermal barrier. Note that CPVC pipe may be installed exposed if used with listed residential sprinklers that are installed in accordance with their listing or if used with listed quick-response (QR) sprinklers, where the QR sprinklers are installed within 8 in. (203 mm) of the ceiling
- Must be joined with listed fittings or materials
- Not permitted to be installed in concealed combustible spaces that require sprinkler protection by NFPA 13

NFPA 13 requires that all of the manufacturer's installation instructions be followed in addition to the design and installation rules of NFPA 13.

Specially Listed Steel Pipe. In the same manner that NFPA 13 previously allowed manufacturers to produce pipe with materials other than steel and copper, a similar provision also permits the use of other types of steel pipe that have a thickness of less than schedule 10. These materials are typically referred to as thin-wall steel pipe and may have a wall thickness similar to that for schedule 5. They must be specifically listed for use in automatic sprinkler systems.

The listing process evaluates a number of pipe properties such as hydraulic characteristics, corrosion resistance, beam strength (for determining hanger spacing for piping support), and joining methods of joining the pipe, among others.

System Valves

Automatic sprinkler systems are required to have at least one listed valve installed to allow for the system to be shut down. As a matter of course, sprinkler systems should never be shut down except when system modifications are being accomplished or during the time following a fire to allow for replacement of any sprinklers that operated. The types of valves used in a sprinkler system vary with the location of the valve in the water supply system or portion thereof.

Valves may be of the isolation type to shut the system off, they may be a one-way or check valve to prevent flow of water in one direction, or they may be a pressure-regulating valve to permit the pressure entering part of the system to be maintained at a certain level. In all cases, the valves must be listed for use in fire protection systems, they must be supervised in their normally open position, and they must be identified as to the area or segment of the system that they control.

Listed control valves are evaluated for such characteristics as the maximum working pressure to which they can be exposed, the hydraulic profile or equivalent pipe lengths that result, and the means of supervising equipment that they may use.

Indicating Features. The purpose of an indicating feature on a valve is to allow a method to quickly determine if the valve is in the open or closed position. One of the more common methods for accomplishing this is the use of a listed outside screw and yoke (OS&Y) valve. The rising stem feature of this valve is the indicator if the valve is open or closed. The stem rises as the valve is set to the open position. The opposite end of the stem is equipped with a gate valve that raises out of the pipe network as the valve wheel is operated. OS&Y valves are often installed at, or near, the system riser.

A postindicator valve (PIV) is frequently installed outside of the structure. The indicating feature on this device is a viewing window with a sliding metal plate. As the valve is operated with the special wrench, the stem, which is connected to the gate device on the end of the stem (the stem is internal to the post

on a PIV), also repositions the sign. When the valve is in the open position, the sign labeled "OPEN" will be evident in the small viewing window on the side of the PIV housing. Likewise, when the valve is operated to the closed position, the sign labeled "CLOSED" will be evident in the viewing window. Figure 16.3.16 illustrates two types of control valves.

Listed indicating butterfly valves (IBV) do not have the same type of physical features of either the OS&Y valve or the PIV valve; thus, it must use an indicating feature that is substantially different from either of the first two valves. The indicating feature with an IBV is usually a directional arrow, mounted on the housing of the valve. This feature points in the "position" of the valve. For example, when the valve is open, the arrow is aligned with the flow direction of the water. When the valve is in the closed position, the arrow points in a direction perpendicular to the pipe, indicating that water cannot travel beyond the valve.

Supervisory Features. Another requirement of NFPA 13 is to provide some means to ensure that the valve remains in its normal position. Supervision of system valves dates back to the 1896 edition of NFPA 13, in which Rule 60 stated "All gate valves in supply pipes to sprinklers to be of indicator pattern, and to be strapped open with riveted leather straps passing around the riser and spoke of the wheel, or secured open with a seal." The methods for supervising valves include the following:

- Electrically supervised in a manner to allow a signal to be heard at a central station facility
- Electrically supervised in a manner to allow a signal to be heard at a constantly attended point at the protected facility
- Locking valves in the open position
- Sealing valves in the open position, with a weekly surveillance program

It is important to remember that, although NFPA 13 allows any of these options, for sprinkler systems required by other building codes, the code typically dictates that the valve be electrically supervised at a central station.

In addition to those valves used to control the system supplies or a portion of the system supply, other types of valves are used to test the system or drain the system pipe. Although such valves are not required to meet the same level of reliability as control valves, they must still be installed to facilitate testing of the system, as well as to allow for the system to be drained during a period of maintenance. The main drain or test valve is located at the system riser. Its purpose is twofold. First, it may be used as a central point to drain water from the entire system. Its second purpose is to conduct the main drain test. This test is done when the system is commissioned, in order to allow for a set of baseline values to be established. The points of interest are (1) the static pressure and (2) the residual pressure when the valve is fully open. Figure 16.3.17 shows the common arrangement of the main drain valve.

Another type of valve used is the inspector's test valve, or the alarm test connection. The location of the valve depends on the type of system. When installed on a wet pipe system, the main purpose of this device is to test the operation of the waterflow device. Although it can be located anywhere after the waterflow device, the preferred location is as close to the system riser as possible. This limits the extent of corrosion within the system. When installed on a dry pipe system, its purpose is twofold. First, it is used to establish the trip time of the dry pipe valve and the transit time of the water to the connection. Second, it establishes the time for the waterflow device to operate and the actual operation of the alarm device. For these reasons, it must be located at the end of the most remote branch line.

INSTALLATION RULES FOR AUTOMATIC SPRINKLER SYSTEMS

The basic principles of NFPA 13 concerning sprinkler system installation are as follows:

1. Sprinklers are to be installed throughout the premises.
2. The maximum allowed protection area per sprinkler is not to be exceeded.
3. Sprinklers are to be positioned to allow for timely operation and distribution.

Installing Sprinklers Throughout the Premises

Installing sprinklers throughout the premises is necessary in order to achieve the desired level of life safety and property protection. Since there are no standardized methods to predict where a fire is likely to start in a structure, the basic rules of NFPA 13 require sprinklers to be installed in most areas of the building. In general, a fire that originates in an unsprinklered area is expected to overpower the capabilities of a system that may be installed in a nearby or adjacent space. In general, this correlation holds true. There have been instances in which sprinklers did actually contain or extinguish a fire that originated in an unsprinklered space. The most notable of these fires was the One Meridian Plaza fire in Philadelphia in 1991. In this incident, an uncontrolled fire had spread between eight stories in a high-rise office building. On reaching the thirtieth floor, which had been equipped with sprinklers, a total of nine sprinklers operated to completely stop the further spread of the fire.

Some codes that focus exclusively on life safety might not require sprinklers in all areas of the building. This is in recognition of the assumption that the threat to life or injury as a result of fire in these spaces is considered minimal. Because NFPA 13 focuses on both property protection and life safety, very few exceptions for omitting sprinkler coverage exist.

Some areas that do not require sprinkler coverage include bathrooms in residential-type occupancies that are not over 55 ft^2 (5.1 m^2) in area and are composed of noncombustible or limited-combustible materials. Small closets in hotel occupancies are also not required to be protected with sprinklers. In both instances, there is recognition that the fuel loading in such spaces is minimal and that fires that originate in such spaces do not normally become threatening to either the occupants or the structure.

Two other exceptions to sprinkler protection center on electrical equipment rooms and elevator shafts. Electrical equipment rooms that (1) use dry-type equipment, (2) are used for no other purpose, and (3) are separated by 2-hour fire-rated construction are not required to be protected with automatic sprinklers. In this instance, strict controls are imposed on the use of the room and the materials of construction.

Passenger elevator shafts that use noncombustible construction and utilize elevator cabs constructed in accordance with ASME 17.1, *Safety Code for Elevators and Escalators,* are not required to be provided with a sprinkler at the top of the shaft. Sprinklers are not required at the bottom of similar shafts, unless the elevator lift mechanism uses hydraulic fluid. It is important to note that such exceptions do not extend to the elevator equipment or machine rooms.

Concealed spaces, such as those found above a ceiling within the building, do not require sprinklers, provided the space is constructed of noncombustible materials. Conversely, concealed spaces of combustible construction or materials require sprinkler protection. There are a number of exceptions to this general rule, however. Exceptions to sprinkler protection center on two basic ideas: (1) that physical limitations within a space may prevent a meaningful arrangement of sprinklers to be installed, and (2) that the nature and arrangement of the combustible materials may have some inherent fire resistance. The 2007 edition of NFPA 13 contains 14 exceptions that address the specific instances in which sprinklers can be omitted from concealed combustible spaces. Buildings are still considered to be sprinklered throughout when these exceptions are applied.

Areas of Coverage

A number of limits are imposed on the size of the area that a particular type of sprinkler can protect. In arriving at the area of coverage for a particular type of sprinkler, a number of variables are considered. These include the type of sprinkler in question, the nature of the hazard being protected, the type of construction contemplated, and the spacing of the construction members. Tables 16.3.7 through 16.3.10 summarize the maximum areas of coverage permitted for standard upright and standard pendent spray sprinklers. Protection areas for other types of sprinklers are provided in NFPA 13. Exceeding the area of coverage limits specified by NFPA 13 can result in failure of the sprinkler to control the fire.

The area of coverage of a sprinkler is established through a set of principles based on an evaluation of the relationship between the distance between sprinklers located on the branch line and the distance between sprinklers on adjacent branch lines. The first value is defined as "S" (along the branch line), whereas the second value is defined as "L" (between adjacent branch lines). In the same manner that maximum limits are imposed on the overall area of coverage, limits are also placed on these distances. Once again, the type of sprinkler, the hazard to be protected, and the characteristics of the construction are factored into these limits. Tables 16.3.7 through 16.3.10 show the permitted values for "S" and "L" identified as the maximum spacing.

The area of coverage is then determined by multiplying the "L" and "S" values together. It should be noted that sprinklers installed on the ends of a branch line near a wall and those sprinklers installed on the branch line that runs closest to a wall receive special treatment and may alter the selected values for "S" and "L." (See NFPA 13 for a further discussion on this issue.) Even a slight deviation in these limits may result in the sprinkler system not being able to adequately control the fire.

Extended coverage (EC) sprinklers use a slightly different method of determining their area of coverage. In essence, the area of coverage is identical to whatever the sprinkler is listed to. Pendant-mounted extended coverage sprinklers are listed with equal-sided, even-numbered dimensions. An EC sprinkler

that is listed for 16 ft × 16 ft (4.9 m × 4.9 m) has an area of coverage of 256 ft^2 (23.8 m^2). These values become fixed with respect to system design. For example, even if this type of sprinkler is used in an area or room with dimensions of 15 ft × 15 ft (4.6 m × 4.6 m), it must still be designed for the listed spacing of 16 ft × 16 ft (4.9 m × 4.9 m), or 256 ft^2 (23.8 m^2). Sidewall sprinklers are treated in a similar manner but the area can be a rectangle with changes in either dimension limited to 2 ft increments. There is an exception to the area of coverage rule. Extended coverage pendent sprinklers listed for an extra-hazard occupancy and storage shall apply the S × L rule.

Sprinkler Activation and Discharge Characteristics

The position of the sprinkler with respect to the ceiling and any nearby construction features, such as lighting fixtures, construction elements, and the like, can impact the performance of the sprinkler in two distinct ways. First, if the sprinkler is located in a manner so that it is not directly exposed to the heat from the fire, the subsequent delay in sprinkler operation may result in the fire becoming too large for proper control by the sprinkler. To minimize this possibility, NFPA 13 controls the positioning of the sprinkler with respect to walls and ceilings.

The second area of concern lies within the distribution pattern of the sprinkler. In other words, once the sprinkler operates, is it likely that the water that discharges from the sprinkler will be able to reach the fire and surrounding objects. NFPA 13 deals with this by specifying obstruction rules for each type of sprinkler. The requirements of NFPA 13 that address sprinkler activation are specific to the type of sprinkler involved. Although specific requirements for a given type of sprinkler vary, the fundamental principles remain the same: (1) control the distance between the sprinkler deflector and the ceiling/roof, and (2) determine if the ceiling construction features will impede heat flow from the fire to the sprinkler. Ceiling construction features were previously discussed. The position of the sprinkler beneath the ceiling is predicated on the principle that a dynamic heat layer consisting of hot gases from the fire develops below the ceiling and ultimately contains a sufficient amount of energy in terms of heat to activate the sprinkler. In essence, heat from the fire rises to the ceiling surface where, if unobstructed, it spreads out across the ceiling. As the layer builds because of the developing fire, the thermally sensitive components of the sprinklers eventually activate, allowing for the discharge of water. For this reason, NFPA 13 limits the distance that the sprinkler can be positioned below the ceiling.

Dealing with obstructions to sprinkler discharge can be a rather complex issue. A building with a completely smooth, flat, horizontal ceiling that utilizes recessed lighting fixtures, or flush-mounted heating, ventilating, and air-conditioning (HVAC) exhaust grilles, and that otherwise has no projections from the ceiling is the most desirable in terms of sprinkler discharge. However, this situation is rare.

The many combinations of architectural features, lighting components, structural members, and related building systems can create detrimental obstructions to sprinkler discharge. Since the first edition of NFPA 13 in 1896, many rules and requirements have been added to address the issue. The fundamental philosophy concerning obstructions has not changed in over 100 years, but details concerning type, size, and shape of obstruction are important as well as how close that obstruction has to be before it becomes a concern.

NFPA 13 addresses three general areas of concern with regard to obstructions. However, rules are specific for each category of sprinkler identified by NFPA 13. The first concern is the overall objective, which is to ensure that a sufficient amount of water from the sprinkler reaches the fire. The concern was previously referred to as a horizontal obstruction and dealt primarily with continuous obstructions such as beams, top chord members, and ducts that are tight or very near the ceiling and in close proximity to the sprinkler.

The second concern deals with the obstruction to sprinkler discharge pattern development. This concern addresses continuous and noncontinuous obstructions such as piping, light fixtures, truss webs, or building columns located within the first 18 in. (457 mm) below the sprinkler deflector. Obstructions located in this zone prevent the proper sprinkler discharge pattern from developing. As a result sprinklers are required to be positioned so that they are located a certain radial distance away from the obstruction. NFPA 13 addresses the correct position for each type of sprinkler.

The 18 in. (457 mm) distance was established in 1952 as the clearance below the newly developed spray sprinkler. It was determined that this volume of clear space was necessary for proper spray pattern development. Starting with the 1996

edition of NFPA 13, the rules for obstructions went through a significant change. Within the 18 in. zone, spray sprinklers are to be separated a radial distance equal to three times the larger dimension of the obstruction. For some types of sprinklers such as extended coverage sprinklers, the separation is increased to four times the dimension. The sensitivity to obstructions is not only affected by the type of sprinkler but also by the occupancy hazard classification. As added in the 1999 edition of NFPA 13, when using standard pendent or upright sprinklers in light- and ordinary-hazard occupancies, only structural members in this zone need be accounted for as obstructions. In general, the obstruction rules in NFPA 13 allow for a portion of the sprinkler's spray pattern to be impacted.

The third area of concern deals with obstructions that prevent the sprinkler discharge from reaching the hazard. These obstructions typically consist of continuous and noncontinuous obstructions that interrupt the water spray pattern once it is below the 18 in. (457 mm) discharge pattern development zone. These types of obstructions can include overhead doors, ducts, or decks. When the width of these obstructions exceeds 4 ft, additional sprinklers are required to be installed beneath them. As indicated by such a large dimension being acceptable, once the pattern has developed, obstructions present much less of a threat to acceptable sprinkler performance.

Another category of obstruction applicable to certain types of sprinklers includes obstructions that are suspended from the ceiling, such as privacy curtains in a hospital or floor-mounted partitions that do not reach the ceiling, such as those found in offices. In both cases, sprinklers must be positioned so that a sufficient portion of the sprinkler discharge sprays over the obstruction.

It is important to note that certain types of sprinklers are more "obstruction sensitive," in that they have little or no tolerance for objects that disrupt the spray pattern. Large-drop and ESFR sprinklers both fit into this category, and their performance can be severely affected by relatively small obstructions.

DESIGN CONSIDERATIONS FOR AUTOMATIC SPRINKLER SYSTEMS

The basic design consideration for sprinkler systems is to verify that the sprinkler system can discharge a sufficient amount of water for the period of time necessary to either control or suppress the types of fires anticipated. Determination of the appropriate occupancy hazard classification is critical in this regard. However, certain installation criteria also play a role. For example, ceiling construction, whether obstructed or unobstructed, influences the area of coverage for a particular sprinkler and this bears on the overall water demand requirements of the system. Another instance focuses on the presence of concealed combustible spaces, which can increase the overall system design area. In protecting a single building or within a single floor area, multiple designs options can be applied. Each option is treated independently.

Two general design methods exist in NFPA 13: (1) the pipe schedule method and (2) the hydraulic design method. The pipe schedule method dates back to the late 1800s. It basically uses a prescribed schedule that specifies the number of sprinklers that can be supplied by a given size pipe. NFPA 13 contains schedules for both copper tube and steel pipe. The use of this particular design method is severely restricted by NFPA 13, almost to the point where it is impractical in most instances.

In addition to the schedule or table that is provided for a light-hazard or ordinary-hazard occupancy (pipe schedule design is no longer permitted for extra hazard), a second table is used to specify the minimum flow and pressure at the base of the system riser (Table 16.3.11). This table is limited to installations no larger than 5000 ft^2 (464.7 m^2). The flow is a minimum, and in the case of a light-hazard occupancy, that flow must be made available at the base of the system riser at a pressure of 15 psi (103.4 kPa) plus the pressure that is necessary to reach the highest sprinkler. In the case of a light-hazard occupancy that has its highest sprinkler positioned 38 ft (11.2 m) above the base of the riser, the minimum flow would have to be available at a pressure of 31.5 psi (217.2 kPa). Table 16.3.11 indicates that not less than 500 gpm (1892.5 L/min) must be provided at this point. If the installation was greater than 5000 ft^2 (464.7 m^2), the minimum residual pressure is increased to 50 psi (344.8 kPa). The above example would require 66.5 psi (458.5 kPa). Such flows are not typical of most municipal water supplies.

The more accurate method of determining the demand for a sprinkler system is through hydraulic calculation. Additionally, this method provides the designer and the building owner with a more cost-effective system. This method offers a number of other advantages in that it is not limited to use with a particular type of pipe, a particular type of sprinkler, or a particular type of occupancy hazard. These are all limitations associated with the pipe schedule approach.

The process by which the calculations are completed is based on an evaluation of the sprinkler system from the hydraulically most remote point. This is that portion of the system that is expected to produce the greatest demand on and tax the system to its greatest extent. It sometimes, but not always, coincides with the physically most remote point in the system (i.e., the point farthest away from the base of the system riser). The concept here is that, if one can satisfy the most demanding point hydraulically, then one can also satisfy any point that is hydraulically closer to the system water supply.

TABLE 16.3.11 Water Supply Requirements for Pipe Schedule Sprinkler Systems

Occupancy Classification	Minimum Residual Pressure Required		Acceptable Flow at Base of Riser		*Duration in Minutes*
	psi	*bar*	*gpm*	*L/min*	
Light hazard	15	1.03	500–750	1892–2839	30–60
Ordinary hazard	20	1.38	850–1500	3217–5677	60–90

Source: NFPA 13, *Standard for the Installation of Sprinkler Systems.*

In determining this most remote point, a design area or system area of operation must be established based on the criteria of NFPA 13. This area should take the shape of a rectangle with a minimum area of 1500 ft^2 (139.4 m^2) for light- and ordinary-hazard occupancies and 2500 ft^2 (232.3 m^2) for extra-hazard occupancies. The selected area is then matched to a corresponding discharge density in accordance with Figure 16.3.18, which is taken from NFPA 13. The designer needs only to satisfy a single point on this curve in order to produce an acceptable design.

A designer is free to select a matching area of sprinkler operation and density along the representative curves. However, it is more advantageous to select the smallest corresponding area of operation (vertical axis) and highest density (horizontal axis). Other points higher on the curve are acceptable but only result in the system requiring more water overall. Interestingly, less water is made available to any given area on the floor when such points are selected.

Up until this point in the design process, the only fixed parameter is the occupancy hazard to be protected. Once the demand point has been selected from the curve, other influencing factors come into play. One of these factors involves the protection (or lack thereof) of concealed combustible spaces. In some instances, the design area must be increased from 1500 to 3000 ft^2 (139.4 to 278.7 m^2). Another factor is the area of coverage for each sprinkler and the spacing that is provided between sprinklers on each branch line (dimension "S," which was previously described).

This type of information becomes critical since the area of system operation is to be converted to a number of sprinklers expected to operate. The number of sprinklers expected to operate is the result of the system area of operation (in units of ft^2) divided by the area of coverage for a sprinkler (in units of ft^2 per sprinkler) (1 ft^2 = 0.0929 m^2). A sprinkler that covers a 200 ft^2 (18.6 m^2) area in a light-hazard occupancy, and in which a system area of operation was selected to be 1500 ft^2 (139.4 m^2), could also be said to have a system area of operation of 1500 ft^2 (139.4 m^2) divided by 200 ft^2 (18.6 m^2) per sprinkler or 7.5 sprinklers. In this process, any fractional amount is always rounded up to the next whole number. In this case, the 1500 ft^2 (139.4 m^2) hydraulically most remote area may also be described as being an eight-sprinkler hydraulically most remote area. This translates to the need to provide a sufficient amount of water to these eight sprinklers in order to control a fire.

The longer dimension of the rectangular area should be parallel to the system branch lines and its length, represented by the number of sprinklers along the branch line in the design area, is determined by the following formula:

$$\frac{1.2\sqrt{A}}{S}$$

where A represents the system design area and S represents the distance between sprinklers along the branch lines. Considering the example in which the design area is 1500 ft^2 and sprinklers are spaced 10 ft (3.1 m) apart along the branch line, the longer side of the design area will contain five sprinklers as follows:

$$\frac{1.2\sqrt{1500}}{10} = 4.6 \text{ sprinklers}$$

(1 ft = 0.305 m)

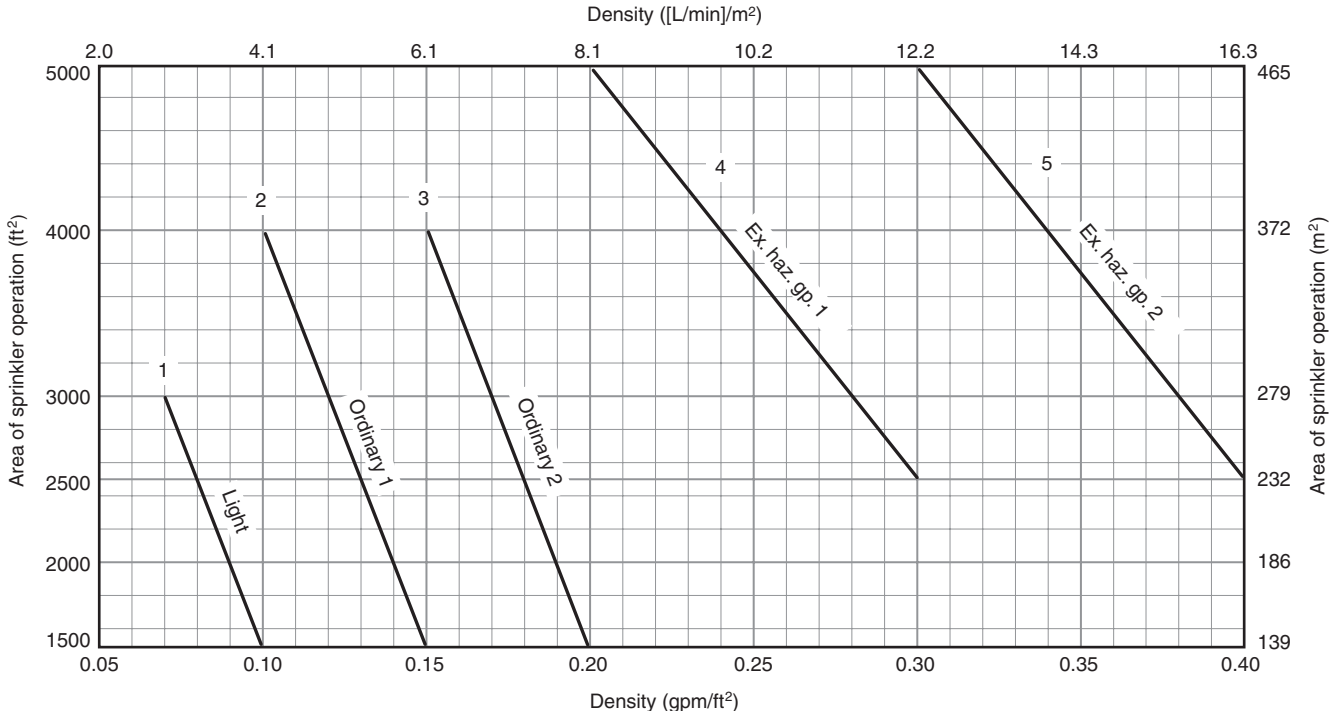

FIGURE 16.3.18 Density/Area Curve (Source: NFPA 13, *Standard for the Installation of Sprinkler Systems*)

As noted before, it is necessary to always round the calculated value up to the nearest whole number of sprinklers—in this case, five. In this example, the remote area consists of a total of eight sprinklers, five on the first branch line in the remote area and three on the second branch line in the remote area.

Using the number of sprinklers is a good means to estimate the size of the remote area. The actual floor area covered must still be verified. This becomes an issue when the distance to the adjacent wall(s) is not symmetrical with the distance to the opposite branch line or sprinklers. When this happens, the assigned area of sprinkler coverage is greater than the actual floor area covered, resulting in a remote area that is too small.

Once the shape and size of the remote area are established, the hydraulic calculation procedures can be initiated. The flow from the most remote sprinkler in the design area can be determined by multiplying the area of coverage of the sprinkler by the selected density. For example, if a density of 0.01 gpm/ft^2 was selected from the design curves and the sprinkler spacing is 200 ft^2 (18.6 m^2) per sprinkler, the flow from the sprinkler is:

$$Q = A \times \text{Density} = 200 \times 0.01 = 20 \text{ gpm}$$

This gives the flow from the most remote sprinkler. The pressure for that first sprinkler is then determined by the following formula, which describes the relationship between the sprinkler orifice (K-factor), the flow (Q), and the pressure (P):

$$Q = \text{K}\sqrt{P}$$

rearranged to $P = (Q/\text{K})^2$.

The flow from the hydraulically most remote sprinkler is then carried upstream to the next sprinkler. The pressure at this sprinkler can then be determined. This pressure is the pressure for the hydraulically most remote sprinkler plus the pressure needed to overcome the losses due to friction for the flow through the pipe connecting the second remote sprinkler on the branch line. Additionally, pressure losses for any fittings and elevation changes are also considered. Once again, the relationship between flow (Q), sprinkler characteristic (K), and pressure (P) is used. The K-factor for the sprinklers used is known as is the pressure; thus, the flow from that sprinkler can be determined.

The total system flow at this point is the additive discharge from these two sprinklers. The flow for these two sprinklers is used to calculate up to the next sprinkler, and the process is repeated as previously described.

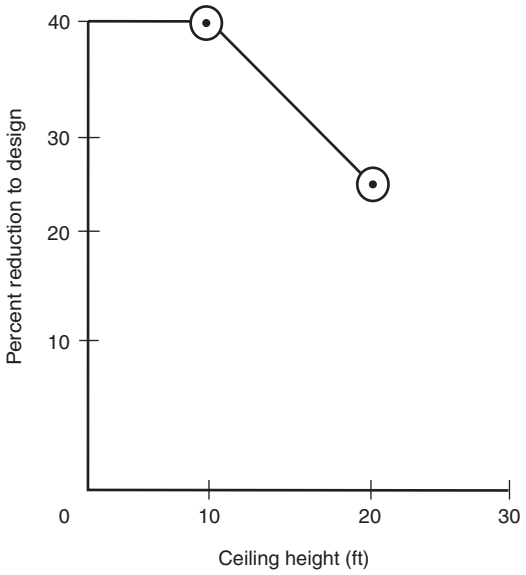
This method of conducting hydraulic calculation uses the Hazen-Williams equation. It was developed in the 1920s and provides sufficiently accurate results for sprinkler systems. The hydraulic design can be completed through the application of formulas, hydraulic tables as indicated in Table 16.3.12, or computer programs. Refer to related chapters of this handbook, the *NFPA Sprinkler Systems Handbook,* or a hydraulics text for more detailed information.

Special Design Features

Where sprinkler systems are used to protect hazards that are not classified by the occupancy hazard classifications specified in NFPA 13, other approaches should be used. Additionally, the approach just described applies to spray sprinklers only. Where other types of sprinklers such as ESFR, large-drop, or residential sprinklers are used, other methods need to be used. See the chapters on sprinklers, residential sprinkler systems, and sprinkler systems for storage applications in this handbook for additional information in this regard.

Under certain circumstances, adjustments to the area/density curve might be necessary. For example, where extended coverage sprinklers are used, NFPA 13 mandates that no fewer than five sprinklers be included in the design of a system. Without this rule, a system that used an extended-coverage sprinkler listed for 400 ft^2 (37.1 m^2) could be designed with only four sprinklers (1500 ft^2 ÷ 400 ft^2 = 3.75 or 4 sprinklers) (1 ft^2 = 0.0929 m^2). Other adjustments require a 30 percent increase to the design area where excessive roof slopes exist or when dry pipe systems are being considered.

A reduction in the system area of operation is permitted where quick-response (QR) sprinklers are used. This provision is limited to those situations in which the occupancy is either a light or ordinary hazard and in which certain ceiling configurations are present. Figure 16.3.19 shows the allowable reduction. The application of this reduction is further limited to spaces containing smooth, flat ceilings that are no higher than 20 ft (6.1 m). Where the ceiling is sloped, the maximum roof height needs to be used. When the size of the remote area is reduced, the density for whatever size was initially selected from Figure 16.3.18 is applied. This special rule was developed as the result



Note: $y = \frac{-3x}{2} + 55$

For ceiling height ≥ 10 ft and ≤ 20 ft, $y = \frac{-3x}{2} + 55$;
For ceiling height < 10 ft, $y = 40$;
For ceiling height > 20 ft, $y = 0$.
For SI units: 1 ft = 0.31 m.

of a series of tests done in 1988, which compared the number of QR sprinklers operating to the number of standard-response sprinklers operating under similar fire scenarios.

One final point on system design involves fire department operations. This chapter has addressed considerations for correct operation of the system, which entail control or suppression of a fire. Final extinguishment of the fire, which can be accomplished by the sprinkler system in many cases, is normally contemplated as a function of the fire department. To ensure that water is available for fire department use while the sprinkler system is operating, NFPA 13 requires an allowance for hose streams. NFPA 13E, *Recommended Practice for Fire Department Operations in Properties Protected by Sprinkler and Standpipe Systems,* provides guidance on the fire department interaction with the sprinkler system.

PLANS, CALCULATIONS, AND SYSTEM ACCEPTANCE

Plans

Factors impacting system design and installation must be documented. Knowledgeable designers need to present the design plans and specifications to the authority having jurisdiction (AHJ) for review and/or approval prior to the commencement of any installation work. The purpose of such documents is to ascertain that the appropriate system elements have been considered and incorporated. Detailed plans should include items such as the layout of the pipe, the location of the sprinklers, the location or spacing of supports, the location of the system riser, the location of any water supply control valves, and the location of the system water supply source, among other items, as required by NFPA 13.

Hydraulic Calculations

Where hydraulic calculations were conducted, they should be detailed and comprehensive. A summary sheet showing the design area of operation, the design density, the occupancy hazard, the hose stream allowance, the water supply information, and the total system demand should also be included. Detailed calculation sheets that document the proper sequence of sprinkler demand points must also be provided. These calculations must originate in the hydraulically most demanding portion of the system and reflect the hydraulic characteristics between that point and the water supply source.

Acceptance Test

The system acceptance or checkout test is used to verify that items previously submitted on the contract plans and reviewed by the AHJ were indeed provided, installed, incorporated, and located as indicated. Test provisions can include items such as a hydrostatic test of the system piping. This test is used to verify the quality of the pipe and fitting installation. In addition to being hydrostatically tested, dry pipe systems must also be pneumatically tested for 24 hours to make sure that air is not being lost to faulty installation of fittings or pipe.

On completion of the acceptance test described in NFPA 13, the contractor's material and test certificate is signed by the installing contractor, the AHJ, and the building owner (or the designated representative). This certificate becomes the basis for final acceptance and commissioning of the system and often becomes a determining factor in allowing the certificate of occupancy to be issued for the building.

Once system acceptance has occurred, it is now incumbent on the building owner to follow up with periodic inspection, testing, and maintenance of the system as specified in NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems.* Future changes to the building or the contents are likely to impact the sprinkler system and need to be accounted for. Ignoring changes to the system and the associated fire hazard can lead to inadequate system performance during a fire. For example, relatively minor architectural changes can create severe obstructions to a sprinkler's discharge pattern and prevent water from reaching the fire area.

MARINE APPLICATIONS

Marine applications of sprinkler systems were formally introduced for the 1996 edition of NFPA 13.

Since 1991, the U.S. Coast Guard has provided a circular on merchant vessel sprinkler systems. This circular basically requires the use of a NFPA 13–type sprinkler system on certain categories of vessels. The prevalence of gaming-type excursion vessels on both inland and coastal routes has been a motivating factor in this aspect of sprinkler protection.

Sprinkler systems are not exclusively limited to these vessel types. The span of marine vessels that will require systems in the near future includes not only excursion boats for both gaming and pleasure but also cruise ships and merchant vessels used to haul various commodities. The Safety of Life at Sea (SOLAS) regulations, promulgated by the International Maritime Organization (IMO), also require sprinkler systems.

The marine chapter in NFPA 13 deals with the unique aspects of a ship's operating environment. In general, all of the current rules of NFPA 13 will still be applicable, except those that are amended or modified by this particular chapter. Many design considerations are similar between a ship and building, but differences exist. These include references to decks instead of floors, shore connections instead of fire department connections, and sprinkler pumps instead of fire pumps. The terms and connotations are similar but the arrangement and importance of each will differ.

One aspect of the design of a sprinkler system on a merchant vessel that is underway, as compared to a building, is that the ship must be entirely self-reliant. That is, occupants cannot be readily evacuated; the fire department cannot be summoned to assist with manual fire suppression; and a maintenance contractor cannot be called in at a moment's notice to repair a system fault. Because of these factors, additional redundant features will be found on the ship that otherwise would not be considered in the design of a land-based structure.

Other conditions that must be considered include the potential for the heaving and rolling that a ship may experience and the resulting impact it would have on sprinkler system piping.

This problem can be dealt with by incorporating some of the seismic design features that are discussed in NFPA 13.

The exposure of certain pipe materials and sprinklers to corrosive atmospheres is also a concern. The use of nonmetallic pipe and the special corrosion-protection measures that are discussed in NFPA 13 are applicable to this situation.

Perhaps the most crucial design consideration is the arrangement and reliability of the water supply. In most circumstances, a nearly infinite supply is readily available to a merchant vessel, but how it is arranged and supplied to the ship's sprinkler system is of paramount importance. A number of water supplies (never less than two) are deemed acceptable, and each must be arranged to ensure that a high level of reliability is obtained. A pressure tank is considered an acceptable method to satisfy part of the water supply requirements. This source must be charged with a quantity of fresh water that will supply the system for a period of at least 1 minute, in the case of a wet pipe system. The supply for a dry pipe system should be adequate to allow for complete filling of the pipe volume plus a quantity of water to permit 1 minute of system discharge.

A sprinkler pump is one of the supply sources that must always be provided. The sprinkler pump has characteristics that are similar to a fire pump, and it must be specifically listed for marine application. The power supply for a sprinkler pump must be arranged to minimize the chances of a fire affecting the starting or operation of the pump. This is done by obtaining the power supply for the pump from the main switchboard on the ship. A backup source of power from a generator must also be provided.

In addition to these arrangements, the water supply for the onboard sprinkler system must also be interconnected with the ship's fire main system. The fire main system is the equivalent of an underground distribution system that is also used to supply strategically located hose outlets on the ship. Figure 16.3.20 shows one basic configuration of a pressure tank, a fire pump, and the ship's fire main.

The fire department connection depicted in Figure 16.3.20 should typically be of the same style and size of those used on fixed structures. Such connections may be supplied by land-based fire department pumpers. In other cases, the source of supply for this connection may be from a fireboat when the vessel is in or near a port area. The companion international shore connection (ISC) is a universal water supply hookup for vessels operating outside of their home port at the time of a fire. As shown in Figure 16.3.20, both types of connections may be used to supplement the other automatic sources of supply for the sprinkler system.

Another feature associated with this unique operating environment is the need to carry additional spare parts to facilitate basic repairs while the vessel is underway. Certain merchant vessels and cruise ships may be as much as four days away from the nearest port capable of repairing system impairments.

SUMMARY

Automatic sprinkler systems serve as one of the most effective methods for providing fire protection and life safety. Sprinkler systems can be installed in various types of buildings and facilities such as manufactured homes, high-rise buildings, warehouse facilities, manufacturing facilities, and, more recently, merchant vessels. Technological advances continue with piping materials, sprinklers, fittings, and hangers both in terms of the products offered and the manner in which they are installed. Advances in technology will continue to produce more effective and cost-efficient sprinkler systems for an increasing number of applications. The greatest obstacle to even broader

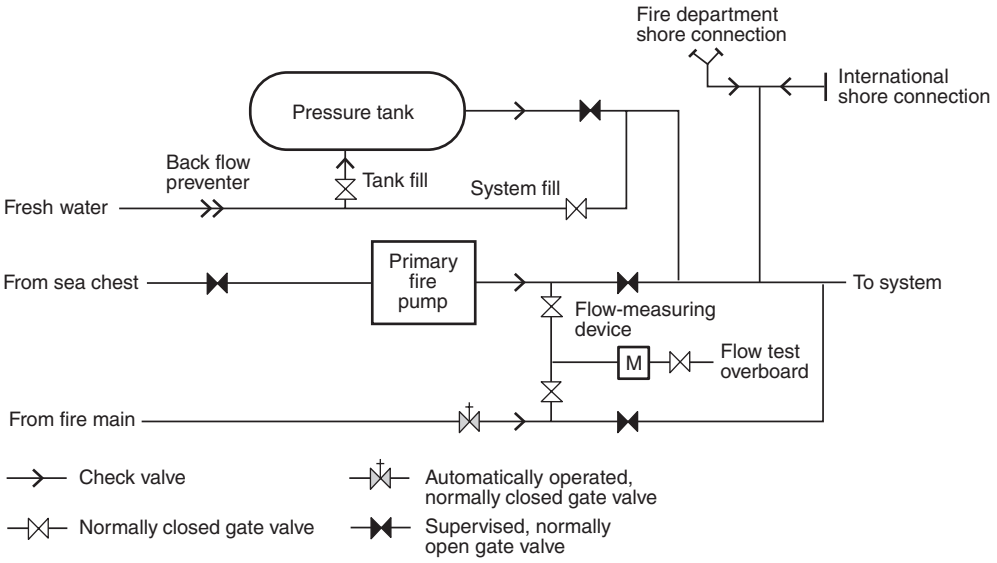

FIGURE 16.3.20 Abbreviated Example of a Water Supply with Fire Pump Backup for Marine Applications

use of sprinkler systems is public perception rather than limitations with available technology.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on automatic sprinkler systems discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 13, *Standard for the Installation of Sprinkler Systems*
NFPA 13D, *Standard for the Installation of Sprinkler Systems in One- and Two-Family Dwellings and Manufactured Homes*
NFPA 13E, *Recommended Practice for Fire Department Operations in Properties Protected by Sprinkler and Standpipe Systems*
NFPA 13R, *Standard for the Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height*
NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection*
NFPA 22, *Standard for Water Tanks for Fire Protection*
NFPA 24, *Standard for the Installation of Private Fire Service Mains and Their Appurtenances*
NFPA 30, *Flammable and Combustible Liquids Code*
NFPA *101®*, *Life Safety Code®*

Chapter 4

Hanging and Bracing of Water-Based Systems

Russell P. Fleming

Chapter Contents

Hangers
Hanger Installation
Earthquake Bracing
Joint Restraint of Underground Piping

Key Terms

automatic sprinkler system, bracing, earthquake, floor-mounted support, hanger, piping (underground), restrained joint system, thrust block, water-based fire protection

Physical support of a water-based fire suppression system is considered essential to the system's proper operation, and specific requirements addressing hanging of automatic sprinkler systems have been included in NFPA 13, *Standard for the Installation of Sprinkler Systems,* since the first edition of the standard was published in 1896. This chapter identifies the various aspects of hanging and bracing that apply to water-based systems, and provides an understanding of some of the assumptions and conventions that underlie the specific rules contained in the NFPA system installation standards.

The earliest sprinkler system hanger rules called for either U-type hangers made of round wrought iron or malleable cast iron, ring clips, or approved adjustable hangers. Flat U-type hangers were permitted if they were at least 3⁄16 in. (5 mm) thick. Hangers were required to be at least 12 in. (300 mm) from sprinklers to avoid interference with water distribution, except that round hangers were permitted as close as 3 in. (75 mm). For concrete construction, cast iron inserts were recommended, although expansion bolts could be used in existing buildings, preferably in a horizontal position. Those familiar with current hanger rules will recognize that some of these rules are still in place.

Guidance for protecting automatic sprinkler systems against earthquakes was first included in the 1947 edition of NFPA 13. The insurance rating bureaus on the West Coast of the United States had urged that special features be included in systems installed in earthquake-prone areas. Yet there were no major earthquakes in the continental United States between 1940 and 1970, and it was not until the San Fernando earthquake in California in 1971 that the NFPA 13 guidance was tested. Following that earthquake it was observed that the performance of the sprinkler system obviously depended on how well the building itself survived the ground movement—if the sprinklered building fared well, so did the sprinkler system. Studies of the performance of sprinkler systems in the Loma Prieta earthquake in the San Francisco area in 1989 and the Northridge earthquake in the Los Angeles area in 1994 were the basis of additional refinements to sprinkler system rules, which are also often applied to other water-based fire protection systems.

The hanger rules of NFPA 13 are also directly referenced or at least serve as the basis for rules within NFPA standards for other water-based fire suppression systems. For this reason, the committee responsible for the hanging and bracing criteria is designated the Committee on Hanging and Bracing of Water-Based Fire Protection Systems. Today, the rules within NFPA 13 that address structural support can be considered in four parts: rules for hangers, rules for hanger installation, rules for bracing systems against earthquake movement, and rules for joint restraint of underground piping systems.

For related topics, see the following chapters in Section 16: Chapter 1, "Principles of Automatic Sprinkler System Performance"; Chapter 2, "Automatic Sprinklers"; and Chapter 3, "Automatic Sprinkler Systems."

Russell P. Fleming, P.E., is executive vice-president for the National Fire Sprinkler Association, Inc., in Patterson, New York. He has served on more than a dozen different NFPA technical committees, including the Technical Correlating Committee on Automatic Sprinklers.

HANGERS

Hanger Types

Various types of hangers (Figure 16.4.1) are used to support fire protection piping, with a variety of components used to attach to the building structure or to attach to the piping. Some types of hangers combine the building attachment component and the pipe attachment component. This would include U-type hangers and short straps, sometimes referred to as clips. Adjustable swivel ring hangers (also commonly known as adjustable steel band hangers), clevis hangers, and split ring hangers are the pipe attachment components used most commonly for suspending horizontal fire protection piping. C-type clamps are the most common structure attachment components for steel structures, and attach rigidly to one edge of the top or bottom flange of a structural member. All-thread mild steel rods are commonly used between the structural attachment and the piping attachment.

Listing of Hangers

Hanger components that attach directly to the building structure or to the piping are required by NFPA standards to be listed for use in fire protection systems. An exception is made within NFPA 13 for components that are made of ferrous metal, are certified by a professional engineer to meet the load requirements stated previously, and are supported adequately and in conformance with the maximum spacing rules.

Hangers made from mild steel rod, such as U-hooks and eye rods, are not required to be listed. Mild steel rods are considered to have demonstrated through practice their ability to support the required loads with adequate safety factors. Pipe straps are not included in the exception and therefore must be listed. Typical fasteners such as screws and bolts are also exempt from the listing requirement.

Special listed pipe can be required to use special hangers or hanger spacing as part of its listing limitations and restrictions. Manufacturers are obligated to make such product data available.

Floor-Mounted Supports

NFPA system installation standards have not traditionally discussed floor supports. Because most fire protection piping systems are located within buildings and because it is desirable to maximize usable floor space, piping is usually supported on hangers from overhead structural members. Nevertheless, floor-mounted supports have often been used for risers other than those protruding straight upward through the floor. A floor support usually includes some type of saddle to help avoid slippage of the pipe.

NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection,* provides rules governing sizing of pipe stands used to support fire protection piping in the absence of a building structure (Tables 16.4.1 and 16.4.2). The criteria include allowance to increase spacing between vertical supports by up to half of the length of braces extending from the vertical supports to the horizontal piping (Figure 16.4.2).

Hanger Loads

There is a difference between the safety factors applied to the hanger versus those for the building structure. In general, the hanger components are expected to support five times the weight of the water-filled piping plus a load of 250 lb (114 kg) at any point of piping support. The intent is not to simultaneously require loading of all hangers, but to represent the possibility of an individual using the piping to support the weight of a human body. This has often been the case in industrial occupancies, where sprinkler system piping may be temporarily loaded during maintenance operations such as ceiling cleaning or painting. The 250 lb (114 kg) load is specified at the point of

TABLE 16.4.2 Pipe Stand Distance

Loop Size		Distance Between Pipe Stands	
in.	*mm*	*ft*	*m*
1	25	10	3.0
1½	40	12	3.7
2	50	14	4.3
2½–8	65–200	15	4.6

Source: NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection.*

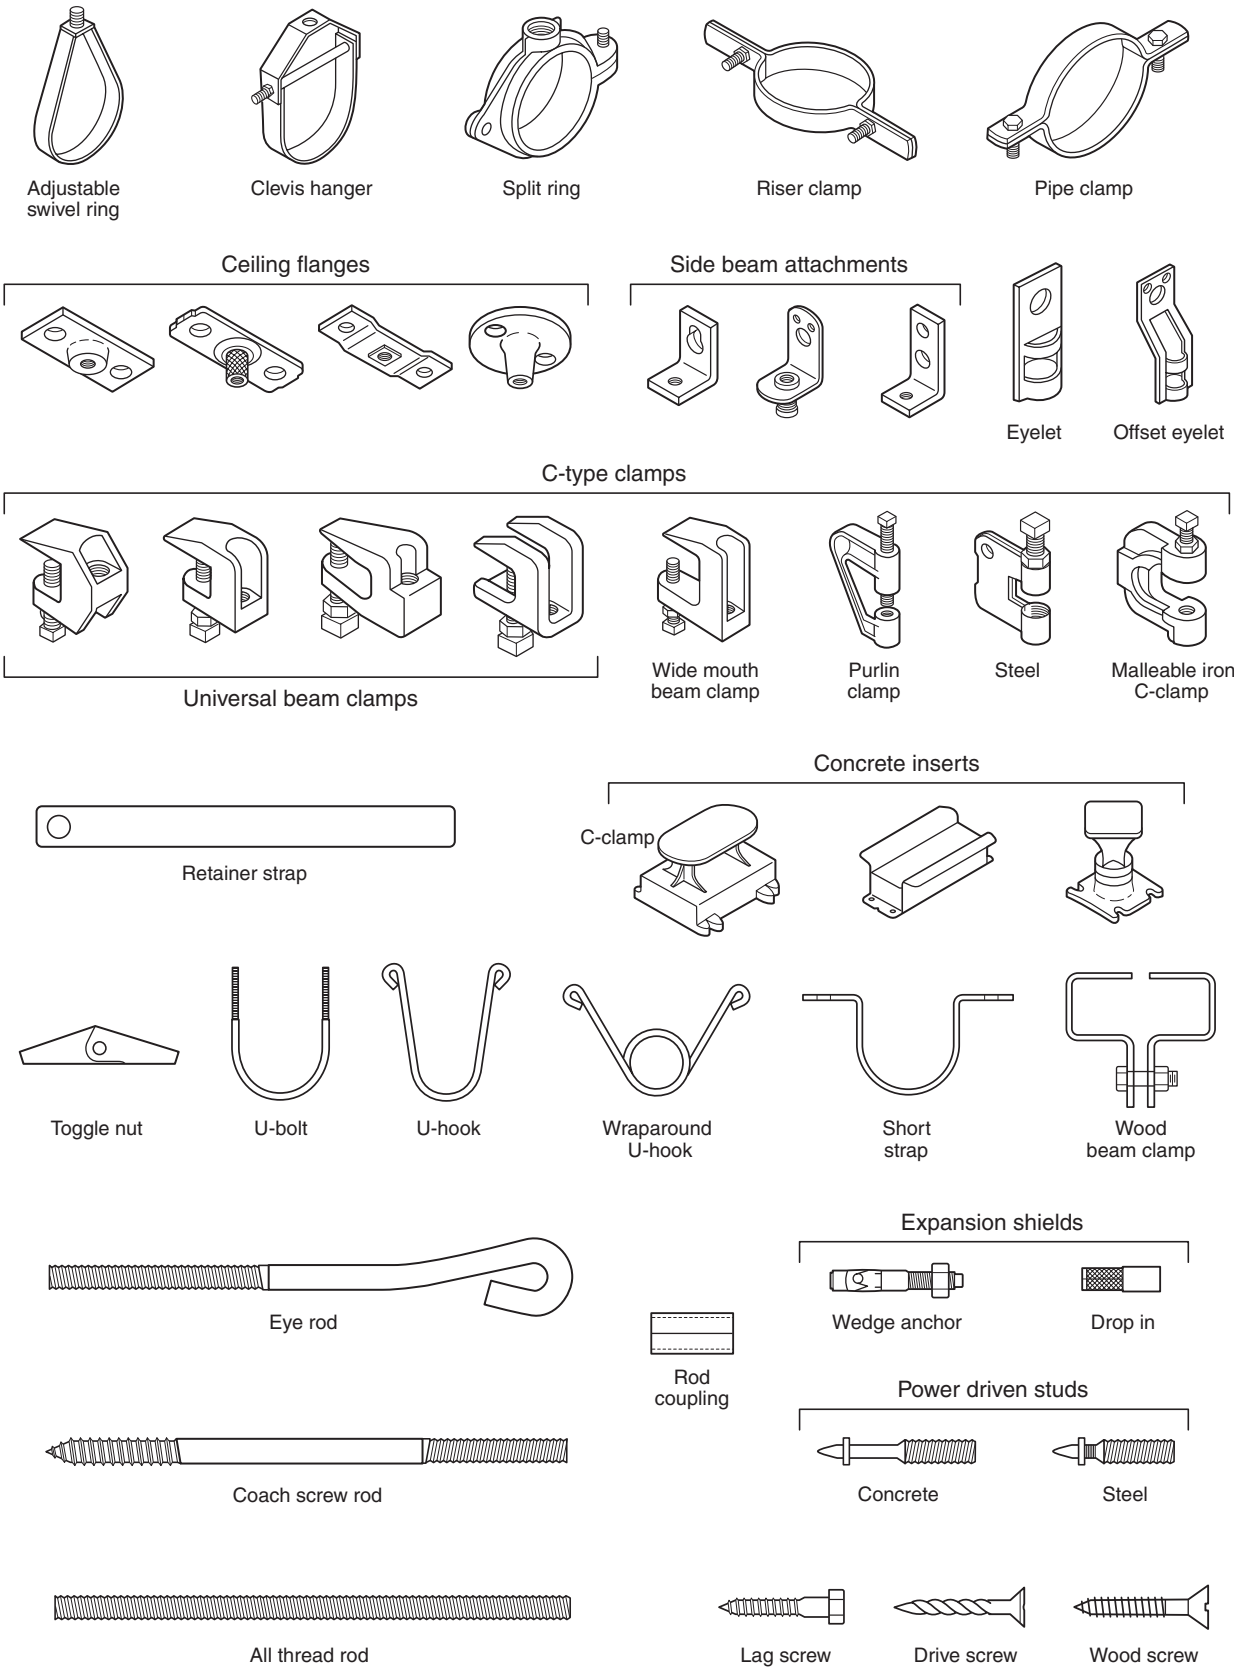

FIGURE 16.4.1 Common Types of Acceptable Hangers

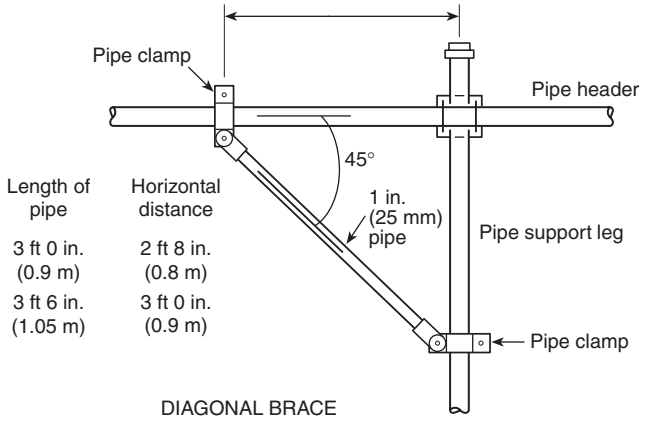

Note: When using diagonal braces as supports, the maximum dimension between support legs can be exceeded by one-half the total horizontal distance of the diagonal braces.

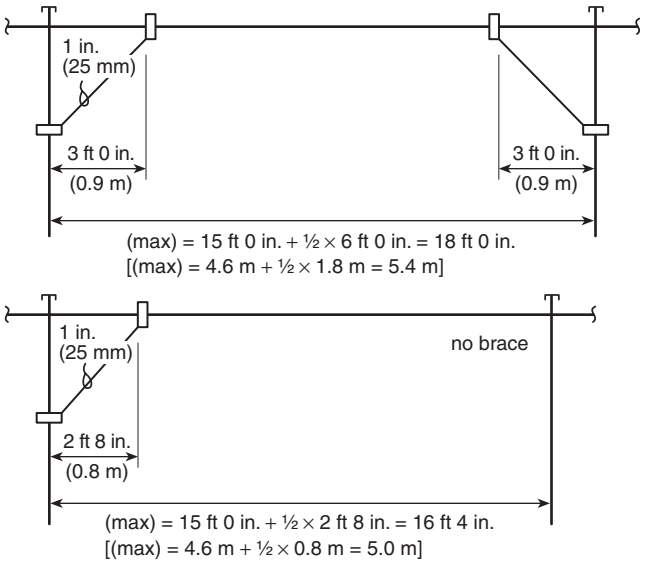

FIGURE 16.4.2 Sway/Support Brace

hanging because it is recognized that some types of piping will not support the additional load at midspan.

The structure itself must be capable of supporting the weight of the water-filled pipe plus a load of 250 lb (114 kg) at each point of support. The safety factor of five is not applied so as to permit the installation of systems in a wider number of existing buildings. There are two exceptions to the structural support requirements stated within the standard. One permits toggle hangers for piping 1½ in. (40 mm) or smaller under ceilings of hollow tile or metal lath and plaster. The other permits drilling or punching vertical members of metal deck for support of pipe 1 in. (25 mm) and smaller and using through bolts. Neither of these special options would be expected to carry the 250 lb (114 kg) load in addition to the weight of the water-filled pipe. The use of a suspended ceiling to support a listed flexible sprinkler drop is another exception, although not specifically addressed as such within NFPA 13.

Trapeze Hangers

Trapeze hangers are used where there is a need to provide a support for hangers between the structural members of the building. Like the trapeze that supports an acrobat, a trapeze hanger provides a span for the support of a sprinkler system or other fire protection piping (Figure 16.4.3).

In a fire sprinkler system, trapeze hangers usually support the larger piping, or mains. This is because it is most efficient to run the branch lines perpendicular to the closely spaced joists or purlins. In this manner, the joists or purlins provide ready points of attachment for hangers for most of the system piping. This means that the mains must generally be supported from the primary structural members that are supporting the joists, or purlins. Where there is a need for points of support between the primary structural members, trapeze hangers can be provided, attached on both ends to adjacent joists or purlins.

NFPA 13 treats trapeze hangers as an extension of the building structure, based on the fact that a trapeze hanger is always an alternative to a modification of the structure that would permit an acceptable point of hanging. This is especially true with wood frame structures. Joists are sometimes added where needed to attach system hangers. Some manufacturers of composite wood joists publish details showing how wood trapeze members are to be affixed between adjacent joists to provide attachment points for sprinkler piping. Because trapeze hangers are considered an extension of the building structure, their requirements are not based on the "five times" safety factor used for hangers, but rather on the requirement used for the building structure, that is, the weight of the water-filled piping plus 250 lb (114 kg).

NFPA 13 contains two tables that simplify the selection of trapeze hangers. Both tables are based on the concept of the trapeze hanger as a simple center-loaded span. Based on the use of steel with a tensile strength of 15 ksi supporting a maximum 15 ft (5 m) of pipe, Table 16.4.3 provides the minimum section modulus needed based on the span of the trapeze and the diameter of the pipe to be supported. Values are separately provided for Schedule 10 pipe and for Schedule 40 pipe, or Schedule 30 for sizes 8 in. (200 mm) and larger. A formula in Appendix A of

Notes:
1. Top values are for Schedule 10 pipe; bottom values are for Schedule 40 pipe.
2. The table is based on a maximum allowable bending stress of 15 ksi and a midspan concentrated load from 15 ft (4.6 m) of water-filled pipe, plus 250 lb (114 kg).

For SI units, 1 in. = 25.4 mm; 1 in.^{3} = 16,387 mm^3; 1 ft = 0.3048 m.

Source: NFPA 13, *Standard for the Installation of Sprinkler Systems.*

NFPA 13 can be used to compute a shorter equivalent length of span where it can be established that the load will be to one side as opposed to the center of the trapeze span.

Table 16.4.4 provides the section modulus available using Schedule 10 pipe, Schedule 40 pipe, or selected steel angles as the trapeze member. It is only necessary to ensure that the trapeze selected from Table 16.4.4 has a section modulus greater than or equal to that needed from Table 16.4.3.

NFPA 13 requires that the trapeze member be secured to prevent slippage. Because pipe is readily available to sprinkler contractors, it is the most common type of trapeze member, and it is typically a smaller pipe size than the pipe being supported. To ensure adequate strength of hanger components, NFPA 13 requires that all ring, strap, or clevis hangers supporting the larger pipe be sized for the larger pipe. The ring or strap must be shaped to accommodate the smaller pipe size. Otherwise the potential exists for the ring or strap to elongate over time with the load, which could result in a change of pitch of the piping.

Aside from steel pipe and angles, other types of structural members are used as trapeze members, provided the section modulus is acceptable. This allows the use of such things as steel channels, where the manufacturers or specifiers would be expected to ensure the minimum tensile strength and to provide information on the available section modulus. Because the section modulus of a nonsymmetrical member changes with orientation, it is important that orientation be considered.

The NFPA 13 language does not specifically allow the use of wood trapeze members, and the language in the standard calling for ferrous hangers and banning the use of nails as fasteners might appear to prohibit their use. This is when it must be recognized that the building designer always has the option of allowing a modification of the building structure to provide a built-in trapeze. The manner in which extensions are made to the building structure must be acceptable to the responsible design professional.

HANGER INSTALLATION

Spacing of hangers is based essentially on the expected beam strength of the piping. For this reason, NFPA 13 and related standards reduce allowable spans for piping with less beam strength than traditional standard weight (Schedule 40) steel pipe. Table 16.4.5 shows the maximum distance between hangers based on type of piping. Other rules, such as the general requirement that hangers be provided on crossmains between every two branch lines, can supersede these maximum spacings.

Special rules relate to hanger installation. For example, nails are not permitted to fasten hangers. Holes must be predrilled for

proper installation of lag screws and coach screw rods. Wood screws must be installed with a screwdriver. Drive screws are permitted only in the horizontal position and only for pipe 2 in. (50 mm) and smaller.

Hangers in Earthquake Areas

Special limitations apply to hangers in areas considered subject to earthquakes. Retaining straps must be provided for all C-type clamps. The retaining strap either must be listed as part of the hanger listing or must meet specified minimum dimensions. In the absence of an adequate lip on the structural member to hold the retaining strap, the strap can be secured with a bolt or screw.

Unless they are specially listed for use in high-risk earthquake areas, powder-driven fasteners are not permitted to attach hangers where the assigned earthquake accelerations exceed half of gravity, or, in other words, where the lateral forces to be resisted exceed half the weight of the water-filled pipe.

Momentum Restraint

Relatively little attention has been given to the subject of restraint or bracing against momentum of waterflow within water-based fire suppression systems. Because linear momentum of fluid flow is conserved, unbalanced momentum forces can occur at changes in piping direction when water surges into a deluge, dry, or preaction system, and to a lesser extent can take place within a wet pipe system as well. However, it is generally believed that the safety factors inherent in the system to resist hydrostatic forces adequately handle such momentum forces, especially with regard to threaded and mechanical joints. To resist permanent shifting of the piping the system relies on the structural attachment components, in combination with the rigidity of the system piping. Where flexible couplings allow angular displacement and the pipe is therefore not capable of resisting loads internally, the hanger attachments must provide sufficient resistance through their method of attachment to avoid being pulled off the building structural component.

Beginning in 1987, NFPA 13 was modified to recognize the impulse force that is the reaction to flow of water through individual sprinklers. Concern was expressed that a single pendent sprinkler extending through a ceiling and operated under high pressure could be lifted above the ceiling from the thrust forces. Subsequent tests showed that a standard K = 5.6 (K_m = 8.0) orifice spray pendent sprinkler operating at 150 psi (10.3 bar) would experience a thrust force of 70–90 lb (10–13 N). Figure 16.4.4 shows the upward deflection of 1 in. (25.4 mm) Schedule 40 pipe under steady state flow of sprinklers with nominal orifice coefficients K = 5.6 (K_m = 80) and K = 8.0 (K_m = 115) at various pressures in the absence of any special restraint.

A pendent sprinkler at the end of a branch line should be given special restraint where the maximum pressure at the sprinkler exceeds 100 psi (6.9 bar) and the sprinkler extends downward through a ceiling. The special restraint involves use of a hanger assembly that prevents upward movement of the sprinkler, located no more than 12 in. (300 mm) from the end of steel pipe branch line, or no more than 6 in. (150 mm) from the end of a copper tube branch line. If these limits are exceeded, the branch line can be extended beyond the last sprinkler on the branch line. A parallel provision applies to pendent sprinklers through ceilings located on armovers.

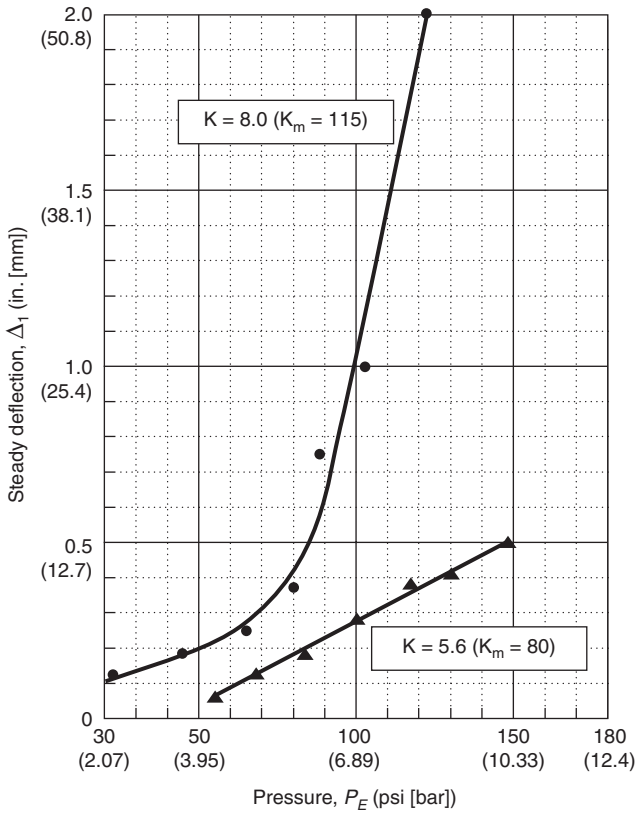

FIGURE 16.4.4 Pipe Deflection

The uplift phenomenon occurs only with the end sprinkler operating. The uplift is considerably reduced with a second sprinkler flowing, and is negligible for the next-to-end sprinkler flowing alone. A formal interpretation was issued by the Committee on Automatic Sprinklers to clarify that the 100 psi (6.9 bar) trigger does not include potential pressure supplied through the fire department connection.

EARTHQUAKE BRACING

Bracing is only one aspect of protecting fire sprinkler systems against earthquakes, but it is probably the most visible aspect. The others are providing necessary flexibility through the use of flexible couplings and clearances and providing restraint. Like bracing, restraint helps to hold piping in place, but to a lesser degree.

Successful bracing of fire protection systems involves determination of appropriate force factors, tentative placement of sway bracing, determination of loads to braces, and verification that the loads can be carried by the sway brace components.

Determination of Force Factors

The determination of seismic force levels is of primary significance in providing bracing, because bracing must be sized and spaced to resist the anticipated forces. NFPA 13 has never dealt

with the issue of where earthquake protection is to be required, but only provided a means of protecting the system. The decision to require protection of sprinkler systems or other mechanical systems against earthquake forces, as well as the magnitude of those forces, is generally stated within building codes, or determined by other authorities having jurisdiction. The decision is based on the past seismic activity of an area and its potential for future earthquakes.

Changes in Protection Criteria. Since past building codes were not always specific with regard to anticipated earthquake forces, NFPA 13 protection criteria traditionally were based on an assumed horizontal acceleration of half of gravity or 0.5 g. This acceleration resulted in a horizontal force factor of $F_p = 0.5W_p$ or a horizontal force equivalent to half the weight of the water-filled piping. This acceleration was judged to be suitably conservative for even highly active earthquake areas, and it was not considered economically justified to fine-tune system bracing loads to accommodate lower expected earthquake forces in some localities. The 0.5 g value continues to serve as the default value for bracing criteria. However, since the 1994 edition, NFPA 13 has permitted the use of other force factors to accommodate code requirements that specify the use of higher or lower horizontal acceleration values. Use of alternative force factors is becoming common for the following two reasons:

1. Both the 1989 Loma Prieta and 1994 Northridge earthquakes in California demonstrated horizontal accelerations in excess of 0.5 g.
2. Earthquake protection of sprinkler systems is now mandated in many areas where expected maximum accelerations are less than 0.5 g.

Essentially, the force equation became $F_p = C_pW_p$, where the value of C_p was determined by the code or other authority, and could be higher or lower than 0.5.

Coordination of Earthquake Protection Provisions. In a tentative interim amendment (TIA) to the 2002 edition, which became effective August 6, 2003, and to an even greater extent in the changes to the 2007 edition, additional changes were made to better coordinate the earthquake protection provisions of NFPA 13 with those of the National Earthquake Hazards Reduction Program's *Recommended Provisions for Seismic Regulations for New Buildings and Other Structures.*[1] These provisions, which have themselves gone through several iterations, were developed through the Building Seismic Safety Council of the National Institute of Building Sciences, with funding from the U.S. Federal Emergency Management Agency. The provisions have served as the basis of successive changes to model building codes in the United States and are now incorporated in ASCE 7, *Minimum Design Loads for Buildings and Other Structures.*[2] ASCE 7 is in turn adopted by reference in current model building codes, with the 2005 edition (ASCE 7-05) adopted by the 2006 editions of both the International Building Code®[3] and *NFPA 5000®, Building Construction and Safety Code®.*

Seismic Design Force Formula. The 2003 TIA to NFPA 13 reduced the allowable fastener loads to match current industry standards, limited the maximum spacing of lateral braces to 40 ft (12.2 m) on center, and provided clarification of how NFPA 13 could be used in conjunction with the seismic design force formula contained in ASCE 7 for use with nonstructural components:

$$F_p = 0.4a_pS_{DS}W_p\frac{1+2(z/h)}{R_p/I_p}$$

where

F_p = Seismic design force

S_{DS} = Design spectral acceleration, short period, found as $S_{DS} = ⅔S_{MS}$, where S_{MS} is the maximum considered earthquake (MCE) acceleration, and is in turn found as $S_{MS} = F_aS_S$, where F_a is an acceleration-based site coefficient and S_S is the short period mapped acceleration (Figure 16.4.5)

W_p = Component weight, in this case the sprinkler piping contributing to the load on a brace

a_p = Component amplification factor affected by the type of seismic attachment

z = Height in the structure of the point of attachment of the component

h = Average roof height of the structure

R_p = Component response modification factor

I_p = Component importance factor

Applying the Force Formula. In using this equation, certain values are assigned for fire sprinkler systems in ASCE 7-05. The importance factor I_p is 1.5. The component response modification factor R_p for a steel piping system is 4.5, and the component amplification factor a_p is 2.5. It is worth noting that these values changed between the 2002 and 2005 editions of ASCE 7. The TIA issued on the 2002 edition of NFPA 13 in 2003 suggested the use of $R_p = 3.5$, correlating with the 2002 edition of ASCE 7. ASCE 7-02 also specified a value of 1.0 for a_p compared to the value of 2.5 specified in the 2005 edition.

As noted above, ASCE 7–05 is the standard referenced by the 2006 editions of the International Building Code and *NFPA 5000,* whereas ASCE 7-02 is referenced for use by the 2003 editions of the International Building Code and *NFPA 5000.* The 2000 edition of the International Building Code also included text parallel to the 2002 edition of ASCE 7. As such, compliance with the 2000 or 2003 editions of these codes would produce an a_p/R_p ratio of 1.0/3.5 = 0.29, whereas compliance with the 2006 editions of these codes produces a ratio of 2.5/4.5 = 0.55, resulting in significantly higher forces with the use of the equation. To some extent this has been offset by the clarification that the calculated design force can be reduced by a factor of 1.4 in recognition of the fact that ASCE 7 is based on strength design, whereas NFPA 13 uses allowable stress design. Prior to the 2007 edition, all loads in NFPA 13 were at allowable stress levels with the exception of the buckling loads for brace members. In the 2007 edition, tables that contained the allowable loads on braces were reduced to add a factor of safety appropriate to the use of allowable stress design.

The $1+2(z/h)$ factor in the design force equation leads to force levels that are three times as high at the top of the building

than at the base, regardless of building height. Because it is presumed that sprinkler systems are installed through the building, the simplifying assumption generally used is that $1+2(z/h) = 3$, with forces determined on the basis of the worst case, or, in other words, the highest level.

The Soil Factor. In the determination of $S_{DS} = \frac{2}{3} S_{MS} = \frac{2}{3} F_a S_S$, F_a is a site-specific soil factor. This factor can range from 0.8 for hard rock up to 2.5 in areas with softer soil and low seismic accelerations. S_S is the short period (0.2 second or 5 cycles per second) seismic acceleration representing a 2 percent probability of being exceeded in 50 years. The 0.2 second period is considered reasonably representative of the shortest effective period of buildings and structures, and the 2 percent probability of being exceeded in 50 years means that it relates to the 2500 year earthquake. Values of S_S are available on maps developed by the U.S. Geological Survey (USGS) and can be accessed at the USGS website. Figures 16.4.5 (a)

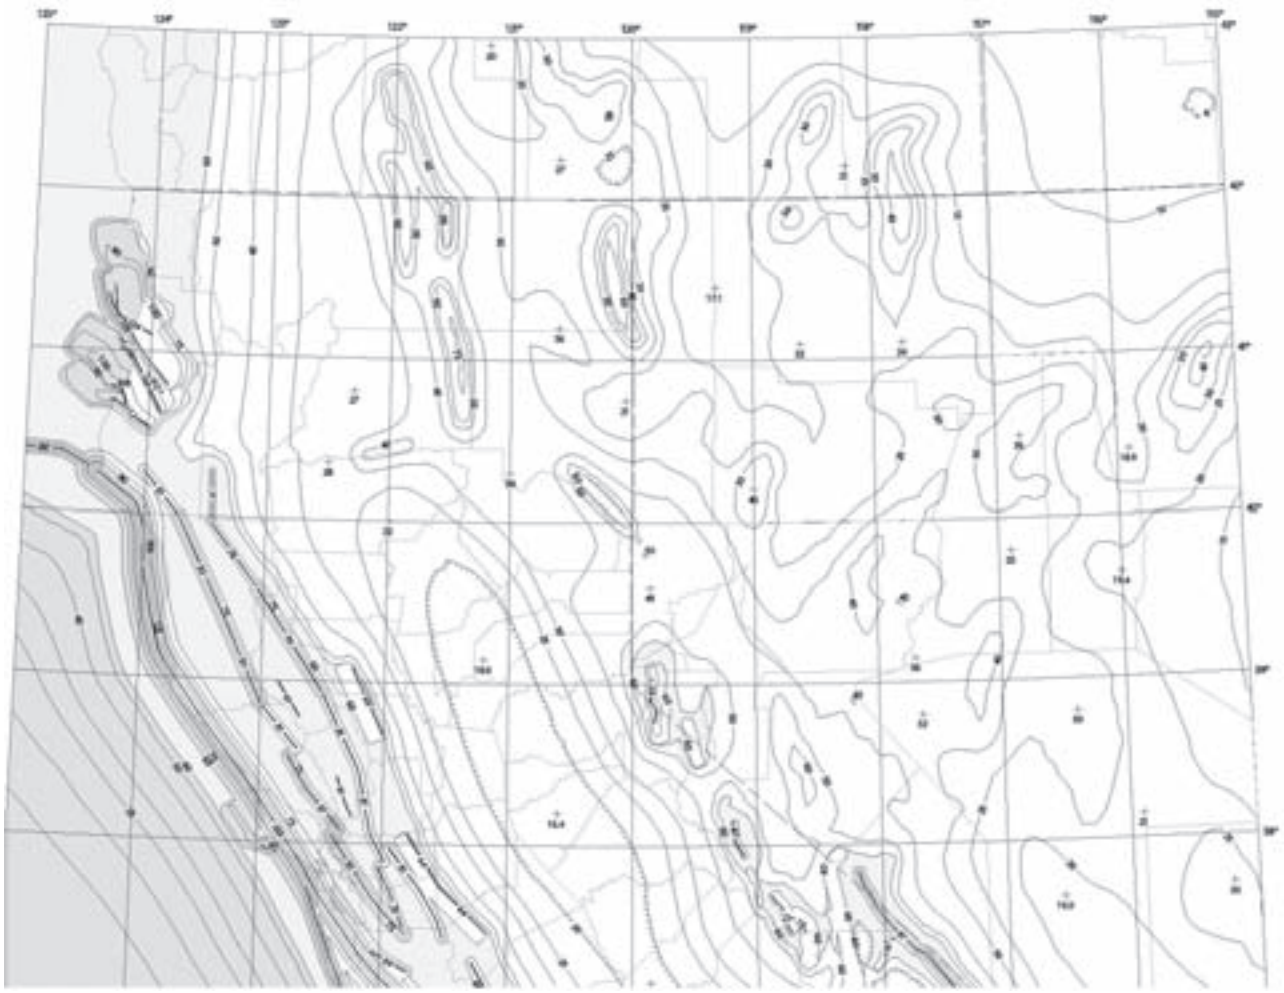
through (d) show the values of S_S for the continental United States and in more specific detail for the seismically active state of California. Figures 16.4.5 (a) and (b) show the maximum considered earthquake ground motion for the coterminous United States of 1.0 second spectral response acceleration (5 percent of critical damping), Site Class B. Figures 16.4.5 (c) and (d) show the maximum considered earthquake ground motion of 1.0 second spectral response acceleration (5 percent of critical damping), Site Class B for Region 1 of the United States.

Using a Seismic Coefficient. A simplified approach to determining seismic forces on sprinkler systems was developed for the 2007 edition of NFPA 13 and involves the factors shown in Table 16.4.6. The table assigns the "seismic coefficient " or acceleration factor C_P based directly on the mapped value of S_S from Figures 16.4.5(a), (b), (c), or (d). Multiplying the acceleration factor C_P by the contributing system weight W_p gives the force that must be resisted by an earthquake brace.

A number of conservative assumptions were used in the development of the NFPA 13 simplified approach. In addition



(c)

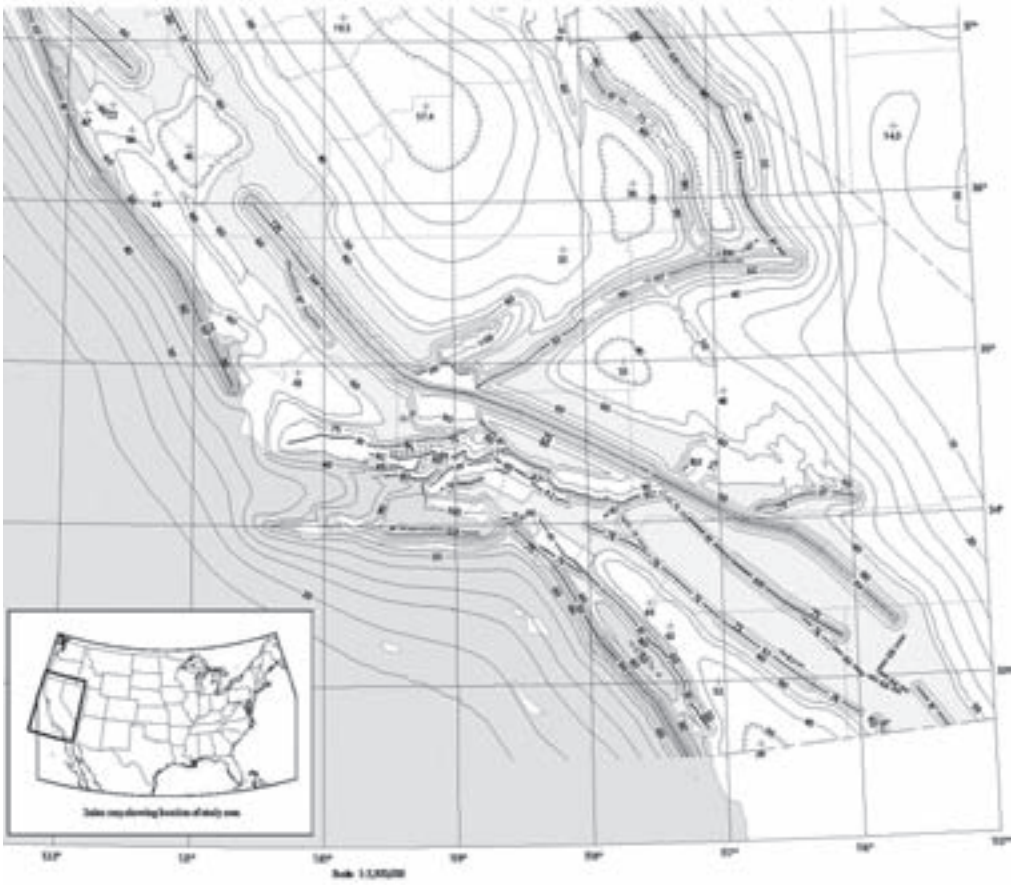
to the top-story assumption discussed above, the table is based on the maximum value of F_a for a given range of S_S, or in other words, poor soil conditions. The user of the standard always has the option to determine lateral forces in accordance with the actual equation of ASCE 7-05, as part of a more detailed analysis allowed by NFPA 13. For mapped acceleration values of S_S less than or equal to 0.33, the table provides a minimum lateral design acceleration of $C_P = 0.31$, which is less than the traditional default value of 0.5, but higher than would be obtained through the use of the ASCE 7 equation in many low-risk seismic areas.

Sway Bracing Placement

Sprinkler systems are provided with sway bracing to resist both lateral and longitudinal horizontal seismic loads as well as to prevent vertical motion resulting from strong seismic loads. The structural components to which bracing is attached must be capable of carrying the added applied loads.

Earthquake bracing can be either lateral (preventing motion perpendicular to the run of the pipe) or longitudinal (parallel to



(d)

FIGURE 16.4.5 Continued

the run of the pipe). A four-way brace is one that prevents both lateral and longitudinal movement.

Both lateral and longitudinal (four-way) bracing is required at the top of the riser. This keeps the top of the riser lined up with the floor/ceiling assembly.

Longitudinal bracing must be provided for all feed and cross mains at maximum 80 ft (24.4 m) intervals. The last brace must be within 40 ft (12.2 m) of the end of the main.

Lateral bracing must be provided for all feed and cross mains, and for branch lines with diameters 2½ in. (65 mm) and larger, although 2½ in. (65 mm) branch line starter pieces are not required to be braced if they do not exceed 12 ft (6.1 m) in length. A major change to the 2007 edition was the limitation of maximum lateral sway brace spacing based on the size of the pipe being braced and the contributory load. The traditional maximum brace spacing of 40 ft (12.2 m) still applies, but in situations involving high lateral forces or heavy branch lines, the maximum spacing may need to be reduced. This reduction is in recognition of the fact that maximum lateral brace spacing is related to the beam strength of the piping and in an attempt to limit pipe deflection as well as pipe stresses.

An exception allows the elimination of lateral bracing where piping is supported by hanger rods less than 6 in. (150 mm) in length. This length is measured between the top of the pipe and the point of attachment to the building structure.

For both longitudinal and lateral bracing, pipe runs less than 12 ft (3.6 m) are allowed to be included with adjacent runs and do not require their own braces provided the maximum distance between braces is observed. Braces within 2 ft (0.6 m) of a turn in the piping run can serve as both a lateral brace for one run and a longitudinal brace for the perpendicular run.

Determination of Loads

Prior to 1999, NFPA 13 permitted two methods of determining the loads to be carried by braces: the assigned load table and the zone of influence method. These two methods somewhat paralleled the pipe schedule method and hydraulic calculation method used to size pipe in sprinkler systems. Just as the role of pipe schedule systems has diminished in favor of consideration of actual water pressures, the assigned load table was deleted in favor of consideration of actual loads.

Using the zone of influence method involves evaluating the load that contributes to each brace. A longitudinal brace is expected to carry the load of the main to which it is connected in a length halfway to the adjacent braces in each direction. A

lateral brace is similarly expected to carry the loads from the piping halfway to the next brace in both directions. However, for the lateral brace this includes the contributions of branch lines as well as mains. During an earthquake, the branch lines are not expected to move uniformly, preventing the contribution of their loads to the longitudinal braces on mains.

The weights of the piping contributing to each brace are accumulated and the total horizontal force calculated as $F_p = C_p W_p$ as explained above. A brace acting as both a lateral brace for one main and a longitudinal brace for another would be expected to carry the combined load simultaneously. Beginning with the 2002 edition of NFPA 13, the value of W_p was specified to be 1.15 times the nominal weight of the water-filled piping to account for the additional weight that might be imposed by fittings or sectional valves. Table 16.4.7 includes piping weights with the 1.15 multiplier.

Where multiple braces are to be installed with the same configuration along a main, it is standard practice to select the worst-case brace for purposes of determining the load to be carried. This would be the brace with the zone of influence that includes the heaviest total piping.

Loads on Sway Brace Components

The sway braces themselves are generally constructed of pipe, but can be of angles, rods, flats, channels, or other structural members with slenderness ratio limited to a maximum of 300. The slenderness ratio is found as l/r where l is the length and r is the least radius of gyration. Traditional bracing resists movement in both tension and compression, but tension-only cable bracing is now also available. Such tension-only bracing systems must be specially listed for use with sprinkler systems. Because the cables can only provide resistance to movement in tension, they must be provided on both sides of the piping at each point of support.

The sway braces are used as part of a sway brace assembly, which in addition to the brace typically consists of the sway brace fitting (the attachment to the pipe being braced) and the structure attachment fitting. These fittings must be listed and have been assigned maximum allowable loads. The allowable loads must be reduced where braces are installed, other than at the full horizontal (90 degree) position. Similar reductions in allowable loads for braces and fasteners are built into the tables contained in NFPA 13. The allowable load for a sway brace assembly is based on the weakest link of the brace, the sway brace fitting, the structure attachment fitting, and the fastener. The allowable load for a brace assembly must meet or exceed the load determined using the assigned load table or zone of influence method.

Sway braces are to be fastened tight and concentric, with eccentric loadings avoided. Welded tab attachments are acceptable for use in connecting longitudinal braces. Pipe must not be braced to building sections that will move differentially. Fastener load tables within the standard are based on various orientation/angle conditions of lag screws in wood, through bolts in wood, expansion shields in concrete and through bolts in steel.

NFPA 13 contains special rules for the fastening of sway braces. C-type clamps (with or without retaining straps) are prohibited from use in attaching sway braces to the building structure. Power-driven fasteners are also prohibited from use in attaching braces unless specifically listed for this service.

An appendix section cautions that although most current concrete fasteners in the marketplace are expansion anchors, the table within the standard is based on the use of "shield-type" or "lead cinch" concrete anchors. Professional engineers may specify alternative fastening arrangements.

Although NFPA 13 states its intent to prevent vertical motion resulting from seismic loads, it is generally expected that the downward force of gravity will sufficiently offset any

TABLE 16.4.7 Piping Weights

*Schedule 30.

upward vertical earthquake loads, and that system hangers have sufficient safety factors to handle any downward vertical earthquake loads. As a result, the standard only addresses the net vertical reaction that would result from strong horizontal loads where the brace angle from vertical is relatively low. Where the horizontal force factor exceeds $0.5W_P$ and the brace angle is less than 45 degrees from vertical, or where the horizontal force factor exceeds $1.0W_P$ and the brace angle is less than 60 degrees from vertical, the braces are to be arranged to resist the net vertical reaction. For traditional rigid braces, this can be accomplished by providing an additional brace on the opposite side of the main. For special listed cable type braces, this can be accomplished by reinforcing the hanger rods to prevent buckling as well as upward movement.

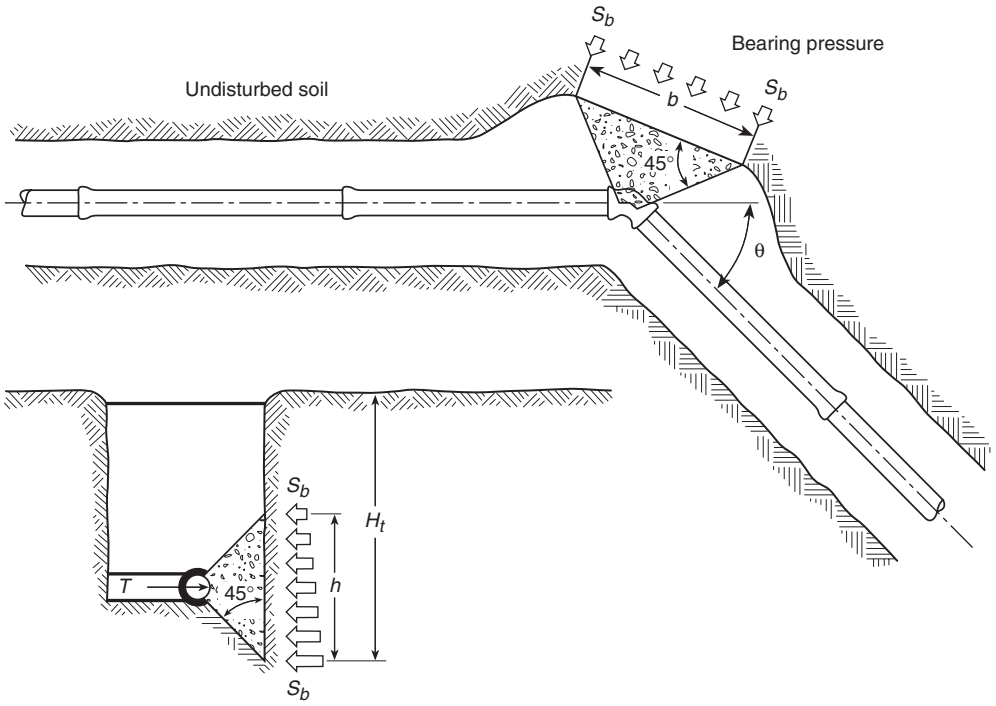
JOINT RESTRAINT OF UNDERGROUND PIPING

Traditional bell and spigot underground piping using push-on joints relies on the resistance provided by the surrounding soil to hold it in place. This is sufficient for straight runs, but the forces at changes in direction must be resisted. For this reason, NFPA standards require all tees, plugs, caps, bends, and hydrant branches to be restrained against movement. NFPA 13 and NFPA 24, *Standard for the Installation of Private Fire Service Mains and Their Appurtenances,* share the criteria for underground piping, including joint restraint.

Like most overhead piping, underground piping with fused joint systems, including welded, soldered, brazed, and threaded pipe, requires no additional joint restraint. Otherwise, joint restraint must be provided through the use of thrust or restrained joint systems.

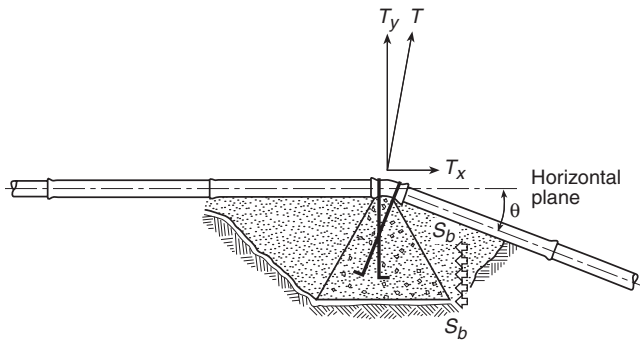
Thrust Blocks

Thrust blocks are large concrete blocks used to transfer horizontal loads to undisturbed soil or to resist upward vertical loads by means of their mass. Thrust blocks must be made of a concrete mix that is not leaner than one part cement, two and a half parts sand, and five parts stone aggregate. If possible, thrust blocks must be placed so that the joints are accessible for repair. (See Annex A in NFPA 13 for additional guidance, including formulas that can be used to size horizontal [bearing] and vertical [gravity] thrust blocks based on the bearing strength of the undisturbed soil, size and orientation of pipe, and maximum expected water pressures [Figures 16.4.6 and 16.4.7].) Care should be taken when obtaining soil bearing strength values because they are often not the same in the horizontal and vertical planes.



T = Thrust force resulting from the change in direction of flow
S_b = Horizontal bearing strength of the soil
h = Block height
H_t = Total depth to bottom of block

FIGURE 16.4.6 Bearing Thrust Block



T = Thrust force resulting from the change of direction of flow
T_x = Horizontal component of the thrust force
T_y = Vertical component of the thrust force
S_b = Horizontal bearing strength of the soil

FIGURE 16.4.7 Gravity Thrust Block

Restrained Joint Systems

Fused joint systems and threaded joints are considered acceptable as restrained joint systems, as are locking mechanical joints, joints using setscrew retainer glands, bolted flange joints, pipe clamps and tie rods, and other methods and devices approved by the authority having jurisdiction. NFPA standards provide specific guidance for sizing the clamps, rods, bolts, and washers associated with restrained joint systems. After installation, all rods, clamps, bolts, nuts, and washers must be cleaned and coated with a bituminous or other material to help prevent corrosion.

Some confusion has been caused in the past by the figure within NFPA 13 showing the "typical connection to a fire protection system riser" (Figure 16.4.8). In this depiction of an underground stub-up, rods are shown as necessary to hold the base of the flange and spigot piece within the bell opening of the last length of bell and spigot piping at the base of the riser. However, such rods and clamps are not necessary if other measures are taken to ensure that sufficient restraint is provided.

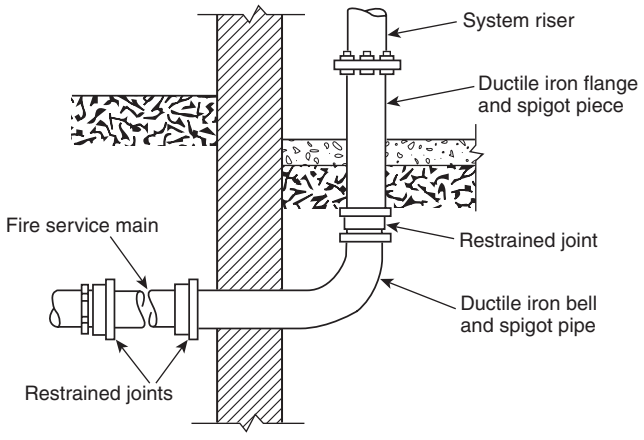


FIGURE 16.4.8 Typical Connection to a Fire Protection System Riser Illustrating Restrained Joints

Adequacy of joint restraint is verified by means of a 2 hour hydrostatic test, at not less than 200 psi (13.8 bar), but at least 50 psi (3.4 bar) above the maximum expected static pressure. The piping between an exterior fire department connection and the check valve in the connection's inlet pipe must also be hydrostatically tested. All thrust blocks should be hardened before testing, and the trench must be backfilled between joints to prevent movement of the pipe. Where necessary to hold the pipe in place, joints can also be backfilled as long as the contractor remains responsible for locating and correcting leaks.

Appendix sections of NFPA 13 and 24 recommend that the underground piping be filled with water for a 24 hour period prior to the hydrostatic test to stabilize the system. These appendix sections also recommend that the test pressure be held for 1 hour, that the pressure then be decreased to zero to look for signs of leakage, and that it then be repressurized for the second hour.

SUMMARY

In the development and application of rules for structural support of fire protection system piping, fire sprinkler systems have received great attention. This is expected given their widespread use. But the features related to hanging and bracing can also readily be applied to other types of fire protection systems and components, including pumps and tanks. The weight of any components required to be braced could be substituted for the weight of system piping in the application of the rules for braces and fasteners. The NFPA 13 hanging and bracing criteria, continually improved over decades based on practical experience, represents the best available guidance on supporting fire systems and protecting them from earthquake damage.

Chapter 5

Sprinkler Systems for Storage Facilities

James E. Golinveaux

Chapter Contents

NFPA Storage Standards
Commodity Classification
Storage Arrangement
Storage Height and Clearance
Automatic Sprinkler Protection
Water Supply
Special Commodities

Key Terms

automatic sprinkler system, bulk storage, commodity classification, pallet, pile storage, plastic, rack storage, storage, warehouse, water supply

This chapter addresses sprinkler system protection for storage operations. It is an unfortunate fact that many of the factors that enhance the efficiency of a storage facility also increase the fire risk presented by that storage. The more efficiently storage volume is used, the more combustible materials there are in that volume, and the more material there is to burn.

Access to the stored materials requires space between storage units. Efficient use of storage space requires that these spaces (flues) be as small as possible. The result is an array that could hardly be any more conducive to maximum burning rate and fire spread than if it had been designed with that purpose in mind. Therefore, well-designed, properly installed, and carefully maintained fire protection is critical if a catastrophic fire is to be avoided.

This chapter reviews basic fire protection principles primarily in the context of NFPA sprinkler system and storage standards. It begins with a discussion of commodity classification and storage arrangement, height, and clearance and then discusses sprinkler systems and associated design factors unique to storage operations. Then it presents an overview of special commodities and special storage facilities. The remaining sections highlight other fire protection features that a comprehensive fire protection program needs and fire safety problems of construction.

This chapter covers fire protection for a broad range of materials and storage arrangements, but it does not discuss the protection of special hazards such as flammable liquids and gases, explosives, and so on. For protection of special hazards, see Section 6, Chapter 10, "Gases"; Section 6, Chapter 12, "Flammable and Combustible Liquids"; Section 16, Chapter 3, "Automatic Sprinkler Systems"; and Section 17, Chapter 8, "Explosion Prevention and Protection."

NFPA STORAGE STANDARDS

NFPA standards outline methods for providing effective fire protection for various types of storage occupancies. These standards include NFPA 13, *Standard for the Installation of Sprinkler Systems.* For the most part, sprinkler systems are the backbone of an effective fire protection strategy for storage facilities. The changing footprint and potential pile collapse in storage facilities make manual fire fighting difficult. A well-designed and properly maintained automatic sprinkler system is the best means of fire control in storage facilities.
